Goodman & Gilman’s
The Pharmacological Basis of
THERAPEUTICS
Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

SECTION I

General Principles 1
1. Drug Invention and the Pharmaceutical Industry .................................................3
   Suzanne M. Rivera and Alfred Goodman Gilman
2. Pharmacokinetics: The Dynamics of Drug Absorption, Distribution, Metabolism, and Elimination .......................................................17
   Iain L. O. Buxton and Leslie Z. Benet
3. Pharmacodynamics: Molecular Mechanisms of Drug Action ......................................41
   Donald K. Blumenthal and James C. Garrison
4. Drug Toxicity and Poisoning ................................................................................73
   Kevin C. Osterhoudt and Trevor M. Penning
5. Membrane Transporters and Drug Response ................................................................89
   Kathleen M. Giacomini and Yuichi Sugiyama
6. Drug Metabolism ................................................................................................123
   Frank J. Gonzalez, Michael Coughtrie, and Robert H. Tukey
7. Pharmacogenetics ................................................................................................145
   Mary V. Relling and Kathleen M. Giacomini

SECTION II

Neuropharmacology 169
   Thomas C. Westfall and David P. Westfall
9. Muscarinic Receptor Agonists and Antagonists .....................................................219
   Joan Heller Brown and Nora Laiken
10. Anticholinesterase Agents ....................................................................................239
    Palmer Taylor
11. Agents Acting at the Neuromuscular Junction and Autonomic Ganglia ..................255
    Ryan E. Hibbs and Alexander C. Zambon
12. Adrenergic Agonists and Antagonists ....................................................................277
    Thomas C. Westfall and David P. Westfall
13. 5-Hydroxytryptamine (Serotonin) and Dopamine .................................................335
    Elaine Sanders-Bush and Lisa Hazelwood
14. Neurotransmission and the Central Nervous System .............................................363
    Perry B. Molinoff
15. Drug Therapy of Depression and Anxiety Disorders .............................................397
    James M. O’Donnell and Richard C. Shelton
16. Pharmacotherapy of Psychosis and Mania .........................................................417
    Jonathan M. Meyer
17. Hypnotics and Sedatives .......................................................................................457
    S. John Mihic and R. Adron Harris
18. Opioids, Analgesia, and Pain Management .........................................................481
    Tony L. Yaksh and Mark S. Wallace
19. General Anesthetics and Therapeutic Gases .......................................................527
    Piyush M. Patel, Hemal H. Patel, and David M. Roth
20. Local Anesthetics .................................................................................................565
    William A. Catterall and Kenneth Mackie
21. Pharmacotherapy of the Epilepsies ......................................................................583
    James O. McNamara
CONTENTS

SECTION V
Hormones and Hormone Antagonists

38. Introduction To Endocrinology: The Hypothalamic-Pituitary Axis .................................................. 1103
   Keith L. Parker and Bernard P. Schimmer
39. Thyroid and Anti-Thyroid Drugs .................................................. 1129
   Gregory A. Brent and Ronald J. Koenig
40. Estrogens and Progestins .................................................. 1163
   Ellis R. Levin and Stephen R. Hammes
41. Androgens ........................................................... 1195
   Peter J. Snyder
42. ACTH, Adrenal Steroids, and Pharmacology of the Adrenal Cortex .................................................. 1209
   Bernard P. Schimmer and John W. Funder
43. Endocrine Pancreas and Pharmacotherapy of Diabetes Mellitus and Hypoglycemia ................. 1237
   Alvin C. Powers and David D’Alessio
44. Agents Affecting Mineral Ion Homeostasis and Bone Turnover .................................................. 1275
   Peter A. Friedman

SECTION VI
Drugs Affecting Gastrointestinal Function

45. Pharmacotherapy of Gastric Acidity, Peptic Ulcers, and Gastroesophageal Reflux Disease .... 1309
   John L. Wallace and Keith A. Sharkey
46. Treatment of Disorders of Bowel Motility and Water Flux; Anti-Emetics; Agents Used in Biliary and Pancreatic Disease .................................................. 1323
   Keith A. Sharkey and John L. Wallace
47. Pharmacotherapy of Inflammatory Bowel Disease .................................................. 1351
   John L. Wallace and Keith A. Sharkey

SECTION VII
Chemotherapy of Microbial Diseases

48. General Principles of Antimicrobial Therapy .................................................................................. 1365
   Tawanda Gumbo
49. Chemotherapy of Malaria .................................................. 1383
   Joseph M. Vinetz, Jérôme Clain, Viengngueun Bounkeua, Richard T. Eastman, and David Fidock
50. Chemotherapy of Protozoal Infections: Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections .................................................. 1419
   Margaret A. Phillips and Samuel L. Stanley, Jr.

Preface

The publication of the twelfth edition of this book is a testament to the vision and ideals of the original authors, Alfred Gilman and Louis Goodman, who, in 1941 set forth the principles that have guided the book through eleven editions: to correlate pharmacology with related medical sciences, to reinterpret the actions and uses of drugs in light of advances in medicine and the basic biomedical sciences, to emphasize the applications of pharmacodynamics to therapeutics, and to create a book that will be useful to students of pharmacology and to physicians. These precepts continue to guide the current edition.

As with editions since the second, expert scholars have contributed individual chapters. A multiauthored book of this sort grows by accretion, posing challenges to editors but also offering memorable pearls to the reader. Thus, portions of prior editions persist in the current edition, and I hasten to acknowledge the contributions of previous editors and authors, many of whom will see text that looks familiar. However, this edition differs noticeably from its immediate predecessors. Fifty new scientists, including a number from outside the U.S., have joined as contributors, and all chapters have been extensively updated. The focus on basic principles continues, with new chapters on drug invention, molecular mechanisms of drug action, drug toxicity and poisoning, principles of antimicrobial therapy, and pharmacotherapy of obstetrical and gynecological disorders. Figures are in full color. The editors have continued to standardize the organization of chapters; thus, students should easily find the basic physiology, biochemistry, and pharmacology set forth in regular type; bullet points highlight important lists within the text; the clinician and expert will find details in extract type under clear headings.

The process of editing brings into view many remarkable facts, theories, and realizations. Three stand out: the invention of new classes of drugs has slowed to a trickle; therapeutics has barely begun to capitalize on the information from the human genome project; and, the development of resistance to antimicrobial agents, mainly through their overuse in medicine and agriculture, threatens to return us to the pre-antibiotic era. We have the capacity and ingenuity to correct these shortcomings.

Many, in addition to the contributors, deserve thanks for their work on this edition; they are acknowledged on an accompanying page. In addition, I am grateful to Professors Bruce Chabner (Harvard Medical School/Massachusetts General Hospital) and Björn Knollmann (Vanderbilt University Medical School) for agreeing to be associate editors of this edition at a late date, necessitated by the death of my colleague and friend Keith Parker in late 2008. Keith and I worked together on the eleventh edition and on planning this edition. In anticipation of the editorial work ahead, Keith submitted his chapters before anyone else and just a few weeks before his death; thus, he is well represented in this volume, which we dedicate to his memory.

Preface to the First Edition

Three objectives have guided the writing of this book—the correlation of pharmacology with related medical sciences, the reinterpretation of the actions and uses of drugs from the viewpoint of important advances in medicine, and the placing of emphasis on the applications of pharmacodynamics to therapeutics.

Although pharmacology is a basic medical science in its own right, it borrows freely from and contributes generously to the subject matter and technics of many medical disciplines, clinical as well as preclinical. Therefore, the correlation of strictly pharmacological information with medicine as a whole is essential for a proper presentation of pharmacology to students and physicians. Furthermore, the reinterpretation of the actions and uses of well-established therapeutic agents in the light of recent advances in the medical sciences is as important a function of a modern text book of pharmacology as is the description of new drugs. In many instances these new interpretations necessitate radical departures from accepted but outworn concepts of the actions of drugs. Lastly, the emphasis throughout the book, as indicated in its title, has been clinical. This is mandatory because medical students must be taught pharmacology from the standpoint of the actions and uses of drugs in the prevention and treatment of disease. To the student, pharmacological data per se are value less unless he/she is able to apply this information in the practice of medicine. This book has also been written for the practicing physician, to whom it offers an opportunity to keep abreast of recent advances in therapeutics and to acquire the basic principles necessary for the rational use of drugs in his/her daily practice.

The criteria for the selection of bibliographic references require comment. It is obviously unwise, if not impossible, to document every fact included in the text. Preference has therefore been given to articles of a review nature, to the literature on new drugs, and to original contributions in controversial fields. In most instances, only the more recent investigations have been cited. In order to encourage free use of the bibliography, references are chiefly to the available literature in the English language.

The authors are greatly indebted to their many colleagues at the Yale University School of Medicine for their generous help and criticism. In particular they are deeply grateful to Professor Henry Gray Barbour, whose constant encouragement and advice have been invaluable.

Drug Invention and the Pharmaceutical Industry

Suzanne M. Rivera and Alfred Goodman Gilman

The first edition of this textbook, published in 1941, is often credited with organizing the field of pharmacology, giving it intellectual validity and an academic identity. That first edition began: “The subject of pharmacology is a broad one and embraces the knowledge of the source, physical and chemical properties, compounding, physiological actions, absorption, fate, and excretion, and therapeutic uses of drugs. A drug may be broadly defined as any chemical agent that affects living protoplasm, and few substances would escape inclusion by this definition.” These two sentences still serve us well. This first section of the 12th edition of this textbook provides the underpinnings for these definitions by exploring the processes of drug invention and development into a therapeutic entity, followed by the basic properties of the interactions between the drug and biological systems: pharmacodynamics, pharmacokinetics (including drug transport and metabolism), and pharmacogenomics. Subsequent sections deal with the use of drugs as therapeutic agents in human subjects.

We intentionally use the term invention to describe the process by which a new drug is identified and brought to medical practice, rather than the more conventional term discovery. This significant semantic change was suggested to us by our colleague Michael S. Brown, MD, and it is appropriate. In the past, drugs were discovered as natural products and used as such. Today, useful drugs are rarely discovered hiding somewhere waiting to be found; rather, they are sculpted and brought into being based on experimentation and optimization of many independent properties. The term invention emphasizes this process; there is little serendipity.

FROM EARLY EXPERIENCES WITH PLANTS TO MODERN CHEMISTRY

Man’s fascination—and sometimes infatuation—with chemicals (i.e., drugs) that alter biological function is ancient and arose as a result of experience with and dependence on plants. Most plants are root-bound, and many have become capable of elaborate chemical syntheses, producing harmful compounds for defense that animals learned to avoid and man learned to exploit. Many examples are described in earlier editions of this text: the appreciation of coffee (caffeine) by the prior of an Arabian convent who noted the behavior of goats that gamboled and frisked through the night after eating the berries of the coffee plant, the use of mushrooms or the deadly nightshade plant (containing the belladonna alkaloids atropine and scopolamine) by professional poisoners, and a rather different use of belladonna (“beautiful lady”) to dilate pupils. Other examples include the uses of the Chinese herb ma huang (containing ephedrine) for over 5000 years as a circulatory stimulant, curare-containing arrow poisons used for centuries by South American Indians to paralyze and kill animals hunted for food, and poppy juice (opium) containing morphine (from the Greek Morpheus, the god of dreams) for pain relief and control of dysenteries. Morphine, of course, has well-known addicting properties, mimicked in some ways by other problematic (“recreational”) natural products—nicotine, cocaine, and ethanol.

While many terrestrial and marine organisms remain valuable sources of naturally occurring compounds with various pharmacological activities, especially including lethal effects on both microorganisms and eukaryotic cells, drug invention became more allied with synthetic organic chemistry as that discipline flourished over the past 150 years. This revolution
began in the dye industry. Dyes, by definition, are colored compounds with selective affinity for biological tissues. Study of these interactions stimulated Paul Ehrlich to postulate the existence of chemical receptors in tissues that interacted with and “fixed” the dyes. Similarly, Ehrlich thought that unique receptors on microorganisms or parasites might react specifically with certain dyes and that such selectivity could spare normal tissue. Ehrlich’s work culminated in the invention of arsphenamine in 1907, which was patented as “salvarsan,” suggestive of the hope that the chemical would be the salvation of humankind. This arsenic-containing compound and other organic arsenicals were invaluable for the chemotherapy of syphilis until the discovery of penicillin. During that period and thanks to the work of Gerhard Domagk, another dye, prontosil (the first clinically useful sulfonamide) was shown to be dramatically effective in treating streptococcal infections. The era of antimicrobial chemotherapy was born, and the fascination with dyes soon spread to the entire and nearly infinite spectrum of organic chemicals. The resulting collaboration of pharmacology with chemistry on the one hand, and with clinical medicine on the other, has been a major contributor to the effective treatment of disease, especially since the middle of the 20th century.

**SOURCES OF DRUGS**

Small Molecules Are the Tradition

With the exception of a few naturally occurring hormones such as insulin, most drugs were small organic molecules (typically <500 Da) until recombinant DNA technology permitted synthesis of proteins by various organisms (bacteria, yeast) and mammalian cells, starting in the 1980s. The usual approach to invention of a small-molecule drug is to screen a collection of chemicals (“library”) for compounds with the desired features. An alternative is to synthesize and focus on close chemical relatives of a substance known to participate in a biological reaction of interest (e.g., congeners of a specific enzyme substrate chosen to be possible inhibitors of the enzymatic reaction), a particularly important strategy in the discovery of anticancer drugs.

While drug discovery in the past often resulted from serendipitous observations of the effects of plant extracts or individual chemicals administered to animals or ingested by man, the approach today relies on high-throughput screening of libraries containing hundreds of thousands or even millions of compounds for their ability to interact with a specific molecular target or elicit a specific biological response (see “Targets of Drug Action” later in the chapter). Chemical libraries are synthesized using modern organic chemical synthetic approaches such as combinatorial chemistry to create large collections of related chemicals, which can then be screened for activity in high-throughput systems. Diversity-oriented synthetic approaches also are of obvious value, while natural products (plant or marine animal collections) are sources of novel and sometimes exceedingly complex chemical structures.

Automated screening procedures employing robotic systems can process hundreds of thousands of samples in just a few days. Reactions are carried out in small trays containing a matrix of tiny wells (typically 384 or 1536). Assay reagents and samples to be tested are coated onto plates or distributed by robots, using ink-jet technology. Tiny volumes are used and chemical samples are thus conserved. The assay must be sensitive, specific, and designed to yield a readily detectable signal, usually a change in absorption or emission of light (fluorescence, luminescence, phosphorescence) or alteration of a radioactive substrate. The signal may result from the interaction of a candidate chemical with a specific protein target, such as an enzyme or a biological receptor protein that one hopes to inhibit or activate with a drug. Alternatively, cell-based high-throughput screens may be performed. For example, a cell may be engineered to emit a fluorescent signal when Ca2+ fluxes into the cell as a result of a ligand-receptor interaction. Cellular engineering is accomplished by transfecting the necessary genes into the cell, enabling it to perform the functions of interest. It is of enormous value that the specific protein target in an assay or the molecules used to engineer a cell for a high-throughput screen are of human origin, obtained by transcription and translation of the cloned human gene. The potential drugs that are identified in the screen (“hits”) are thus known to react with the human protein and not just with its relative (ortholog) obtained from mouse or another species.

Several variables affect the frequency of hits obtained in a screen. Among the most important are the “drugability” of the target and the stringency of the screen in terms of the concentrations of compounds that are tested. The slang term “drugability” refers to the ease with which the function of a target can be altered in the desired fashion by a small organic molecule. If the protein target has a well-defined binding site for a small molecule (e.g., a catalytic or allosteric site), chances are excellent that hits will be obtained. If the goal is to employ a small molecule to mimic or disrupt the interaction between two proteins, the challenge is much greater.

**From Hits to Leads**

Only rarely do any of the initial hits in a screen turn out to be marketable drugs. Initial hits often have modest
affinity for the target, and lack the desired specificity and pharmacological properties of a successful pharmaceutical. Skilled medicinal chemists synthesize derivatives of the hits, making substitutions at accessible positions, and begin in this way to define the relationship between chemical structure and biological activity. Many parameters may require optimization, including affinity for the target, agonist/antagonist activity, permeability across cell membranes, absorption and distribution in the body, metabolism of the drug, and unwanted effects. While this approach was driven largely by instinct and trial and error in the past, modern drug development frequently takes advantage of determination of a high-resolution structure of the putative drug bound to its target. X-ray crystallography offers the most detailed structural information if the target protein can be crystallized with the lead drug bound to it. Using techniques of molecular modeling and computational chemistry, the structure provides the chemist with information about substitutions likely to improve the “fit” of the drug with the target and thus enhance the affinity of the drug for its target (and, hopefully, optimize selectivity of the drug simultaneously). Nuclear magnetic resonance (NMR) spectroscopy is another valuable technique for learning the structure of a drug-receptor complex. NMR studies are done in solution, with the advantage that the complex need not be crystallized. However, the structures obtained by NMR spectroscopy usually are not as precise as those from X-ray crystallography, and the protein target must not be larger than roughly 35–40 kDa.

The holy grail of this approach to drug invention will be to achieve success entirely through computation. Imagine a database containing detailed chemical information about millions of chemicals and a second database containing detailed structural information about all human proteins. The computational approach is to “roll” all the chemicals over the protein of interest to find those with high-affinity interactions. The dream gets bolder if we acquire the ability to roll the chemicals that bind to the target of interest over all other human proteins to discard compounds that have unwanted interactions. Finally, we also will want to predict the structural and functional consequences of a drug binding to its target (a huge challenge), as well as all relevant pharmacokinetic properties of the molecules of interest. We are a long way from realization of this fabulous dream; however, we are sufficiently advanced to imagine it and realize that it could someday be a reality. Indeed, computational approaches have suggested new uses for old drugs and offered explanations for recent failures of drugs in the later stages of clinical development (e.g., torcetrapib; see below) (Kim et al., 2010; Kinnings et al., 2009; Xie et al., 2007, 2009).

**Large Molecules Are Increasingly Important**

Protein therapeutics were uncommon before the advent of recombinant DNA technology. Insulin was introduced into clinical medicine for the treatment of diabetes following the experiments of Banting and Best in 1921. Insulin could be produced in great quantities by purification from porcine or bovine pancreas obtained from slaughterhouses. These insulins are active in man, although antibodies to the foreign proteins are occasionally problematic.

Growth hormone, used to treat pituitary dwarfism, is a case of more stringent species specificity: only the human hormone could be used after purification from pituitary glands harvested during autopsy. The danger of this approach was highlighted when patients who had received the human hormone developed Creutzfeldt-Jakob disease (the human equivalent of mad cow disease), a fatal degenerative neurological disease caused by prion proteins that contaminated the drug preparation. Thanks to gene cloning and the ability to produce large quantities of proteins by expressing the cloned gene in bacteria or eukaryotic cells grown in enormous (30,000-liter) bioreactors, protein therapeutics now utilize highly purified preparations of human (or humanized) proteins. Rare proteins can now be produced in quantity, and immunological reactions are minimized. Proteins can be designed, customized, and optimized using genetic engineering techniques. Other types of macromolecules may also be used therapeutically. For example, antisense oligonucleotides are used to block gene transcription or translation, as are small interfering RNAs (siRNAs).

Proteins utilized therapeutically include various hormones, growth factors (e.g., erythropoietin, granulocyte-colony stimulating factor), and cytokines, as well as a rapidly increasing number of monoclonal antibodies now widely used in the treatment of cancer and autoimmune diseases. Murine monoclonal antibodies can be “humanized” (by substituting human for mouse amino acid sequences). Alternatively, mice have now been “engineered” by replacement of critical mouse genes with their human equivalents, such that they make completely human antibodies. Protein therapeutics are administered parenterally, and their receptors or targets must be accessible extracellularly.
TARGETS OF DRUG ACTION

The earliest drugs came from observation of the effects of plants after their ingestion by animals. One could observe at least some of the effects of the chemical(s) in the plant and, as a side benefit, know that the plant extract was active when taken orally. Valuable drugs were discovered with no knowledge of their mechanism or site of action. While this approach is still useful (e.g., in screening for the ability of natural products to kill microorganisms or malignant cells), modern drug invention usually takes the opposite approach—starting with a statement (or hypothesis) that a certain protein or pathway plays a critical role in the pathogenesis of a certain disease, and that altering the protein’s activity would therefore be effective against that disease. Crucial questions arise:

- can one find a drug that will have the desired effect against its target?
- does modulation of the target protein affect the course of disease?
- does this project make sense economically?

The effort that may be expended to find the desired drug will be determined by the degree of confidence in the answers to the latter two questions.

Is the Target “Drugable”?  
The drugability of a target with a low-molecular-weight organic molecule relies on the presence of a binding site for the drug that can be approached with considerable affinity and selectivity. If the target is an enzyme or a receptor for a small ligand, one is encouraged. If the target is related to another protein that is known to have, for example, a binding site for a regulatory ligand, one is hopeful. However, if the known ligands are large peptides or proteins with an extensive set of contacts with their receptor, the challenge is much greater. If the goal is to disrupt interactions between two proteins, it may be necessary to find a “hot spot” that is crucial for the protein-protein interaction, and such a region may not be detected. Accessibility of the drug to its target also is critical. Extracellular targets are intrinsically easier to approach and, in general, only extracellular targets are accessible to macromolecular drugs.

Has the Target Been Validated?  
This question is obviously a critical one. A negative answer, frequently obtained only retrospectively, is a common cause of failure in drug invention. Based on extensive study of a given biological process, one may believe that protein X plays a critical role in pathological alterations of that process. However, biological systems frequently contain redundant elements, and they are adaptable. When the activity of protein X is, e.g., inhibited by a drug, redundancy in the system may permit compensation. The system also may adapt to the presence of the drug, perhaps by regulating the expression of the target or of functionally related gene products. In general, the more important the function, the greater the complexity of the system. For example, many mechanisms control feeding and appetite, and drugs to control obesity have been notoriously difficult to find. The discovery of the hormone leptin, which suppresses appetite, was based on mutations in mice that cause loss of either leptin or its receptor; either kind of mutation results in enormous obesity in both mice and people. Leptin thus appeared to be a marvelous opportunity to treat obesity. However, obese individuals have high circulating concentrations of leptin and appear quite insensitive to its action.

Modern techniques of molecular biology offer new and powerful tools for validation of potential drug targets, to the extent that the biology of model systems resembles human biology. Genes can be inserted, disrupted, and altered in mice. One can thereby create models of disease in animals or mimic the effects of long-term disruption or activation of a given biological process. If, for example, disruption of the gene encoding a specific enzyme or receptor has a beneficial effect in a valid murine model of a human disease, one may believe that the potential drug target has been validated. Mutations in humans also can provide extraordinarily valuable information. For example, loss-of-function mutations in the PCSK9 gene (encoding proprotein convertase subtilisin/kexin type 9) greatly lower concentrations of LDL cholesterol in plasma and reduce the risk of myocardial infarction (Horton et al., 2009). This single powerful observation speaks to a well-validated drug target. Based on these findings, many drug companies are actively seeking inhibitors of PCSK9 function.

Is This Drug Invention Effort Economically Viable?  
Drug invention and development is extraordinarily expensive, as discussed later in the chapter. Economic realities influence the direction of science. For example, investor-owned companies generally cannot afford to develop products for rare diseases or for diseases that are common only in economically underdeveloped
parts of the world. Funds to invent drugs targeting rare diseases or diseases primarily affecting developing countries (especially parasitic diseases) can come from taxpayers or very wealthy philanthropists; such funds generally will not come from private investors involved in running for-profit companies.

**ADDITIONAL PRECLINICAL RESEARCH**

Following the path just described can yield a potential drug molecule that interacts with a validated target and alters its function in the desired fashion (either enhancing or inhibiting the functions of the target). Now one must consider all aspects of the molecule in question—its affinity and selectivity for interaction with the target, its pharmacokinetic properties (absorption, distribution, excretion, metabolism), issues with regard to its large-scale synthesis or purification from a natural source, its pharmaceutical properties (stability, solubility, questions of formulation), and its safety. One hopes to correct, to the extent possible, any obvious deficiencies by modification of the molecule itself or by changes in the way the molecule is presented for use.

Before being administered to people, potential drugs are tested for general toxicity by monitoring the activity of various systems in two species of animals for extended periods of time. Compounds also are evaluated for carcinogenicity, genotoxicity, and reproductive toxicity. Animals are used for much of this testing, although the predictive value of results obtained in non-human species is certainly not perfect. Usually one rodent (usually mouse) and one non-rodent (often rabbit) species are used. *In vitro* and *ex vivo* assays are utilized when possible, both to spare animals and to minimize cost. If an unwanted effect is observed, an obvious question is whether it is mechanism-based (i.e., caused by interaction of the drug with its intended target) or due to an off-target effect of the drug. If the latter, there is hope of minimizing the effect by further optimization of the molecule.

Before clinical trials of a potential new drug may proceed in the U.S. (that is, before the drug candidate can be administered to a human subject), the sponsor must file an IND (Investigational New Drug) application, which is a request to the U.S. Food and Drug Administration (FDA; see the next section) for permission to administer the drug to human test subjects. The IND describes the rationale and preliminary evidence for efficacy in experimental systems, as well as pharmacology, toxicology, chemistry, manufacturing, and so forth. It also describes the plan for investigating the drug in human subjects. The FDA has 30 days to review the application, by which time the agency may disapprove the application, ask for more data, or allow initial clinical testing to proceed. In the absence of an objection or request for more information within 30 days by the FDA, a clinical trial may begin.

**CLINICAL TRIALS AND THE ROLE OF THE FDA**

The FDA is a regulatory agency within the U.S. Department of Health and Human Services. As its mission statement indicates, the FDA:

> is responsible for protecting the public health by assuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, our nation’s food supply, cosmetics, and products that emit radiation. The FDA is also responsible for advancing the public health by helping to speed innovations that make medicines and foods more effective, safer, and more affordable; and helping the public get the accurate, science-based information they need to use medicines and foods to improve their health (FDA, 2009).

The first drug-related legislation in the U.S., the Federal Food and Drug Act of 1906, was concerned only with the interstate transport of adulterated or misbranded foods and drugs. There were no obligations to establish drug efficacy or safety. This act was amended in 1938, after the deaths of 105 children from “elixir sulfanilamide,” a solution of sulfanilamide in diethylene glycol, an excellent but highly toxic solvent and an ingredient in antifreeze. The enforcement of the amended act was entrusted to the FDA. Toxicity studies as well as approval of a New Drug Application (NDA; see the next section) were required before a drug could be promoted and distributed. Although a new drug’s safety had to be demonstrated, no proof of efficacy was required. In the 1960s, thalidomide, a hypnotic drug with no obvious advantages over others, was introduced in Europe. Epidemiological research eventually established that this drug, taken early in pregnancy, was responsible for an epidemic of a relatively rare and severe birth defect, phocomelia. In reaction to this catastrophe, the U.S. Congress passed the Harris-Kefauver amendments to the Food, Drug, and Cosmetic Act in 1962. These amendments established the requirement for proof of efficacy as well of documentation of relative safety in terms of the risk-to-benefit ratio for the disease entity to be treated (the more serious the disease, the greater the acceptable risk).

One of the agency’s primary responsibilities is to protect the public from harmful medications. However, the FDA clearly faces an enormous challenge, especially in view of the widely held belief that
The mission cannot possibly be accomplished with the available resources. Moreover, harm from drugs that cause unanticipated adverse effects is not the only risk of an imperfect system; harm also occurs when the approval process delays the marketing of a new drug with important beneficial effects. Determining safety and efficacy prior to mass marketing requires careful consideration.

The Conduct of Clinical Trials

Clinical trials (as applied to drugs) are investigations in human subjects intended to acquire information about the pharmacokinetic and pharmacodynamic properties of a potential drug. Depending on the nature and phase of the trial, it may be designed to evaluate a drug’s safety, its efficacy for treatment or prevention of specific conditions in patients, and its tolerability and side effects. Efficacy must be proven and an adequate margin of safety established for a drug to be approved for sale in the U.S. The U.S. National Institutes of Health notes seven ethical requirements that must be met before a clinical trial can begin. These include social value, scientific validity, fair and objective selection of subjects, informed consent, favorable ratio of risks to benefits, approval and oversight by an independent review board (IRB), and respect for human subjects.

FDA-regulated clinical trials typically are conducted in four phases. The first three are designed to establish safety and efficacy, while Phase IV post-marketing trials delineate additional information regarding new indications, risks, and optimal doses and schedules. Table 1–1 and Figure 1–1 summarize the important features of each phase of clinical trials, especially the attrition at each successive stage over a relatively long and costly process.

When initial Phase III trials are complete, the sponsor (usually a pharmaceutical company) applies to the FDA for approval to market the drug; this application is called either a New Drug Application (NDA) or a Biologics License Application (BLA). These applications contain comprehensive information, including individual case-report forms from the hundreds or thousands of individuals who have received the drug during its Phase III testing. Applications are reviewed by teams of specialists, and the FDA may call on the help of panels of external experts in complex cases. The use of such external advisory committees greatly expands the

talent pool available to assist in making important and difficult decisions.

Under the provisions of the Prescription Drug User Fee Act (PDUFA, enacted initially in 1992 and renewed in 2007), pharmaceutical companies now provide a significant portion of the FDA budget via user fees, a legislative effort to expedite the drug approval review process. PDUFA also broadened the FDA’s drug safety program and increased resources for review of television drug advertising. The larger FDA staffing now in place has shortened the time required for review; nevertheless, the process is a lengthy one. A 1-year review time is considered standard, and 6 months is the target if the drug candidate is granted priority status because of its importance in filling an unmet need. Unfortunately, these targets are not always met.

Before a drug is approved for marketing, the company and the FDA must agree on the content of the “label” (package insert)—the official prescribing information. This label describes the approved indications for use of the drug and clinical pharmacological information including dosage, adverse reactions, and special warnings and precautions (sometimes posted in a “black box”). Promotional materials used by pharmaceutical companies cannot deviate from information contained in the package insert. Importantly, the physician is not bound by the package insert; a physician in the U.S. may legally prescribe a drug for any purpose that she or he deems reasonable. However, third-party payers (insurance companies, Medicare, and so on) generally will not reimburse a patient for the cost of a drug used for an “off-label” indication unless the new use is supported by one of several compendia such as the U.S. Pharmacopeia. Furthermore, a physician may be vulnerable to litigation if untoward effects result from an unapproved use of a drug.

**Determining “Safe” and “Effective”**

To demonstrate efficacy to the FDA requires performing “adequate and well-controlled investigations,” generally interpreted to mean two replicate clinical trials that are usually, but not always, randomized, double-blind, and placebo-controlled. Is a placebo the proper control? The World Medical Association’s *Declaration of Helsinki* (2000) discourages use of placebo controls when an alternative treatment is available for comparison. What must be measured in the trials? In a straightforward trial, a readily quantifiable parameter (a secondary or surrogate end point), thought to be predictive of relevant clinical outcomes, is measured in matched drug- and placebo-treated groups. Examples of surrogate end points include LDL cholesterol as a predictor of myocardial infarction, bone mineral density as a predictor of fractures, or hemoglobin A\(_1c\) as a predictor of the complications of diabetes mellitus. More stringent trials would require demonstration of reduction of the incidence of myocardial infarction in patients taking a candidate drug in comparison with those taking an...
HMG-CoA reductase inhibitor (statin) or other LDL cholesterol-lowering agent, or reduction in the incidence of fractures in comparison with those taking a bisphosphonate. Use of surrogate end points significantly reduces cost and time required to complete trials but there are many mitigating factors, including the significance of the surrogate end point to the disease or condition that the candidate drug is intended to treat.

Some of the difficulties are well illustrated by recent experiences with ezetimibe, a drug that inhibits absorption of cholesterol from the gastrointestinal tract and lowers LDL cholesterol concentrations in plasma, especially when used in combination with a statin. Lowering of LDL cholesterol was assumed to be an appropriate surrogate end point for the effectiveness of ezetimibe to reduce myocardial infarction and stroke, consequences of cholesterol accumulation in foam cells beneath the endothelium of vessels. Surprisingly, the ENHANCE trial demonstrated that the combination of ezetimibe and a statin did not reduce intima-media thickness of carotid arteries (a more direct measure of sub-endothelial cholesterol accumulation) compared with the statin alone, despite the fact that the drug combination lowered LDL cholesterol concentrations substantially more than did either drug alone (Kastelein et al., 2008). Critics of ENHANCE argue that the patients in the study had familial hypercholesterolemia, had been treated with statins for years, and did not have carotid artery thickening at the initiation of the study. Should ezetimibe have been approved? Must we return to measurement of true clinical end points (e.g., myocardial infarction) before approval of drugs that lower cholesterol by novel mechanisms? The costs involved in such extensive and expensive trials must be borne somehow (costs are discussed later in the chapter). Such a study (IMPROVE-IT) is now in progress; thousands of patients are enrolled and we will know the outcome in a few years.

The drug torcetrapib provides a related example in the same therapeutic area. Torcetrapib elevates HDL cholesterol (the “good cholesterol”), and higher levels of HDL cholesterol are statistically associated with (are a surrogate end point for) a lower incidence of myocardial infarction. Surprisingly, clinical administration of torcetrapib caused a significant increase in mortality from cardiovascular events, ending a development path of 15 years and $800 million. (For a recent computational-systems biologic analysis that may explain this failure, see Xie et al., 2009.) In this case, approval of the drug based on this secondary end point would have been a mistake (Cutler, 2007).

The concept of drug safety is perhaps even more complex (Institute of Medicine, 2007). No drug is totally safe; all drugs produce unwanted effects in at least some people at some dose. Many unwanted and serious effects of drugs occur so infrequently, perhaps only once in several thousand patients, that they go undetected in the relatively small populations (a few thousand) in the standard Phase III clinical trial (Table 1–1). To detect and verify that such events are in fact drug-related would require administration of the drug to tens or hundreds of thousands of people during clinical trials, adding enormous expense and time to drug development and delaying access to potentially beneficial therapies. In general, the true spectrum and incidence of untoward effects becomes known only after a drug is released to the broader market and used by a large number of people (Phase IV, post-marketing surveillance). Drug development costs, and thus drug prices, could be reduced substantially if the public were willing to accept more risk. This would require changing the way we think about a pharmaceutical company’s liability for damages from an unwanted effect of a drug that was not detected in clinical trials deemed adequate by the FDA.

While the concept is obvious, many lose sight of the fact that extremely severe unwanted effects of a drug, including death, may be deemed acceptable if its therapeutic effect is sufficiently unique and valuable. Such dilemmas can become issues for great debate. The sufficiency of a therapeutic effect in the presence of an unwanted effect of a drug may be quite subjective. One person’s meat may indeed be another person’s poison. Great effort may be made to quantify the ratio of risks to benefits, but the answers are frequently not simple.

Several strategies exist to detect adverse reactions after marketing of a drug, but debate continues about the most efficient and effective method. Formal approaches for estimation of the magnitude of an adverse drug response include the follow-up or “cohort” study of patients who are receiving a particular drug; the “case-control” study, where the frequency of drug use in cases of adverse responses is compared to controls; and meta-analysis of pre- and post-marketing studies. Because of the shortcomings of these types of studies to detect what may be a relatively rare event, additional approaches must be used. Spontaneous reporting of adverse reactions has proven to be an effective way to generate an early signal that a drug may be causing an adverse event (Aagard and Hansen, 2009). It is the only practical way to detect rare events, events that occur after prolonged use of drug, adverse effects that are delayed in appearance, and many drug-drug interactions. Recently, considerable effort has gone into improving the reporting system in the U.S., called MedWatch (Brewer and Colditz, 1999; Kessler et al., 1993; see also Appendix 1). Still, the voluntary reporting system in the U.S. is not nearly as robust as the legally mandated systems of some other countries. A disturbing number of physicians are not aware that the FDA has a reporting system for adverse drug reactions, even though the system has been repeatedly publicized in major medical journals (Trontell, 2004). Relatively few physicians actually file adverse drug response reports; those received frequently are incomplete or of such poor quality that the data are not considered reliable (Fontarosa et al., 2004).

The most important spontaneous reports are those that describe serious reactions. Reports on newly marketed drugs (within the first 5 years of a drug’s introduction) are the most significant, even though the physician may not be able to attribute a causal role to a particular drug. This system provides early warning signals of unexpected adverse effects that can then be investigated by more
formal techniques. However, the system also serves to monitor changes in the nature or frequency of adverse drug reactions due to aging of the population, changes in the disease itself, or the introduction of new, concurrent therapies. The primary sources for the reports are responsible, alert physicians; other potentially useful sources are nurses, pharmacists, and students in these disciplines. In addition, hospital-based pharmacy and therapeutics committees and quality assurance committees frequently are charged with monitoring adverse drug reactions in hospitalized patients, and reports from these committees should be forwarded to the FDA. The simple forms for reporting may be obtained 24 hours a day, 7 days a week by calling 800-FDA-1088; alternatively, adverse reactions can be reported directly using the Internet (www.fda.gov/medwatch). Health professionals also may contact the pharmaceutical manufacturer, who is legally obligated to file reports with the FDA. With this facile reporting system, the clinician can serve as a vital sentinel in the detection of unexpected adverse reactions to drugs.

PUBLIC POLICY CONSIDERATIONS AND CRITICISMS OF THE PHARMACEUTICAL INDUSTRY

There is no doubt that drugs can save lives, prolong lives, and improve the quality of people’s lives. Like adequate nutrition, vaccinations and medications are important for public health. However, in a free-market economy, access to safe and effective drugs (or any kind of healthcare, for that matter) is not equitable. Not surprisingly, there is a substantial tension between those who would treat drugs as entitlements and those who view drugs as high-tech products of a capitalistic society. Supporters of the entitlement position argue that the constitutional right to life should guarantee access to drugs and other healthcare, and they are critical of pharmaceutical companies and others who profit from the business of making and selling drugs. Free-marketers point out that, without a profit motive, it would be difficult to generate the resources and innovation required for new drug development.

The media tend to focus on public policy with regard to the ethics of drug testing, the effectiveness of government regulations, and conflicts of interest on the part of researchers, physicians, and others who may have a personal stake in the success of a drug. In addition, high-profile legal battles have been waged recently over access to experimental (non-FDA-approved) drugs and over injuries and deaths resulting from both experimental and approved drugs. Clearly the public has an interest in both the pharmaceutical industry and its oversight. Consequently, drug development is not only a scientific process but also a political one in which attitudes can change quickly. Little more than a decade ago Merck was named as America’s most admired company by *Fortune* magazine seven years in a row—a record that still stands. Today, Johnson and Johnson is the only pharmaceutical company in the top 50 of the most-admired list, and this likely reflect their sales of consumer products, such as band-aids and baby oil, rather than pharmaceuticals. The next sections explore some of the more controversial issues surrounding drug invention and development and consider some of the more strident criticisms that have been leveled at the pharmaceutical industry (Angell, 2004).

Mistrust of Scientists and Industry

Those critical of the pharmaceutical industry frequently begin from the position that people (and animals) need to be protected from greedy and unscrupulous companies and scientists (Kassirer, 2005). They can point to the very unfortunate (and highly publicized) occurrences of graft, fraud, and misconduct by scientists and industry executives, and unethical behavior in university laboratories and community physicians’ offices. These problems notwithstanding, development of new and better drugs is good for people and animals. In the absence of a government-controlled drug development enterprise, our current system relies predominantly on investor-owned pharmaceutical companies that, like other companies, have a profit motive and an obligation to shareholders.

Pricing and Profitability

The price of prescription drugs causes great consternation among consumers, especially as many health insurers seek to control costs by choosing not to cover certain “brand name” products. Further, a few drugs (especially for treatment of cancer) have been introduced to the market in recent years at prices that greatly exceeded the costs of development, manufacture, and marketing of the product. Many of these products were discovered in government laboratories or in university laboratories supported by federal grants. The U.S. is the only large country in the world that places no controls on drug prices and where price plays no role in the drug approval process. Many U.S. drugs cost much more in the United States than overseas. The result is that U.S. consumers subsidize drug costs for the rest of the world, including the economically developed world, and they are irritated by that fact.

As explained earlier, the drug development process is long, expensive, and highly risky (Figure 1–1 and Table 1–1). Only a small fraction of compounds that enter the development pipeline ever make
it to market as therapeutic agents. Consequently, drugs must be priced to recover the substantial costs of invention and development, and to fund the marketing efforts needed to introduce new products to physicians and patients. Nevertheless, as U.S. healthcare spending continues to rise at an alarming pace, prescription drugs account for only ~10% of total healthcare expenditures (Kaiser Family Foundation, 2009), and a significant fraction of this drug cost is for low-priced nonproprietary medicines. Although the increase in prices is significant in certain classes of drugs (e.g., antineoplastic agents), the total price of prescription drugs is growing at a slower rate than other healthcare costs. Even drastic reductions in drug prices that would severely limit new drug invention would not lower the overall healthcare cost by more than a few percent.

Are profit margins excessive among the major pharmaceutical companies? There is no objective answer to this question. Pragmatic answers come from the markets and from company survival statistics. A free-market system says that rewards should be greater for particularly risky fields of endeavor, and the rewards should be greater for those willing to take the risk. The pharmaceutical industry is clearly one of the more risky. The costs to bring products to market are enormous; the success rate is low (accounting for much of the cost); effective patent protection is only about a decade (see “Intellectual Property and Patents” later in the chapter), requiring every company to completely reinvent itself on a roughly 10-year cycle (about equal to the lifespan of a CEO or an executive vice president for research and development); regulation is stringent; product liability is great even after an approved product has reached the market; competition is fierce.

The ratio of the price of a company’s stock to its annual earnings per share of stock is called the price-to-earnings ratio (P/E) and is a measure of the stock market’s predictions about a company’s prospects. A decade ago, pharmaceutical companies’ stocks were priced at a 20% premium to the market; today they sell at a 34% discount; this is a dramatic change. A decade or two ago, the pharmaceutical industry was incredibly fragmented, with the biggest players commanding only very modest shares of the total market. Mergers and acquisitions continue to narrow the field. For example, Hoechst AG, Roussel Uclaf, and Marion Merrell Dow plus Rhone-Poulenc became Aventis, which then merged with Sanofi-Synthélabo to become Sanofi-Aventis. The giant Pfizer represents the consolidation of Warner Lambert, Park Davis, Searle, Monsanto, Pharmacia, Upjohn, and Agouron, among others. Pfizer’s acquisition of Wyeth is currently pending; Wyeth is the result of the consolidation of American Home Products, American Cyanamid, Ayerst, A. H. Robbins, Ives Laboratories, and Genetics Institute. The pharmaceutical world is shrinking.

Who Pays?
Healthcare in the U.S. is funded by a mix of private payers and government programs. Correspondingly, the cost of prescription drugs is borne by consumers (“out-of-pocket”), private insurers, and public insurance programs like Medicare, Medicaid, and the State Children’s Health Insurance Program (SCHIP). Recent initiatives by major retailers and mail-order pharmacies run by private insurers to offer consumer incentives for purchase of generic drugs have helped to contain the portion of household expenses spent on pharmaceuticals; however, more than one-third of total retail drug costs in the U.S. are paid with public funds—tax dollars.

Healthcare in the U.S. is more expensive than everywhere else, but it is not, on average, demonstrably better than everywhere else. However, the U.S. is considerably more socio-economically diverse than many of the countries with which comparisons are made. Forty-five million Americans are uninsured and seek routine medical care in emergency rooms. Remedies are the current subjects of complex medical, public health, economic, and political debates. Solutions to these real problems must recognize both the need for effective ways to incentivize innovation and to permit, recognize, and reward compassionate medical care.

Intellectual Property and Patents
Drug invention, like any other, produces intellectual property eligible for patent protection. Without patent protection, no company could think of making the investments necessary for drug invention and development. With the passage of the Bayh-Dole Act (35 USC 200) in 1980, the federal government created strong incentives for scientists at academic medical centers to approach drug invention with an entrepreneurial spirit. The Act transferred intellectual property rights to the researchers themselves and in some instances to their respective institutions in order to encourage the kinds of partnerships with industry that would bring new products to market, where they could benefit the public. This resulted in the development of “technology transfer” offices at virtually every major university, which help scientists to apply for patents and to negotiate licensing arrangements with industry (Geiger and Sá, 2008). While the need to protect intellectual property is generally accepted, the encouragement of public-private research collaborations has given rise to concerns about conflicts of interest by scientists and universities (Kaiser, 2009).

Despite the complications that come with university-industry relations, patent protection is enormously important for innovation. As noted in 1859 by Abraham Lincoln (the only U.S. president to ever hold a patent [# 6469, for a device to lift boats over shoals]), by giving the inventor exclusive use of his or her invention for limited time, the patent system “added the fuel of interest to the fire of genius, in the discovery and production of new and useful things.” The U.S. patent protection system mandates that when a new drug is invented, the patent covering the property lasts only 20 years from
the time the patent is filed. During this period, the patent owner may bring suit to prevent others from marketing the product, giving the manufacturer of the brand-name version exclusive rights to market and sell the drug. When the patent expires, equivalent products can come on the market, where they are sold much more cheaply than the original drug, and without the huge development costs borne by the original patent holder. The marketer of the so-called generic product must demonstrate “therapeutic equivalence” of the new product: it must contain equal amounts of the same active chemical ingredient and achieve equal concentrations in blood when administered by the same routes.

Note, however, that the long time course of drug development, usually more than 10 years (Figure 1–1), dramatically reduces the time during which patent protection functions as intended. Although The Drug Price Competition and Patent Term Restoration Act of 1984 (the “Hatch-Waxman Act”) permits a patent holder to apply for extension of a patent term to compensate for delays in marketing due to FDA approval processes, patents can be extended only for half the time period consumed by the regulatory approval process, for a maximum of 14 years. The average new drug brought to market now enjoys only ~10-12 years of patent protection. Some argue that patent protection for drugs should be shortened, based on the hope that earlier generic competition will lower healthcare costs. The counter-argument is that new drugs would have to bear higher prices to provide adequate compensation to companies during a shorter period of protected time. If that is true, lengthening patent protection would actually permit lower prices. Recall that patent protection is worth little if a superior competitive product is invented and brought to market at any time in the patent cycle.

Drug Promotion

In an ideal world, physicians would learn all they need to know about drugs from the medical literature, and good drugs would thereby sell themselves; we are a long way from the ideal. Instead we have print advertising and visits from salespeople directed at physicians, and extensive so-called “direct-to-consumer” advertising aimed at the public (in print, on the radio, and especially on television). There are roughly 100,000 pharmaceutical sales representatives in the U.S. who target ~10 times that number of physicians. It has been noted that college cheerleading squads are attractive sources for recruitment of this sales force. The amount spent on promotion of drugs approximates or perhaps even exceeds that spent on research and development. Pharmaceutical companies have been especially vulnerable to criticism for some of their marketing practices.

Promotional materials used by pharmaceutical companies cannot deviate from information contained in the package insert. In addition, there must be an acceptable balance between presentation of therapeutic claims for a product and discussion of unwanted effects. Nevertheless, direct-to-consumer advertising of drugs remains controversial and is permitted only in the U.S. and New Zealand. Physicians frequently succumb with misgivings to patients’ advertising-driven requests for specific medications. The counter-argument is that patients are educated by such marketing efforts and in many cases will then seek medical care, especially for conditions that they may have been denying (e.g., depression) (Donohue et al., 2007).

The major criticism of drug marketing involves some of the unsavory approaches used to influence physician behavior. Gifts of value (e.g., sports tickets) are now forbidden, but dinners where drug-prescribing information is presented are widespread. Large numbers of physicians are paid as “consultants” to make presentations in such settings. It has been noted that the pharmaceutical companies’ sales representatives frequently deliver more pizza and free drug samples than information to a doctor’s office. These practices have now been brought squarely into the public view, and acceptance of any gift, no matter how small, from a drug company by a physician, is now forbidden at many academic medical centers and by law in several states (e.g., Vermont and Minnesota).

The board of directors of the Pharmaceutical Research and Manufacturers of America (PhRMA) has recently adopted an enhanced code on relationships with U.S. healthcare professionals. This code prohibits the distribution of non-educational items, prohibits company sales representatives from providing restaurant meals to healthcare professionals, and requires companies to ensure that their representatives are trained about laws and regulations that govern interactions with healthcare professionals.

Exploitation or “Medical Imperialism”

There is concern about the degree to which U.S. and European patent protection laws have restricted access to potentially life-saving drugs in developing countries. Because development of new drugs is so expensive, private-sector investment in pharmaceutical innovation naturally has focused on products that will have lucrative markets in wealthy countries such as the U.S., which combines patent protection with a free-market economy. However, to lower costs, companies increasingly test their experimental drugs outside the U.S. and the E.U., in countries such as China, India, Russia, and Mexico, where there is less regulation and easier access to large numbers of patients. If the drug is successful in obtaining marketing approval, consumers in these countries often cannot afford the drugs they helped to develop. Some ethicists have argued that this practice
violates the justice principle articulated in The Belmont Report (1979), which states that “research should not unduly involve persons from groups unlikely to be among the beneficiaries of subsequent applications of the research.” On the other hand, the conduct of trials in developing nations also frequently brings needed medical attention to underserved populations. Some concerns about the inequitable access to new pharmaceuticals in the very countries where they have been tested have been alleviated by exemptions made to the World Trade Organization’s Agreement on Trade Related Aspects of Intellectual Property Rights (TRIPS) agreement. The TRIPS agreement originally made pharmaceutical product patent protection mandatory for all developing countries beginning in 2005. However, recent amendments have exempted the least developed countries from pharmaceutical patent obligations at least through 2016. Consequently, those developing countries that do not currently provide patent protection for pharmaceutical products can legally import less expensive versions of the same drugs from countries such as India where they are manufactured.

**Product Liability**

Product liability laws are intended to protect consumers from defective products. Pharmaceutical companies can be sued for faulty design or manufacturing, deceptive promotional practices, violation of regulatory requirements, or failure to warn consumers of known risks. So-called “failure to warn” claims can be made against drug makers even when the product is approved by the FDA. Although the traditional defense offered by manufacturers in such cases is that a “learned intermediary” (the patient’s physician) wrote the prescription for the drug in question, the rise of direct-to-consumer advertising by drug companies has undermined this argument. With greater frequency, courts are finding companies that market prescription drugs directly to consumers responsible when these advertisements fail to provide an adequate warning of potential adverse effects.

Although injured patients are entitled to pursue legal remedies when they are harmed, the negative effects of product liability lawsuits against pharmaceutical companies may be considerable. First, fear of liability that causes pharmaceutical companies to be overly cautious about testing also delays access to the drug. Second, the cost of drugs increases for consumers when pharmaceutical companies increase the length and number of trials they perform to identify even the smallest risks, and when regulatory agencies increase the number or intensity of regulatory reviews. To the extent that these price increases may actually reduce the number of people who can afford to buy the drugs, there can be a negative effect on public health. Third, excessive liability costs create disincentives for development of so-called “orphan drugs,” pharmaceuticals that would be of benefit to a very small number of patients. Should pharmaceutical companies be liable for failure to warn when all of the rules were followed and the product was approved by the FDA but the unwanted effect was not detected because of its rarity or another confounding factor? The only way to find “all” of the unwanted effects that a drug may have is to market it—to conduct a Phase IV “clinical trial” or observational study. Enlightened self-interest works both ways, and this basic friction between risk to patients and the financial risk of drug development does not seem likely to be resolved except on a case-by-case basis.

The Supreme Court of the U.S. added further fuel to these fiery issues in 2009 in the case *Wyeth v. Levine*. A patient (Levine) suffered gangrene of an arm following inadvertent arterial administration of the drug promethazine. The health-care provider had intended to administer the drug by so-called intravenous push. The FDA-approved label for the drug *warned against* but did not prohibit administration by intravenous push. The state courts and then the U.S. Supreme Court held both the health-care provider and the company liable for damages. FDA approval of the label apparently neither protects a company from liability nor prevents individual states from imposing regulations more stringent than those required by the federal government. Perhaps this decision rested more on the intricacies of the law than on consideration of proper medical practice.

**“Me Too” Versus True Innovation: The Pace of New Drug Development**

“Me-too drug” is a term used to describe a pharmaceutical that is usually structurally similar to one or more drugs that already are on the market. The other names for this phenomenon are “derivative medications, “molecular modifications,” and “follow-up drugs.” In some cases, a me-too drug is a different molecule developed deliberately by a competitor company to take market share from the company with existing drugs on the market. When the market for a class of drugs is especially large, several companies can share the market and make a profit. Other me-too drugs result coincidentally from numerous companies developing products simultaneously without knowing which drugs will be approved for sale.

Some me-too’s are simply slightly altered formulations of a company’s own drug, packaged and promoted as if it really offers something new. An example of this type of me-too is the heartburn medication esomeprazole, which is marketed by the same company that makes omeprazole. Omeprazole is a mixture of two stereoisomers; esomeprazole contains only one of the isomers and is eliminated less rapidly. Development of esomeprazole created a new period of market exclusivity, although generic versions of omeprazole are marketed, as are branded congeners of omeprazole/esomeprazole.

There are valid criticisms of me-too drugs. First, it is argued that an excessive emphasis on profit will stifle true innovation. Of the 487 drugs approved by the FDA between 1998 and 2003,
only 67 (14%) were considered by the FDA to be new molecular entities. Second, to the extent that some me-too drugs are more expensive than the older versions they seek to replace, the costs of healthcare are increased without corresponding benefit to patients. Nevertheless, for some patients, me-too drugs may have better efficacy or fewer side effects or promote compliance with the treatment regimen. For example, the me-too that can be taken but once a day and not more frequently is convenient and promotes compliance. Some “me-toos” add great value from a business and medical point of view. Atorvastatin was the seventh statin to be introduced to market; it subsequently became the best-selling drug in the world.

Critics of the pharmaceutical companies argue that they are not innovative and do not take risks and, further, that medical progress is actually slowed by their excessive concentration on me-too products. Figure 1–2 summarizes a few of the facts behind this and some of the other arguments just discussed. Clearly, smaller numbers of new molecular entities have been approved by the FDA over the past decade, despite the industry’s enormous investment in research and development. This disconnect has occurred at a time when combinatorial chemistry was blooming, the human genome was being sequenced, highly automated techniques of screening were being developed, and new techniques of molecular biology and genetics were offering novel insights into the pathophysiology of human disease. Some blame mismanagement of the companies. Some say that industry science is not of high quality, an argument readily refuted. Some believe that the low-hanging fruit has been plucked, that drugs for complex diseases, such as neural degeneration or psychiatric and behavioral disorders, will be harder to develop. The biotechnology industry has had its successes, especially in exploiting relatively obvious opportunities that the new recombinant DNA technologies made available (e.g., insulin, growth hormone, erythropoietin, and more recently, monoclonal antibodies to approachable extracellular targets). Despite their innovations, the biotechnology companies have not, on balance, been more efficient at drug invention or discovery than the traditional major pharmaceutical companies.

Whatever the answers, the trends evident in Figure 1–2 must be reversed (Garnier, 2008). The current path will not sustain today’s companies as they face a major wave of patent expirations over the next several years.
years. Acquisition of other companies as a business strategy for survival can be successful for only so long. There are arguments, some almost counter-intuitive, that development of much more targeted, individualized drugs, based on a new generation of molecular diagnostic techniques and improved understanding of disease in individual patients, could improve both medical care and the survival of pharmaceutical companies. Finally, many of the amazing advances in genetics and molecular biology are still very new, particularly when measured in the time frame required for drug development. One can hope that modern molecular medicine will sustain the development of more efficacious and more specific pharmacological treatments for an ever wider spectrum of human diseases.

BIBLIOGRAPHY

In order to understand and control the therapeutic action of drugs in the human body, one must know how much drug will reach the site(s) of drug action and when this will occur. The absorption, distribution, metabolism (biotransformation), and elimination of drugs are the processes of pharmacokinetics (Figure 2–1). Understanding and employing pharmacokinetic principles can increase the probability of therapeutic success and reduce the occurrence of adverse drug effects in the body.

**PHYSICOCHEMICAL FACTORS IN TRANSFER OF DRUGS ACROSS MEMBRANES**

The absorption, distribution, metabolism, excretion, and action of a drug all involve its passage across cell membranes. Mechanisms by which drugs cross membranes and the physicochemical properties of molecules and membranes that influence this transfer are critical to understanding the disposition of drugs in the human body. The characteristics of a drug that predict its movement and availability at sites of action are its molecular size and structural features, degree of ionization, relative lipid solubility of its ionized and non-ionized forms, and its binding to serum and tissue proteins. In most cases, a drug must traverse the plasma membranes of many cells to reach its site of action. Although barriers to drug movement may be a single layer of cells (intestinal epithelium) or several layers of cells and associated extracellular protein (skin), the plasma membrane represents the common barrier to drug distribution.

**Cell Membranes.** The plasma membrane consists of a bilayer of amphipathic lipids with their hydrocarbon chains oriented inward to the center of the bilayer to form a continuous hydrophobic phase and their hydrophilic heads oriented outward. Individual lipid molecules in the bilayer vary according to the particular membrane and can move laterally and organize themselves with cholesterol (e.g., sphingolipids), endowing the membrane with fluidity, flexibility, organization, high electrical resistance, and relative impermeability to highly polar molecules. Membrane proteins embedded in the bilayer serve as structural anchors, receptors, ion channels, or transporters to transduce electrical or chemical signaling pathways and provide selective targets for drug actions. In contrast to earlier proposals that cell membranes are fluid and thus proteins collide in an unordered fashion, we now understand that membranes are highly ordered and compartmented (Pinaud et al., 2009; Singer, 2004). These proteins may be associated with caveolin and sequestered within caveolae; they may be excluded from caveolae; or they may be organized in signaling domains rich in cholesterol and sphingolipid not containing caveolin or other scaffolding proteins (i.e., lipid rafts).

Cell membranes are relatively permeable to water either by diffusion or by flow resulting from hydrostatic or osmotic differences across the membrane, and bulk flow of water can carry with it drug molecules. However, proteins with drug molecules bound to them are too large and polar for this type of membrane passage to occur. Transmembrane movement of drug generally is limited to unbound drug; thus drug-protein complexes constitute an inactive reservoir of drug that can influence both therapeutic as well as unwanted drug effects. Paracellular passage through intercellular gaps is sufficiently large that transfer across capillary endothelium is generally limited by blood flow and not by other factors. As described later, such membrane passage is an important factor in filtration across the glomerulus in the kidney. Important exceptions exist in such capillary diffusion; “tight” intercellular junctions are present in specific tissues, and paracellular passage in them is limited. Capillaries of the central nervous system (CNS) and a variety of epithelial tissues have tight junctions. Bulk flow of water can carry with it small water-soluble substances, but bulk-flow transfer is limited when the molecular mass of the solute exceeds 100–200 Da. Accordingly, most large lipophilic drugs must pass through the cell membrane itself (Figure 2–2).
Passive Flux Across Membranes. Drugs cross membranes either by passive processes or by mechanisms involving the active participation of components of the membrane. In passive transfer, the drug molecule usually penetrates by diffusion along a concentration gradient by virtue of its solubility in the lipid bilayer. Such transfer is directly proportional to the magnitude of the concentration gradient across the membrane, to the lipid-water partition coefficient of the drug, and to the membrane surface area exposed to the drug. The greater the partition coefficient, the higher is the concentration of drug in the membrane and the faster is its diffusion. After a steady state is attained, the concentration of the unbound drug is the same on both sides of the membrane if the drug is a non-electrolyte. For ionic compounds, the steady-state concentrations depend on the electrochemical gradient for the ion and on differences in pH across the membrane, which will influence the state of ionization of the molecule disparately on either side of the membrane and can effectively trap drug on one side of the membrane.

Weak Electrolytes and the Influence of pH. Many drugs are weak acids or bases that are present in solution as both the non-ionized and ionized species. The non-ionized molecules usually are more lipid soluble and can diffuse readily across the cell membrane. In contrast, the ionized molecules usually are less able to penetrate the lipid membrane because of their low lipid solubility, and passage will depend on the leakiness of the membrane related to the membrane’s electrical resistance. Therefore, the transmembrane distribution of a weak electrolyte is influenced by its $pK_a$ and the pH gradient across the membrane. The $pK_a$ is the pH at which half the drug (weak acid or base electrolyte) is in its ionized form.

To illustrate the effect of pH on distribution of drugs, the partitioning of a weak acid ($pK_a = 4.4$) between plasma (pH = 7.4) and gastric juice (pH = 1.4) is depicted in Figure 2–3. Assume that the gastric mucosal membrane behaves as a simple lipid barrier with a high electrical resistance that is permeable only to the lipid-soluble, non-ionized form of the acid. The ratio of non-ionized to ionized drug at each pH is readily calculated from the Henderson-Hasselbalch equation:

$$\log \frac{[\text{protonated form}]}{[\text{unprotonated form}]} = pK_a - \text{pH} \quad \text{(Equation 2–1)}$$
This equation relates the pH of the medium around the drug and the drug’s acid dissociation constant ($pK_a$) to the ratio of the protonated (HA or BH$^+$) and unprotonated (A$^-$ or B) forms, where $\frac{[A^-][H^+]}{[HA]} = K_a = [A^-][H^+]/[HA]$ describes the dissociation of an acid, and $B = [B][H^+]/[BH^+]$ describes the dissociation of the protonated form of a base.

In the example of Figure 2–3, the ratio of non-ionized to ionized drug in plasma is 1:1000; in gastric juice, the ratio is 1:0.001, as given in brackets in Figure 2–3. The total concentration ratio between the plasma and the gastric juice therefore would be 1000:1 if such a system came to a steady state. For a weak base with a $pK_a$ of 4.4 (e.g., chlordiazepoxide), the ratio would be reversed, as would the thick horizontal arrows in Figure 2–3, which indicate the predominant species at each pH. Accordingly, at steady state, an acidic drug will accumulate on the more basic side of the membrane and a basic drug on the more acidic side.

Common ionizable groups on drug molecules are carboxylic acids ($pK_a \approx 4.5$) and primary amino groups ($pK_a \approx 9.5$), but myriad others are possible. Resonance structures and electron-withdrawing groups can change the $pK_a$, and many compounds have multiple ionizable groups; thus, $pK_a$ values vary over a broad range. Furthermore, some drugs contain quaternary amines with a permanent positive charge. One consequence of a drug being ionized at physiological pH is illustrated by the relative lack of sedative effects of second generation histamine H$_1$ antagonists: second generation antihistamines are ionized molecules (less lipophilic) that cross the blood-brain barrier poorly compared to first-generation agents (uncharged at pH 7.4). The effects of net charge are observable elsewhere in the body, in the kidney tubules, for instance. Urine pH can vary over a ride range, from 4.5 to 8. As urine pH drops (as [H$^+$] increases), weak acids (A$^-$) and weak bases (B) will exist to a greater extend in their protonated forms (HA and BH$^+$); the reverse is true as pH rises, where A$^-$ and B will be favored. In the kidney tubules where a lipid soluble (uncharged) drug can be reabsorbed by passive diffusion, excretion of the drug can be promoted by altering the pH of the urine to favor the ionized state (A$^-$ or BH$^+$). Thus, alkaline urine favors excretion of weak acids; acid urine favors excretion of weak bases. Elevation of urine pH (by giving sodium bicarbonate) will promote urinary excretion of weak acids such as aspirin ($pK_a \approx 3.5$) and urate ($pK_a \approx 5.8$). This principle of in trapping is an important process in drug distribution.

These considerations have obvious implications for the absorption and excretion of many drugs, as will be discussed more specifically. The establishment of concentration gradients of weak electrolytes across membranes with a pH gradient is a physical process and does not require an active electrolyte transport system. All that is necessary is a membrane preferentially permeable to one form of the weak electrolyte and a pH gradient across the membrane. The establishment of the pH gradient, however, is an active process.

**Carrier-Mediated Membrane Transport.** While passive diffusion through the bilayer is dominant in the disposition of most drugs, carrier-mediated mechanisms also play an important role. Active transport is characterized by a direct requirement for energy, movement against an electrochemical gradient, saturation, selectivity, and competitive inhibition by co-transported compounds. Na$^+$.K$^+$.ATPase is an important example of an active transport mechanism that is a therapeutic target of digoxin in the treatment of heart failure (Chapter 28). Secondary active transport uses the electrochemical energy stored in a gradient to move another molecule against a concentration gradient; e.g., the Na$^+$–Ca$^{2+}$ exchange protein uses the energy stored in the Na$^+$ gradient established by the Na$^+$, K$^+$.ATPase mechanism to export cytosolic Ca$^{2+}$ and maintain it at a low basal level, ~100 nM in most cells (Chapter 3); similarly, the Na$^+$-dependent glucose transporters SGLT1 and SGLT2 move glucose across membranes of gastrointestinal (GI) epithelium and renal tubules by coupling glucose transport to downhill Na$^+$ flux.

Facilitated diffusion describes a carrier-mediated transport process in which there is no input of energy, and therefore enhanced movement of the involved substance is down a chemical gradient as in the permeation of glucose across a muscle cell membrane mediated by the insulin-sensitive glucose transporter GLUT4. Such mechanisms, which may be highly selective for a specific conformational structure of a drug, are involved in the transport of endogenous
Absorption is the movement of a drug from its site of administration into the central compartment (Figure 2–1) and the extent to which this occurs. For solid dosage forms, absorption first requires dissolution of the tablet or capsule, thus liberating the drug. The clinician is concerned primarily with bioavailability rather than absorption. Bioavailability is a term used to indicate the fractional extent to which a dose of drug reaches its site of action or a biological fluid from which the drug has access to its site of action. For example, a drug given orally must be absorbed first from the GI tract, but net absorption may be limited by the characteristics of the dosage form, the drug’s physicochemical properties, by intestinal metabolism, and by transporter export back into the intestinal lumen. The absorbed drug then passes through the liver, where metabolism and biliary excretion may occur before the drug enters the systemic circulation. Accordingly, a fraction of the administered and absorbed dose of drug will be inactivated or diverted in substantially (first-pass effect). This decrease in availability is a function of the anatomical site from which absorption takes place; other anatomical, physiological, and pathological factors can influence bioavailability (described later), and the choice of the route of drug administration must be based on an understanding of these conditions. Moreover, knowledge of drugs that undergo significant metabolism or require active transport across the intestinal and hepatic membranes instructs our understanding of adverse events in therapeutics, since some drugs are substrates for the same drug metabolizing enzymes or drug transporters and thus compete for metabolism and transport.

Oral (Enteral) Versus Parenteral Administration. Often there is a choice of the route by which a therapeutic agent may be administered, and knowledge of the advantages and disadvantages of the different routes of administration is then of primary importance. Some characteristics of the major routes employed for systemic drug effect are compared in Table 2–1.

Oral ingestion is the most common method of drug administration. It also is the safest, most convenient, and most economical. Disadvantages to the oral route include limited absorption of some drugs because of their physical characteristics (e.g., low water solubility or poor membrane permeability), emesis as a result of irritation to the GI mucosa, destruction of some drugs by digestive enzymes or low gastric pH, irregularities in absorption or propulsion in the presence of food or other drugs, and the need for cooperation on the part of the patient. Such cooperation is frequently not forthcoming, since tolerating certain oral medications means accepting unwanted effects, such as GI pain, which may require use of an alternate route of administration (Cosman, 2009). In addition, drugs in the GI tract may be metabolized by the enzymes of the intestinal flora, mucosa, or liver before they gain access to the general circulation.

Parenteral injection of drugs has certain distinct advantages over oral administration. In some instances, parenteral administration is essential for the drug to be delivered in its active form, as in the case of monoclonal antibodies such as infliximab, an antibody directed against tumor necrosis factor α (TNF α) used in the treatment of rheumatoid arthritis. Availability usually is more rapid, extensive, and predictable when a drug is given by injection. The effective dose can therefore be delivered more accurately. In emergency therapy and when a patient is unconscious, uncooperative, or unable to retain anything given by mouth, parenteral therapy may be a necessity. The injection of drugs, however, has its disadvantages: asepsis must be maintained, and this is of particular concern when drugs are given over time, such as in intravenous or intrathecal administration; pain may accompany the injection; and it is sometimes difficult for patients to perform the injections themselves if self-medication is necessary.

Oral Administration. Absorption from the GI tract is governed by factors such as surface area for absorption, blood flow to the site of absorption, the physical state of the drug (solution, suspension, or solid dosage form), its water solubility, and the drug’s concentration at the site of absorption. For drugs given in solid form, the rate of dissolution may limit their absorption, especially drugs of low aqueous solubility. Since most drug absorption from the GI tract occurs by passive diffusion, absorption is favored when the drug is in the non-ionized and more lipophilic form. Based on the pH-partition concept (Figure 2–3), one would predict that drugs that are weak acids would be better absorbed from the stomach (pH 1-2) than from the upper intestine (pH 3-6), and vice versa for weak bases. However, the epithelium of the stomach is lined with a thick mucus layer, and its surface area is small; by contrast, the villi of the upper intestine provide an extremely large surface area (~200 m²). Accordingly, the rate of absorption of a drug from the intestine will be greater than that from the stomach even if the drug is predominantly ionized in the intestine and largely non-ionized in the stomach. Thus, any factor that accelerates gastric emptying (recumbent position, right side)
will be likely to increase the rate of drug absorption (Queckenberg and Fuhr, 2009), whereas any factor that delays gastric emptying is expected to have the opposite effect, regardless of the characteristics of the drug. Gastric motor activity and gastric emptying rate are governed by neural and humoral feedback provided by receptors found in the gastric musculature and proximal small intestine. In healthy individuals, gastric emptying rate is influenced by a variety of factors including the caloric content of food; volume, osmolality, temperature, and pH of ingested fluid; diurnal and inter-individual variation; metabolic state (rest/exercise); and the ambient temperature. Such factors will influence ingested drug absorption. Gastric emptying is influenced in women by the effects of estrogen (i.e., slower than in men for premenopausal women and those taking estrogen replacement therapy).

Drugs that are destroyed by gastric secretions and low pH or that cause gastric irritation sometimes are administered in dosage forms with an enteric coating that prevents dissolution in the acidic gastric contents. These pharmacologically inactive coatings, often of cellulose polymers, have a threshold of dissolution between pH 5 and 6. Enteric coatings are useful for drugs such as aspirin, which can cause significant gastric irritation in many patients, and for presenting a drug such as mesalamine to sites of action in the ileum and colon (Figure 47–4).

**Controlled-Release Preparations.** The rate of absorption of a drug administered as a tablet or other solid oral dosage form is partly dependent on its rate of dissolution in GI fluids. This is the basis for controlled-release, extended-release, sustained-release, and prolonged-action pharmaceutical preparations that are designed to produce slow, uniform absorption of the drug for 8 hours or longer. Such preparations are offered for medications in all major drug categories. Potential advantages of such preparations are reduction in the frequency of administration of the drug as compared with conventional dosage forms (often with improved compliance by the patient), maintenance of a therapeutic effect overnight, and decreased incidence and/or intensity of both undesired effects (by dampening of the peaks in drug concentration) and nontherapeutic blood levels of the drug (by elimination of troughs in concentration) that often occur after administration of immediate-release dosage forms.

Many controlled-release preparations fulfill these expectations and may be preferred in some therapeutic situations (e.g., therapy for depression [Nemeroff, 2003] and ADHD [Manos et al., 2007]) or treatment with dihydropyridine Ca$^{2+}$ entry blockers (Chapters 26-28). However, such products do have drawbacks: variability of the systemic concentration achieved may be greater for controlled-release than for immediate-release dosage forms; the dosage form may fail, and “dose dumping” with resulting toxicity can occur because the total dose of drug in a controlled-release preparation may be several times the amount contained in the conventional preparation, although current regulatory approval requirements generally preclude such occurrences. Controlled-release dosage forms are most appropriate for drugs with short half-lives ($t_{1/2} < 4$ hours) or in selected patient
groups such as those receiving anti-epileptics (Bialer, 2007; Pellock et al., 2004). So-called controlled-release dosage forms are sometimes developed for drugs with long $t_{1/2}$ values (>12 hours). These usually more expensive products should not be prescribed unless specific advantages have been demonstrated. The availability of controlled-release dosage forms of some drugs can lead to abuse, as in the case of controlled-release oxycodone marketed as OxyContin. Crushing and snorting the delayed-release tablets results in a rapid release of the drug, increased absorption, and high peak serum concentrations (Aquila et al., 2009).

**Sublingual Administration.** Absorption from the oral mucosa has special significance for certain drugs despite the fact that the surface area available is small. Venous drainage from the mouth is to the superior vena cava, bypassing the portal circulation and thereby protecting the drug from rapid intestinal and hepatic first-pass metabolism. For example, nitroglycerin is effective when retained sublingually because it is non-ionized and has very high lipid solubility. Thus, the drug is absorbed very rapidly. Nitroglycerin also is very potent; absorption of a relatively small amount produces the therapeutic effect (“unloading” of the heart; Chapter 27).

**Transdermal Absorption.** Not all drugs readily penetrate the intact skin. Absorption of those that do is dependent on the surface area over which they are applied and their lipid solubility because the epidermis behaves as a lipid barrier (Chapter 65). The dermis, however, is freely permeable to many solutes; consequently, systemic absorption of drugs occurs much more readily through abraded, burned, or denuded skin. Inflammation and other conditions that increase cutaneous blood flow also enhance absorption. Toxic effects sometimes are produced by absorption through the skin of highly lipid-soluble substances (e.g., a lipid-soluble insecticide in an organic solvent). Absorption through the skin can be enhanced by suspending the drug in an oily vehicle and rubbing the resulting preparation into the skin. Because hydrated skin is more permeable than dry skin, the dosage form may be modified or an occlusive dressing may be used to facilitate absorption. Controlled-release topical patches have become increasingly available, including nicotine for tobacco-smoking withdrawal, scopolamine for motion sickness, nitroglycerin for angina pectoris, testosterone and estrogen for replacement therapy, various estrogens and progestins for birth control, and fentanyl for pain relief.

**Subcutaneous.** Injection into a subcutaneous site can be done only with drugs that are not irritating to tissue; otherwise, severe pain, necrosis, and tissue sloughing may occur. The rate of absorption following subcutaneous injection of a drug often is sufficiently constant and slow to provide a sustained effect. Moreover, altering the period over which a drug is absorbed may be varied intentionally, as is accomplished with insulin for injection using particle size, protein complexation, and pH to provide short-acting (3–6 hours), intermediate-acting (10–18 hours), and long-acting (18–24 hours) preparations. The incorporation of a vasoconstrictor agent in a solution of a drug to be injected subcutaneously also retards absorption. Thus, the injectable local anesthetic lidocaine incorporates epinephrine into the dosage form. Absorption of drugs implanted under the skin in a solid pellet form occurs slowly over a period of weeks or months; some hormones (e.g., contraceptives) are administered effectively in this manner, and implantable devices (e.g., a plastic rod delivering etonogestrel) can provide effective contraception for 3 years (Blumenthal et al., 2008).

**Intramuscular.** Drugs in aqueous solution are absorbed quite rapidly after intramuscular injection depending on the rate of blood flow to the injection site. This may be modulated to some extent by local heating, massage, or exercise. For example, while absorption of insulin generally is more rapid from injection in the arm and
abdominal wall than the thigh, jogging may cause a precipitous drop in blood sugar when insulin is injected into the thigh rather than into the arm or abdominal wall because running markedly increases blood flow to the leg. A hot bath accelerates absorption from all these sites owing to vasodilation. Generally, the rate of absorption following injection of an aqueous preparation into the deltoid or vastus lateralis is faster than when the injection is made into the glutus maximus. The rate is particularly slower for females after injection into the glutus maximus. This has been attributed to the different distribution of subcutaneous fat in males and females and because fat is relatively poorly perfused. Very obese or emaciated patients may exhibit unusual patterns of absorption following intramuscular or subcutaneous injection. Slow, constant absorption from the intramuscular site results if the drug is injected in solution in oil or suspended in various other repository (depot) vehicles. Antibiotics often are administered in this manner. Substances too irritating to be injected subcutaneously sometimes may be given intramuscularly.

**Intra-arterial.** Occasionally, a drug is injected directly into an artery to localize its effect in a particular tissue or organ, such as in the treatment of liver tumors and head-neck cancers. Diagnostic agents sometimes are administered by this route (e.g., technetium-labeled human serum albumin). Intra-arterial injection requires great care and should be reserved for experts. The dampening, first-pass, and cleansing effects of the lung are not available when drugs are given by this route.

**Intrathecal.** The blood-brain barrier and the blood-cerebrospinal fluid (CSF) barrier often preclude or slow the entrance of drugs into the CNS. Therefore, when local and rapid effects of drugs on the meninges or cerebrospinal axis are desired, as in spinal anesthesia or treatment of acute CNS infections, drugs sometimes are injected directly into the spinal subarachnoid space. Brain tumors also may be treated by direct intraventricular drug administration. More recent developments include special targeting of substances to the brain via administration of tight junctions (Matsuhisa et al., 2009).

**Pulmonary Absorption.** Provided that they do not cause irritation, gaseous and volatile drugs may be inhaled and absorbed through the pulmonary epithelium and mucous membranes of the respiratory tract. Access to the circulation is rapid by this route because the lung’s surface area is large. The principles governing absorption and excretion of anesthetic and other therapeutic gases are discussed in Chapter 19.

In addition, solutions of drugs can be atomized and the fine droplets in air (aerosol) inhaled. Advantages are the almost instantaneous absorption of a drug into the blood, avoidance of hepatic first-pass loss, and in the case of pulmonary disease, local application of the drug at the desired site of action. For example, owing to the ability to meter doses and create fine aerosols, drugs can be given in this manner for the treatment of allergic rhinitis or bronchial asthma (Chapter 36).

Pulmonary absorption is an important route of entry of certain drugs of abuse and of toxic environmental substances of varied composition and physical states. Both local and systemic reactions to allergens may occur subsequent to inhalation.

**Topical Application**

**Mucous Membranes.** Drugs are applied to the mucous membranes of the conjunctiva, nasopharynx, oropharynx, vagina, colon, urethra, and urinary bladder primarily for their local effects. Occasionally, as in the application of synthetic anti-diuretic hormone to the nasal mucosa, systemic absorption is the goal. Absorption through mucous membranes occurs readily. In fact, local anesthetics applied for local effect sometimes may be absorbed so rapidly that they produce systemic toxicity.

**Eye.** Topically applied ophthalmic drugs are used primarily for their local effects (Chapter 64). Systemic absorption that results from drainage through the nasolacrimal canal is usually undesirable. Because drug that is absorbed via drainage is not subject to first-pass intestinal and hepatic metabolism, unwanted systemic pharmacological effects may occur when β-adrenergic receptor antagonists or corticosteroids are administered as ophthalmic drops. Local effects usually require absorption of the drug through the cornea; corneal infection or trauma thus may result in more rapid absorption.

Ophthalmic delivery systems that provide prolonged duration of action (e.g., suspensions and ointments) are useful additions to ophthalmic therapy. Ocular inserts, such as the use of pilocarpine-containing inserts for the treatment of glaucoma, provide continuous delivery of small amounts of drug. Very little is lost through drainage; hence systemic side effects are minimized.

**Novel Methods of Drug Delivery**

Drug-eluting stents and other devices are being used to target drugs locally and minimize systemic exposure. The systemic toxicity of potentially important compounds can be decreased significantly by combination with a variety of drug carrier vehicles that modify distribution. For example, linkage of the cytotoxic agent calicheamicin to an antibody directed to an antigen found on the surface of certain leukemic cells can target the drug to its intended site of action, improving the therapeutic index of calicheamicin.

Recent advances in drug delivery include the use of biocompatible polymers with functional monomers attached in such a way as to permit linkage of drug molecules to the polymer. A drug-polymer conjugate can be designed to be a stable, long-circulating prodrug by varying the molecular weight of the polymer and the cleavable linkage between the drug and the polymer. The linkage is designed to keep the drug inactive until it released from the backbone polymer by a disease-specific trigger, typically enzyme activity in the targeted tissue that delivers the active drug at or near the site of pathology. Nanoparticles are offering new opportunities for diagnosis, targeted drug delivery, and imaging of clinical effect (Prestidge et al., 2010; Sajja et al., 2009).

**Bioequivalence**

Drug products are considered to be pharmaceutical equivalents if they contain the same active ingredients and are identical in strength or concentration, dosage form, and route of administration. Two pharmaceutically equivalent drug products are considered to be bioequivalent when the rates and extents of bioavailability of the active ingredient in the two products are not significantly different under suitable test conditions. In the past, dosage forms of a drug from different manufacturers and even different lots of preparations from a single manufacturer sometimes differed in their bioavailability. Such differences were seen primarily among oral dosage forms of poorly soluble, slowly absorbed drugs such as the urinary anti-infective, metronidazole (FLAGYL). When first introduced, the generic form was not bioequivalent because the generic manufacturer was not able to mimic the proprietary process used to microsize the drug for absorption initially. Differences in crystal form, particle size, or other
physical characteristics of the drug that are not rigidly controlled in formulation and manufacture affect disintegration of the dosage form and dissolution of the drug and hence the rate and extent of drug absorption.

The potential non-equivalence of different drug preparations has been a matter of concern (Meredith, 2009). However, no prospective clinical study has shown an FDA-approved generic drug product to yield significantly different therapeutic effects, even when testing published anecdotal reports of non-equivalence. Because of the legitimate concern of clinicians and the financial consequences of generic prescribing, this topic will continue to be actively addressed. Generic versus brand name prescribing is further discussed in connection with drug nomenclature and the choice of drug name in writing prescription orders (Appendix I).

**DISTRIBUTION OF DRUGS**

Following absorption or systemic administration into the bloodstream, a drug distributes into interstitial and intracellular fluids. This process reflects a number of physiological factors and the particular physicochemical properties of the individual drug. Cardiac output, regional blood flow, capillary permeability, and tissue volume determine the rate of delivery and potential amount of drug distributed into tissues. Initially, liver, kidney, brain, and other well-perfused organs receive most of the drug; delivery to muscle, most viscera, skin, and fat is slower, and this second distribution phase may require minutes to several hours before the concentration of drug in tissue is in equilibrium with that in blood. The second phase also involves a far larger fraction of body mass (e.g., muscle) than does the initial phase and generally accounts for most of the extravascularly distributed drug. With exceptions such as the brain, diffusion of drug into the interstitial fluid occurs rapidly because of the highly permeable nature of the capillary endothelial membrane. Thus, tissue distribution is determined by the partitioning of drug between blood and the particular tissue. Lipid solubility and transmembrane pH gradients are important determinants of such uptake for drugs that are either weak acids or bases. However, in general, ion trapping associated with transmembrane pH gradients is not large because the pH difference between tissue and blood (~7.0 versus 7.4) is small. The more important determinant of blood-tissue partitioning is the relative binding of drug to plasma proteins and tissue macromolecules that limits the concentration of free drug.

**Plasma Proteins.** Many drugs circulate in the bloodstream bound to plasma proteins. Albumin is a major carrier for acidic drugs; $\alpha_1$-acid glycoprotein binds basic drugs. Nonspecific binding to other plasma proteins generally occurs to a much smaller extent. The binding is usually reversible; covalent binding of reactive drugs such as alkylating agents occurs occasionally. In addition to the binding of drugs to carrier proteins such as albumin, certain drugs may bind to proteins that function as specific hormone carrier proteins, such as the binding of estrogen or testosterone to sex hormone-binding globulin or the binding of thyroid hormone to thyroxin-binding globulin.

The fraction of total drug in plasma that is bound is determined by the drug concentration, the affinity of binding sites for the drug, and the number of binding sites. Mass-action relationships determine the unbound and bound concentrations (described later). At low concentrations of drug (less than the plasma protein binding dissociation constant), the fraction bound is a function of the concentration of binding sites and the dissociation constant. At high drug concentrations (greater than the dissociation constant), the fraction bound is a function of the number of binding sites and the drug concentration. Therefore, plasma binding is a nonlinear, saturable process. For most drugs, the therapeutic range of plasma concentrations is limited; thus, the extent of binding and the unbound fraction are relatively constant. The percentage values listed for protein binding in Appendix II refer to binding in the therapeutic range unless otherwise indicated. The extent of plasma protein binding also may be affected by disease-related factors. For example, hypoalbuminemia secondary to severe liver disease or nephrotic syndrome results in reduced binding and an increase in the unbound fraction. Also, conditions resulting in the acute-phase reaction response (e.g., cancer, arthritis, myocardial infarction, Crohn’s disease) lead to elevated levels of $\alpha_1$-acid glycoprotein and enhanced binding of basic drugs. Changes in protein binding due to disease states and drug-drug interactions are clinically relevant mainly for a small subset of so-called high-clearance drugs of narrow therapeutic index (described later) that are administered intravenously, such as lidocaine (Benet and Hoener, 2002). When changes in plasma protein binding occur in patients, unbound drug rapidly equilibrates throughout the body and only a transient significant change in unbound plasma concentration will occur. Only drugs that show an almost instantaneous relationship between free plasma concentration and effect (e.g., anti-arrhythmics) will show a measureable effect. Thus, unbound plasma drug concentrations will really exhibit significant changes only when either drug input or clearance of unbound drug occurs, as a consequence of metabolism or active transport. A more common problem resulting from competition of drugs for plasma protein-binding sites is misinterpretation of measured concentrations of drugs in plasma because most assays do not distinguish free drug from bound drug.

Importantly, binding of a drug to plasma proteins limits its concentration in tissues and at its site of action because only unbound drug is in equilibrium across membranes. Accordingly, after distribution equilibrium is achieved, the concentration of active, unbound drug in intracellular water is the same as that in plasma except when carrier-mediated transport is involved. Binding of a drug to plasma protein also limits the drug’s glomerular filtration because this process does not immediately change the concentration of free drug in the plasma (water is also filtered). However, plasma protein binding generally does not limit renal tubular secretion or
biotransformation because these processes lower the free drug concentration, and this is followed rapidly by dissociation of drug from the drug-protein complex, thereby reestablishing equilibrium between bound and free drug. Drug transport and metabolism also are limited by binding to plasma proteins, except when these are especially efficient, and drug clearance, calculated on the basis of unbound drug, exceeds organ plasma flow.

**Tissue Binding.** Many drugs accumulate in tissues at higher concentrations than those in the extracellular fluids and blood. For example, during long-term administration of the anti-malarial agent quinacrine, the concentration of drug in the liver may be several thousand times that in the blood. Such accumulation may be a result of active transport or, more commonly, binding. Tissue binding of drugs usually occurs with cellular constituents such as proteins, phospholipids, or nuclear proteins and generally is reversible. A large fraction of drug in the body may be bound in this fashion and serve as a reservoir that prolongs drug action in that same tissue or at a distant site reached through the circulation. Such tissue binding and accumulation also can produce local toxicity, as in the case of the accumulation of the aminoglycoside antibiotic gentamicin in the kidney and vestibular system.

**Fat as a Reservoir.** Many lipid-soluble drugs are stored by physical solution in the neutral fat. In obese persons, the fat content of the body may be as high as 50%, and even in lean individuals fat constitutes 10% of body weight; hence fat may serve as a reservoir for lipid-soluble drugs. For example, as much as 70% of the highly lipid-soluble barbiturate thiopental may be present in body fat 3 hours after administration, when plasma concentrations are negligible and no anesthetic effects are measurable. Fat is a rather stable reservoir because it has a relatively low blood flow. However, among highly lipophilic drugs (e.g., remifentanil and some β blockers), the degree of lipophilicity does not predict their distribution in obese individuals.

**Bone.** The tetracycline antibiotics (and other divalent metal-ion chelating agents) and heavy metals may accumulate in bone by adsorption onto the bone crystal surface and eventual incorporation into the crystal lattice. Bone can become a reservoir for the slow release of toxic agents such as lead or radium into the blood; their effects thus can persist long after exposure has ceased. Local destruction of the bone medulla also may lead to reduced blood flow and prolongation of the reservoir effect because the toxic agent becomes sealed off from the circulation; this may further enhance the direct local damage to the bone. A vicious cycle results, whereby the greater the exposure to the toxic agent, the slower is its rate of elimination. The adsorption of drug onto the bone crystal surface and incorporation into the crystal lattice have therapeutic advantages for the treatment of osteoporosis. Phosphonates such as sodium etidronate bind tightly to hydroxyapatite crystals in mineralized bone matrix. However, unlike naturally occurring pyrophosphates, etidronate is resistant to degradation by pyrophosphatases and thus stabilizes the bone matrix.

**Redistribution.** Termination of drug effect after withdrawal of a drug usually is by metabolism and excretion but also may result from redistribution of the drug from its site of action into other tissues or sites. Redistribution is a factor in terminating drug effect primarily when a highly lipid-soluble drug that acts on the brain or cardiovascular system is administered rapidly by intravenous injection or by inhalation. A good example of this is the use of the intravenous anesthetic thiopental, a highly lipid-soluble drug. Because blood flow to the brain is so high, the drug reaches its maximal concentration in brain within a minute of its intravenous injection. After injection is concluded, the plasma concentration falls as thiopental diffuses into other tissues, such as muscle. The concentration of the drug in brain follows that of the plasma because there is little binding of the drug to brain constituents. Thus, in this example, the onset of anesthesia is rapid, but so is its termination. Both are related directly to the concentration of drug in the brain.

**CNS and Cerebrospinal Fluid.** The distribution of drugs into the CNS from the blood is unique. One reason for this is that the brain capillary endothelial cells have continuous tight junctions; therefore, drug penetration into the brain depends on transcellular rather than paracellular transport. The unique characteristics of brain capillary endothelial cells and pericapillary glial cells constitute the blood-brain barrier. At the choroid plexus, a similar blood-CSF barrier is present, except that it is epithelial cells that are joined by tight junctions rather than endothelial cells. The lipid solubility of the non-ionized and unbound species of a drug is therefore an important determinant of its uptake by the brain; the more lipophilic a drug, the more likely it is to cross the blood-brain barrier. This situation often is used in drug design to alter drug distribution to the brain; e.g., the so-called second-generation antihistamines, such as loratadine, achieve far lower brain concentrations than do agents such as diphenhydramine and thus are non-sedating. Drugs may penetrate into the CNS by specific uptake transporters normally involved in the transport of nutrients and endogenous compounds from blood into the brain and CSF.

Another important factor in the functional blood-brain barrier involves membrane transporters that are efflux carriers present in the brain capillary endothelial cell and capable of removing a large number of chemically diverse drugs from the cell. MDR1 (P-gp) and the organic anion–transporting polypeptide (OATP) are two of the more notable of these. The effects of these exporters are to dramatically limit access of the drug to the tissue expressing the efflux transporter. Together, P-gp and the OATP family export a large array of structurally
diverse drugs (see Chapter 5 and Maeda et al., 2008). Expression of OATP isoforms and their polymorphic forms in the GI tract, liver, and kidney, as well as the blood-brain barrier, has important implications for drug absorption and elimination, as well as tissue penetration. Expression of these efflux transporters accounts for the relatively restricted pharmacological access to the brain and other tissues such as the testes, where drug concentrations may be below those necessary to achieve a desired effect despite adequate blood flow. This situation occurs with HIV protease inhibitors and with lopinavir, a potent, systemically active opioid that lacks the central effects characteristic of other opioids (Chapter 19). Efflux transporters that actively secrete drug from the CSF into the blood also are present in the choroid plexus (see Chapter 5 for details of the contribution of drug transporters to barrier function). Drugs also may exit the CNS along with the bulk flow of CSF through the arachnoid villi. In general, the blood-brain barrier’s function is well maintained; however, meningeal and encephalic inflammation increase local permeability. Recently, blood-brain barrier disruption has emerged as a strategy in the treatment of certain brain tumors such as primary CNS lymphomas (Angelov et al., 2009). The goal of this treatment is to enhance delivery of chemotherapy to the brain tumor while maintaining cognitive function that is often damaged by conventional radiotherapy.

**Placental Transfer of Drugs.** The transfer of drugs across the placenta is of critical importance because drugs may cause anomalies in the developing fetus. Administered immediately before delivery, as is often the case with the use of tocolytics in the treatment of preterm labor, they also may have adverse effects on the neonate. Lipid solubility, extent of plasma binding, and degree of ionization of weak acids and bases are important general determinants in drug transfer across the placenta. The fetal plasma is slightly more acidic than that of the mother (pH 7.0-7.2 versus 7.4), so that ion trapping of basic drugs occurs. As in the brain, P-gp and other export transporters are present in the placenta and function to limit fetal exposure to potentially toxic agents. The view that the placenta is an absolute barrier to drugs is, however, inaccurate, in part because a number of influx transporters are also present (Weier et al., 2008). The fetus is to some extent exposed to all drugs taken by the mother.

**EXCRETION OF DRUGS**

Drugs are eliminated from the body either unchanged by the process of excretion or converted to metabolites. Excretory organs, the lung excluded, eliminate polar compounds more efficiently than substances with high lipid solubility. Lipid-soluble drugs thus are not readily eliminated until they are metabolized to more polar compounds.

The kidney is the most important organ for excreting drugs and their metabolites. Substances excreted in the feces are principally unabsorbed orally ingested drugs or drug metabolites excreted either in the bile or secreted directly into the intestinal tract and not reabsorbed. Excretion of drugs in breast milk is important not because of the amounts eliminated, but because the excreted drugs are potential sources of unwanted pharmacological effects in the nursing infant (Buhimschi and Weiner, 2009). Excretion from the lung is important mainly for the elimination of anesthetic gases (Chapter 19).

**Renal Excretion.** Excretion of drugs and metabolites in the urine involves three distinct processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption. Changes in overall renal function generally affect all three processes to a similar extent. Even in healthy persons, renal function is not constant. In neonates, renal function is low compared with body mass but matures rapidly within the first few months after birth. During adulthood, there is a slow decline in renal function, ~1% per year, so that in elderly patients a substantial degree of functional impairment may be present.

The amount of drug entering the tubular lumen by filtration depends on the glomerular filtration rate and the extent of plasma binding of the drug; only unbound drug is filtered. In the proximal renal tubule, active, carrier-mediated tubular secretion also may add drug to the tubular fluid. Transporters such as P-gp and the multidrug-resistance–associated protein type 2 (MRP2), localized in the apical brush-border membrane, are responsible for the secretion of amphipathic anions and conjugated metabolites (such as glucuronides, sulfates, and glutathione adducts), respectively (Chapters 5 and 6). Solute carrier transporters that are more selective for organic cationic drugs are involved in the secretion of organic bases. Membrane transporters, mainly located in the distal renal tubule, also are responsible for any active reabsorption of drug from the tubular lumen back into the systemic circulation; however, most such reabsorption occurs by non-ionic diffusion.

In the proximal and distal tubules, the non-ionized forms of weak acids and bases undergo net passive reabsorption. The concentration gradient for back-diffusion is created by the reabsorption of water with Na⁺ and other inorganic ions. Since the tubular cells are less permeable to the ionized forms of weak electrolytes, passive reabsorption of these substances depends on the pH. When the tubular urine is made more alkaline, weak acids are largely ionized and thus are excreted more rapidly and to a greater extent. When the tubular urine is made more acidic, the fraction of drug ionized is reduced, and excretion is likewise reduced. Alkalization and acidification of the urine have the opposite effects on the excretion of weak bases. In the treatment of drug poisoning, the excretion of some drugs can be hastened by appropriate alkalization or acidification of the urine. Whether alteration of urine pH results in a significant change in drug elimination depends on the extent and persistence of the pH change and the contribution of pH-dependent passive reabsorption to total drug elimination. The effect is greatest for weak acids and bases with pKᵦ values in the range of urinary pH (5-8). However, alkalization of urine can produce a 4-6-fold increase in excretion of a relatively strong acid such as salicylate when urinary pH is changed.
Pharmacokinetics: The Dynamics of Drug Absorption, Distribution, Metabolism, and Elimination

CHAPTER 2

METABOLISM OF DRUGS

The lipophilic characteristics of drugs that promote their passage through biological membranes and subsequent access to their sites of action hinder their excretion from the body. Renal excretion of unchanged drug is a major route of elimination for 25–30% of drugs administered to humans. The majority of therapeutic agents are lipophilic compounds filtered through the glomerulus and reabsorbed into the systemic circulation during passage through the renal tubules. The metabolism of drugs and other xenobiotics into more hydrophilic metabolites is essential for their elimination from the body, as well as for termination of their biological and pharmacological activity. In general, biotransformation reactions generate more polar, inactive metabolites that are readily excreted from the body. However, in some cases, metabolites with potent biological activity or toxic properties are generated. Many of the enzyme systems that transform drugs to inactive metabolites also generate biologically active metabolites of endogenous compounds, as in steroid biosynthesis. Understanding drug metabolism has spawned the new disciplinary focus of pharmacogenetics, which offers the promise that understanding the expression and activities of specific metabolizing enzyme isoforms in a given individual will permit the clinician to tailor treatments, particularly in chemotherapy (Dawood and Leyland-Jones, 2009), to maximize therapeutic outcomes and minimize risks of toxicity or drug-drug interactions.

Drug metabolism or biotransformation reactions are classified as either phase I functionalization reactions or phase II biosynthetic (conjugation) reactions. Phase I reactions introduce or expose a functional group on the parent compound such as occurs in hydrolysis reactions. Phase I reactions generally result in the loss of pharmacological activity, although there are examples of retention or enhancement of activity. In rare instances, metabolism is associated with an altered pharmacological activity. Prodrugs are pharmacologically inactive compounds designed to maximize the amount of the active species that reaches its site of action. Inactive prodrugs are converted rapidly to biologically active metabolites often by the hydrolysis of an ester or amide linkage. Such is the case with a number of angiotensin-converting enzyme (ACE) inhibitors employed in the management of high blood pressure. Enalapril, for instance, is relatively inactive until converted by esterase activity to the diacid enalaprilat. If not excreted rapidly into the urine, the products of

Biliary and Fecal Excretion. Transporters are also present in the canalicular membrane of the hepatocyte, and these actively secrete drugs and metabolites into bile. P-gp and BCRP (breast cancer resistance protein, or ABCG2) transport a plethora of amphipathic lipid-soluble drugs, whereas MRP2 is mainly involved in the secretion of conjugated metabolites of drugs (e.g., glutathione conjugates, glucuronides, and some sulfates). Ultimately, drugs and metabolites present in bile are released into the GI tract during the digestive process. Because secretory transporters also are expressed on the apical membrane of enterocytes, direct secretion of drugs and metabolites may occur from the systemic circulation into the intestinal lumen. Subsequently, drugs and metabolites can be reabsorbed back into the body from the intestine, which, in the case of conjugated metabolites such as glucuronides, may require their enzymatic hydrolysis by the intestinal microflora. Such enterohepatic recycling, if extensive, may prolong significantly the presence of a drug (or toxin) and its effects within the body prior to elimination by other pathways. For this reason, drugs may be given orally to bind substances excreted in the bile. In the case of mercury poisoning, for example, a resin can be administered orally that binds with dimethyl mercury excreted in the bile, thus preventing reabsorption and further toxicity.

Enterohepatic recycling also can be an advantage in the design of drugs. Ezetimibe is the first of a class of drugs that specifically reduces the intestinal absorption of cholesterol (Lipka, 2003). The drug is absorbed into the intestinal epithelial cell, where it is believed to interfere with the sterol transporter system, preventing both free cholesterol and plant sterols (phytosterols) from being transported into the cell from the intestinal lumen. The drug is absorbed rapidly and glucuronidated to an active metabolite in the intestinal cell before secretion into the blood. Absorbed ezetimibe is avidly taken up by the liver from the portal blood and excreted into the bile, resulting in low peripheral blood concentrations. The glucuronide conjugate is hydrolyzed and absorbed, and is equally effective in inhibiting sterol absorption. This enterohepatic recycling is responsible for a half-life in the body of >20 hours. The principal benefit is a reduction in low-density lipoprotein cholesterol (see Chapter 31 and Dembowski and Davidson, 2009).

Excretion by Other Routes. Excretion of drugs into sweat, saliva, and tears is quantitatively unimportant. Elimination by these routes depends mainly on diffusion of the non-ionized lipid-soluble form of drugs through the epithelial cells of the glands and depends on the pH. Drugs excreted in the saliva enter the mouth, where they are usually swallowed. The concentration of some drugs in saliva parallels that in plasma. Saliva therefore may be a useful biological fluid in which to determine drug concentrations when it is difficult or inconvenient to obtain blood. The same principles apply to excretion of drugs in breast milk. Since milk is more acidic than plasma, basic compounds may be slightly concentrated in this fluid; conversely, the concentration of acidic compounds in the milk is lower than in plasma. Non-electrolytes, such as ethanol and urea, readily enter breast milk and reach the same concentration as in plasma, independent of the pH of the milk. Thus, the administration of drugs to breast-feeding women carries the general caution that the suckling infant will be exposed to some extent to the medication and/or its metabolites. In certain cases, such as treatment with the β blocker atenolol, the infant may be exposed to significant amounts of drug (Ito and Lee, 2003). Although excretion into hair and skin is quantitatively unimportant, sensitive methods of detection of drugs in these tissues have forensic significance.
phase I biotransformation reactions then can react with endogenous compounds to form a highly water-soluble conjugate.

Phase II conjugation reactions lead to the formation of a covalent linkage between a functional group on the parent compound or phase I metabolite and endogenously derived glucuronic acid, sulfate, glutathione, amino acids, or acetate. These highly polar conjugates generally are inactive and are excreted rapidly in the urine and feces. An example of an active conjugate is the 6-glucuronide metabolite of morphine, which is a more potent analgesic than its parent.

The enzyme systems involved in the biotransformation of drugs are localized primarily in the liver, although every tissue examined has some metabolic activity. Other organs with significant metabolic capacity include the GI tract, kidneys, and lungs. Following oral administration of a drug, a significant portion of the dose may be metabolically inactivated in either the intestinal epithelium or the liver before the drug reaches the systemic circulation. This so-called first-pass metabolism significantly limits the oral availability of highly metabolized drugs. Within a given cell, most drug-metabolizing activity is found in the smooth endoplasmic reticulum and the cytosol, although drug biotransformations also can occur in the mitochondria, nuclear envelope, and plasma membrane. The enzyme systems involved in phase I reactions are located primarily in the endoplasmic reticulum, whereas the phase II conjugation enzyme systems are mainly cytosolic. Often, drugs biotransformed through a phase I reaction in the endoplasmic reticulum are conjugated at this same site or in the cytosolic fraction of the same cell in a sequential fashion. These biotransforming reactions are carried out by CYPs (cytochrome P450 isoforms) and by a variety of transferases. These enzyme families, the major reactions they catalyze, and their roles in drug metabolism and adverse drug responses are presented in detail in Chapter 6.

**CLINICAL PHARMACOKINETICS**

The fundamental tenet of clinical pharmacokinetics is that a relationship exists between the pharmacological effects of a drug and an accessible concentration of the drug (e.g., in blood or plasma). This relationship has been documented for many drugs and is of benefit in the therapeutic management of patients. For some drugs, no clear or simple relationship has been found between pharmacological effect and concentration in plasma, whereas for other drugs, routine measurement of drug concentration is impractical as part of therapeutic monitoring. In most cases, as depicted in Figure 2–1, the concentration of drug at its sites of action will be related to the concentration of drug in the systemic circulation. The pharmacological effect that results may be the clinical effect desired, a toxic effect, or in some cases an effect unrelated to the known therapeutic efficacy or toxicity. Clinical pharmacokinetics attempts to provide both a quantitative relationship between dose and effect and a framework within which to interpret measurements of concentrations of drugs in biological fluids and their adjustment through changes in dosing for the benefit of the patient. The importance of pharmacokinetics in patient care is based on the improvement in therapeutic efficacy and the avoidance of unwanted effects that can be attained by application of its principles when dosage regimens are chosen and modified.

The four most important parameters governing drug disposition are bioavailability, the fraction of drug absorbed as such into the systemic circulation; volume of distribution, a measure of the apparent space in the body available to contain the drug based on how much is given versus what is found in the systemic circulation; clearance, a measure of the body’s efficiency in eliminating drug from the systemic circulation; and elimination $t_{1/2}$, a measure of the rate of removal of drug from the systemic circulation. We will deal with each of these parameters in turn, and will explore mathematical relationships that use them to describe the time course of plasma drug accumulation and to design dosage regimens based on physiologic and pathophysiologic variables of individual patients.

**Clearance**

Clearance is the most important concept to consider when designing a rational regimen for long-term drug administration. The clinician usually wants to maintain steady-state concentrations of a drug within a therapeutic window or range associated with therapeutic efficacy and a minimum of toxicity for a given agent. Assuming complete bioavailability, the steady-state concentration of drug in the body will be achieved when the rate of drug elimination equals the rate of drug administration. Thus:

$$\text{Dosing rate} = CL \cdot C_{ss} \quad (\text{Equation 2–2})$$

where $CL$ is clearance of drug from the systemic circulation and $C_{ss}$ is the steady-state concentration of drug. If the desired steady-state concentration of drug in plasma or blood is known, the rate of clearance of drug by the patient will dictate the rate at which the drug should be administered.

The concept of clearance is extremely useful in clinical pharmacokinetics because its value for a particular drug usually is constant over the range of concentrations encountered clinically. This is true because systems for elimination of drugs such as metabolizing enzymes and transporters usually are not saturated, and thus the absolute rate of elimination of the drug is essentially a linear function of its concentration in plasma. That is, the elimination of most drugs follows first-order kinetics, where a constant fraction of drug in the body is eliminated per unit of time. If mechanisms for elimination of a given drug become saturated, the kinetics approach zero order, in which a constant amount of drug is eliminated per unit of time.
Under such a circumstance, clearance (CL) will vary with the concentration of drug, often according to the equation

\[ CL = \frac{v_m}{K_m + C} \]  

(Equation 2–3)

where \( K_m \) represents the concentration at which half the maximal rate of elimination is reached (in units of mass/volume) and \( v_m \) is equal to the maximal rate of elimination (in units of mass/time). Thus, clearance is derived in units of volume/time. This equation is analogous to the Michaelis-Menten equation for enzyme kinetics. Design of dosage regimens for drugs with zero-order elimination kinetics is more complex than when elimination is first-order (described later).

Principles of drug clearance are similar to those of renal physiology, where, e.g., creatinine clearance is defined as the rate of elimination of creatinine in the urine relative to its concentration in plasma. At the simplest level, clearance of a drug is its rate of elimination by all routes normalized to the concentration of drug \( C \) in some biological fluid where measurement can be made:

\[ CL = \text{rate of elimination}/C \]  

(Equation 2–4)

Thus, when clearance is constant, the rate of drug elimination is directly proportional to drug concentration. Note that clearance does not indicate how much drug is being removed, but rather the volume of biological fluid such as blood or plasma from which drug would have to be completely removed to account for the clearance per unit of body weight (e.g., mL/min per kg). Clearance can be defined further as blood clearance (\( CL_b \)), plasma clearance (\( CL_p \)), or clearance based on the concentration of unbound drug (\( CL_u \)), depending on the measurement made (\( C_u, C_p, \text{ or } C_b \)), or clearance of its concentration in plasma. The relationship between plasma (subscript \( p \); acellular) and blood (subscript \( b \); all components) clearance at steady state is given by

\[ \frac{CL_p}{CL_b} = \frac{C_b}{C_p} = 1 + H \left[ \frac{C_{rbc}}{C_p} - 1 \right] \]  

(Equation 2–7)

Clearance from the blood therefore may be estimated by dividing the plasma clearance by the drug’s blood-to-plasma concentration ratio, obtained from knowledge of the hematocrit (\( H = 0.45 \)) and the red cell to plasma concentration ratio. In most instances, the blood clearance will be less than liver blood flow (1.5 L/min) or, if renal excretion also is involved, the sum of the blood flows to each eliminating organ. For example, the plasma clearance of the immunomodulator, tacrolimus, ~2 L/min, is more than twice the hepatic plasma flow rate and even exceeds the organ’s blood flow despite the fact that the liver is the predominant site of this drug’s extensive metabolism. However, after taking into account the extensive distribution of tacrolimus into red cells, its clearance from the blood is only ~63 mL/min, and it is actually a low- rather than high-clearance drug, as might be interpreted from the plasma clearance value alone. Sometimes, however, clearance from the blood by metabolism exceeds liver blood flow, and this indicates extrahepatic metabolism. In the case of the \( \beta \) receptor antagonist, esmolol, the blood clearance value (11.9 L/min) is greater than cardiac output (~5.3 L/min) because the drug is metabolized efficiently by esterases present in red blood cells.

A further definition of clearance is useful for understanding the effects of pathological and physiological variables on drug elimination, particularly with respect to an individual organ. The rate of presentation of drug to the organ is the product of blood flow (\( Q \)) and the arterial drug concentration (\( C_A \)), and the rate of exit of drug from the organ is the product of blood flow and the venous drug concentration (\( C_V \)). The difference between these rates at steady state is the rate of drug elimination by that organ:

\[ \text{Rate of elimination} = Q \cdot C_A - Q \cdot C_V \]  

(Equation 2–8)
Division of Equation 2–8 by the concentration of drug entering the organ of elimination $C_A$ yields an expression for clearance of the drug by the organ in question:

$$CL_{organ} = Q \frac{C_A - C_V}{C_A} = Q \cdot E \quad \text{(Equation 2–9)}$$

The expression $(C_A - C_V)/C_A$ in Equation 2–9 can be referred to as the extraction ratio ($E$) of the drug. While not employed in general medical practice, calculations of a drug’s extraction ratio(s) are useful for modeling the effects of disease of a given metabolizing organ on clearance and in the design of ideal therapeutic properties of drugs in development.

**Hepatic Clearance.** The concepts developed in Equation 2–9 have important implications for drugs that are eliminated by the liver. Consider a drug that is removed efficiently from the blood by hepatic processes—metabolism and/or excretion of drug into the bile. In this instance, the concentration of drug in the blood leaving the liver will be low, the extraction ratio will approach unity, and the clearance of the drug from blood will become limited by hepatic blood flow. Drugs that are cleared efficiently by the liver (e.g., drugs in Appendix II with systemic clearances >6 mL/min/kg, such as diltiazem, imipramine, lidocaine, morphine, and propranolol) are restricted in their rate of elimination not by intra-hepatic processes but by the rate at which they can be transported in the blood to the liver.

Additional complexities also may be considered. For example, the equations presented earlier do not account for drug binding to components of blood and tissues, nor do they permit an estimation of the intrinsic capacity of the liver to eliminate a drug in the absence of limitations imposed by blood flow, termed intrinsic clearance. In biochemical terms and under first-order conditions, intrinsic clearance is a measure of the ratio of the Michaelis-Menten kinetic parameters for the eliminating process (i.e., $v_m/K_m$) and thus reflects the maximum metabolic or transport capability of the clearing organ. Extensions of the relationships of Equation 2–9 to include expressions for protein binding and intrinsic clearance have been proposed for a number of models of hepatic elimination (Hallifax and Houston, 2009). Models indicate that when the capacity of the eliminating organ to metabolize the drug is large in comparison with the rate of presentation of drug to the organ, clearance will approximate the organ’s blood flow. By contrast, when the drug-metabolizing capacity is small in comparison with the rate of drug presentation, clearance will be proportional to the unbound fraction of drug in blood and the drug’s intrinsic clearance. Appreciation of these concepts allows understanding of a number of possibly puzzling experimental results. For example, enzyme induction or hepatic disease may change the rate of drug metabolism in an isolated hepatic microsomal enzyme system but not change clearance in the whole animal. For a drug with a high extraction ratio, clearance is limited by blood flow, and changes in intrinsic clearance owing to enzyme induction or hepatic disease should have little effect. Similarly, for drugs with high extraction ratios, changes in protein binding owing to disease or competitive binding interactions by other drugs should have little effect on clearance. Conversely, changes in intrinsic clearance and protein binding will affect the clearance of drugs with low intrinsic clearances such as warfarin, and thus extraction ratios, but changes in blood flow will have little effect.

**Renal Clearance.** Renal clearance of a drug results in its appearance in the urine. In considering the impact of renal disease on the clearance of a drug, complications that relate to filtration, active secretion by the kidney tubule, and reabsorption from it must be considered along with blood flow. The rate of filtration of a drug depends on the volume of fluid that is filtered in the glomerulus and the unbound concentration of drug in plasma, because drug bound to protein is not filtered. The rate of secretion of drug by the kidney will depend on the drug’s intrinsic clearance by the transporters involved in active secretion as affected by the drug’s binding to plasma proteins, the degree of saturation of these transporters, and the rate of delivery of the drug to the secretory site. In addition, processes involved in drug reabsorption from the tubular fluid must be considered. The influences of changes in protein binding and blood flow and in the number of functional nephrons are analogous to the examples given earlier for hepatic elimination.

**DISTRIBUTION**

**Volume of Distribution.** Volume is a second fundamental parameter that is useful in considering processes of drug disposition. The volume of distribution ($V$) relates the amount of drug in the body to the concentration of drug ($C$) in the blood or plasma depending on the fluid measured. This volume does not necessarily refer to an identifiable physiological volume but rather to the fluid volume that would be required to contain all of the drug in the body at the same concentration measured in the blood or plasma:

$$\text{Amount of drug in body}/V = C \quad \text{or} \quad V = \text{amount of drug in body}/C \quad \text{(Equation 2–10)}$$

A drug’s volume of distribution therefore reflects the extent to which it is present in extravascular tissues and not in the plasma. It is reasonable to view $V$ as an imaginary volume, since for many drugs the volume of distribution exceeds the known volume of any and all body compartments. For example, the value of $V$ for the highly lipophilic anti-malarial chloroquine is some 15,000 L, yet the plasma volume of a typical 70-kg man is 3 L, blood volume is ~5.5 L, extracellular fluid volume outside the plasma is 12 L, and the volume of total-body water is ~42 L.

Many drugs exhibit volumes of distribution far in excess of these values. For example, if 500 µg of the cardiac glycoside digoxin were in the body of a 70-kg subject, a plasma concentration of ~0.75 ng/mL would be observed. Dividing the amount of drug in the body by the plasma concentration yields a volume of distribution for digoxin of ~667 L, or a value ~15 times greater than the total-body volume of a 70-kg man. In fact, digoxin distributes preferentially to muscle and adipose tissue and to its specific receptors (Na⁺,K⁺-ATPase), leaving a very small amount of drug in the plasma to be measured. For drugs that are bound extensively to plasma proteins...
but that are not bound to tissue components, the volume of distribution will approach that of the plasma volume because drug bound to plasma protein is measurable in the assay of most drugs. In contrast, certain drugs have high volumes of distribution even though most of the drug in the circulation is bound to albumin because these drugs are also sequestered elsewhere.

The volume of distribution may vary widely depending on the relative degrees of binding to high-affinity receptor sites, plasma and tissue proteins, the partition coefficient of the drug in fat, and accumulation in poorly perfused tissues. As might be expected, the volume of distribution for a given drug can differ according to patient’s age, gender, body composition, and presence of disease. Total-body water of infants younger than 1 year of age, for example, is 75–80% of body weight, whereas that of adult males is 60% and that of females is 55%.

Several volume terms are used commonly to describe drug distribution, and they have been derived in a number of ways. The volume of distribution defined in Equation 2–10 considers the body as a single homogeneous compartment. In this one-compartment model, all drug administration occurs directly into the central compartment, and distribution of drug is instantaneous throughout the volume (V). Clearance of drug from this compartment occurs in a first-order fashion, as defined in Equation 2–4; that is, the amount of drug eliminated per unit of time depends on the amount (concentration) of drug in the body compartment. Figure 2–4A and Equation 2–11 describe the decline of plasma concentration with time for a drug introduced into this central compartment:

\[
C = \frac{[\text{dose}]}{V} e^{-kt}
\]  

(Equation 2–11)

where \( k \) is the rate constant for elimination that reflects the fraction of drug removed from the compartment per unit of time. This rate constant is inversely related to the \( t_{1/2} \) of the drug \( [kt_{1/2} = 0.693 = \ln 2] \).

The idealized one-compartment model discussed earlier does not describe the entire time course of the plasma concentration. That is, certain tissue reservoirs can be distinguished from the central compartment, and the drug concentration appears to decay in a manner that can be described by multiple exponential terms (Figure 2–4B).

**Rate of Distribution.** The multiple exponential decay observed for a drug that is eliminated from the body with first-order kinetics results from differences in the rates at which the drug equilibrates to and within tissues. The rate of equilibration will depend on the ratio of the perfusion of the tissue to the partition of drug into the tissue. In many cases, groups of tissues with similar perfusion-partition ratios all equilibrate at essentially the same rate such that only one apparent phase of distribution is seen (rapid initial fall of concentration of intravenously injected drug, as in Figure 2–4B). It is as though the drug starts in a “central” volume (Figure 2–1), which

\[
V_{\text{A}} = \frac{V_{\text{ss}}}{1 + \frac{V_{\text{ss}}}{V_{\text{A}}}}
\]

Figure 2–4  *Plasma concentration-time curves following intravenous administration of a drug (500 mg) to a 70-kg patient.*  
**A.** Drug concentrations are measured in plasma at 2-hour intervals following drug administration. The semi-logarithmic plot of plasma concentration (\( C_p \)) versus time appears to indicate that the drug is eliminated from a single compartment by a first-order process (Equation 2–11) with a \( t_{1/2} \) of 4 hours \( (k = 0.693/t_{1/2} = 0.173 \text{ hr}^{-1}) \). The volume of distribution (V) may be determined from the value of \( C_p \) obtained by extrapolation to \( t = 0 \) \( (C_p^0 = 16 \mu g/mL) \). Volume of distribution (Equation 2–10) for the one-compartment model is 31.3 L, or 0.45 L/kg \((V = [\text{dose}]/C_p^0)\). The clearance for this drug is 90 mL/min; for a one-compartment model, \( CL = kV \).

**B.** Sampling before 2 hours indicates that in fact the drug follows multi-exponential kinetics. The terminal disposition \( t_{1/2} \) is 4 hours, clearance is 84 mL/min (Equation 2–6), \( V_{\text{A}} \) is 29 L (Equation 2–11), and \( V_{\text{ss}} \) is 26.8 L. The initial or “central” distribution volume for the drug \( (V = [\text{dose}]/C_p^0) \) is 16.1 L. The example chosen indicates that multicompartment kinetics may be overlooked when sampling at early times is neglected. In this particular case, there is only a 10% error in the estimate of clearance when the multicompartment characteristics are ignored. For many drugs, multicompartment kinetics may be observed for significant periods of time, and failure to consider the distribution phase can lead to significant errors in estimates of clearance and in predictions of the appropriate dosage. Also, the difference between the “central” distribution volume and other terms reflecting wider distribution is important in deciding a loading dose strategy.
Steady State

consists of plasma and tissue reservoirs that are in rapid equilibrium with it, and distributes to a “final” volume, at which point concentrations in plasma decrease in a log-linear fashion with a rate constant of $k$ (Figure 2–4B). The multicompartment model of drug disposition can be viewed as though the blood and highly perfused lean organs such as heart, brain, liver, lung, and kidneys cluster as a single central compartment, whereas more slowly perfused tissues such as muscle, skin, fat, and bone behave as the final compartment (the tissue compartment).

If the pattern or ratio of blood flow to various tissues changes within an individual or differs among individuals, rates of drug distribution to tissues also will change. However, changes in blood flow may cause some tissues that were originally in the “central” volume to equilibrate sufficiently more slowly so as to appear only in the “final” volume. This means that central volumes will appear to vary with disease states that cause altered regional blood flow (such as would be seen in cirrhosis of the liver). After an intravenous bolus dose, drug concentrations in plasma may be higher in individuals with poor perfusion (e.g., shock) than they would be if perfusion were better. These higher systemic concentrations may in turn cause higher concentrations (and greater effects) in tissues such as brain and heart, whose usually high perfusion has not been reduced by the altered hemodynamic state. Thus, the effect of a drug at various sites of action can vary depending on perfusion of these sites.

Multicompartment Volume Terms. Two different terms have been used to describe the volume of distribution for drugs that follow multiple exponential decay. The first, designated $V_{area}$, is calculated as the ratio of clearance to the rate of decline in concentration during the elimination (final) phase of the logarithmic concentration versus time curve:

$$V_{area} = \frac{CL}{k} = \frac{dose}{k \cdot AUC} \quad (\text{Equation 2–12)}$$

The estimation of this parameter is straightforward, and the volume term may be determined after administration of a single dose of drug by the intravenous or oral route (where the value for the dose must be corrected for bioavailability). However, another multicompartment volume of distribution term may be more useful, especially when the effect of disease states on pharmacokinetics is to be determined. The volume of distribution at steady state ($V_{ss}$) represents the volume in which a drug would appear to be distributed during steady state if the drug existed throughout that volume at the same concentration as that in the measured fluid (plasma or blood). $V_{ss}$ also may be appreciated as shown in Equation 2–13, where $V_c$ is the volume of distribution of drug in the central compartment and $V_f$ is the volume term for drug in the tissue compartment:

$$V_{ss} = V_c + V_f \quad (\text{Equation 2–13)}$$

Although $V_{area}$ is a convenient and easily calculated parameter, it varies when the rate constant for drug elimination changes, even when there has been no change in the distribution space. This is so because the terminal rate of decline of the concentration of drug in blood or plasma depends not only on clearance but also on the rates of distribution of drug between the “central” and “final” volumes. $V_{ss}$ does not suffer from this disadvantage. The value of $V_{area}$ will always be greater than $V_{ss}$. As will be described, the extent of this difference will depend on the difference in $t_{1/2}$ observed during a dosing interval at steady state versus the value found for the terminal $t_{1/2}$. $V_{ss}$ can only be determined accurately if the drug is given intravenously.

Steady State. Equation 2–2 (dosing rate = CL · C$_{ss}$) indicates that a steady-state concentration eventually will be achieved when a drug is administered at a constant rate. At this point, drug elimination (the product of clearance and concentration; Equation 2–4) will equal the rate of drug availability. This concept also extends to regular intermittent dosage (e.g., 250 mg of drug every 8 hours). During each interdose interval, the concentration of drug rises with absorption and falls by elimination. At steady state, the entire cycle is repeated identically in each interval (Figure 2–5). Equation 2–2

![Figure 2–5](image-url)
still applies for intermittent dosing, but it now describes the average steady-state drug concentration ($C_{ss}$) during an interdose interval.

**Half-Life.** The $t_{1/2}$ is the time it takes for the plasma concentration to be reduced by 50%. For a one-compartment model (Figure 2–4A), $t_{1/2}$ may be determined readily by inspection and used to make decisions about drug dosage. However, as indicated in Figure 2–4B, drug concentrations in plasma often follow a multi-exponential pattern of decline, reflecting the changing amount of drug in the body. When using pharmacokinetics to calculate drug dosing in disease, note in Equation 2–14 that $t_{1/2}$ changes as a function of both clearance and volume of distribution.

$$t_{1/2} = 0.693 \cdot V_{ss}/CL$$  \hspace{1cm} (Equation 2–14)

This $t_{1/2}$ reflects the decline of systemic drug concentrations during a dosing interval at steady-state as depicted in Figure 2–5.

Examples of the marked differences in terminal versus steady-state $t_{1/2}$ (which reflect the difference between $V_{ss}$ and $V_{ss}$) are gentamicin and indomethacin. A terminal $t_{1/2}$ of 53 hours is observed for gentamicin (versus the steady-state value of 2.3 hours); biliary cycling probably is responsible for the 120-hour terminal value for indomethacin (compared to the steady-state value of 2.4 hours). The appreciation of longer terminal $t_{1/2}$ values for some medications may relate to their accumulation in tissues during chronic dosing or shorter periods of high-dose treatment. Such is the case for gentamicin, where the terminal $t_{1/2}$ is associated with renal and otoprotoxicities. The relevance of a particular $t_{1/2}$ may be defined in terms of the fraction of the clearance and volume of distribution that is related to each $t_{1/2}$ and whether plasma concentrations or amounts of drug in the body are best related to measures of response.

**Clearance** is the measure of the body’s ability to eliminate a drug; thus, as clearance decreases, owing to a disease process, e.g., $t_{1/2}$, would be expected to increase. However, this reciprocal relationship is valid only when the disease does not change the volume of distribution. For example, the $t_{1/2}$ of diazepam increases with increasing age; however, it is not clearance that changes as a function of age but rather the volume of distribution. Similarly, changes in protein binding of a drug may affect its clearance as well as its volume of distribution, leading to unpredictable changes in $t_{1/2}$ as a function of disease. The $t_{1/2}$ of tolbutamide, e.g., decreases in patients with acute viral hepatitis in a fashion opposite from what one might expect. The disease alters the drug’s protein binding in both plasma and tissues, causing no change in volume of distribution but an increase in clearance because higher concentrations of unbound drug are present in the bloodstream.

Although it can be a poor index of drug elimination from the body per se (disappearance of drug may be the result of formation of undetected metabolites that have therapeutic or unwanted effects), the $t_{1/2}$ defined in Equation 2–14 provides an approximation of the time required to reach steady state after a dosage regimen is initiated or changed (e.g., four half-lives to reach ~94% of a new steady state) and a means to estimate the appropriate dosing interval (see the later discussion and Sahin and Benet, 2008).

**Extent and Rate of Bioavailability**

**Bioavailability.** It is important to distinguish between the rate and extent of drug absorption and the amount of drug that ultimately reaches the systemic circulation. The amount of the drug that reaches the systemic circulation depends not only on the administered dose but also on the fraction of the dose ($F$) that is absorbed and escapes any first-pass elimination. This fraction is the drug’s bioavailability. Reasons for incomplete absorption were discussed earlier. Also, as noted previously, if the drug is metabolized in the intestinal epithelium or the liver, or excreted in bile, some of the active drug absorbed from the GI tract will be eliminated before it can reach the general circulation and be distributed to its sites of action.

Knowing the extraction ratio ($E_H$) for a drug across the liver (Equation 2–9), it is possible to predict the maximum oral availability ($F_{max}$), assuming that hepatic elimination follows first-order processes:

$$F_{max} = 1 - E_H = 1 - (CL_{hepatic}/Q_{hepatic})$$  \hspace{1cm} (Equation 2–15)

Thus, if the hepatic blood clearance for the drug is large relative to hepatic blood flow, the extent of availability will be low when the drug is given orally (e.g., lidocaine or propranolol). This reduction in availability is a function of the physiological site from which absorption takes place, and no modification of dosage form will improve the availability under conditions of linear kinetics. Incomplete absorption and/or intestinal metabolism following oral dosing will, in practice, reduce this predicted maximal value of $F$.

When drugs are administered by a route that is subject to first-pass loss, the equations presented previously that contain the terms dose or dosing rate (Equations 2–2, 2–6, 2–11, and 2–12) also must include the bioavailability term $F$ such that the available dose or dosing rate is used. For example, Equation 2–2 is modified to

$$F \cdot \text{dosing rate} = CL \cdot C_{ss}$$  \hspace{1cm} (Equation 2–16)

where the value of $F$ is between 0 and 1. The value of $F$ varies widely for drugs administered by mouth. Etidronate, a bisphosphonate used to stabilize bone matrix in the treatment of Paget’s disease and osteoporosis, has an $F$ of 0.03, meaning that only 3% of the drug appears in the bloodstream following oral dosing. In the case of etidronate,
therapy using oral administration is still useful, and the dose of the drug administered per kilogram is larger than would be given by injection.

Rate of Absorption. Although the rate of drug absorption does not, in general, influence the average steady-state concentration of the drug in plasma, it may still influence drug therapy. If a drug is absorbed rapidly (e.g., a dose given as an intravenous bolus) and has a small “central” volume, the concentration of drug initially will be high. It will then fall as the drug is distributed to its “final” (larger) volume (Figure 2–4B). If the same drug is absorbed more slowly (e.g., by slow infusion), a significant amount of the drug will be distributed while it is being administered, and peak concentrations will be lower and will occur later. Controlled-release oral preparations are designed to provide a slow and sustained rate of absorption in order to produce smaller fluctuations in the plasma concentration-time profile during the dosing interval compared with more immediate-release formulations. A given drug may act to produce both desirable and undesirable effects at several sites in the body, and the rates of distribution of drug to these sites may not be the same. The relative intensities of these different effects of a drug thus may vary transiently when its rate of administration is changed. Since the beneficial, nontoxic effects of drugs are based on knowledge of an ideal or desired plasma concentration range, maintaining that range while avoiding large swings between peak and trough concentrations can improve therapeutic outcome.

Nonlinear Pharmacokinetics

Nonlinearity in pharmacokinetics (i.e., changes in such parameters as clearance, volume of distribution, and t\(_{1/2}\)) as a function of dose or concentration of drug) usually is due to saturation of either protein binding, hepatic metabolism, or active renal transport of the drug.

Saturable Protein Binding. As the molar concentration of drug increases, the unbound fraction eventually also must increase (as all binding sites become saturated). This usually occurs only when drug concentrations in plasma are in the range of tens to hundreds of micrograms per milliliter. For a drug that is metabolized by the liver with a low intrinsic clearance-extraction ratio, saturation of plasma-protein binding will cause both V and CL to increase as drug concentrations increase; t\(_{1/2}\) thus may remain constant (Equation 2–14). For such a drug, C\(_{ss}\) will not increase linearly as the rate of drug administration is increased. For drugs that are cleared with high intrinsic clearance-extraction ratios, C\(_{ss}\) can remain linearly proportional to the rate of drug administration. In this case, hepatic clearance will not change, and the increase in V will increase the half-time of disappearance by reducing the fraction of the total drug in the body that is delivered to the liver per unit of time. Most drugs fall between these two extremes, and the effects of nonlinear protein binding may be difficult to predict.

Saturable Elimination. In this situation, the Michaelis-Menten equation (Equation 2–3) usually describes the nonlinearity. All active processes are undoubtedly saturable, but they will appear to be linear if values of drug concentrations encountered in practice are much less than K\(_{m}\). When drug concentrations exceed K\(_{m}\), nonlinear kinetics are observed. The major consequences of saturation of metabolism or transport are the opposite of those for saturation of protein binding. Saturation of protein binding will lead to increased CL because CL increases as drug concentration increases, whereas saturation of metabolism or transport may decrease CL. When both conditions are present simultaneously, they may virtually cancel each others’ effects, and surprisingly linear kinetics may result; this occurs over a certain range of concentrations for salicylic acid, for example.

Saturable metabolism causes oral first-pass metabolism to be less than expected (higher F), and there is a greater fractional increase in C\(_{ss}\) than the corresponding fractional increase in the rate of drug administration. The latter can be seen most easily by substituting Equation 2–3 into Equation 2–2 and solving for the steady-state concentration:

\[
C_{ss} = \frac{\text{dosing rate} \cdot K_m}{v_m - \text{dosing rate}}
\]

As the dosing rate approaches the maximal elimination rate (v\(_{m}\)), the denominator of Equation 2–17 approaches zero, and C\(_{ss}\) increases disproportionately. Because saturation of metabolism should have no effect on the volume of distribution, clearance and the relative rate of drug elimination decrease as the concentration increases; therefore, the log C\(_{ss}\) time curve is concave-decreasing until metabolism becomes sufficiently desaturated and first-order elimination is present. Thus, the concept of a constant t\(_{1/2}\) is not applicable to nonlinear metabolism occurring in the usual range of clinical concentrations. Consequently, changing the dosing rate for a drug with nonlinear metabolism is difficult and unpredictable because the resulting steady state is reached more slowly, and importantly, the effect is disproportionate to the alteration in the dosing rate.

The anti-seizure medication phenytoin provides an example of a drug for which metabolism becomes saturated in the therapeutic range of concentrations. Its t\(_{1/2}\) is 6-24 hours. For clearance, K\(_{m}\) (5-10 mg/L) is typically near the lower end of the therapeutic range (10-20 mg/L). For some individuals, especially young children and newborns being treated for emergent seizures, K\(_{m}\) may be as low as 1 mg/L. If, for an adult, the target concentration is 15 mg/L and this is attained at a dosing rate of 300 mg/day, then from Equation (2–17), v\(_{m}\) equals 320 mg/day. For such a patient, a dose that is 10% less than optimal (i.e., 270 mg/day) will produce a C\(_{ss}\) of 5 mg/L, well below the desired value. In contrast, a dose that is 10% greater than optimal (330 mg/day) will exceed metabolic capacity (by 10 mg/day) and cause a long, slow and unending climb in concentration during which toxicity will occur. Dosage cannot be controlled so precisely (<10% error). Therefore, for patients in whom the target concentration for phenytoin is more than ten times greater than the K\(_{m}\), alternating between inefficacious therapy and toxicity is almost unavoidable. For a drug such as phenytoin that has a narrow therapeutic index and exhibits nonlinear metabolism, therapeutic drug monitoring (described later) is most important. When the patient is a neonate, appreciation of this concept is of particular concern because signs and symptoms of toxicity are particularly difficult to monitor. In such cases, a pharmacokinetic consult is appropriate.

Design and Optimization of Dosage Regimens

Following administration of a dose of drug, its effects usually show a characteristic temporal pattern (Figure 2–6).
Onset of the effect is preceded by a lag period, after which the magnitude of the effect increases to a maximum and then declines; if a further dose is not administered, the effect eventually disappears as the drug is eliminated. This time course reflects changes in the drug’s concentration as determined by the pharmacokinetics of its absorption, distribution, and elimination.

Accordingly, the intensity of a drug’s effect is related to its concentration above a minimum effective concentration, whereas the duration of the drug’s effect reflects the length of time the drug level is above this value. These considerations, in general, apply to both desired and undesired (adverse) drug effects, and as a result, a therapeutic window exists that reflects a concentration range that provides efficacy without unacceptable toxicity.

Similar considerations apply after multiple dosing associated with long-term therapy, and they determine the amount and frequency of drug administration to achieve an optimal therapeutic effect. In general, the lower limit of a drug’s therapeutic range is approximately equal to the drug concentration that produces about half the greatest possible therapeutic effect, and the upper limit of the therapeutic range is such that no more than 5-10% of patients will experience a toxic effect. For some drugs, this may mean that the upper limit of the range is no more than twice the lower limit. Of course, these figures can be highly variable, and some patients may benefit greatly from drug concentrations that exceed the therapeutic range, whereas others may suffer significant toxicity at much lower values (e.g., with digoxin).

For a limited number of drugs, some effect of the drug is easily measured (e.g., blood pressure, blood glucose) and can be used to optimize dosage using a trial-and-error approach. Even in an ideal case, certain quantitative issues arise, such as how often to change dosage and by how much. These usually can be settled with simple rules of thumb based on the principles discussed (e.g., change dosage by no more than 50% and no more often than every 3-4 half-lives). Alternatively, some drugs have very little dose-related toxicity, and maximum efficacy usually is desired. In such cases, doses well in excess of the average required will ensure efficacy (if this is possible) and prolong drug action. Such a “maximal dose” strategy typically is used for penicillins.

For many drugs, however, the effects are difficult to measure (or the drug is given for prophylaxis), toxicity and lack of efficacy are both potential dangers, or the therapeutic index is narrow. In these circumstances, doses must be titrated carefully, and drug dosage is limited by toxicity rather than efficacy. Thus, the therapeutic goal is to maintain steady-state drug levels within the therapeutic window. For most drugs, the actual concentrations associated with this desired range are not known and need not be known. It is sufficient to understand that efficacy and toxicity generally depend on concentration and how drug dosage and frequency of administration affect the drug level. However, for a small number of drugs for which there is a small (2-3 fold) difference between concentrations resulting in efficacy and toxicity (e.g., digoxin, theophylline, lidocaine, aminoglycosides, cyclosporine, tacrolimus, sirolimus, warfarin, and anticoagulants), a plasma concentration range associated with effective therapy has been defined. In these cases, a target-level strategy is reasonable, wherein a desired (target) steady-state concentration of the drug (usually in plasma) associated with efficacy and minimal toxicity is chosen, and a dosage is computed that is expected to achieve this value. Drug concentrations are subsequently measured, and dosage is adjusted if necessary to approximate the target more closely (described later).
In most clinical situations, drugs are administered in a series of repetitive doses or as a continuous infusion to maintain a steady-state concentration of drug associated with the therapeutic window. Calculation of the appropriate maintenance dosage is a primary goal. To maintain the chosen steady-state or target concentration, the rate of drug administration is adjusted such that the rate of input equals the rate of loss. This relationship was defined previously in Equations 2–2 and 2–16 and is expressed here in terms of the desired target concentration:

\[
 \text{Dosing rate} = \text{target } C_p \cdot \frac{CL}{F} \quad (\text{Equation 2–18})
\]

If the clinician chooses the desired concentration of drug in plasma and knows the clearance and bioavailability for that drug in a particular patient, the appropriate dose and dosing interval can be calculated.

**Example.** Oral digoxin is to be used as a maintenance dose to gradually “digitalize” a 63 year old, 84-kg patient with congestive heart failure. A steady-state plasma concentration of 0.7-0.9 ng/mL is selected as an appropriate conservative target based on prior knowledge of the action of the drug in patients with heart failure to maintain levels at or below the 0.5-1.0 ng/mL range (Bauman et al., 2006). Based on the fact that the patient’s creatinine clearance \( CL_{\text{cr}} \) is 56 mL/min, digoxin’s clearance may be estimated from data in Appendix II.

\[
 CL = 0.88 \times CL_{\text{cr}} + 0.33 \text{ mL} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
= 0.88 \times 56/84 + 0.33 \text{ mL} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
= 0.92 \text{ mL} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
= 77 \text{ mL} \cdot \text{min}^{-1} = 4.6 \text{ L} \cdot \text{hr}^{-1}
\]

Equation (2–18) then is used to calculate an appropriate dosing rate knowing that the oral bioavailability of digoxin is 70% \( (F = 0.7) \).

\[
 \text{Dosing rate} = \frac{\text{Target } C_p}{F} \cdot \frac{CL}{F} \\
= 0.75 \text{ ng} \cdot \text{mL}^{-1} \times (0.92/0.7) \text{ mL} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
= 0.99 \text{ ng} \cdot \text{min}^{-1} \cdot \text{kg}^{-1} \\
\text{or 83 ng} \cdot \text{min}^{-1} \text{ for an 84-kg patient} \\
\text{or 83 ng} \cdot \text{min}^{-1} \times 60 \text{ min} \times 24/24 \text{ hr} \\
= 0.12 \text{ mg/24 hr}
\]

In practice, the dosing rate would be rounded to the closest dosage size, 0.125 mg/24 hr, which would result in a steady-state plasma concentration of 0.78 ng/mL \( (0.75 \times 125/120) \). Digoxin is a well characterized example of a drug that is difficult to dose and must be monitored regularly. While guidelines based on calculations of the sort suggested here are useful (Bauman et al., 2006), it is clear that tablet sizes are limiting and tablet sizes intermediate to those available are needed. Since the coefficient of variation for the clearance equation when used for digoxin treatment in this patient group is large (52%), it is common for patients who are not monitored regularly to require hospital admission to adjust medication. Monitoring the clinical status of patients (new or increased ankle edema, inability to sleep in a recumbent position, decreased exercise tolerance) whether accomplished by home health follow up or regular visits to the clinician, is essential to avoid untoward results.

**Dosing Interval for Intermittent Dosage.** In general, marked fluctuations in drug concentrations between doses are not desirable. If absorption and distribution were instantaneous, fluctuations in drug concentrations between doses would be governed entirely by the drug’s elimination \( t_{1/2} \). If the dosing interval \( T \) were chosen to be equal to the \( t_{1/2} \), then the total fluctuation would be 2-fold; this is often a tolerable variation.

Pharmacodynamic considerations modify this. If a drug is relatively nontoxic such that a concentration many times that necessary for therapy can be tolerated easily, the maximal-dose strategy can be used, and the dosing interval can be much longer than the elimination \( t_{1/2} \) (for convenience). The \( t_{1/2} \) of amoxicillin is ~2 hours, but dosing every 2 hours would be impractical. Instead, amoxicillin often is given in large doses every 8 or 12 hours. For some drugs with a narrow therapeutic range, it may be important to estimate the maximal and minimal concentrations that will occur for a particular dosing interval. The minimal steady-state concentration \( C_{\text{ss}, \text{min}} \) may be reasonably determined by the use of Equation 1–19:

\[
 C_{\text{ss}, \text{min}} = \frac{F \cdot \text{dose}}{V_{\text{ss}}} 
 \cdot \frac{1 - \exp(-kT)}{\exp(-kT)} \quad (\text{Equation 2–19})
\]

where \( k \) equals 0.693 divided by the clinically relevant plasma \( t_{1/2} \) and \( T \) is the dosing interval. The term \( \exp(-kT) \) is, in fact, the fraction of the last dose (corrected for bioavailability) that remains in the body at the end of a dosing interval.

For drugs that follow multi-exponential kinetics and are administered orally, estimation of the maximal steady-state concentration \( C_{\text{ss}, \text{max}} \) involves a complicated set of exponential constants for distribution and absorption. If these terms are ignored for multiple oral dosing, one easily may predict a maximal steady-state concentration by omitting the \( \exp(-kT) \) term in the numerator of Equation 2–19 (see Equation 2–20). Because of the approximation, the predicted maximal concentration from Equation 2–20 will be greater than that actually observed.

**Example.** In the patient with congestive heart failure discussed earlier, an oral maintenance dose of 0.125 mg digoxin per 24 hours was calculated to achieve an average plasma concentration of 0.78 ng/mL during the dosage interval. Digoxin has a narrow therapeutic index, and plasma levels ≤1.0 ng/mL usually are associated with efficacy and minimal toxicity. What are the maximum and minimum plasma concentrations associated with the preceding regimen? This first requires estimation of digoxin’s volume of distribution based on available pharmacokinetic data (Appendix II).

\[
 V_{\text{ss}} = 3.1 \times CL_{\text{cr}} + 3.8 \text{ L} \cdot \text{kg}^{-1} \\
= 3.1 \times (56/84) + 3.8 \text{ L} \cdot \text{kg}^{-1}
\]

Combining this value with that of digoxin’s clearance provides an estimate of digoxin’s elimination \( t_{1/2} \) in the patient (Equation 2–14).

\[
 t_{1/2} = \frac{0.693 \times V_{\text{ss}} / CL}{4.4 \text{ L} \cdot \text{hr}^{-1}} = 75 \text{ hr} = 3.1 \text{ days}
\]
Accordingly, the fractional rate constant of elimination is equal to 0.22 day\(^{-1}\) (0.693/3.1 days). Maximum and minimum digoxin plasma concentrations then may be predicted depending on the dosage interval. With \(T = 1\) day (i.e., 0.125 mg given every day):

\[
C_{ss, \ max} = \frac{F \cdot \text{dose} / V_{ss}}{1 - \exp(-kT)} = \frac{0.7 \times 0.125 \ \text{mg} / 496 \ \text{L}}{0.2} = 0.88 \ \text{ng/mL} \quad \text{(Equation 2–20)}
\]

\[
C_{ss, \ min} = C_{ss, \ max} \cdot \exp(-kT) = (0.88 \ \text{ng/mL})(0.8) = 0.7 \ \text{ng/mL} \quad \text{(Equation 2–21)}
\]

Thus, the plasma concentrations would fluctuate minimally about the steady-state concentration of 0.78 ng/mL, well within the recommended therapeutic range of 0.5-1.0 ng/mL. In this patient example, twice the daily dose (2 \(\times\) 0.125 mg) could be given every other day. The average steady-state concentration would remain at 0.78 ng/mL, while the predicted maximum concentration would be 0.98 ng/mL (in Equation 2–20; dose = 0.25 mg and \(T = 2\) days) and the minimum concentration would be 0.62 ng/mL (in Equation 2–21; 0.98 \(\times\) 0.64). While this result would maintain a therapeutic concentration and avoid large excursions from it between doses, it does not favor patient compliance. Dosing must be compatible with the patient’s routine and every other day dosing is problematic in this patient population.

### Loading Dose

The **loading dose** is one or a series of doses that may be given at the onset of therapy with the aim of achieving the target concentration rapidly. The appropriate magnitude for the loading dose is

\[
\text{Loading dose} = \text{target } C_p \cdot V_{ss} / F \quad \text{(Equation 2–22)}
\]

A loading dose may be desirable if the time required to attain steady state by the administration of drug at a constant rate (4 elimination \(t_{1/2}\) values) is long relative to the temporal demands of the condition being treated. For example, the \(t_{1/2}\) of lidocaine is usually 1-2 hours. Arrhythmias encountered after myocardial infarction obviously may be life-threatening, and one cannot wait 4-8 hours to achieve a therapeutic concentration of lidocaine by infusion of the drug at the rate required to attain this concentration. Hence, use of a loading dose of lidocaine in the coronary care unit is standard.

The use of a loading dose also has significant disadvantages. First, the particularly sensitive individual may be exposed abruptly to a toxic concentration of a drug. Moreover, if the drug involved has a long \(t_{1/2}\), it will take a long time for the concentration to fall if the level achieved is excessive. Loading doses tend to be large, and they are often given parenterally and rapidly; this can be particularly dangerous if toxic effects occur as a result of actions of the drug at sites that are in rapid equilibrium with plasma. This occurs because the loading dose calculated on the basis of \(V_{ss}\) subsequent to drug distribution is at first constrained within the initial and smaller “central” volume of distribution. It is therefore usually advisable to divide the loading dose into a number of smaller fractional doses that are administered over a period of time. Alternatively, the loading dose should be administered as a continuous intravenous infusion over a period of time. Ideally, this should be given in an exponentially decreasing fashion to mirror the concomitant accumulation of the maintenance dose of the drug, and this is accomplished using computerized infusion pumps.

**Example.** Accumulation of digoxin (“digitalization”) in the patient described earlier is gradual if only a maintenance dose is administered (for at least 12 days, based on \(t_{1/2} = 3.1\) days). A more rapid response could be obtained (if deemed necessary) by using a loading-dose strategy and Equation 2–22. Here a target \(C_p\) of 0.9 ng/mL is chosen as a target below the recommended maximum of 1.0 ng/mL.

\[
\text{Loading dose} = 0.9 \ \text{ng/mL} \times 
\]

To avoid toxicity, this oral loading dose, would be given as an initial 0.25-mg dose followed by a 0.25-mg dose 6-8 hours later, with careful monitoring of the patient and the final 0.125-mg dose given 12-14 hours later.

### Individualizing Dosage

A rational dosage regimen is based on knowledge of \(F, CL, V_{ss}\) and \(t_{1/2}\) and some information about rates of absorption and distribution of the drug together with potential effects of the disease on these parameters. Recommended dosage regimens generally are designed for an “average” patient; usual values for the important determining parameters and appropriate adjustments that may be necessitated by disease or other factors are presented in Appendix II. This “one size fits all” approach, however, overlooks the considerable and unpredictable inter-patient variability that usually is present in these pharmacokinetic parameters. For many drugs, one standard deviation in the values observed for \(F, CL, V_{ss}\) is \(\pm 20\%\), \(50\%\), and \(30\%\), respectively. This means that 95% of the time the \(C_{ss}\) that is achieved will be between 35% and 270% of the target; this is an unacceptably wide range for a drug with a low therapeutic index. Individualization of the dosage regimen to a particular patient therefore is critical for optimal therapy. The pharmacokinetic principles described earlier provide a basis for modifying the dosage regimen to obtain a desired degree of efficacy with a minimum of unacceptable adverse effects. In situations where the drug’s plasma concentration can be measured and related to the therapeutic window, additional guidance for dosage modification is obtained from blood levels taken during therapy and evaluated in a pharmacokinetic consult available in many institutional settings. Such measurement and adjustment are appropriate for many drugs with low therapeutic indices (e.g., cardiac glycosides, anti-arrhythmic agents, anticonvulsants, immunosuppressants, theophylline, and warfarin).

### Therapeutic Drug Monitoring

The major use of measured concentrations of drugs (at steady state) is to refine the estimate of \(CL/F\) for the patient being treated, using Equation 2–16 as rearranged below:

\[
CL/F \text{ (patient)} = \text{dosing rate} / C_{ss} \text{ (measured)} \quad \text{(Equation 2–23)}
\]
The new estimate of \( CL/\mathit{F} \) can be used in Equation 2–18
to adjust the maintenance dose to achieve the desired
target concentration.

 Certain practical details and pitfalls associated
with therapeutic drug monitoring should be kept in
mind. The first of these relates to the time of sampling
for measurement of the drug concentration. If intermit-
tent dosing is used, when during a dosing interval
should samples be taken? It is necessary to distinguish
between two possible uses of measured drug concen-
trations to understand the possible answers. A concentra-
tion of drug measured in a sample taken at virtually
any time during the dosing interval will provide informa-
tion that may aid in the assessment of drug toxicity.
This is one type of therapeutic drug monitoring. It
should be stressed, however, that such use of a mea-
ured concentration of drug is fraught with difficulties
because of inter-individual variability in sensitivity to
the drug. When there is a question of toxicity, the drug
concentration is just one of many items used to interpret
the clinical situation.

 Changes in the effects of drugs may be delayed
relative to changes in plasma concentration because
of a slow rate of distribution or pharmacodynamic fac-
tors. Concentrations of digoxin, e.g., regularly exceed
2 ng/mL (a potentially toxic value) shortly after an
oral dose, yet these peak concentrations do not cause
toxicity; indeed, they occur well before peak effects.
Thus, concentrations of drugs in samples obtained
shortly after administration can be uninformative or
even misleading.

 The purpose of sampling during supposed steady
state is to modify the estimate of \( CL/\mathit{F} \) and thus the
choice of dosage. Early post-absorptive concentrations
do not reflect clearance; they are determined primarily
by the rate of absorption, the “central” (rather than the
steady-state) volume of distribution, and the rate of dis-
tribution, all of which are pharmacokinetic features of
virtually no relevance in choosing the long-term main-
tenance dosage. When the goal of measurement is
adjustment of dosage, the sample should be taken well
after the previous dose, as a rule of thumb, just before
the next planned dose, when the concentration is at its
minimum. The exceptions to this approach are drugs
that are eliminated nearly completely between doses
and act only during the initial portion of each dosing
interval. If it is questionable whether efficacious con-
centrations of such drugs are being achieved, a sample
taken shortly after a dose may be helpful. On the other
hand, if a concern is whether low clearance (as in renal
failure) may cause accumulation of drug, concentrations
measured just before the next dose will reveal such
accumulation and are considerably more useful for this
purpose than is knowledge of the maximal concen-
tration. For such drugs, determination of both maximal
and minimal concentrations is recommended. These
two values can offer a more complete picture of the
behavior of the drug in a specific patient (particularly if
obtained over more that one dosing period) can better
support pharmacokinetic modeling.

 A second important aspect of the timing of sam-
pling is its relationship to the beginning of the main-
teinance-dosage regimen. When constant dosage is given,
steady state is reached only after four \( t_{1/2} \) have passed.
If a sample is obtained too soon after dosage is begun,
it will not reflect this state and the drug’s clearance
accurately. Yet, for toxic drugs, if sampling is delayed
until steady state is ensured, the damage may have been
done. Some simple guidelines can be offered. When it
is important to maintain careful control of concentra-
tions, the first sample should be taken after two \( t_{1/2} \) (as
calculated and expected for the patient), assuming that
no loading dose has been given. If the concentration
already exceeds 90% of the eventual expected mean
steady-state concentration, the dosage rate should
be halved, another sample obtained in another two
(supposed) \( t_{1/2} \), and the dosage halved again if this sam-
ple exceeds the target. If the first concentration is not
too high, the initial rate of dosage is continued; even if
the concentration is lower than expected, it is usually
reasonable to await the attainment of steady state in
another two estimated \( t_{1/2} \) and then to proceed to adjust
dosage as described earlier.

 If dosage is intermittent, there is a third concern with the time at
which samples are obtained for determination of drug concentrations.
If the sample has been obtained just prior to the next dose, as recom-
manded, concentration will be a minimal value, not the mean.
However, as discussed earlier, the estimated mean concentration may
be calculated by using Equation 2–16.

 If a drug follows first-order kinetics, the average, minimum,
and maximum concentrations at steady state are linearly related to
dose and dosing rate (see Equations 2–16, 2–19, and 2–20).
Therefore, the ratio between the measured and desired concentra-
tions can be used to adjust the dose, consistent with available dosage
sizes:

\[
\frac{C_{SS\text{(measured)}}}{C_{SS\text{(predicted)}}} = \frac{\text{Dose (previous)}}{\text{Dose (new)}}
\]

(Equation 2–24)

In the previously described patient given 0.125 mg digoxin every
24 hours, for example, if the measured minimum (trough) steady-
state concentration were found to be 0.35 ng/mL rather than the pre-
dicted level of 0.7 ng/mL, an appropriate, practical change in the
Changes in plasma protein binding have been shown to increase the daily dose by 0.125 mg to 0.25-mg digoxin daily.

\[
\text{Dose (new)} = \frac{C_{ss}(\text{predicted})}{C_{ss}(\text{measured})} \times \text{Dose (previous)}
\]

\[
= \frac{0.7}{0.35} \times 0.125 = 0.25/24 \text{ hour}
\]

In practice, one would change the dose from the 0.125-mg tablet to the 0.25-mg tablet by providing a new prescription.

**Compliance.** Ultimately, therapeutic success depends on the patient actually taking the drug according to the prescribed dosage regimen—“Drugs don’t work if you don’t take them.” Noncompliance with the prescribed dosing schedule is a major reason for therapeutic failure, especially in the long-term treatment of heart failure as in our example patient being administered digoxin where the absence of intermediate tablet sizes influences the regimens that can be practically constructed (our patient ultimately required an alternate day or alternate dose schedule). Moreover, treatment of chronic disease using antihypertensive, anti-retroviral, and anticonvulsant agents also represents a compliance problem. When no special efforts are made to address this issue, only about 50% of patients follow the prescribed dosage regimen in a reasonably satisfactory fashion, approximately one-third comply only partly, and about one in six patients is essentially noncompliant (Devabhaktuni and Bangalore 2009). Missed doses are more common than too many doses. The number of doses drugs do not appear to be as important as the number of times a day doses must be remembered (Ho et al., 2009). Reducing the number of required dosing occasions can improve adherence to a prescribed dosage regimen. Equally important is the need to involve patients in the responsibility for their own health using a variety of strategies based on improved communication regarding the nature of the disease and the overall therapeutic plan (Appendix I).

**BIBLIOGRAPHY**

Pharmacodynamics is the study of the biochemical and physiological effects of drugs and their mechanisms of action. Understanding pharmacodynamics can provide the basis for the rational therapeutic use of a drug and the design of new and superior therapeutic agents. Simply stated, pharmacodynamics refers to the effects of a drug on the body. In contrast, the effects of the body on the actions of a drug are pharmacokinetic processes (Chapter 2), and include absorption, distribution, metabolism, and excretion of drugs (often referred to collectively as ADME). Many adverse effects of drugs and drug toxicities can be anticipated by understanding a drug’s mechanism(s) of action, its pharmacokinetics, and its interactions with other drugs. Thus, both the pharmacodynamic properties of a drug and its pharmacokinetics contribute to safe and successful therapy. The effects of many drugs, both salutary and deleterious, may differ widely from patient to patient due to genetic differences that alter the pharmacokinetics and the pharmacodynamics of a given drug. This aspect of pharmacology is termed pharmacogenetics and is covered in Chapter 7.

PHARMACODYNAMIC CONCEPTS

The effects of most drugs result from their interaction with macromolecular components of the organism. These interactions alter the function of the pertinent component and initiate the biochemical and physiological changes that are characteristic of the response to the drug. The term drug receptor or drug target denotes the cellular macromolecule or macromolecular complex with which the drug interacts to elicit a cellular response, i.e., a change in cell function. Drugs commonly alter the rate or magnitude of an intrinsic cellular response rather than create new responses. Drug receptors are often located on the surface of cells, but may also be located in specific intracellular compartments such as the nucleus. Many drugs also interact with acceptors (e.g., serum albumin) within the body. Acceptors are entities that do not directly cause any change in biochemical or physiological response. However, interactions of drugs with acceptors such as serum albumin can alter the pharmacokinetics of a drug’s actions.

From a numerical standpoint, proteins form the most important class of drug receptors. Examples include the receptors for hormones, growth factors, transcription factors, and neurotransmitters; the enzymes of crucial metabolic or regulatory pathways (e.g., dihydrofolate reductase, acetylcholinesterase, and cyclic nucleotide phosphodiesterases); proteins involved in transport processes (e.g., Na⁺,K⁺-ATPase); secreted glycoproteins (e.g., Wnts); and structural proteins (e.g., tubulin). Specific binding of drugs to other cellular constituents such as DNA is also exploited for therapeutic purposes. For example, nucleic acids are particularly important drug receptors for certain cancer chemotherapeutic agents and antiviral drugs.

Physiological Receptors

A major group of drug receptors consists of proteins that normally serve as receptors for endogenous regulatory ligands. These drug targets are termed physiological receptors. Many drugs act on physiological receptors and are particularly selective because physiological receptors have evolved to recognize and respond to individual signaling molecules with great selectivity. Drugs that bind to physiological receptors and mimic the regulatory effects of the endogenous
signaling compounds are termed agonists. If the drug binds to the same recognition site as the endogenous agonist (the primary or orthosteric site on the receptor) the drug is said to be a primary agonist. Allosteric (allo-topic) agonists bind to a different region on the receptor referred to as an allosteric or allotropic site. Drugs that block or reduce the action of an agonist are termed antagonists. Antagonism most commonly results from competition with an agonist for the same or overlapping site on the receptor (a syntopic interaction), but can also occur by interacting with other sites on the receptor (allosteric antagonism), by combining with the agonist (chemical antagonism), or by functional antagonism by indirectly inhibiting the cellular or physiological effects of the agonist. Agents that are only partly as effective as agonists regardless of the concentration employed are termed partial agonists. Many receptors exhibit some constitutive activity in the absence of a regulatory ligand; drugs that stabilize such receptors in an inactive conformation are termed inverse agonists (Figure 3–1) (Kenakin, 2004; Milligan, 2003). Note that partial agonists and inverse agonists that interact syntopically with a full agonist will behave as competitive antagonists.

**Drug Specificity**

The strength of the reversible interaction between a drug and its receptor, as measured by the dissociation constant, is defined as the affinity of one for the other. Both the affinity of a drug for its receptor and its intrinsic activity are determined by its chemical structure. The chemical structure of a drug also contributes to the drug’s specificity. A drug that interacts with a single type of receptor that is expressed on only a limited number of differentiated cells will exhibit high specificity. An example of such a drug is ranitidine, an 

H2 receptor antagonist used to treat ulcers (Chapter 45). If, however, a receptor is expressed ubiquitously on a variety of cells throughout the body, drugs acting on such a widely expressed receptor will exhibit widespread effects, and could produce serious side effects or toxicities if the receptor serves important functions in multiple tissues.

There are numerous examples of drugs that work through a discrete action, but have effects throughout the body. These include the inotropic drug digoxin, which inhibits the ubiquitously expressed enzyme Na\(^+\),K\(^+\)-ATPase (Chapter 28), and the antifolate anticancer drugs such as methotrexate that inhibit dihydrofolate reductase, an enzyme required by all cells for the synthesis of purines and thymidylate (Chapters 60 and 61). The Na\(^+\) channel blocker lidocaine has effects in peripheral nerves, the heart, and the central nervous system (CNS) because Na\(^+\) channels are highly expressed in all these tissues (Chapters 20 and 29). Lidocaine has local anesthetic effects when administered locally to prevent or relieve pain, but can also have cardiac and CNS effects if it reaches the systemic circulation. Even if the primary action of a drug is localized, as might be the case with injected lidocaine, the subsequent physiological effects of the drug may be widespread. One example would be immunosuppressant drugs (Chapter 35) that specifically inhibit cells of the immune system; their use is limited by the risk of

![Figure 3–1. Regulation of the activity of a receptor with conformation-selective drugs. The ordinate is the activity of the receptor produced by \(R_a\), the active receptor conformation (e.g., stimulation of adenylyl cyclase by a β adrenergic receptor). If a drug \(L\) selectively binds to \(R_e\), it will produce a maximal response. If \(L\) has equal affinity for \(R_i\) and \(R_a\), it will not perturb the equilibrium between them and will have no effect on net activity; \(L\) would appear as an inactive compound. If the drug selectively binds to \(R_i\), then the net amount of \(R_a\) will be diminished. If \(L\) can bind to receptor in an active conformation \(R_a\) but also bind to inactive receptor \(R_i\) with lower affinity, the drug will produce a partial response; \(L\) will be a partial agonist. If there is sufficient \(R_a\) to produce an elevated basal response in the absence of ligand (agonist-independent constitutive activity), then activity will be inhibited; \(L\) will then be an inverse agonist. Inverse agonists selectively bind to the inactive form of the receptor and shift the conformational equilibrium toward the inactive state. In systems that are not constitutively active, inverse agonists will behave like competitive antagonists, which helps explain why the properties of inverse agonists and the number of such agents previously described as competitive antagonists were only recently appreciated. Receptors that have constitutive activity and are sensitive to inverse agonists include benzodiazepine, histamine, opioid, cannabinoid, dopamine, bradykinin, and adenosine receptors.](image-url)
opportunistic systemic infections. Other examples of drugs that act locally but have global effects are diuretics (Chapter 25) that act on cells in the kidney to alter serum electrolytes such as K+. However, the hypokalemia that a diuretic such as furosemide can cause can significantly increase the risk of skeletal muscle cramps and cardiac arrhythmias.

Many clinically important drugs exhibit a broad (low) specificity because the drug is able to interact with multiple receptors in different tissues. Such broad specificity might enhance the clinical utility of a drug, but also contribute to a spectrum of adverse side effects due to off-target interactions. One example of a drug that interacts with multiple receptors is amiodarone, an agent used to treat cardiac arrhythmias. In cardiac muscle, amiodarone inhibits Na+, Ca2+, and K+ channels, and noncompetitively inhibits β-adrenergic receptors (Table 29–3). All of these drug-receptor interactions may contribute to its therapeutic efficacy and widespread use to treat many forms of arrhythmia. However, amiodarone also has a number of serious toxicities, some of which are due to the drug’s structural similarity to thyroid hormone and its ability to interact with nuclear thyroid receptors. Amiodarone’s salutary effects and toxicities may also be mediated through interactions with receptors that are poorly characterized or unknown.

Some drugs are administered as racemic mixtures of stereoisomers. The stereoisomers can exhibit different pharmacodynamic as well as pharmacokinetic properties. For example, the antiarrhythmic drug sotalol is prescribed as a racemic mixture; the d- and l-enantiomers are equipotent as K+ channel blockers, but the l-enantiomer is a much more potent β-adrenergic antagonist (Chapter 29). Labetolol (Chapter 12) is another drug that has complex pharmacodynamic properties because it is used clinically as a racemic mixture containing equal amounts of four diastereomers. The R,R isomer is a potent β1 adrenergic antagonist and partial β2 receptor agonist; the S,R and S,S isomers have little or no β antagonist activity but do possess significant α1 adrenergic antagonist activity, and the R,S isomer is essentially devoid of adrenergic blocking activity. It should always be considered that a given drug has multiple mechanisms of action that depend upon many factors, including receptor specificity, the tissue-specific expression of the receptor(s), drug access to target tissues, drug concentration in different tissues, pharmacogenetics, and interactions with other drugs.

The pharmacological properties of many drugs differ depending upon whether the drug is used acutely or chronically. In some cases, chronic administration of a drug causes a down-regulation or desensitization of receptors that can require dose adjustments to maintain adequate therapy. Chronic administration of nitrovasodilators to treat angina results in the rapid development of complete tolerance, a process known as tachyphylaxis. To avoid tachyphylaxis, it is necessary to interrupt nitrovasodilator therapy every night for at least 18 hours (Chapter 27). Differential development of tolerance to different effects of a drug can also occur. Tolerance to the analgesic effects of opioids can develop with chronic administration, whereas little tolerance to the effects of these agents on respiratory depression occurs under the same dosing conditions (Chapter 18). Drug resistance may also develop due to pharmacokinetic mechanisms (i.e., the drug is metabolized more rapidly with chronic exposure), the development of mechanisms that prevent the drug from reaching its receptor (i.e., increased expression of the multidrug resistance transporter in drug-resistant cancer cells; see Chapter 5), or the clonal expansion of cancer cells containing drug-resistant mutations in the drug receptor (e.g., imatinib-resistant mutations in BCR-ABL; Chapter 62).

Some drug effects do not occur by means of macromolecular receptors, such as the therapeutic neutralization of gastric acid by the antacid bases aluminum and magnesium hydroxides [Al (OH)3 and Mg (OH)2]. Drugs such as mannitol act according to colligative properties to increase the osmolarity of various body fluids and cause changes in the distribution of water to promote diuresis, catharsis, expansion of circulating volume in the vascular compartment, or reduction of cerebral edema (Chapter 25). The oral administration of cholesterol-binding agents (e.g., cholestyramine resin) is used to decrease serum cholesterol by limiting absorption of dietary cholesterol from the intestine (Chapter 31).

Anti-infective drugs such as antibiotics, antivirals, and drugs used to treat parasitic infections target receptors or cell processes that are critical for the growth or survival of the infective agent but are nonessential or lacking in the host organism. Thus, the therapeutic goal of anti-infective drugs involves delivering drugs to the pathogenic organism in sufficient concentrations to kill or suppress the growth of the pathogen without causing untoward effects on the patient. For instance, antibiotics such as penicillin inhibit a key enzyme required for synthesis of bacterial cell walls, an enzyme not present in humans or animals. A major challenge with many anti-infectives is the rapid development of drug resistance. Resistance to antibiotics, antivirals, and other drugs can result through a variety of mechanisms including mutation of the target receptor, increased expression of enzymes that degrade or increase efflux of the drug from the infective agent, and development of alternative biochemical pathways that circumvent the drug’s effects on the infective agent (Chapter 48).

Structure-Activity Relationships and Drug Design

A significant number of clinically useful drugs were developed in an era when drug discovery primarily involved screening compounds for their capacity to elicit salutary effects in patients or an animal disease model such as the spontaneously hypertensive rat or seizure-prone mouse. The receptors responsible for the clinical effects of many of these drugs have yet to be identified, although significant efforts are devoted toward identifying their mechanisms of action. Conversely, sequencing of the entire human genome has identified novel genes related by sequence to known
receptors, but because the endogenous and exogenous ligands for these putative receptors are still unknown, these are referred to as orphan receptors. Orphan receptors are still found in the G–protein coupled receptor and nuclear hormone receptor families. Detailed knowledge of a drug’s molecular target(s) can inform the development of new drugs with greater efficacy and lower toxicities. With the advent of transgenic animal models, it is now feasible to develop animal models that can test hypotheses regarding the possible physiological effects of altering a specific receptor’s function and to predict the effects of receptor antagonists and agonists by genetically altering the receptor’s expression and function. The methods and rationale currently used by the pharmaceutical industry to design and invent new drugs is covered fully in Chapter 1 and outlined briefly below.

Both the affinity of a drug for its receptor and its intrinsic activity are determined by its chemical structure. This relationship frequently is quite stringent. Relatively minor modifications in the drug molecule may result in major changes in its pharmacological properties based on altered affinity for one or more receptors. The stringent nature of chemical structure to specificity of binding of a drug to its receptor is illustrated by the capacity of receptors to interact selectively with optical isomers, as described for the antimuscarinic actions of dl-hyoscyamine (atropine, effects of which are due to the l-isomer) versus d-hyoscyamine.

Exploitation of structure-activity relationships on many occasions has led to the synthesis of valuable therapeutic agents. Because changes in molecular configuration need not alter all actions and effects of a drug equally, it is sometimes possible to develop a congener with a more favorable ratio of therapeutic to adverse effects, enhanced selectivity among different cells or tissues, or more acceptable secondary characteristics than those of the parent drug. Therapeutically useful antagonists of hormones or neurotransmitters have been developed by chemical modification of the structure of the physiological agonist. Minor modifications of structure also can have profound effects on the pharmacokinetic properties of drugs. For example, addition of a phosphate ester at the N3 position in the antiseizure drug phenytoin (5,5-diphenyl-2,4-imidazolidinedione) produces a prodrug (FOSPHENYTOIN) that is more soluble in intravenous solutions than its parent. This modification results in far more reliable distribution in the body and a drug that must be cleaved by esterase to become active.

Given adequate information about both the molecular structures and the pharmacological activities of a relatively large group of congeners, it is possible to use computer analysis to identify the chemical properties (i.e., the pharmacophore) required for optimal action at the receptor: size, shape, position, and orientation of charged groups or hydrogen bond donors, and so on. Advances in molecular modeling of organic compounds and the methods for drug target (receptor) discovery and biochemical measurement of the primary actions of drugs at their receptors have enriched the quantification of structure-activity relationships and its use in drug design (Carlson and McCammon, 2000). The importance of specific drug-receptor interactions can be evaluated further by analyzing the responsiveness of receptors that have been selectively mutated at individual amino acid residues. Such information increasingly is allowing the optimization or design of chemicals that can bind to a receptor with improved affinity, selectivity, or regulatory effect. Similar structure-based approaches also are used to improve pharmacokinetic properties of drugs, particularly if knowledge of their metabolism is known. Knowledge of the structures of receptors and of drug-receptor complexes, determined at atomic resolution by x-ray crystallography, is even more helpful in the design of ligands and in understanding the molecular basis of drug resistance and circumventing it (i.e., x-ray crystal structures of BCR-ABL and BCR-ABL mutants in complex with imatinib and other small molecule inhibitors). Emerging technology in the field of pharmacogenetics (Chapter 7) is improving our understanding of the nature of and variation in receptors, and is positioned to permit molecular diagnostics in individual patients to predict those who will most benefit from a particular drug (Jain, 2004).

## Quantitative Aspects of Drug Interactions with Receptors

Receptor occupancy theory assumes that response emanates from a receptor occupied by a drug, a concept that has its basis in the law of mass action. The basic currency of receptor pharmacology is the dose-response (or concentration-response) curve, a depiction of the observed effect of a drug as a function of its concentration in the receptor compartment. Figure 3–2 shows a typical dose-response curve; it reaches a maximal asymptotic value when the drug occupies all the receptor sites.

![Figure 3–2. Graded responses (y axis as a percentage of maximal response) expressed as a function of the concentration of drug A present at the receptor. The hyperbolic shape of the curve in panel A becomes sigmoid when plotted semi-logarithmically, as in panel B. The concentration of drug that produces 50% of the maximal response quantifies drug activity and is referred to as the EC50 (effective concentration for 50% response). The range of concentrations needed to fully depict the dose-response relationship (~3 log₁₀ [10] units) is too wide to be useful in the linear format of Figure 3–2A; thus, most dose-response curves use log [Drug] on the x axis, as in Figure 3–2B. Dose-response curves presented in this way are sigmoidal in shape and have three properties: threshold, slope, and maximal asymptote. These three parameters quantitate the activity of the drug.](image-url)
Some drugs cause low-dose stimulation and high-dose inhibition of response. These U-shaped relationships for some receptor systems are said to display hormesis. Several drug-receptor systems can display this property (e.g., prostaglandins, endothelin, and purinergic and serotonergic agonists, among others), which is likely to be at the root of some drug toxicities (Calabrese and Baldwin, 2003).

**Affinity, Efficacy, and Potency.** In general, the drug-receptor interaction is characterized by (1) binding of drug to receptor and (2) generation of a response in a biological system, as illustrated in Equation 3-1 where the drug or ligand is denoted as \( L \) and the inactive receptor as \( R \). The first reaction, the reversible formation of the ligand-receptor complex \( LR \), is governed by the chemical property of affinity.

\[
L + R \xrightleftharpoons[k_{-1}]{k_{+1}} LR \xrightleftharpoons[k_{-2}]{k_{+2}} LR^* \quad (Equation \ 3-1)
\]

where \( LR^* \) is produced in proportion to \([LR]\) and leads to a response. This simple relationship illustrates the reliance of the affinity of the ligand \( (L) \) with receptor \( (R) \) on both the forward or association rate \( (k_{+1}) \) and the reverse or dissociation rate \( (k_{-1}) \). At any given time, the concentration of ligand-receptor complex \([LR]\) is equal to the product of \( k_{+1}[L][R] \), the rate of formation of the bi-molecular complex \( LR \), minus the product \( k_{-1}[LR] \), the rate dissociation of \( LR \) into \( L \) and \( R \). At equilibrium (i.e., when \( \delta[LR]/\delta t = 0 \)), \( k_{+1}[L][R] = k_{-1}[LR] \). The equilibrium dissociation constant \( (K_D) \) is then described by ratio of the off and on rate constants \( (k_{-1}/k_{+1}) \).

Thus, at equilibrium,

\[
K_D = \frac{[L][R]}{[LR]} = \frac{k_{-1}}{k_{+1}} \quad (Equation \ 3-2)
\]

The **affinity constant** or **equilibrium association constant** \( (K_A) \) is the reciprocal of the equilibrium dissociation constant (i.e., \( K_A = 1/K_D \)); thus a high-affinity drug has a low \( K_D \) and will bind a greater number of a particular receptor at a low concentration than a low-affinity drug. As a practical matter, the affinity of a drug is influenced most often by changes in its off-rate \( (k_{-1}) \) rather than its on-rate \( (k_{+1}) \).

Equation 3-2 permits us to write an expression of the fractional occupancy \( (f) \) of receptors by agonist:

\[
f = \frac{[\text{ligand-receptor complexes}]}{[\text{total receptors}]} = \frac{[LR]}{[R] + [LR]} \quad (Equation \ 3-3)
\]

This can be expressed in terms of \( K_A \) (or \( K_D \)) and \([L]\):

\[
f = \frac{K_A[L]}{1 + K_A[L]} = \frac{[L]}{[L] + K_D} \quad (Equation \ 3-4)
\]

This relationship illustrates that when the concentration of drug equals the \( K_D \) (or \( 1/K_A \)), \( f = 0.5 \), that is, the drug will occupy 50% of the receptors. Note that this relationship describes only receptor occupancy, not the eventual response that is often amplified by the cell. Many signaling systems reach a full biological response with only a fraction of receptors occupied (described later). Potency is defined by example in Figure 3–3. Basically, when two drugs produce equivalent responses, the drug whose dose-response curve (plotted as in Figure 3–3A) lies to the left of the other (i.e., the concentration producing a half-maximal effect \( EC_{50} \) is smallest) is said to be the more potent.

**Response to Drugs.** The second reaction shown in Equation 3-1 is the reversible formation of the active

\[
\text{Figure 3–3. Two ways of quantifying agonism. A, The relative potency of two agonists (Drug X, red line; Drug Y, purple line) obtained in the same tissue is a function of their relative affinities and intrinsic efficacies. The EC}_{50} \text{ of Drug X occurs at a concentration that is one-tenth the EC}_{50} \text{ of Drug Y. Thus, Drug X is more potent than Drug Y. B, In systems where the two drugs do not both produce the maximal response characteristic of the tissue, the observed maximal response is a nonlinear function of their relative intrinsic efficacies. Drug X is more efficacious than Drug Y; their asymptotic fractional responses are } 100\% \text{ (Drug X) and 50\% (Drug Y).}
\]
ligand-receptor complex, LR*. The ability of a drug to
activate a receptor and generate a cellular response is a
reflection of its efficacy. Historically, efficacy has
been treated as a proportionality constant that quanti-
tifies the extent of functional change imparted to a
receptor-mediated response system on binding a drug.
Thus, a drug with high efficacy may be a full agonist,
eliciting, at some concentration, a full response. A drug
with a lower efficacy at the same receptor may not elicit
a full response at any dose (Figure 3–1). When it is pos-
sible to describe the relative efficacy of drugs at a par-
ticular receptor, a drug with a low intrinsic efficacy will
be a partial agonist. A drug that binds to a receptor and
exhibits zero efficacy is an antagonist. When the
response of an agonist is measured in a simple biolog-
ical system, the apparent dissociation constant, $K_{app}$, is
a macroscopic equilibrium constant that reflects both
the ligand binding equilibrium and the subsequent equi-
librium that results in the formation of the active recep-
tor LR*.

Quantifying Agonism. When the relative potency of two
agonists of equal efficacy is measured in the same bio-
logical system, and downstream signaling events are the
same for both drugs, the comparison yields a relative
measure of the affinity and efficacy of the two agonists
(Figure 3–3). It is convenient to describe agonist
response by determining the half-maximally effective
concentration ($EC_{50}$) for producing a given effect. Thus,
measuring agonist potency by comparison of $EC_{50}$ val-
ues is one method of measuring the capability of differ-
ent agonists to induce a response in a test system and
for predicting comparable activity in another. Another
method of estimating agonist activity is to compare
maximal asymptotes in systems where the agonists do
not produce maximal response (Figure 3–3B). The
advantage of using maxima is that this property depends
solely on efficacy, whereas drug potency is a mixed
function of both affinity and efficacy.

Quantifying Antagonism. Characteristic patterns of
antagonism are associated with certain mechanisms of
blockade of receptors. One is straightforward competi-
tive antagonism, whereby a drug with affinity for a
receptor but lacking intrinsic efficacy competes with
the agonist for the primary binding site on the receptor
(Ariens, 1954; Gaddum, 1957). The characteristic pat-
tern of such antagonism is the concentration-dependent
production of a parallel shift to the right of the agonist
dose-response curve with no change in the maximal
response (Figure 3–4A). The magnitude of the right-
ward shift of the curve depends on the concentration
of the antagonist and its affinity for the receptor
(Schild, 1957).

A partial agonist similarly can compete with a
“full” agonist for binding to the receptor. However,
increasing concentrations of a partial agonist will
inhibit response to a finite level characteristic of the
drug’s intrinsic efficacy; a competitive antagonist will
reduce the response to zero. Partial agonists thus can
be used therapeutically to buffer a response by inhibit-
ing excessive receptor stimulation without totally abol-
ishing receptor stimulation (for instance, pindolol, a $\beta$
agonist with slight intrinsic agonist activity, will
prevent overstimulation of the heart by blocking effects
of endogenous catecholamines but will assure slight
receptor stimulation in patients overly sensitive to the
negative inotropic and negative chronotropic effects of
$\beta$ blockade).

An antagonist may dissociate so slowly from the
receptor that its action is exceedingly prolonged, as with
the opiate partial agonist buprenorphine and the Ca$^{2+}$
channel blocker amlodipine. In the presence of a slowly
dissociating antagonist, the maximal response to the
agonist will be depressed at some antagonist concen-
trations (Figure 3–4B). Operationally, this is referred
to as noncompetitive antagonism, although the molec-
ular mechanism of action really cannot be inferred
unequivocally from the effect. An antagonist may also
interact irreversibly (covalently) with a receptor, as do
the $\alpha$ adrenergic antagonist phenoxybenzamine and the
acetylcholinesterase inhibitor DFP (diisopropylfluoro-
phosphate), to produce relatively irreversible effects.
An irreversible antagonist competing for the same
binding site as the agonist can produce the pattern of
antagonism shown in Figure 3–4B. Noncompetitive
antagonism can also be produced by another type of
drug, referred to as an allosteric or alltopic antago-
nist. This type of drug produces its effect by binding to
a site on the receptor distinct from that of the primary
agonist, thereby changing the affinity of the receptor
for the agonist. In the case of an allosteric antagonist,
the affinity of the receptor for the agonist is decreased
by the antagonist (Figure 3–4C). In contrast, a drug
binding at an allosteric site could potentiate the effects
of primary agonists (Figure 3–4D); such a drug would
be referred to as an allosteric agonist or co-agonist
(May et al., 2007).

The affinity of a competitive antagonist ($K$) for its receptor
can be determined in radioligand binding assays or by measuring
the functional response of a system to a drug in the presence of the
Concentration curves are run with the agonist alone and with the
Figure 3–4. Mechanisms of receptor antagonism. A. Competitive antagonism occurs when the agonist A and antagonist I compete for the same binding site on the receptor. Response curves for the agonist are shifted to the right in a concentration-related manner by the antagonist such that the EC50 for the agonist increases (e.g., L versus L′, L″, and L‴) with the concentration of the antagonist. B. If the antagonist binds to the same site as the agonist but does so irreversibly or pseudo irreversibly (slow dissociation but no covalent bond), it causes a shift of the dose-response curve to the right, with further depression of the maximal response. Allosteric effects occur when an allosteric ligand I or P binds to a different site on the receptor to either inhibit (I) the response (see panel C) or potentiate (P) the response (see panel D). This effect is saturable; inhibition or potentiation reaches a limiting value when the allosteric site is fully occupied.
agonist plus an effective concentration of the antagonist (Figure 3–4A). As more antagonist (I) is added, a higher concentration of the agonist (A) is needed to produce an equivalent response (the half-maximal or 50% response is a convenient and accurately determined level of response).

The extent of the rightward shift of the concentration-dependence curve is a measure of the affinity of the inhibitor, and a higher-affinity inhibitor will cause a greater rightward shift than a lower-affinity inhibitor at the same inhibitor concentration. Using Equations 3–3 and 3–4, one may write mathematical expressions of fractional occupancy (f) of the receptor by agonist for the agonist alone (control) and agonist in the presence of inhibitor.

For the agonist drug (L) alone,

\[ f_{control} = \frac{[L]}{[L] + K_D} \]  (Equation 3-5)

For the case of agonist plus antagonist (I),

\[ f_I = \frac{[L]}{[L] + K_D \left(1 + \frac{[I]}{K_I}\right)} \]  (Equation 3-6)

Assuming that equal responses result from equal fractional receptor occupancies in both the absence and presence of antagonist, one can set the fractional occupancies equal at agonist concentrations (L and L’) that generate equivalent responses in Figure 3–4A. Thus,

\[ \frac{L}{L + K_D} = \frac{L'}{L' + K_D \left(1 + \frac{[I]}{K_I}\right)} \]  (Equation 3-7)

Simplifying, one gets:

\[ \frac{L'}{L} - 1 = \frac{[I]}{K_I} \]  (Equation 3-8)

where all values are known except \( K_I \). Thus, one can determine the \( K_I \) for a reversible, competitive antagonist without knowing the \( K_D \) for the agonist and without needing to define the precise relationship between receptor and response.

**PHARMACODYNAMIC VARIABILITY: INDIVIDUAL AND POPULATION PHARMACODYNAMICS**

Individuals vary in the magnitude of their response to the same concentration of a single drug or to similar drugs, and a given individual may not always respond in the same way to the same drug concentration. Attempts have been made to define and measure individual “sensitivity” (or “resistance”) to drugs in the clinical setting, and progress has been made in understanding some of the determinants of sensitivity to drugs that act at specific receptors. Drug responsiveness may change because of disease or because of previous drug administration. Receptors are dynamic, and their concentration and function may be up- or down-regulated by endogenous and exogenous factors.

Data on the correlation of drug levels with efficacy and toxicity must be interpreted in the context of the pharmacodynamic variability in the population (e.g., genetics, age, disease, and the presence of co-administered drugs). The variability in pharmacodynamic response in the population may be analyzed by constructing a quantal concentration-effect curve (Figure 3–5A). The dose of a drug required to produce a specified effect in 50% of the population is the median effective dose (\( ED_{50} \) Figure 3–5A). In preclinical studies of drugs, the median lethal dose (\( LD_{50} \)) is determined in experimental animals (Figure 3–5B). The \( LD_{50}/ED_{50} \) ratio is an indication of the therapeutic index, which is a statement of how selective the drug is in producing its desired effects versus its adverse effects. A similar term, the therapeutic window, is the range of steady-state concentrations of drug that provides therapeutic efficacy with minimal toxicity (Figure 3–6). In clinical studies, the dose, or preferably the concentration, of a drug required to produce toxic effects can be compared with the concentration required for therapeutic effects in the population to evaluate the clinical therapeutic index. Since pharmacodynamic variation in the population may be marked, the concentration or dose of drug required to produce a therapeutic effect in most of the population usually will overlap the concentration required to produce toxicity in some of the population, even though the drug’s therapeutic index in an individual patient may be large. Also, the concentration-percent curves for efficacy and toxicity need not be parallel, adding yet another complexity to determination of the therapeutic index in patients. Finally, no drug produces a single effect, and the therapeutic index for a drug will vary depending on the effect being measured.

A clear demonstration of the relation of plasma drug concentration to efficacy or toxicity is not achievable for many drugs; even when such a relationship can be determined, it usually predicts only a probability of efficacy or toxicity. In trials of antidepressant drugs, such a high proportion of patients respond to placebo that it is difficult to determine the plasma drug level associated with efficacy. There is a quantal concentration-response curve for efficacy and adverse effects (Figure 3–5B); for many drugs, the concentration that achieves efficacy in all the population may produce adverse effects in some individuals. Thus, a population therapeutic window expresses a range of concentrations at which the likelihood of
efficacy is high and the probability of adverse effects is low (Figure 3–6). It does not guarantee either efficacy or safety. Therefore, use of the population therapeutic window to adjust dosage of a drug should be complemented by monitoring appropriate clinical and surrogate markers for drug effect(s).

Factors Modifying Drug Action. Many factors can influence the therapeutic efficacy and safety of a drug in an individual patient. These same factors give rise to inter-individual variability in the dose required to obtain optimal therapeutic effect with minimal adverse effects. Some of the factors that contribute to the wide patient-to-patient variability in the dose required for optimal therapy observed with many drugs are shown in Figure 3–7. Therapeutic success and safety result from integrating evidence of efficacy and safety with knowledge of the individual factors that determine response in a given patient. Determinants of inter-individual variation in response to drugs that are due to pharmacokinetics include disease-related alterations such as impaired renal and liver clearance due to renal and hepatic disease, circulatory failure, altered drug binding to plasma proteins, impaired GI absorption, and pharmacokinetic drug interactions. The effects of these factors on variability of drug pharmacokinetics are described more thoroughly in Chapters 2 and 5–7.

Pharmacogenetics. Pharmacogenetics refers to the genetic and genomic variations that give rise to variability in both pharmacokinetic and pharmacodynamic aspects of drug therapy. These factors
prescribed dosage and drug effects. (Modified with permission from Koch-Weser J. Serum drug concentrations as therapeutic guides. N Engl J Med, 1972, 287:227–231. Copyright © Massachusetts Medical Society. All rights reserved.)

Figure 3–7. Factors that influence the relationship between prescribed dosage and drug effects. (Modified with permission from Koch-Weser J. Serum drug concentrations as therapeutic guides. N Engl J Med, 1972, 287:227–231. Copyright © Massachusetts Medical Society. All rights reserved.)

Contribute significantly to the inter-individual variability of responsiveness to many drugs (Chapter 7). Among the best examples of a drug with significant inter-individual sensitivity due to genetic factors affecting both pharmacokinetics and pharmacodynamics is the anticoagulant drug warfarin (Chapter 30). In order to achieve optimal anticoagulant therapy with minimal adverse effects (i.e., excessive clotting due to under dosing, or excessive bleeding due to overdosing), it is necessary to stay within a very narrow dose range (i.e., warfarin’s therapeutic index is very low). There is considerable inter-individual variation in this optimal dose range, on the order of 10-fold or more, and nearly 60% of the variability is due to genetic variation in the primary metabolizing enzyme (CYP2C9) and in the drug’s receptor, vitamin K epoxide reductase complex, subunit 1 (VKORC1). Polymorphisms in CYP2C9 (especially homozygosity in the *3/*3 allele) increase sensitivity towards warfarin, whereas coding region polymorphisms in VKORC1 result in a warfarin-resistant phenotype. In 2007, the FDA recommended that pharmacogenetics be used to optimize warfarin dosing, but did not provide specific protocols to be used. Subsequently, an algorithm that incorporates clinical and pharmacogenetic data was shown to be significantly better than algorithms that lack genetic data in predicting the initial appropriate dose of warfarin that is close to the required stable dose. The patients who benefited most by the pharmacogenetic algorithm were the 46% who required either low or high dosing to achieve optimal anticoagulation (Klein et al., 2009).

Combination Therapy. Marked alterations in the effects of some drugs can result from co-administration with other agents, including prescription and non-prescription drugs, as well as supplements and nutraceuticals. Such interactions can cause toxicity, or inhibit the drug effect and the therapeutic benefit. Drug interactions always should be considered when unexpected responses to drugs occur. Understanding the mechanisms of drug interactions provides a framework for preventing them. Drug interactions may be pharmacokinetic (the delivery of a drug to its site of action is altered by a second drug) or pharmacodynamic (the response of the drug target is modified by a second drug). Examples of pharmacokinetic interactions that can enhance or diminish the delivery of drug to its site of action are provided in Chapter 2. In a patient with multiple comorbidities requiring a variety of medications, it may be difficult to identify adverse effects due to medication interactions, and to determine whether these are pharmacokinetic, pharmacodynamic, or some combination of interactions.

Combinations of drugs often are employed to therapeutic advantage when their beneficial effects are additive or synergistic, or because therapeutic effects can be achieved with fewer drug-specific adverse effects by using submaximal doses of drugs in concert. Combination therapy often constitutes optimal treatment for many conditions, including heart failure (Chapter 28), hypertension (Chapter 27), and cancer (Chapters 60-63). There are many examples of pharmacodynamic interactions that can produce significant adverse effects. Nitrovasodilators produce relaxation of vascular smooth muscle (vasodilation) via NO-dependent elevation of cyclic GMP in vascular smooth muscle. The pharmacologic effects of sildenafil, tadalafil, and vardenafil result from inhibition of the type 5 cyclic nucleotide phosphodiesterase (PDE5) that hydrolyzes cyclic GMP to 5′GMP in the vasculature. Thus, co-administration of an NO donor (e.g., nitroglycerin) with a PDE5 inhibitor can cause potentially catastrophic hypotension. The oral anticoagulant warfarin has a narrow margin between therapeutic inhibition of clot formation and bleeding complications and is subject to numerous important pharmacokinetic and pharmacodynamic drug interactions. Alterations in dietary vitamin K intake may also significantly affect the pharmacodynamics of warfarin and dosing changes may be required if a patient’s diet is inconsistent. Similarly, antibiotics that alter the intestinal flora reduce the bacterial synthesis of vitamin K, thereby enhancing the effect of warfarin. Nonsteroidal anti-inflammatory drugs (NSAIDs) cause gastric and duodenal ulcers (Chapter 34), and their concurrent administration with warfarin increases the risk of GI bleeding almost 4-fold compared with warfarin alone. By inhibiting platelet aggregation, aspirin increases the incidence of bleeding in warfarin-treated patients. A subset of NSAIDs, including indomethacin, ibuprofen, piroxicam, and cyclooxygenase (COX)-2 inhibitors, can antagonize antihypertensive therapy, especially with regimens employing angiotensin-converting enzyme inhibitors, angiotensin receptor antagonists, and β adrenergic receptor antagonists. The effect on arterial pressure ranges from trivial to severe. In contrast, aspirin and sulindac produce little, if any, elevation of blood pressure when used concurrently with these antihypertensive drugs. Anti-arrhythmic drugs such as sotalol and quinidine that block K+ channels can cause the polymorphic ventricular tachycardia known as torsades de pointes (Chapter 29). The abnormal repolarization that leads to this polymorphic ventricular tachycardia is potentiated by hypokalemia, and diuretics that produce K+ loss increase the risk of this drug-induced arrhythmia.

Most drugs are evaluated in young and middle-aged adults, and data on their use in children and the elderly are sparse. At the extremes of age, drug pharmacokinetics and pharmacodynamics can be altered, possibly requiring substantial alteration in the dose or dosing regimen to safely produce the desired clinical effect.
MECHANISMS OF DRUG ACTION

Receptors That Affect Concentrations of Endogenous Ligands

A large number of drugs act by altering the synthesis, storage, release, transport, or metabolism of endogenous ligands such as neurotransmitters, hormones, and other intercellular mediators. For instance, there are many examples of drugs that act on neuroeffector junctions by altering neurotransmitter synthesis, storage of neurotransmitter in vesicles, release of neurotransmitters into the synaptic cleft, and subsequent removal of the neurotransmitter from the synaptic cleft by hydrolysis or transport into the pre-synaptic or post-synaptic neuron. The effects of these drugs can either enhance or diminish the effects of the neurotransmitter in order to achieve the desired therapeutic effect. For instance, some of the drugs acting on adrenergic neurotransmission (Chapters 8 and 12) include α-methyltyrosine (inhibits synthesis of norepinephrine (NE)), cocaine (blocks NE reuptake), amphetamine (promotes NE release), and selegeline (inhibits NE breakdown). There are similar examples for other neurotransmitter systems including acetylcholine (ACH; Chapters 8 and 10), dopamine (DA), and serotonin (5HT; Chapters 13-15). Drugs that affect the synthesis of circulating mediators such as vasoactive peptides (e.g., angiotensin-converting enzyme inhibitors; Chapter 26) and lipid-derived autacoids (e.g., cyclooxygenase inhibitors; Chapter 33) are also widely used in the treatment of hypertension, inflammation, myocardial ischemia, and other disease states.

Receptors That Regulate the Ionic Milieu

A relatively small number of drugs act by affecting the ionic milieu of blood, urine, and the GI tract. The receptors for these drugs are ion pumps and transporters, many of which are expressed only in specialized cells of the kidney and GI system. Drug effects on many of these receptors can have effects throughout the body due to changes in blood electrolytes and pH. For instance, most of the diuretics (e.g., furosemide, chlorothiazide, amiloride) act by directly affecting ion pumps and transporters in epithelial cells of the nephron that increase the movement of Na+ into the urine, or by altering the expression of ion pumps in these cells (e.g., aldosterone). Chapter 25 provides a detailed description of the mechanisms of action of diuretic drugs. Another therapeutically important target is the H+,K+-ATPase (proton pump) of gastric parietal cells. Irreversible inhibition of this proton pump by drugs such as esomeprazole reduces gastric acid secretion by 80-95% (Chapter 45) and is a mainstay of therapy for peptic ulcer.

Cellular Pathways Activated by Physiological Receptors

Signal Transduction Pathways. Physiological receptors have at least two major functions, ligand binding and message propagation (i.e., signaling). These functions imply the existence of at least two functional domains within the receptor: a ligand-binding domain and an effector domain. The structure and function of these domains in many families of receptors have been deduced from high-resolution crystal structures of the receptor proteins and/or by analysis of the behavior of intentionally mutated receptors. Many drugs target the extracellular ligand-binding domain of physiological receptors. Examples include the widely used β adrenergic antagonists. However, drugs can affect the receptor by targeting either domain, as in the case of anticancer drugs used to target the epidermal growth factor receptor (EGFR; Chapters 60-62). Cetuximab is a monoclonal antibody that targets the extracellular ligand-binding domain of the EGFR and inhibits epidermal growth factor (EGF) signaling, whereas the small molecule drugs gefitinib and erlotinib bind the intracellular effector domain and block the protein tyrosine kinase activity of the activated EGFR.

The regulatory actions of a receptor may be exerted directly on its cellular target(s), on effector protein(s), or may be conveyed by intermediary cellular signaling molecules called transducers. The receptor, its cellular target, and any intermediary molecules are referred to as a receptor-effector system or signal transduction pathway. Frequently, the proximal cellular effector protein is not the ultimate physiological target but rather is an enzyme, ion channel, or transport protein that creates, moves, or degrades a small molecule (e.g., a cyclic nucleotide, inositol trisphosphate, or NO) or ion (e.g., Ca2+) termed a second messenger. If the effector is an ion channel or ion pump, the effect of ligand binding can be a change in membrane potential that alters the excitability of the cell. Second messengers can diffuse in the proximity of their synthesis or release and convey information to a variety of targets, which may integrate multiple signals. Even though these second messengers originally were thought of as freely diffusible molecules within the cell, imaging studies show that their diffusion and intracellular actions are
constrained by compartmentation—selective localization of receptor-transducer-effector-signal termination complexes—established by protein-lipid and protein-protein interactions (Bailie, 2009). All cells express multiple forms of proteins designed to localize signaling pathways by protein-protein interactions; these proteins are termed scaffolds or anchoring proteins. Examples of scaffold molecules include the AKAPs (A-kinase anchoring proteins) that bind the regulatory subunit of the cyclic AMP dependent protein kinase (PKA) near its substrate(s) in various subcellular compartments (Carnegie et al., 2009).

Signal Integration and Amplification. Receptors and their associated effector and transducer proteins also act as integrators of information as they coordinate signals from multiple ligands with each other and with the differentiated activity of the target cell. For example, signal transduction systems regulated by changes in cyclic AMP (cAMP) and intracellular Ca²⁺ are integrated in many excitable tissues. In cardiac myocytes, an increase in cellular cAMP caused by activation of β adrenergic receptors enhances cardiac contractility by augmenting the rate and amount of Ca²⁺ delivered to the contractile apparatus; thus, cAMP and Ca²⁺ are positive contractile signals in cardiac myocytes. By contrast, cAMP and Ca²⁺ produce opposing effects on the contractility of smooth muscle cells: as usual, Ca²⁺ is a contractile signal, however, activation of β adrenergic receptors on these cells activates the cAMP-PKA pathway, which leads to relaxation through the phosphorylation of proteins that mediate Ca²⁺ signaling, such as myosin light chain kinase and ion channels that hyperpolarize the cell membrane. Thus, the distinct patterns of integration of signal transduction systems within target cells can lead to a variety of pharmacodynamic effects that result from functional interactions downstream from the receptors. These functional interactions can be synergistic, additive, or antagonistic.

Another important property of physiological receptors is their capacity to significantly amplify a physiological signal. Neurotransmitters, hormones, and other extracellular ligands are often present at the ligand-binding domain of a receptor in very low concentrations (nM to μM levels). However, the effector domain or the signal transduction pathway often contains enzymes and kinase cascades to catalytically amplify the intended signal. In this regard, the description of receptor occupancy-cellular response in Equation 3-1 is an oversimplification. The ability of virtually all receptors to amplify physiological signals makes them excellent targets for natural ligands and drugs. When, e.g., a single agonist molecule binds to a receptor that is an ion channel, hundreds of thousands to millions of ions flow through the channel every second. Similarly, the binding of a single photon to cis-retinal in the photoreceptor rhodopsin is eventually amplified ~1 × 10⁶-fold. In the case of nuclear receptors, a single steroid hormone molecule binding to its receptor initiates the transcription of many copies of specific mRNAs, which in turn can give rise to multiple copies of a single protein.

Structural and Functional Families of Physiological Receptors

Receptors for physiological regulatory molecules can be assigned to functional families whose members share similar molecular structures and biochemical mechanisms with common features. Table 3-1 outlines six major families of receptors with examples of their physiological ligands, signal transduction systems, and drugs that affect these systems. The basic structure of their ligand-binding domains, effector domains, and how agonist binding influences the regulatory activity of the receptor is well understood for each of these signal transduction systems. The relatively small number of biochemical mechanisms and structural formats used for cellular signaling is fundamental to the ways in which target cells integrate signals from multiple receptors to produce additive, sequential, synergistic, or mutually inhibitory responses.

G Protein-Coupled Receptors (GPCRs)

Receptors and G Proteins. GPCRs span the plasma membrane as a bundle of seven α-helices (Palczewski et al., 2000) (Figure 3–8). Humans express over 800 GPCRs that make up the third largest family of genes in humans, with roughly half of these GPCRs dedicated to sensory perception (smell, taste, and vision). The remaining receptors regulate an impressive number of physiological functions including nerve activity, tension of smooth muscle, metabolism, rate and force of cardiac contraction, and the secretion of most glands in the body. Included among the ligands for GPCRs are neurotransmitters such as ACh, biogenic amines such as NE, all eicosanoids and other lipid signaling molecules, peptide hormones, opioids, amino acids such as GABA, and many other peptide and protein ligands. GPCRs are important regulators of nerve activity in the CNS and are the receptors for the neurotransmitters of the peripheral autonomic nervous system. For example, ACh released by the parasympathetic nervous system regulates the functions of glands and smooth muscle through
its action on muscarinic receptors. NE released by the sympathetic nervous system interacts with α and β adrenergic receptors to regulate cardiac function and the tone of vascular smooth muscle (Chapters 8-12). Because of their number and physiological importance, GPCRs are the targets for many drugs; perhaps half of all non-antibiotic prescription drugs act at these receptors.

**Receptor Subtypes.** There are multiple receptor subtypes within families of receptors. Ligand-binding studies with multiple chemical entities initially identified receptor subtypes; molecular cloning has greatly accelerated the discovery and definition of additional receptor subtypes; their expression as recombinant proteins has facilitated the discovery of subtype-selective drugs. Distinct but related receptors may display distinctive
patterns of selectivity among agonist or antagonist ligands. When selective ligands are not known, the receptors are more commonly referred to as isoforms rather than as subtypes. The distinction between classes and subtypes of receptors, however, is often arbitrary or historical. The α1, α2, and β adrenergic receptors differ from each other both in ligand selectivity and in coupling to G proteins (Gq, Gi, and Gs, respectively), yet α and β are considered receptor classes and α1 and α2 are considered subtypes. The α1A, α1B, and α1C receptor isoforms differ little in their biochemical properties, although their tissue distributions are distinct. The β1, β2, and β3 adrenergic receptor subtypes exhibit differences in both tissue distribution and regulation by...
phosphorylation by G–protein receptor kinases (GRKs) and PKA.

Pharmacological differences among receptor subtypes are exploited therapeutically through the development and use of receptor-selective drugs. Such drugs may be used to elicit different responses from a single tissue when receptor subtypes initiate different intracellular signals, or they may serve to differentially modulate different cells or tissues that express one or another receptor subtype. For example, β2 adrenergic agonists such as terbutaline are used for bronchodilation in the treatment of asthma in the hope of minimizing cardiac side effects caused by stimulation of the β1 adrenergic receptor (Chapter 12). Conversely, the use of β1-selective antagonists minimizes the chance of bronchoconstriction in patients being treated for hypertension or angina (Chapters 12 and 27). Increasing the selectivity of a drug among tissues or among responses elicited from a single tissue may determine whether the drug’s therapeutic benefits outweigh its unwanted effects.

**Receptor Dimerization.** Receptor-ligand interactions alone do not regulate all GPCR signaling.GPCRs undergo both homo- and heterodimerization and possibly oligomerization. Heterodimerization can result in receptor units with altered pharmacology compared with either individual receptor. As an example, opioid receptors can exist as homodimers of μ or δ receptors, or as μδ heterodimers with distinctly different pharmacodynamic properties than either homodimer (Chapter 18). Evidence is emerging that dimerization of receptors may regulate the affinity and specificity of the complex for G proteins, and regulate the sensitivity of the receptor to phosphorylation by receptor kinases and the binding of arrestin, events important in termination of the action of agonists and removal of receptors from the cell surface. Dimerization also may permit binding of receptors to other regulatory proteins such as transcription factors. Thus, the receptor-G protein-effector systems are complex networks of convergent and divergent interactions involving both receptor-receptor and receptor-G protein coupling that permit extraordinarily versatile regulation of cell function. Dimerization of single membrane spanning receptors is central to their activation (described later in the chapter).

**G Proteins.** GPCRs couple to a family of heterotrimeric GTP-binding regulatory proteins termed G proteins. G proteins are signal transducers that convey the information that agonist is bound to the receptor from the receptor to one or more effector proteins (Gilman, 1987). G–protein-regulated effectors include enzymes such as adenylyl cyclase, phospholipase C, cyclic GMP phosphodiesterase (PDE6), and membrane ion channels selective for Ca2+ and K+ (Table 3–1, Figure 3–8). The G protein heterotrimer is composed of a guanine nucleotide-binding α subunit, which confers specific recognition to both receptors and effectors, and an associated dimer of β and γ subunits that helps confer membrane localization of the G protein heterotrimer by prenylation of the γ subunit. In the basal state of the receptor-heterotrimer complex, the α subunit contains bound GDP and the α-GDP:βγ complex is bound to the unliganded receptor (Figure 3–8). The G protein family is comprised of 23 α subunits (which are the products of 17 genes), 7 β subunits, and 12 γ subunits. The α subunits fall into four families (Gαs, Gαi, Gαq, and Gα12/13) which are responsible for coupling GPCRs to relatively distinct effectors. The Gαs subunit uniformly activates adenylyl cyclase; the Gαi subunit can inhibit certain isoforms of adenylyl cyclase; the Gαq α subunit activates all forms of phospholipase Cβ; and the Gα12/13 α subunits couple to guanine nucleotide exchange factors (GEFs), such as p115RhoGEF for the small GTP-binding proteins Rho and Rac. The signaling specificity of the large number of possible βγ combinations is not yet clear; nonetheless, it is known that K+ channels, Ca2+ channels, and PI-3 kinase (PI3K) are some of the effectors of free βγ dimer (Figure 3–8).

**G Protein Activation.** When an agonist binds to a GPCR, there is a conformational change in the receptor that is transmitted from the ligand-binding pocket to the second and third intracellular loops of the receptor which couple to the G protein heterotrimer. This conformational change causes the α subunit to exchange its bound GDP for GTP (Figure 3-8). Binding of GTP activates the α subunit and causes it to release both the βγ dimer and the receptor, and both the GTP-bound α subunit and the βγ heterodimer become active signaling molecules (Gilman, 1987). The interaction of the agonist-bound GPCR with the G protein is transient; following activation of one G protein, the receptor is freed to interact with other G proteins. Depending on the nature of the α subunit, the active, GTP-bound form binds to and regulates effectors such as adenylyl cyclase (via Gαs) or phospholipase Cβ (via Gαq). The βγ subunit can regulate many effectors including ion channels and enzymes such as PI3-K (Figure 3–8). The G protein remains active until the GTP bound to the α subunit is hydrolyzed to GDP. The α subunit has a slow intrinsic rate of GTP hydrolysis that is modulated by a family of proteins termed regulators of G protein signaling (RGSs). The RGS proteins greatly accelerate the hydrolysis of GTP and are potentially attractive drug targets (Ross and Wilkie, 2000). Once the GDP bound to the α subunit is hydrolyzed to GDP, the βγ subunit and receptor recombine to form the inactive receptor-G protein heterotrimer basal complex that can be reactivated by another ligand-binding event (Figure 3–8).
Second Messengers

Cyclic AMP. Cyclic AMP is synthesized by adenyl cyclase under the control of many GPCRs; stimulation is mediated by the Gα subunit, inhibition by the Gβγ subunit. The cyclic AMP pathway provides a good basis for understanding the architecture and regulation of many second messenger signaling systems (for an overview of cyclic nucleotide action, see Beavo and Brunton, 2002).

There are nine membrane-bound isoforms of adenyl cyclase (AC) and one soluble isofrom found in mammals (Hanoune and Defer, 2001). The membrane-bound ACs are glycoproteins of ~120 kDa with considerable sequence homology: a small cytoplasmic domain; two hydrophobic transmembrane domains, each with six membrane-spanning helices; and two large cytoplasmic domains. Membrane-bound ACs exhibit basal enzymatic activity that is modulated by binding of GTP-liganded α subunits of the stimulatory and inhibitory G proteins (Gs and Gi). Numerous other regulatory interactions are possible, and these enzymes are catalogued based on their structural homology and their distinct regulation by G protein enzymes. In cells with specialized functions, cAMP has additional targets such as cyclic nucleotide-gated channels, and transcription factors. For instance, phosphorylation of the cyclic AMP-dependent protein kinase (PKA), the PKA holoenzyme consisting of two catalytic (C) subunits, inhibition by the Gβγ subunit. The cyclic AMP pathway provides a good basis for understanding the architecture and regulation of many second messenger signaling systems (for an overview of cyclic nucleotide action, see Beavo and Brunton, 2002).
nucleotide-binding domains of PKG are expressed as a single polypeptide, which dimerizes to form the PKG holoenzyme.

PKG exists in two homologous forms, PKG-I and PKG-II. PKG-I has an acetylated N terminus, is associated with the cytoplasm and has two isoforms (Iα and Iβ) that arise from alternate splicing. PKG-II has a myristylated N terminus, is membrane-associated and can be localized by PKG-ancho ring proteins in a manner analogous to that known for PKA, although the docking domains of PKA and PKG are very different structurally. Pharmacologically important effects of elevated cyclic GMP include modulation of platelet activation and relaxation of smooth muscle (Rybalkin et al., 2003).

**PDEs.** Cyclic nucleotide phosphodiesterases form another family of important signaling proteins whose activities are regulated via the rate of gene transcription as well as by second messengers (cyclic nucleotides or Ca2+) and interactions with other signaling proteins such as β arrestin and protein kinases. PDEs hydrolyze the cyclic 3′,5′-phosphodiester bond in cAMP and cGMP, thereby terminating their action.

The enzymes comprise a superfamily with >50 different PDE proteins divided into 11 subfamilies on the basis of amino acid sequence, substrate specificity, pharmacological properties, and allosteric regulation (Conti and Beavo, 2007). PDEs share a conserved catalytic domain at the carboxyl terminus, as well as regulatory domains and targeting domains that localize a given enzyme to a specific cellular compartment. The substrate specificities of the different PDEs include those specific for cAMP hydrolysis, cGMP hydrolysis, and some that hydrolyze both cyclic nucleotides. PDEs (mainly PDE3 forms) are drug targets for treatment of diseases such as asthma, cardiovascular diseases such as heart failure, atherosclerotic coronary and peripheral arterial disease, and neurological disorders. PDE5 inhibitors (e.g., sildenafil) are used in treating chronic obstructive pulmonary disease and erectile dysfunction. By inhibiting PDE5, these drugs increase accumulation of cellular cGMP in the smooth muscle of the corpus cavernosum, thereby enhancing its relaxation and improving its capacity for engorgement (Mehats et al., 2002).

### Other Second Messengers

Ca2+. Calcium is an important messenger in all cells and can regulate diverse responses including gene expression, contraction, secretion, metabolism, and electrical activity. Ca2+ can enter the cell through Ca2+ channels in the plasma membrane (See “Ion Channels”, below) or be released by hormones or growth factors from intracellular stores. In keeping with its role as a signal, the basal Ca2+ level in cells is maintained in the 100 nM range by membrane Ca2+ pumps that extrude Ca2+ to the extracellular space and a sarcoplasmic reticulum (SR) Ca2+-ATPase (SERCA) in the membrane of the endoplasmic reticulum (ER) that accumulates Ca2+ into its storage site in the ER/SR.

Hormones and growth factors release Ca2+ from its intracellular storage site, the ER, via a signaling pathway that begins with activation of phospholipase C at the plasma membrane, of which there are two primary forms, PLCβ and PLCγ. GPCRs that couple to Gq or Gi activate PLCβ by activating the G protein α subunit (Figure 3–8) and releasing the βγ dimer. Both the active, Gq-GTP-bound α subunit and the βγ dimer can activate certain isoforms of PLCβ. PLCγ isoforms are activated by tyrosine phosphorylation, including phosphorylation by receptor and non-receptor tyrosine kinases. For example, growth factor receptors such as the epidermal growth factor receptor (EGFR) are receptor tyrosine kinases (RTKs) that autophosphorylate on tyrosine residues upon binding their cognate growth factor. The phosphotyrosine formed on the cytoplasmic domain of the RTK is a binding site for signaling proteins that contain SH2 domains, such as PLCγ. Once recruited to the RTK’s SH2 domain, PLCγ is phosphorylated/activated by the RTK.

PLCs are cytosolic enzymes that translocate to the plasma membrane upon receptor stimulation. When activated, they hydrolyze a minor membrane phospholipid, phosphatidylinositol-4, 5-bisphosphate, to generate two intracellular signals, inositol-1,4,5-trisphosphate (IP3) and the lipid, diacylglycerol (DAG). Both of these molecules lead to signaling events by activating families of protein kinases. DAG directly activates members of the protein kinase C (PKC) family. IP3 diffuses to the ER where it activates the IP3 receptor in the ER membrane causing release of stored Ca2+ from the ER. Release of Ca2+ from these intracellular stores raises Ca2+ levels in the cytoplasm many fold within seconds and activates calmodulinsensitive enzymes such as cyclic AMP PDE and a family of Ca2+/calmodulin-sensitive protein kinases (e.g., phosphorylase kinase, myosin light chain kinase, and CaM kinases II and IV) (Hudmon and Schulman, 2002). Depending on the cell’s differentiated function, the Ca2+/calmodulin kinases and PKC may regulate the bulk of the downstream events in the activated cells. For example, release of the sympathetic transmitter norepinephrine onto vascular smooth muscle cells stimulates α adrenergic receptors, activates the Gq-PLC-IP3 pathway, triggers the release of Ca2+, and leads to contraction by stimulating the Ca2+/calmodulin-sensitive myosin light chain kinase to phosphorylate the regulatory subunits of the contractile protein, myosin.

The IP3-stimulated release of Ca2+ from the ER, its reuptake, and the refilling of the ER pool of Ca2+ are regulated by a novel set of Ca2+ channels. The IP3 receptor is a ligand-gated Ca2+ channel found in high concentrations in the membrane of the ER (Patterson et al., 2004). It is a large protein of ~2700 amino acids with three major domains. The N-terminal region contains the IP3-binding site, and the middle region contains a regulatory domain that can be phosphorylated by a number of protein kinases including PKA and PKG. The C-terminal region contains six membrane-spanning helices that form the Ca2+ pore. The functional channel is formed by four subunits arranged as a tetramer. In addition to IP3, which
markedly stimulates Ca\(^{2+}\) flux, the IP\(_3\) channel is regulated by Ca\(^{2+}\) and by the activities of PKA and PKG. Ca\(^{2+}\) concentrations in the 100-300 nM range enhance Ca\(^{2+}\) release, but concentrations near 1 \(\mu\)M inhibit release, which can create the oscillatory patterns of Ca\(^{2+}\) release seen in certain cells. Phosphorylation of the IP\(_3\) receptor by PKA enhances Ca\(^{2+}\) release, but phosphorylation of an accessory protein, IRAG, by PKG inhibits Ca\(^{2+}\) release. In smooth muscle, this effect of PKG represents part of the mechanism by which cyclic GMP relaxes vessel tone. In skeletal and cardiac muscle, Ca\(^{2+}\) release from intracellular stores (the sarcoplasmic reticulum) occurs through a process termed Ca\(^{2+}\)-induced Ca\(^{2+}\) release, and is primarily mediated by the ryanodine receptor (RyR). Ca\(^{2+}\) entry into a skeletal or cardiac myocyte through L-type Ca\(^{2+}\) channels causes conformational changes in the ryanodine receptor that induce the release of large quantities of Ca\(^{2+}\) into the sarcoplasm. Drugs that activate the RyR include caffeine; drugs that inhibit the RyR include dantrolene.

Calcium released into the cytoplasm from the ER is rapidly removed by plasma membrane Ca\(^{2+}\) pumps, and the ER pool of Ca\(^{2+}\) is refilled with extracellular Ca\(^{2+}\) flowing through store-operated Ca\(^{2+}\) channels (SOC) in the plasma membrane. These currents are termed Ca\(^{2+}\) release-activated currents, or I\(_{\text{CRAC}}\). The mechanism by which ER store depletion opens the store-operated channels requires two proteins, the channel itself, termed Orai1, and an ER sensor termed STIM1. The Orai1 channel is a 33-kDa protein with four membrane-spanning helices and no homology with other Ca\(^{2+}\) channels (Prakriya, 2009). Orai1 is highly selective for Ca\(^{2+}\). The C-terminal end of the channel contains coiled-coil domains thought to interact with the STIM1 sensor. STIM1 is a 77-kDa protein containing a Ca\(^{2+}\) sensor domain termed an EF hand. This domain is located at the N-terminus of the protein on the inside of the ER membrane before the single membrane-spanning domain. There are multiple protein-protein interaction motifs in the middle and C-terminal end of the molecule. Specifically, there are two coiled-coil domains on the C-terminal side of the transmembrane domain in STIM1 that may interact with coiled-coil domains in the Orai1 channel. Under resting conditions, the STIM1 protein is uniformly distributed on the ER membrane. Release of Ca\(^{2+}\) from the ER stores results in dimerization of STIM1 and movement to the plasma membrane where STIM1 and Orai1 form clusters, opening the Ca\(^{2+}\) pore of Orai1 and refilling of the ER Ca\(^{2+}\) pool (Fahrner et al., 2009).

### Ion Channels

The lipid bilayer of the plasma membrane is impermeable to anions and cations, yet changes in the flux of ions across the plasma membrane are critical regulatory events in both excitable and non-excitable cells. To establish and maintain the electrochemical gradients required to maintain a membrane potential, all cells express ion transporters for Na\(^+\), K\(^+\), Ca\(^{2+}\), and Cl\(^-\). For example, the Na\(^+\),K\(^+\)-ATPase pump expends cellular ATP to pump Na\(^+\) out of the cell and K\(^+\) into the cell. The electrochemical gradients thus established are used by excitable tissues such as nerve and muscle to generate and transmit electrical impulses, by non-excitable cells to trigger biochemical and secretory events, and by all cells to support a variety of secondary symport and antiport processes (Chapter 5).

Passive ion fluxes down cellular electrochemical gradients are regulated by a large family of ion channels located in the membrane. Humans express ~232 distinct ion channels to precisely regulate the flow of Na\(^+\), K\(^+\), Ca\(^{2+}\), and Cl\(^-\) across the cell membrane (Jegla et al., 2009). Because of their roles as regulators of cell function, these proteins are important drug targets. The diverse ion channel family can be divided into subfamilies based on the mechanisms that open the channels, their architecture, and the ions they conduct. They can also be classified as voltage-activated, ligand-activated, store-activated, stretch-activated, and temperature-activated channels. Examples of channels that are major drug targets are detailed next.

### Voltage-Gated Channels

Humans express multiple isoforms of voltage-gated channels for Na\(^+\), K\(^+\), Ca\(^{2+}\), and Cl\(^-\) ions. In nerve and muscle cells, voltage-gated Na\(^+\) channels are responsible for the generation of robust action potentials that depolarize the membrane from its resting potential of ~70 mV up to a potential of +20 mV within a few milliseconds. These Na\(^+\) channels are composed of three subunits, a pore-forming \(\alpha\) subunit and two regulatory \(\beta\) subunits. The \(\alpha\) subunit is a 260 kDa protein containing four domains that form a Na\(^+\) ion-selective pore by arranging into a pseudo-tetramer shape. The \(\beta\) subunits are ~36 kDa proteins that span the membrane once (Figure 3–9A). Each domain of the \(\alpha\) subunit contains six membrane-spanning helices (S1-S6) with an extracellular loop between S5 and S6, termed the pore-forming or P loop; the P loop dips back into the pore and, combined with residues from the corresponding P loops from the other domains, provides a selectivity filter for the Na\(^+\) ion. Four other helices surrounding the pore (one S4 helix from each of the domains) contain a set of charged amino acids that form the voltage sensor and cause a conformational change in the pore at more positive voltages leading to opening of the pore and depolarization of the membrane (Purves and McNamara, 2008). The voltage-activated Na\(^+\) channels in pain neurons are targets for local anesthetics such as lidocaine and tetracaine, which block the pore, inhibit depolarization, and thus block the sensation of pain. They are also the targets of the naturally occurring marine toxins, tetrodotoxin and saxitoxin (Chapter 20). Voltage-activated Na\(^+\) channels are also important targets of many drugs used to treat cardiac arrhythmias (Chapter 29).
Voltage-gated Ca\textsuperscript{2+} channels have a similar architecture to voltage-gated Na\textsuperscript{+} channels with a large $\alpha$ subunit (four domains of six membrane-spanning helices) and three regulatory subunits (the $\beta$, $\delta$ and $\gamma$ subunits). There are multiple isoforms of these channels that are widely expressed in nerve, cardiac and smooth muscle cells. Ca\textsuperscript{2+} channels can be responsible for initiating an action potential (as in the pacemaker cells of the heart), but are more commonly responsible for modifying the shape and duration of an action potential initiated by fast voltage-gated Na\textsuperscript{+} channels (Purves and McNamara, 2008). These channels initiate the influx of Ca\textsuperscript{2+} that stimulates the release of neurotransmitters in the central, enteric, and autonomic nervous systems, and that control heart rate and impulse conduction in cardiac tissue (Chapters 8, 14, and 27). The L-type voltage-gated Ca\textsuperscript{2+} channels are subject to additional regulation via phosphorylation by PKA. Thus, when the sympathetic nervous system releases norepinephrine onto $\beta$ adrenergic receptors in cardiac tissue, raising cAMP and activating PKA, the phosphorylated L-type channels allow more Ca\textsuperscript{2+} to flow into the cytoplasm, increasing the force of contraction. Voltage-gated Ca\textsuperscript{2+} channels expressed in smooth muscle regulate vascular tone; the intracellular concentration of Ca\textsuperscript{2+} is critical to regulating the phosphorylation state of the contractile apparatus via the activity of the Ca\textsuperscript{2+}/calmodulin-sensitive myosin light chain kinase. Accordingly, the Ca\textsuperscript{2+} channel antagonists such as nifedipine, diltiazem, and verapamil are effective vasodilators and are widely used to treat angina, cardiac arrhythmias, and hypertension.

Voltage-gated K\textsuperscript{+} channels are the most numerous and structurally diverse members of the voltage-gated channel family. Humans express ~78 distinct K\textsuperscript{+} channels and nearly all of them are

---

**Figure 3–9. Schematic diagram of two types of ion channels regulated by receptors and drugs.**

A. Diagram of a voltage-activated Na\textsuperscript{+} channel with the pore in the open and closed state. The P loops are shown in blue, angled into the pore to form the selectivity filter. The S4 helices forming the voltage sensor are shown in orange, with the positively charged amino acids displayed as red dots.

B. Ligand-gated nicotinic acetylcholine receptor expressed in the skeletal muscle neuromuscular junction. The pore is made up of five subunits, each with a large extracellular domain and four transmembrane helices (one of these subunits is shown at the left of panel B). The helix that lines the pore is shown in blue. The receptor is composed of 2 $\alpha$ subunits, and $\beta$, $\gamma$, and $\delta$ subunits. See text for discussion of other ligand-gated ion channels. Detailed descriptions of specific channels are given throughout the text in relation to the therapeutic actions of drugs affecting these channels (see especially Chapters 11, 14 and 20). (Adapted with permission from Purves, D, Augustine, GJ, Fitzpatrick, D, Hall, WC, LaMantia, AS, McNamara, JO, and White, LE (eds). *Neuroscience*, 4ed. Sinauer Associates, Inc., 2008.)
voltage-gated (Jegla et al., 2009). The voltage-gated $K_v$ channels form channels as tetramers with topology similar to the Na$^+$ and Ca$^{2+}$ channels, but rather than having four domains, they consist of four separate subunits that each incorporate six membrane-spanning domains. The inwardly rectifying $K_v$ channel subunits only contain two membrane-spanning domains surrounding the pore. In each of these cases, the native channel is a tetramer formed from four individual subunits. A final group of $K_v$ channels is the tandem or two-pore domain “leak” $K_v$ channels; each subunit in this group has four membrane-spanning domains surrounding two $P$ loops, and these form channels as dimers. The inwardly rectifying channels and the two-pore channels are voltage insensitive and are regulated by G proteins and H$^+$ ions and are greatly stimulated by general anesthetics. All these channels are expressed in nerve, cardiac tissue, skeletal and smooth muscle, as well as non-excitable tissues. Increasing $K^+$ conductance through these channels drives the membrane potential more negative; thus, these channels are important in regulating resting membrane potential and resetting the resting membrane at $-70$ to $-90$ mV following depolarization. Some forms of epilepsy are caused by natural mutations in $K_v$ channels, and drugs such as retigabine that favor opening of $K_v$ channels are under study for the treatment of epilepsy (Rogawski and Bazil, 2008). The cardiac KCNH2 channel, known as hERG (human ether-a-go-go-related gene), is responsible for hereditary as well as acquired (drug-induced) long QT syndrome. It is also the primary target of many anti-arrhythmic drugs that prolong repolarization.

Ligand-Gated Channels. Channels activated by the binding of a ligand to a specific site in the channel protein have a diverse architecture and set of ligands. Major ligand-gated channels in the nervous system are those that respond to excitatory neurotransmitters such as acetylcholine or glutamate (or agonists such as AMPA and NMDA) and inhibitory neurotransmitters such as glycine or $\gamma$-aminobutyric acid (GABA) (Purves and McNamara, 2008). Activation of these channels is responsible for the majority of synaptic transmission by neurons both in the CNS and in the periphery (Chapters 8, 11, and 14). In addition, there are a variety of more specialized ion channels that are activated by intracellular small molecules, and are structurally distinct from conventional ligand-gated ion channels. These include ion channels that are formally members of the $K_v$ family, such as the hyperpolarization and cAMP-gated (HCN) channel expressed in the heart (Wahl-Schott and Biel, 2009) that is responsible for the slow depolarization seen in phase 4 of AV and SA nodal cell action potentials (Chapter 29), and the cyclic nucleotide-gated (CNG) channels important for vision (Chapter 64). The intracellular small molecule category of ion channels also includes the IP$_3$-sensitive Ca$^{2+}$ channel responsible for release of Ca$^{2+}$ from the ER and the sulfonylurea “receptor” (SUR1) that associates with the $K_{\text{ATP}}$ channel to regulate the ATP-dependent $K^+$ channel ($K_{\text{ATP}}$) in pancreatic beta cells. The $K_{\text{ATP}}$ channel is the target of oral hypoglycemic drugs such as sulfonylureas and meglitinides that stimulate insulin release from pancreatic $\beta$ cells and are used to treat type 2 diabetes (Chapter 43). Other specialized channels include the 5-HT$_3$-regulated channel expressed on afferent vagal nerves that stimulates emesis. Ondansetron is an important antagonist of the 5-HT$_3$-gated channel used to inhibit emesis caused by drugs or disease (Chapter 46).

The nicotinic acetylcholine receptor provides an instructive example of a ligand-gated ion channel. Isoforms of this channel are expressed in the CNS, autonomic ganglia and at the neuromuscular junction (Figure 3–9B). The pentameric channel consists of four different subunits ($\alpha, \beta, \delta, \gamma$) in the neuromuscular junction or two different subunits ($\alpha, \beta$) in autonomic ganglia (Purves and McNamara, 2008). Each $\alpha$ subunit has an identical acetylcholine binding site; the different compositions of the other three subunits between the neuronal and neuromuscular junction receptors accounts for the ability of competitive antagonists such as rocuronium to inhibit the receptor in the neuromuscular junction without effect on the ganglionic receptor. This property is exploited to provide muscle relaxation during surgery with minimal autonomic side effects (Chapter 11). Each subunit of the receptor contains a large, extracellular N-terminal domain, four membrane-spanning helices (one of which lines the pore in the assembled complex), and an internal loop between helices 3 and 4 that forms the intracellular domain of the channel. The pore opening in the channel measures ~3 nm whereas the diameter of a Na$^+$ or K$^+$ ion is only 0.3 nm or less. Accordingly, ligand-gated ion channels do not possess the exquisite ion selectivity found in most voltage-activated channels and activation of the nicotinic acetylcholine receptor allows passage of both Na$^+$ and K$^+$ ions.

The major excitatory transmitter at CNS synapses is glutamate. There are three types of ionotropic glutamate receptors (AMPA, NMDA, and kainate), named after the ligands that selectively activate them. They have a topology similar to that of the nicotinic acetylcholine receptor: the channel is made up of five subunits organized with a large extracellular region, a pore, and a small intracellular face. Activation of these channels with glutamate markedly increases Na$^+$ and K$^+$ conductance leading to depolarization. NMDA receptors are less ion-selective; activation increases Na$^+$, K$^+$, and Ca$^{2+}$ conductance, with the Ca$^{2+}$ signal being used for additional signaling events.

Over one-third of synapses in the brain are inhibitory; the major inhibitory transmitters are glycine and $\gamma$-aminobutyric acid (GABA). Glycine and ionotropic GABA$_A$ receptors have a topology like that of the glutamate and nicotinic acetylcholine receptors, with five subunits ($\alpha, \beta, \gamma, \delta$ and $\rho$), a ligand-binding domain, and pore-forming helices. Activation of these channels increases Cl$^-$ conductance, which hyperpolarizes the cell membrane and inhibits excitability (Purves and McNamara, 2008). GABA$_A$ receptors are targets of important sedative-hypnotic drugs such as the benzodiazepines and barbiturates, and are also important in the mechanisms of ethanol and general anesthetics (Chapters 17, 19, and 23).

TRP Channels. The transient receptor potential (TRP) channels comprise a superfamily of ubiquitously
expressed ion channels that is remarkable in its diversity and domain structure (Clapham 2003; Venkatachalam and Montell, 2007). Although the TRP channels are not presently targets of approved drugs, there is significant interest in developing drugs that can alter the function of these ion channels because of their roles in various sensory phenomena such as pain, temperature, osmolarity, touch, olfaction, vision, and hearing. Because these channels contain multiple domains, they can act as signal integrators and most can be activated by multiple mechanisms. There are 27 TRP channel genes in humans, representing six different TRP channel families. TRP channels contain six membrane-spanning segments and the functional ion channels consist of tetrameric complexes. Closely related TRP channels can form heterotetramers. The TRP channels are cation channels, but as with other heteromultimeric ion channels, the subunit composition of the multimeric channels can prescribe a number of important channel characteristics, including ion selectivity and activation properties. The intracellular domains of TRP channels can include ankyrin domains, protein kinase domains, and ADP-ribose pyrophosphatase domains. Mutations in TRP channels are known to cause several disease including hypomagnesemia and hypocalcemia, and various renal disorders and neurodegenerative diseases.

Transmembrane Receptors Linked to Intracellular Enzymes

Mammalian cells express a diverse group of physiological membrane receptors with extracellular ligand-binding domains and an intrinsic enzymatic activity on the cytoplasmic surface of the cell. These molecules include the receptor tyrosine kinases (RTKs) such as the epidermal growth factor (EGF) and insulin receptors, which contain intrinsic tyrosine kinases in the cytoplasmic domain of the receptor; tyrosine kinase-associated receptors without enzymatic activity, such as the receptors for γ-interferon, which recruit the cytoplasmic Janus tyrosine kinases (JAKs); receptor serine-threonine kinases such as the TGF-β receptor; and receptors linked to other enzyme activities such as the receptors for natriuretic peptides, which have a cytoplasmic guanylate cyclase activity that produces a soluble second messenger, cyclic GMP (see the next section). Receptors responsible for innate immunity, the Toll-like receptors and those for tumor necrosis factors (TNF-α), have many features in common with the JAK-STAT receptors.

Receptor Tyrosine Kinases. The receptor tyrosine kinases include receptors for hormones such as insulin, for multiple growth factors such EGF, platelet-derived growth factor (PDGF), nerve growth factor (NGF), fibroblast growth factor (FGF), vascular endothelial growth factor (VEGF), and ephrins. With the exception of the insulin receptor, which has α and β chains (Chapter 43), these molecules consist of single polypeptide chains with large, cysteine-rich extracellular domains, short transmembrane domains, and an intracellular region containing one (or in some cases two) protein tyrosine kinase domains. Activation of growth factor receptors leads to cell survival, cell proliferation, and differentiation. Activation of the ephrin receptors leads to neuronal angiogenesis, axonal migration, and guidance (Ferguson, 2008; Hubbard and Till, 2000).

The inactive state of growth factor receptors is monomeric; binding of ligand induces dimerization of the receptor and cross-phosphorylation of the kinase domains on multiple tyrosine residues. Some of these tyrosine residues are in the activation loop of the kinase and their phosphorylation serves to further activate the receptor kinase (Figure 3–10A). The phosphorylation of other tyrosine residues forms docking sites for the SH2 domains contained in a large number of signaling proteins (Ferguson, 2008). There are over 100 proteins encoded in the human genome containing SH2 domains, and following receptor activation, large signaling complexes are formed on the receptor that eventually lead to cell proliferation. Molecules recruited to phosphotyrosine-containing proteins by their SH2 domains include PLCγ which raises intracellular levels of Ca2+ and activates PKC, as described earlier. The α and β isoforms of phosphatidylinositol 3-kinase (PI3-K) contain SH2 domains, dock at the phosphorylated receptor, are activated, and increase the level of phosphatidylinositol 3,4,5 trisphosphate (PIP3), a molecule that forms other kinds of docking sites at the plasma membrane for signaling molecules such as protein kinase B (PKB, also known as Akt). PKB can regulate the mammalian target of rapamycin (mTOR) in the various signaling pathways and the Bad protein that is important in apoptosis.

In addition to recruiting enzymes, phosphotyrosine-presenting proteins can attract SH2 domain-containing adaptor molecules with activity such as Grb2, which in turn attract guanine nucleotide exchange factors (GEFs) such as Sos that can activate the small GTP-binding protein, Ras. The small GTP binding proteins Ras and Rho belong to a large family of small monomeric GTPases; only members of the Ras and Rho subfamilies are activated by extracellular receptors. The Ras family includes four isoforms H-ras, K-ras, n-Ras, and Rheb (activated by the insulin receptor). Spontaneous activating mutations in Ras are responsible for a large fraction of human cancers; thus, molecules that inhibit Ras are of great interest in cancer chemotherapy. The Rho family includes Rho, Rac, and Cdc42, which are responsible for relaying signals from the membrane to the cytoskeleton. All of the small GTPases are activated by GEFs that are regulated by a variety of mechanisms and inhibited by GTPase activating proteins (GAPs) (Etienne-Manneville and Hall, 2002).
**Figure 3–10. Diagram showing the mechanism of activation of a receptor tyrosine kinase and a cytokine receptor.**

**A.** Activation of the EGF receptor. The extracellular structure of the unliganded receptor (a) contains four domains (I-IV), which rearrange significantly upon binding two EGF molecules. (b). The conformational changes lead to activation of the cytoplasmic tyrosine kinase domains and tyrosine phosphorylation of intracellular regions to form SH2 binding sites. (c). The adapter molecule Grb2 binds to the phosphorylated tyrosine residues and activates the Ras-MAP kinase cascade.

**B.** Activation of a cytokine receptor. Binding of the cytokine causes dimerization of the receptor and recruits the Janus Kinases (JAKs) to the cytoplasmic tails of the receptor. JAKs trans-phosphorylate and lead to the phosphorylation of the signal transducers and activators of transcription (STATs). The phosphorylated STATS translocate to the nucleus and regulate transcription. There are proteins termed suppressors of cytokine signaling (SOCS) that inhibit the JAK-STAT pathway (Alexander and Hilton, 2004).
Activation of members of the Ras family leads in turn to activation of a protein kinase cascade termed the mitogen-activated protein kinase (MAP kinase or MAPK) pathway. Activation of the MAPK pathway is one of the major routes used by growth factor receptors to signal to the nucleus and stimulate cell growth. The first enzyme in the pathway is Rap which is a MAP kinase kinase kinase (MKKK). Rap phosphorylates and activates a MAP kinase kinase (MKK) termed MEK. MEK phosphorylates a MAP kinase termed ERK. ERK is an interesting member of the kinase family; its activation is achieved by phosphorylation of closely spaced tyrosine and threonine residues in the kinase activation loop. ERK phosphorylates a number of transcription factors in the nucleus, including Elk-1 and CREB, to regulate gene transcription and cause cell proliferation (Manning and Davis, 2003). Drugs that act at receptors in this diverse family include insulin for the treatment of diabetes mellitus and imatinib, a small molecule protein kinase inhibitor designed to inhibit both receptor and non-receptor tyrosine kinases. Imatinib is used to treat chronic myelogenous leukemia and several solid tumors with dysregulated tyrosine kinases.

**JAK-STAT Receptor Pathway.** Cells express a family of receptors for cytokines such as γ-interferon and hormones like growth hormone and prolactin, which signal to the nucleus by a more direct manner than the receptor tyrosine kinases. These receptors have no intrinsic enzymatic activity, rather the intracellular domain binds a separate, intracellular tyrosine kinase termed a Janus kinase (JAK). Upon the dimerization induced by ligand binding, JAKs phosphorylate other proteins termed signal transducers and activators of transcription (STATs), which translocate to the nucleus and regulate transcription (Figure 3–10B). The entire pathway is termed the JAK–STAT pathway (Gough et al., 2008; Wang et al., 2009). There are four JAKs and six STATs in mammals which, depending on the cell type and signal, combine differently to activate gene transcription. For example, prolactin appears to use JAK1, JAK2, and STAT5 to stimulate milk production.

**Receptor Serine-Threonine Kinases.** Protein ligands such as TGF-β activate a family of receptors that are analogous to the receptor tyrosine kinases except that they have a serine/threonine kinase domain in the cytoplasmic region of the protein. There are two isoforms of the monomeric receptor protein, type I (7 forms) and type II (5 forms). In the basal state, these proteins exist as monomers; upon binding an agonist ligand, they dimerize, leading to phosphorylation of the kinase domain of the type I monomer, which activates the receptor. The activated receptor then phosphorylates a gene regulatory protein termed a Smad. There are multiple Smads in cells; once phosphorylated by the activated receptor on a serine residue, Smad dissociates from the receptor, migrates to the nucleus, associates with transcription factors and regulates genes leading to morphogenesis and transformation. There are also inhibitory Smads (the Smad6 or Smad7 isoforms) that compete with the phosphorylated Smads to terminate signaling.

**Toll-Like Receptors.** Signaling related to the innate immune system is carried out by a family of over ten single membrane-spanning receptors termed Toll-like receptors (TLR), which are highly expressed in hematopoietic cells. In a single polypeptide chain, these receptors contain a large extracellular ligand-binding domain, a short membrane-spanning domain, and a cytoplasmic region termed the TIR domain that lacks intrinsic enzymatic activity. Ligands for TLR are comprised of a multitude of pathogen products including lipids, peptidoglycans, lipopeptides, and viruses. Activation of these receptors produces an inflammatory response to the pathogenic microorganisms. As with all single membrane-spanning receptors, the first step in activation of TLR by ligands is dimerization, which in turn causes signaling proteins to bind to the receptor to form a signaling complex.

Ligand-induced dimerization recruits a series of adaptor proteins including Mal and the myeloid differentiation protein 88 (MyD88) to the intracellular TIR domain, which in turn recruit the interleukin-associated kinases termed IRAKs. The IRAKs autophosphorylate in the complex and subsequently form a more stable complex with MyD88. The phosphorylation event also recruits TRAF6 to the complex, which facilitates interaction with a ubiquitin ligase that attaches a polyubiquitin molecule to TRAF6. This complex can now interact with the protein kinase TAK1 and the adaptor TAB1. TAK1 is a member of the MAP kinase family, which activates the NF-κB kinases; phosphorylation of the NF-κB transcription factors causes their translocation to the nucleus and transcriptional activation of a variety of inflammatory genes (Gay and Gangloff, 2007).

**TNF-α Receptors.** The mechanism of action of tumor necrosis factor α (TNF-α) signaling to the NF-κB transcription factors is very similar to that used by Toll-like receptors in that the intracellular domain of the receptor has no enzymatic activity. The TNF-α receptor is another single membrane-spanning receptor with an extracellular ligand-binding domain, a transmembrane domain, and a cytoplasmic domain termed the death domain.

TNF-α binds a complex composed of TNF-receptor1 and TNF-receptor2. Upon trimerization, the death domains bind the adaptor protein TRADD, which recruits the receptor interacting protein 1 (RIP1) to form a receptor-adaptor complex at the membrane. RIP1 is poly-ubiquinated, resulting in recruitment of the TAK1 kinase and the IκB kinase (IKK) complex to the ubiquinated molecules (Skaug et al., 2009). The activation loop of IKK is phosphorylated in the complex eventually resulting in IκBα being released.
Receptors That Stimulate Synthesis of Cyclic GMP

The signaling pathways that regulate the synthesis of cyclic GMP in cells include hormonal regulation of transmembrane guanylate cyclases such as the atrial natriuretic peptide receptor (ANP) and the activation of soluble forms of guanylate cyclase by nitric oxide (NO). The downstream effects of cyclic GMP are carried out by multiple isoforms of PKG, cyclic GMP-gated ion channels, and cyclic GMP-modulated phosphodiesterases that degrade cyclic AMP (described later).

Natriuretic Peptide Receptors. The class of membrane receptors with intrinsic enzymatic activity includes the receptors for three small peptide ligands released from cells in cardiac tissues and the vascular system. These peptides are atrial natriuretic peptide (ANP), which is released from atrial storage granules following expansion of intravascular volume or stimulation with presor hormones; brain natriuretic peptide (BNP), which (in spite of its name) is synthesized and released in large amounts from ventricular tissue in response to volume overload; and C-type natriuretic peptide (CNP), which is synthesized in the brain and endothelial cells. Like BNP, CNP is not stored in granules; rather, its synthesis and release are increased by growth factors and sheer stress on vascular endothelial cells (Potter et al., 2009). The major physiological effects of these hormones are to decrease blood pressure (ANP, BNP), to reduce cardiac hypertrophy and fibrosis (BNP), and to stimulate long bone growth (CNP).

The transmembrane receptors for ANP, BNP, and CNP are ligand-activated guanylate cyclases. The ANP and BNP receptors contain a ~450 amino acid extracellular domain that binds the peptide, a short 20 amino acid transmembrane domain, and large intracellular domains that contain a kinase homology region, a dimerization domain, and a C-terminal guanylate cyclase domain. Phosphorylation of serine residues in the kinase domain is important for activity; dephosphorylation of these residues leads to desensitization of the receptor. Ligand binding brings the juxtamembrane regions together and stimulates guanylate cyclase activity (Figure 3–11).

The ANP receptor (NPR-A) is the molecule that responds to ANP and BNP. The protein is widely expressed and prominent in kidney, lung, adipose, and cardiac and vascular smooth muscle cells. ANP and BNP play a role in maintaining the normal state of the cardiovascular system as NPR-A knockout mice have hypertension and cardiac hypertrophy. A synthetic BNP agonist, nesiritide, is used for treatment of acute decompensated heart failure (Chapter 28). The NPR-B receptor responds to CNP and has a physical structure similar to the NPR-A receptor. It is also widely expressed but prominent in bone, brain, kidney, lung, liver, and cardiac and vascular smooth muscle. A role for CNP in bone is suggested by the observation that NPR-B knockout mice exhibit both dwarfishism and cardiac hypertrophy. The natriuretic peptide C receptor (NPR-C) has an extracellular domain similar to those of NPR-A and NPR-B but does not contain the intracellular kinase or guanylate cyclase domains. It has no enzymatic activity and is thought to function as a clearance receptor, removing excess natriuretic peptide from the circulation (Potter et al., 2009).

NO Synthase and Soluble Guanylate Cyclase. Nitric oxide (NO) is a unique signal, a very labile gas produced locally in cells by the enzyme nitric oxide synthase (NOS); the resulting NO is able to markedly stimulate the soluble form of guanylate cyclase to produce cyclic GMP. There are three forms of nitric oxide synthase, neuronal NOS (nNOS or NOS1), endothelial NOS (eNOS or NOS3), and inducible NOS (iNOS or NOS2). All three forms of this enzyme are widely expressed but are especially important in the cardiovascular system, where they are found in myocytes, vascular smooth muscle cells, endothelial cells, hematopoietic cells, and platelets.

NOS produces NO by catalyzing the oxidation of the guanido nitrogen of L-arginine, producing L-citrulline and NO. The enzymes require co-factors including tetrahydrobiopterin and calmodulin. The nNOS and eNOS forms of the enzyme are markedly activated by Ca²⁺/calmodulin; the inducible form is less sensitive to Ca²⁺ but the level of iNOS protein in cells can be increased over 1000-fold by inflammatory stimuli such as endotoxin, TNF-α, interleukin-1β and interferon-γ. The ability of Ca²⁺ to activate eNOS and nNOS is important in certain cells where neurotransmitters that open Ca²⁺ channels or activate PLC can relax smooth muscle. An example is the ability of ACh released by the parasympathetic nervous system to relax sphincters. Soluble guanylate cyclase is a heterodimer composed of α and β subunits. The N-terminal end of the molecule contains a protoporphyrin-IX heme domain. NO binds to this domain at low nM concentrations and produces a 200- to 400-fold increase in the Vmax of guanylate cyclase, leading to a marked elevation of cyclic GMP in the cell (Tsai and Kass, 2009).

The cellular effects of cyclic GMP on the vascular system are mediated by a number of mechanisms, but especially by PKG. For example, in vascular smooth muscle, activation of PKG leads to vasodilation by:
Inhibiting IP₃-mediated Ca²⁺ release from intracellular stores.

Phosphorylating voltage-gated Ca²⁺ channels to inhibit Ca²⁺ influx.

Phosphorylating phospholamban, a modulator of the sarcoplasmic Ca²⁺ pump, leading to a more rapid reuptake of Ca²⁺ into intracellular stores.

Phosphorylating and opening the Ca²⁺-activated K⁺ channel leading to hyperpolarization of the cell membrane, which closes L-type Ca²⁺ channels and reduces the flux of Ca²⁺ into the cell (Tsai and Kass, 2009).

NUCLEAR HORMONE RECEPTORS AND TRANSCRIPTION FACTORS

In humans, nuclear hormone receptors comprise a superfamily of 48 receptors that respond to a diverse set of ligands. The receptor proteins are transcription factors able to regulate the expression of genes controlling numerous physiological processes such as reproduction, development, and metabolism. Well-known members of the family include receptors for circulating steroid hormones such as androgens, estrogens, glucocorticoids, thyroid hormone, and vitamin D. Other members of the family are receptors for a diverse group of fatty acids, bile acids, lipids, and lipid metabolites. The latter receptors function as sensors for the metabolic state of the cell and respond to changes in locally available molecules (McEwan, 2009). Examples include a number of nuclear receptors that are important in inducing drug metabolizing enzymes, such as the retinoic acid receptor (RXR); the liver X receptor (LXR—the ligand is 22-OH cholesterol); the farnesoid X receptor (FXR—the ligand is chenodeoxycholic acid); and the peroxisome proliferator-activated receptors (PPARs α, β, and γ; 15 deoxy prostaglandin J₂ is one possible ligand for PPARγ; the cholesterol-lowering fibrates bind to and regulate PPARγ). In the inactive state, receptors for steroids such as glucocorticoids reside in the cytoplasm and translocate to the nucleus.
Upon binding ligand. Other members of the family such as the LXR and FXR receptors reside in the nucleus and are activated by changes in the concentration of hydrophobic lipid molecules.

Nuclear hormone receptors contain four major domains in a single polypeptide chain. The N-terminal domain can contain an activation region (AF-1) essential for transcriptional regulation followed by a very conserved region with two zinc fingers that bind to DNA (the DNA-binding domain). The N-terminal activation region (AF-1) is subject to regulation by phosphorylation and other mechanisms that stimulate or inhibit the overall ability of the nuclear receptor to activate transcription. The C terminal half of the molecule contains a hinge region (which can be involved in binding DNA), the domain responsible for binding the hormone or ligand (the ligand-binding domain or LBD), and specific sets of amino acid residues for binding co-activators and co-repressors in a second activation region (AF-2). The x-ray structures of nuclear hormone receptors show that the LBD is formed from a bundle of 12 helices and that ligand binding induces a major conformational change in helix 12 (Privalsky, 2004; Tontonoz and Spiegelman, 2008). This conformational change also affects the binding of the co-regulatory proteins essential for activation of the receptor-DNA complex (Figure 3–12).

When bound to DNA, most of the nuclear hormone receptors act as dimers—some as homodimers, others as heterodimers. Steroid hormone receptors such as the glucocorticoid receptor are commonly homodimers, whereas those for lipids are heterodimers with the RXR receptor. The receptor dimers bind to repetitive DNA sequences, either direct repeat sequences or an inverted repeat termed hormone response elements (HRE) that are specific for each type of receptor (e.g., AGGTCA half-sites oriented as an inverted repeat with a three-base spacer for the estrogen receptor). The hormone response elements in DNA are found upstream of the regulated genes or in some cases within the regulated genes. An agonist-bound nuclear hormone receptor often activates a large number of genes to carry out a program of cellular differentiation or metabolic regulation. For example, stimulation of the LXR receptor in hepatocytes activates 29 genes and inhibits 14 others (Kalaany and Mangelsdorf, 2006).

**Figure 3–12. Diagram of nuclear hormone receptor activation.** A nuclear hormone receptor (OR) is shown in complex with the retinoic acid receptor (RXR). When an agonist (yellow triangle) and co-activator bind, a conformational change occurs in helix 12 (black bar) and gene transcription is stimulated. If co-repressors are bound, activation does not occur. See text for details; see also Figure 6–13.

An important property of these receptors is that they must bind their ligand, the appropriate HRE, and a co-regulator (from a family of over 100 proteins co-regulators) to regulate their target genes. There are co-activators such as the steroid receptor co-activator (SRC) family, the p160 family proteins, CARM and CBP/p300 or PCG-Iα, and co-repressors such as the silencing mediator of retinoid hormone receptor (SMRT) and nuclear hormone receptor co-repressor (NCor) (Privalsky, 2004). The activity of the nuclear hormone receptors in a given cell depends not only on the ligand, but the ratio of co-activators and co-repressors recruited to the complex. Co-activators recruit enzymes to the transcription complex that modify chromatin, such as histone acetylase, which serves to unravel DNA for transcription. Co-repressors recruit proteins such as histone deacetylase, which keeps DNA tightly packed and inhibits transcription.

Depending on the chemical nature of the bound ligand and the combination of co-activators and co-repressors recruited to the complex, nuclear hormone receptors may differentially regulate their target genes. This property explains the ability of certain drugs to act as selective modulators of the receptor and gene expression. For example, compounds such as 17β-estradiol are estrogen receptor agonists in all tissues, whereas tamoxifen and raloxifene are termed selective estrogen receptor modulators (SERMs). Tamoxifen and raloxifene are partial agonists at the estrogen receptor; upon binding, these agents elicit unique conformations of the ligand-binding domain. Thus, depending on the specific tissue, different combinations of co-activators and co-repressors are bound to the receptor-DNA complex, yielding gene-selective functions. For example, tamoxifen is an antagonist in breast tissue by virtue of recruiting co-repressors to the transcription factor complex but is an agonist in the endometrium because it recruits co-activators (Riggs and Hartmann, 2003) (Chapter 40).

**APOPTOSIS**

The maintenance of many organs requires the continuous renewal of cells. Examples include mucosal cells lining the intestine and a variety of cells in the immune system including T-cells and neutrophils. Cell renewal requires a balance between survival and expansion of the cell population, or cell death and removal. The process by which cells are genetically programmed for death is termed apoptosis. Apoptosis is a highly regulated program of biochemical reactions that leads to cell rounding, shrinking of the cytoplasm, condensation of the nucleus and nuclear material, and changes in the cell membrane that eventually lead to presentation of phosphatidylserine on the outer surface of the cell. Phosphatidylserine is recognized as a sign of apoptosis by macrophages, which engulf and phagocytize the dying cell. Notably, during this process the membrane of the apoptotic cell remains intact and the cell does not release its cytoplasm or nuclear material. Thus, unlike necrotic cell death, the apoptotic process does not initiate an inflammatory response. Understanding the
pathways regulating apoptosis is important because apoptosis plays an important role in normal cells and because alterations in apoptotic pathways are implicated in a variety of diseases such as cancer, and neurodegenerative and autoimmune diseases (Bremer et al., 2006; Ghavami et al., 2009). Thus, maintaining or restoring normal apoptotic pathways is the goal of major drug development efforts to treat diseases that involve dysregulated apoptotic pathways (Fesik, 2005) and selectively stimulating apoptotic pathways could be useful in removing unwanted cells.

Two major signaling pathways induce apoptosis. Apoptosis can be initiated by external signals that have features in common with those used by ligands such as TNF-α or by an internal pathway activated by DNA damage, improperly folded proteins, or withdrawal of cell survival factors (Figure 3-13). Regardless of the mode of initiation, the apoptotic program is carried out by a large family of cysteine proteases termed caspases. The caspases are highly specific cytoplasmic proteases that are inactive in normal cells but become activated by apoptotic signals (Danial and Korsmeyer, 2004; Ghobrial et al., 2005; Strasser et al., 2000).

The external apoptosis signaling pathway can be activated by ligands such as TNF, FAS (another member of the TNF family, also called Apo-1), or the TNF-related apoptosis-inducing ligand (TRAIL). The receptors for FAS and TRAIL are transmembrane receptors with no enzymatic activity, similar to the organization of the TNF receptor described above. They have large external ligand-binding domains, short transmembrane domains, and a cytoplasmic death domain capable of binding intracellular adaptor proteins. Upon binding TNF, FAS ligand, or TRAIL, these receptors form a receptor dimer, undergo a conformational change, and recruit adapter proteins to the death domain. The adaptor proteins are TNF-associated death domain binding protein (TRADD), FADD, or TRAF2. These adaptor proteins then recruit the receptor-interacting protein kinase (RIP1) and caspase 8 to form a complex of RIP1, TRADD/
FADD/TRAF2, and caspase 8, which results in the activation of caspase 8. The FAS and TRAIL receptors recruit different adaptors, termed FADD/MORT, which are capable of attracting and then activating caspase 8 by autoproteolytic cleavage. Regardless of the upstream complexes that activate caspase 8, stimulation of its proteolytic activity leads to the activation of caspase 3, which initiates the apoptotic program. The final steps of apoptosis are carried out by caspase 6 and 7, leading to degradation of enzymes, structural proteins, and DNA fragmentation characteristic of cell death (Danial and Korsmeyer, 2004; Wilson et al., 2009) (Figure 3–13).

The internal apoptosis pathway can be activated by signals such as DNA damage leading to increased transcription of the p53 gene and involves damage to the mitochondria by pro-apoptotic members of the Bcl-2 family of proteins. This family includes pro-apoptotic members such as BAX, Bak, and Bad, which induce damage at the mitochondrial membrane. There are also anti-apoptotic Bcl-2 members, such as Bcl-2, Bcl-X, and Bcl-W, which serve to inhibit mitochondrial damage and are negative regulators of the system (Rong and Distelhorst, 2008). When DNA damage occurs, p53 transcription is activated and holds the cell at a cell cycle check point until the damage is repaired. If the damage cannot be repaired, apoptosis is initiated through the pro-apoptotic Bcl-2 members such as BAX. BAX is activated, translocates to the mitochondria, overcomes the anti-apoptotic proteins, and induces the release of cytochrome c and a protein termed the “second mitochondria-derived activator of caspase” (SMAC). SMAC binds to and inactivates the inhibitors of apoptosis proteins (IAPs) that normally prevent caspase activation. Cytochrome C combines in the cytosol with another protein, apoptotic activating protease factor -1 (Apaf-1), and with caspase 9. This complex leads to activation of caspase 9 and ultimately to the activation of caspase 3 (Ghobrial et al., 2005; Wilson et al., 2009). Once activated, caspase 3 activates the same downstream pathways as the external pathway described above, leading to the cleavage of proteins, cytoskeletal elements, DNA repair proteins, with subsequent DNA condensation and membrane blebbing that eventually lead to cell death and engulfment by macrophages (Figure 3–13).

**RECEPTOR DESSENSITIZATION AND REGULATION OF RECEPTORS**

Receptors not only initiate regulation of biochemical events and physiological function but also are themselves subject to many regulatory and homeostatic controls. These controls include regulation of the synthesis and degradation of the receptor, covalent modification, association with other regulatory proteins, and relocalization within the cell. Transducer and effector proteins are regulated similarly. Modulatory inputs may come from other receptors, directly or indirectly, and receptors are almost always subject to feedback regulation by their own signaling outputs.

Continued stimulation of cells with agonists generally results in a state of desensitization (also referred to as adaptation, refractoriness, or down-regulation) such that the effect that follows continued or subsequent exposure to the same concentration of drug is diminished. This phenomenon, called tachyphylaxis, occurs rapidly and is important therapeutically; an example is attenuated response to the repeated use of β-adrenergic receptor agonists as bronchodilators for the treatment of asthma (Chapters 12 and 36).

Desensitization can result from temporary inaccessibility of the receptor to agonist or from fewer receptors being synthesized and available at the cell surface (e.g., down-regulation of receptor number). Phosphorylation of GPCR receptors by specific GPCR kinases (GRKs) plays a key role in triggering rapid desensitization. Phosphorylation of agonist-occupied GPCRs by GRKs facilitates the binding of cytosolic proteins termed arrestins to the receptor, resulting in the uncoupling of G protein from the receptor (Moore et al., 2007). The β-arrestins recruit proteins, such as PDE4, that limit cyclic AMP signaling, and clathrin and β2-adaptin, that promote sequestration of receptor from the membrane (internalization), thereby providing a scaffold that permits additional signaling steps.

Conversely, supersensitivity to agonists also frequently follows chronic reduction of receptor stimulation. Such situations can result, e.g., following withdrawal from prolonged receptor blockade (e.g., the long-term administration of β adrenergic receptor antagonists such as metoprolol) or in the case where chronic denervation of a preganglionic fiber induces an increase in neurotransmitter release per pulse, indicating postganglionic neuronal supersensitivity. Supersensitivity can be the result of tissue response to pathological conditions, such as occurs in cardiac ischemia due to the synthesis and recruitment of new receptors to the surface of the myocyte.

It seems likely that effects of several classes of CNS-active agents depend on similar agonist- and antagonist-induced changes in receptor-effector systems (Chapters 14, 15, and 18).

**Diseases Resulting from Receptor Malfunction.** Alteration in receptors and their immediate signaling effectors can be the cause of disease. The loss of a receptor in a highly specialized signaling system may cause a relatively limited, if dramatic, phenotypic disorder (e.g., deficiency of the androgen receptor and testicular feminization syndrome; Chapter 41). Deficiencies in widely employed signaling pathways have broad effects, as are seen in myasthenia gravis and some forms of insulin-resistant diabetes mellitus, which result from autoimmune depletion of nicotinic cholinergic receptors (Chapter 11) or insulin receptors (Chapter 43), respectively. The expression of constitutively active, aberrant, or ectopic receptors, effectors, and coupling proteins potentially can lead to supersensitivity, subsensitivity, or other untoward responses (Smit et al., 2007). Among the most significant events is the appearance of aberrant...
receptors as products of oncogenes that transform otherwise normal cells into malignant cells. Virtually any type of signaling system may have oncogenic potential.

**PHARMACODYNAMIC INTERACTIONS IN A MULTICELLULAR CONTEXT**

It is instructive to examine the pharmacodynamic interactions of physiological ligands and drugs that can occur in the context of a pathophysiological setting. Consider the vascular wall of an arteriole (Figure 3–14). Several cell types interact at this site, including vascular smooth muscle cells (SMCs), endothelial cells (ECs), platelets, and post-ganglionic sympathetic neurons. A variety of physiological receptors and ligands are represented, including ligands that cause SMCs to contract (angiotensin II [AngII], norepinephrine [NE]) and relax (nitric oxide [NO], B-type natriuretic peptide [BNP], and epinephrine), as well as ligands that alter SMC gene expression (platelet-derived growth factor [PDGF], AngII, NE, and eicosanoids). The intracellular second messengers Ca\(^{2+}\), cAMP, and cGMP are also shown.

AngII has both acute and chronic effects on SMC. Interaction of AngII with AT\(_1\) receptors (AT\(_1\)-R) causes the formation of the second messenger IP\(_3\) through the action of the AT\(_1\)-R with the G\(_q\)-PLC-IP\(_3\) pathway. IP\(_3\) causes the release of Ca\(^{2+}\) from the endoplasmic reticulum; the Ca\(^{2+}\) binds and activates calmodulin and its target protein, myosin light chain kinase (MLCK). The activation of MLCK results in the phosphorylation of myosin, leading to smooth muscle cell contraction. Activation of the sympathetic nervous system also regulates SMC tone through release of NE from post-ganglionic sympathetic neurons impinging on SMCs. NE binds \(\alpha_1\) adrenergic receptors that couple to the G\(_q\)-PLC-IP\(_3\) pathway, causing an increase in intracellular Ca\(^{2+}\) and, as a result, contraction, an effect that is additive to that of AngII. The contraction of SMCs is opposed by several physiological mediators that promote relaxation, including NO, BNP, and epinephrine. NO is formed in ECs by the action of two NO synthase enzymes, eNOS and iNOS. The NO formed in ECs diffuses into SMCs, and activates the soluble form of guanylate cyclase (sGC), which catalyzes the formation of cyclic GMP from GTP. The increase in cyclic GMP activates PKG, which phosphorylates protein substrates in SMCs that reduce intracellular concentrations of Ca\(^{2+}\) by several different mechanisms including reducing entry of extracellular Ca\(^{2+}\) through L-type voltage-gated Ca\(^{2+}\) channels. Intracellular concentrations

---

**Figure 3–14.** Interaction of multiple signaling systems regulating vascular smooth muscle cells. The membrane receptors and channels are sensitive to pharmacological antagonists. See text for explanation of signaling and contractile pathways and abbreviations.
of cyclic GMP are also increased by activation of the transmembrane BNP receptor (BNP-R), whose guanylate cyclase activity is increased when BNP binds. BNP is released from cardiac muscle in response to increased filling pressures. The contractile state of the arteriole is thus regulated acutely by a variety of physiological mediators working through a number of signal transduction pathways. In a patient with hypertension, SMC tone in an arteriole may be elevated above normal due to one or more changes in endogenous ligands or signaling pathways. These include elevated circulating concentrations of AngII, increased activity of the sympathetic nervous system, and decreased NO production by endothelial cells. Pharmacotherapy might include the use of one or more drugs to block or counteract the acute pathological changes in blood pressure as well as to prevent long-term changes in vessel wall structure due to stimulation of SMC proliferation and alterations in SMC gene expression.

Drugs commonly used to treat hypertension include \( \beta_1 \) antagonists to reduce secretion of renin (the rate-limiting first step in AngII synthesis), a direct renin inhibitor (aliskiren) to block the rate-limiting step in AngII production, angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril) to reduce the concentrations of circulating AngII, \( \text{AT}_1 \) receptor blockers (e.g., losartan) to block AngII binding to \( \text{AT}_1 \) receptors on SMCs, \( \alpha_1 \) adrenergic blockers to block NE binding to SMCs, sodium nitroprusside to increase the quantities of NO produced, or a \( \text{Ca}^{2+} \) channel blocker (e.g., nifedipine) to block \( \text{Ca}^{2+} \) entry into SMCs. \( \beta_1 \) antagonists would also block the baroreceptor reflex increase in heart rate and blood pressure elicited by a drop in blood pressure induced by the therapy. ACE inhibitors also inhibit the degradation of a vasodilating peptide, bradykinin (Chapter 26). Thus, the choices and mechanisms are complex, and the appropriate therapy in a given patient depends on many considerations, including the diagnosed causes of hypertension in the patient, possible side effects of the drug, efficacy in a given patient, and cost.

Some of the mediators that cause coronary vasoconstriction and hypertension, such as AngII and NE, can also have chronic effects on the vascular wall through mechanisms involving alterations in SMC gene expression. These effects on gene expression can alter the biochemical and physiological properties of the SMC by stimulating hypertrophy, proliferation, and synthesis of proteins that remodel the extracellular matrix. The pathways involved in these chronic effects include many of the same pathways used by growth factor receptors, such as PDGF which can also be involved in the vascular wall remodeling that occurs in neointimal hyperplasia associated with coronary artery restenosis. One of the beneficial effects of using ACE inhibitors and \( \text{AT}_1 \) receptor blockers in the treatment of hypertension is their ability to prevent the long-term pathological remodeling of the vascular wall that results from chronic activation of \( \text{AT}_1 \) receptors by AngII.

Cheng Y, Prusoff WH. Relationship between the inhibition constant (K<sub>i</sub>) and the concentration of inhibitor which causes 50 per cent inhibition (I<sub>50</sub>) of an enzymatic reaction. *Biochem Pharmacol*, 1973, 22:3099–3108.

**Pharmacology** deals with drugs and their chemical properties or characteristics, their mode of action, the physiological response to drugs, and the clinical uses of drugs. Pharmacology intersects with **toxicology** when the physiological response to a drug is an **adverse effect**. Toxicology is often regarded as the science of poisons or poisoning, but developing a strict definition for poison is problematic. A **poison** is any substance, including any drug, that has the capacity to harm a living organism. The Renaissance physician Paracelsus (1493-1541) is famously credited with offering the philosophical definition of poisons: “What is there that is not poison? All things are poison and nothing is without poison. Solely the dose determines that a thing is not a poison.” However, **poisoning** inherently implies that damaging physiological effects result from exposure to pharmaceuticals, illicit drugs, or chemicals. So each drug in the pharmacopeia is a potential poison, and individual dose-, situation-, environment-, and gene-related factors contribute to a drug’s ability to achieve its adverse potential.

Some chemicals may inherently be poisons, such as lead, which has no known necessary physiological role in the human body, and which is known to cause neuronal injury even at very low exposure levels. Most pharmaceuticals are threshold poisons; at therapeutic dosing the drug is used to confer a health advantage, but at higher doses the drug may produce a toxic effect. For instance, iron is a nutrient essential for heme synthesis and numerous physiological enzyme functions, but overdose of ferrous sulfate can lead to life-threatening multi-organ dysfunction.

**DOSE-RESPONSE**

Evaluation of the dose-response or the dose-effect relationship is crucially important to toxicologists. There is a graded dose-response relationship in an **individual** and a quantal dose-response relationship in the **population** (see Chapters 2 and 3). Graded doses of a drug given to an individual usually result in a greater magnitude of response as the dose is increased. In a quantal dose-response relationship, the percentage of the population affected increases as the dose is raised; the relationship is quantal in that the effect is specified to be either present or absent in a given individual (Figure 4–1). This quantal dose-response phenomenon is extremely important in toxicology and is used to determine the **median lethal dose** (LD\(_{50}\)) of drugs and other chemicals.

The LD\(_{50}\) of a compound is determined experimentally, usually by administration of the chemical to mice or rats (orally or intraperitoneally) at several doses in the lethal range (Figure 4–1A).

To linearize such data, the response (death) can be converted to units of deviation from the mean, or **probits** (probability units). The probit designates the deviation from the median; a probit of 5 corresponds to a 50% response, and because each probit equals one standard deviation, a probit of 4 equals 16% and a probit of 6 equals 84%. A plot of the percentage of the population responding, in probit units, against log dose yields a straight line (Figure 4–1B). The LD\(_{50}\) is determined by drawing a vertical line from the point on the line where the probit unit equals 5 (50% mortality). The slope of the dose-effect curve also is important. The LD\(_{50}\) for both compounds depicted in Figure 4–1 is the same (~10 mg/kg); however, the slopes of the dose-response curves are quite different. At a dose equal to one-half the LD\(_{50}\) (5 mg/kg), less than 5% of the animals exposed to compound B would die, but 30% of the animals given compound A would die.

Figure 4–2 illustrates the relationship between a quantal dose-response curve for the therapeutic effect of a drug to generate a median effective dose (ED\(_{50}\)), the concentration of drug at which 50% of the population will have the desired response, and a quantal dose-response curve for lethality by the same agent. These two curves can be used to generate a therapeutic index (TI), which quantifies the relative safety of a drug. Clearly, the higher the ratio, the safer the drug.

\[
TI = \frac{LD_{50}}{ED_{50}}
\]
Drugs show a wide range of TI, from 1-2 to >100. Drugs with a low TI must be administered with caution. Agents that fall into this category include the cardiac glycoside digitalis and cancer chemotherapeutic agents. Agents with very high TI are extremely safe and include some antibiotics (e.g., penicillin), unless there is a known allergic response.

The use of median effective and median lethal doses is not without disadvantages, because median doses do not consider that the slopes of the dose-response curves for therapeutic and lethal (toxic) effects may differ. As an alternative the ED_{99} for the therapeutic effect can be compared to the LD_{1} for lethality (toxic effect), to yield a margin of safety.

\[
\text{Margin of safety} = \frac{\text{LD}_{1}}{\text{ED}_{99}}
\]

The quantal dose-response curves described thus far represent linearization of sigmoidal dose-response curves (Figure 4–1). However, not all dose-response curves follow this shape. “U”-shaped dose-response curves can be observed for essential metals and vitamins (Figure 4–3). At low dose, adverse effects are observed since there is a deficiency of these nutrients to maintain homeostasis. As dose increases, homeostasis is achieved, and the bottom of the “U”-shaped dose-response curve is reached. As dose increases to surpass the amount required to maintain homeostasis, overdose toxicity can ensue. Thus, adverse effects are seen at both low and high dose.

FIGURE 4–3. U-Shaped dose-response curve for essential metals and vitamins. Vitamins and essential metals are essential for life and their lack can cause adverse responses (plotted on the vertical axis), as can their excess, giving rise to a U-shaped concentration-dependence curve.

Drugs show a wide range of TI, from 1-2 to >100. Drugs with a low TI must be administered with caution. Agents that fall into this category include the cardiac glycoside digitalis and cancer chemotherapeutic agents. Agents with very high TI are extremely safe and include some antibiotics (e.g., penicillin), unless there is a known allergic response.

The use of median effective and median lethal doses is not without disadvantages, because median doses do not consider that the slopes of the dose-response curves for therapeutic and lethal (toxic) effects may differ. As an alternative the ED_{99} for the therapeutic effect can be compared to the LD_{1} for lethality (toxic effect), to yield a margin of safety.

\[
\text{Margin of safety} = \frac{\text{LD}_{1}}{\text{ED}_{99}}
\]

The quantal dose-response curves described thus far represent linearization of sigmoidal dose-response curves (Figure 4–1). However, not all dose-response curves follow this shape. “U”-shaped dose-response curves can be observed for essential metals and vitamins (Figure 4–3). At low dose, adverse effects are observed since there is a deficiency of these nutrients to maintain homeostasis. As dose increases, homeostasis is achieved, and the bottom of the “U”-shaped dose-response curve is reached. As dose increases to surpass the amount required to maintain homeostasis, overdose toxicity can ensue. Thus, adverse effects are seen at both low and high dose.

PHARMACOKINETICS VERSUS TOXICOKINETICS

The principles of pharmacokinetics (absorption, distribution, metabolism, and elimination) are described in Chapters 2, 5, and 6, and specific details are provided throughout this text. Toxicokinetics (the pharmacokinetics of a drug under circumstances that produce toxicity or
excessive exposure) may differ significantly after poisoning, and these differences may profoundly alter treatment decisions and prognosis. Ingesting larger than therapeutic doses of a pharmaceutical may prolong its absorption, alter its protein binding and apparent volume of distribution, and change its metabolic fate. When confronted with a potential poisoning, two questions are foremost in the clinician’s mind:

1. How long does an asymptomatic patient need to be monitored (drug absorption and dynamics)?
2. How long will it take an intoxicated patient to get better (drug elimination and dynamics)?

**Drug Absorption.** Aspirin poisoning is a leading cause of overdose morbidity and mortality as reported to U.S. poison control centers (Bronstein et al., 2008). In therapeutic dosing, aspirin reaches peak plasma concentrations in ~1 hour (Chapter 34). However, after overdose, several drug-related and physiology-related factors change. Aspirin overdose may cause spasm of the pyloric valve, delaying entry of the drug into the small intestine. Aspirin, especially enteric coated forms, may coalesce into bezoars, reducing the effective surface area for absorption. Peak plasma salicylate concentrations from aspirin overdose may not be reached for 4-35 hours after ingestion (Rivera et al., 2004).

**Drug Elimination.** After therapeutic dosing, valproic acid has an elimination half-life ($t_{1/2}$) of ~14 hours (see Appendix II). Valproic acid poisoning may lead to coma. In predicting the duration of coma, it is important to consider that, after overdose, first-order metabolic processes appear to become saturated and the apparent elimination $t_{1/2}$ may exceed 30-45 hours (Sztajnkrycer, 2002). Such consideration has important clinical ramifications pertaining to prognosis, resource utilization, and therapy.

Table 4–1 lists some pharmaceuticals notorious for their predilection to have initial symptoms develop after a typical 4-6 hour emergency medical observation period for a suspected drug overdose.

**Types of Therapeutic Drug Toxicity**

In therapeutics, a drug typically produces numerous effects, but usually only one is sought as the primary goal of treatment; most of the other effects are undesirable effects of that drug for that therapeutic indication (Figure 4–4). *Side effects* of drugs usually are bothersome but not deleterious; they include effects such as dry mouth occurring with tricyclic antidepressant therapy. Other undesirable effects may be characterized as toxic effects.

**Dose-Dependent Reactions.** Toxic effects of drugs may be classified as pharmacological, pathological, or genotoxic. Typically, the incidence and seriousness of the toxicity is proportionately related to the concentration of the drug in the body and to the duration of the exposure. Drug overdose provides a dramatic example of dose-dependent toxicities.

**Pharmacological Toxicity.** The CNS depression produced by barbiturates is largely predictable in a dose-dependent fashion. The progression of clinical effects goes from anxiolysis to sedation to somnolence to coma. Similarly, the degree of hypotension produced by nifedipine is related to the dose of the drug administered. Tardive dyskinesia (Chapter 16), an extrapyramidal motor disorder associated with use of antipsychotic medications, seems to be dependent upon duration of exposure. Pharmacological toxicity can also occur when the correct dose is given: there is phototoxicity associated with exposure to sunlight in patients treated with tetracyclines, sulfonamides, chlorpromazine, and nalidixic acid.

**Pathological Toxicity.** Acetaminophen is metabolized to non-toxic glucuronide and sulfate conjugates, and to a highly reactive metabolite $N$-acetyl-$p$-benzoquinoneimine (NAPQI) via CYP
Isoforms. NAPQI is referred to as a biologically reactive intermediate, and such intermediates often arise due to drug metabolism. At therapeutic dosing, NAPQI binds to nucleophilic glutathione; but, in overdose, glutathione depletion may lead to the pathological finding of hepatic necrosis (Figure 4–5).

**Genotoxic Effects.** Ionizing radiation and many environmental chemicals are known to injure DNA, and may lead to mutagenic or carcinogenic toxicities. Many of the cancer chemotherapeutic agents (Chapters 60-63) may be genotoxic. Discussions of genotoxicity can be found in Chapters 6 and 7.

**Allergic Reactions.** An allergy is an adverse reaction that results from previous sensitization to a particular chemical or to one that is structurally similar. Such reactions are mediated by the immune system. For a low-molecular-weight chemical to cause an allergic reaction, it or its metabolic product usually acts as a hapten, combining with an endogenous protein to form an antigenic complex. Such antigens induce the synthesis of antibodies, usually after a latent period of at least 1-2 weeks. Subsequent exposure to the chemical results in an antigen-antibody interaction that provokes the typical manifestations of allergy. Dose-response relationships usually are not apparent for the provocation of allergic reactions. Allergic responses have been divided into four general categories based on the mechanism of immunological involvement.

**Type I: Anaphylactic Reactions.** Anaphylaxis is mediated by IgE antibodies. The Fc portion of IgE can bind to receptors on mast cells and basophils. If the Fab portion of the antibody molecule then binds antigen, various mediators (e.g., histamine, leukotrienes, and prostaglandins) are released and cause vasodilation, edema, and an inflammatory response. The main targets of this type of reaction are the gastrointestinal (GI) tract (food allergies), the skin (urticaria and atopic dermatitis), the respiratory system (rhinitis and asthma), and the vasculature (anaphylactic shock). These responses tend to occur quickly after challenge with an antigen to which the individual has been sensitized and are termed immediate hypersensitivity reactions.

**Type II: Cytolytic Reactions.** Type II allergies are mediated by both IgG and IgM antibodies and usually are attributed to their capacity to activate the complement system. The major target tissues for cytolytic reactions are the cells in the circulatory system. Examples of type II allergic responses include penicillin-induced hemolytic anemia, quinidine-induced thrombocytopenic purpura, and sulfonamide-induced granulocytopenia. Fortunately, these autoimmune reactions to drugs usually subside within several months after removal of the offending agent.

**Type III: Arthus Reactions.** Type III allergic reactions are mediated predominantly by IgG; the mechanism involves the generation of antigen-antibody complexes that subsequently fix complement. The complexes are deposited in the vascular endothelium, where a destructive inflammatory response called serum sickness occurs. This phenomenon contrasts with the type II reaction, in which the inflammatory response is induced by antibodies directed against tissue antigens. The clinical symptoms of serum sickness include urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. Several drugs, including commonly used antibiotics, can induce serum sickness-like reactions. These reactions usually last 6-12 days and then subside after the offending agent is eliminated.

**Type IV: Delayed Hypersensitivity Reactions.** These reactions are mediated by sensitized T-lymphocytes and macrophages. When sensitized cells come in contact with antigen, an inflammatory reaction is generated by the production of lymphokines and the subsequent influx of neutrophils and macrophages. An example of type IV or delayed hypersensitivity is the contact dermatitis caused by poison ivy.

**Idiosyncratic Reactions.** Idiosyncrasy is an abnormal reactivity to a chemical that is peculiar to a given individual. The idiosyncratic response may take the form of extreme sensitivity to low doses or extreme insensitivity to high doses of drugs. Idiosyncratic reactions can result from genetic polymorphisms that cause individual differences in drug pharmacokinetics, from pharmacodynamic factors such as drug-receptor interactions (Evans and Rolling, 1999), or from variability in expression of enzyme activity. The use of genetic information to explain interindividual differences in drug responses or to individualize dosages of drugs...
for patients with known genetic polymorphisms is referred to as pharmacogenetics (Chapter 7).

An increased incidence of peripheral neuropathy is seen in patients with inherited deficiencies in acetylation when isoniazid is used to treat tuberculosis, e.g., slow and fast acetylators exist due to polymorphisms in N-acetyl transferase. Many black males (~10%) develop a serious hemolytic anemia when they receive primaquine as an antimalarial therapy. Such individuals have a deficiency of erythrocyte glucose-6-phosphate dehydrogenase. Genetically determined resistance to the anticoagulant action of warfarin is due to an alteration in the vitamin K epoxide reductase.

**Drug–Drug Interactions.** Patients are commonly treated with more than one drug, have individual dietary choices, and may also be using over-the-counter (OTC) medications, vitamins, and other “natural” supplements. This polypharmaceutical nature of healthcare requires consideration of potential drug interactions (Figure 4–6). Similar to changes in pharmacokinetics and pharmacodynamics seen after drug overdose, drug interactions may lead to altered rates of absorption, altered protein binding, or different rates of biotransformation or excretion of one or both interacting compounds. The pharmacodynamics of a drug can be altered by competition at receptors, and nonreceptor pharmacodynamic interactions can occur when two drugs have similar actions through different cellular mechanisms. Induction or inhibition of drug metabolism by CYPs (Chapter 6) are among the most clinically challenging of drug interactions.

**Interaction of Absorption.** A drug may cause either an increase or a decrease in the absorption of another drug from the intestinal lumen. Ranitidine, an antagonist of histamine H2 receptors, raises gastrointestinal pH and may increase the absorption of basic drugs such as triazolam (O’Connor-Semmes et al., 2001). Conversely, the bile-acid sequestrant cholestyramine leads to significantly reduced serum concentrations of propranolol, and may diminish its effect for a given dosage (Hibbard et al., 1984).

**Interaction of Protein Binding.** Many drugs, such as aspirin, barbiturates, phenytoin, sulfonamides, valproic acid, and warfarin, are highly protein-bound in the plasma, and it is the free (unbound) drug that produces the clinical effects. These drugs may have enhanced toxicity in overdose if protein binding sites become saturated, in physiological states that lead to hypoalbuminemia, or when displaced from plasma proteins by other drugs. The anticoagulant effects of warfarin may be enhanced by displacement from plasma proteins by simultaneous valproic acid therapy (Guthrie et al., 1995).

**Interaction of Metabolism.** A drug can frequently influence the metabolism of one or several other drugs (Chapter 6), and this is especially notable within hepatic CYPs. Acetaminophen is partially transformed by CYP2E1 to the toxic metabolite NAPQI (Figure 4–5). Intake of ethanol, a potent inducer of the 2E1 isoenzyme, may lead to increased susceptibility to acetaminophen poisoning after overdose (Dart et al., 2006). Similarly, a number of second-generation piperidine antihistamines (terfenadine, astemizole) were removed from the market when they were noted to lead to QT interval prolongation and tachydysrhythmias when co-administered with macrolide antibiotics.

**Interaction of Receptor Binding.** Buprenorphine is an opioid with partial agonist and antagonist receptor activities. It can be used as an analgesic but is more commonly used to treat opioid addiction. The drug binds opioid receptors with high affinity, and can prevent euphoria from concomitant use of narcotic drugs of abuse.

**Interaction of Therapeutic Action.** Aspirin is an inhibitor of platelet aggregation and heparin is an anticoagulant; given together they may increase risk for bleeding. Sulfonylureas cause hypoglycemia by stimulating pancreatic insulin release, whereas biguanide drugs (metformin) lead to decreased hepatic glucose production, and these drugs can be used together to control diabetic hyperglycemia.

A drug interaction is said to be *additive* when the combined effect of two drugs equals the sum of the effect of each agent given alone. A *synergistic* effect is one in which the combined effect exceeds the sum of the effects of each drug given alone. *Potentiation* describes the creation of a toxic effect from one drug due to the presence of another drug. *Antagonism* is the interference of one drug with the action of another. Drug antagonism may confer a therapeutic advantage when one drug is to be used as an antidote for the toxicity of another drug. *Functional* or physiological

![Figure 4–6. Mechanisms and classification of drug interactions.](image-url)
antagonism occurs when two chemicals produce opposite effects on the same physiological function; this is the basis for most supportive care provided to patients treated for drug overdose poisoning. **Chemical antagonism, or inactivation,** is a reaction between two chemicals to neutralize their effects, such as is seen with chelation therapy. **Dispositional antagonism** is the alteration of the disposition of a substance (its absorption, biotransformation, distribution, or excretion) so that less of the agent reaches the target organ or its persistence in the target organ is reduced. **Receptor antagonism** entails the blockade of the effect of a drug with another drug that competes at the receptor site.

### DESCRIPTIVE TOXICITY TESTING IN ANIMALS

Two main principles underlie all descriptive toxicity tests performed in animals. First, those effects of chemicals produced in laboratory animals, when properly qualified, apply to human toxicity. When calculated on the basis of dose per unit of body surface, toxic effects in human beings usually are encountered in the same range of concentrations as those in experimental animals. On the basis of body weight, human beings generally are more vulnerable than experimental animals. Such information is used to select dosages for clinical trials of candidate therapeutic agents and to attempt to set limits on permissible exposure to environmental toxicants.

Second, exposure of experimental animals to toxic agents in high doses is a necessary and valid method to discover possible hazards to human beings who are exposed to much lower doses. This principle is based on the quantal dose-response concept. As a matter of practicality, the number of animals used in experiments on toxic materials usually will be small compared with the size of human populations potentially at risk. For example, 0.01% incidence of a serious toxic effect (such as cancer) represents 25,000 people in a population of 250 million. Such an incidence is unacceptably high. Yet, detecting an incidence of 0.01% experimentally probably would require a minimum of 30,000 animals. To estimate risk at low dosage, large doses must be given to relatively small groups. The validity of the necessary extrapolation is clearly a crucial question.

Chemicals are first tested for toxicity by estimation of the LD₅₀ in two animal species by two routes of administration; one of these is the expected route of exposure of human beings to the chemical being tested. The number of animals that die in a 14-day period after a single dose is recorded. The animals also are examined for signs of intoxication, lethargy, behavioral modification, and morbidity. The chemical is next tested for toxicity by repeat exposure, usually for 90 days. This study is performed most often in two species by the route of intended use or exposure with at least three doses. A number of parameters are monitored during this period, and at the end of the study, organs and tissues are examined by a pathologist.

Long-term or chronic studies are carried out in animals at the same time that clinical trials are undertaken. For drugs, the length of exposure depends somewhat on the intended clinical use. If the drug normally would be used for short periods under medical supervision, as would an antimicrobial agent, a chronic exposure of animals for 6 months might suffice. If the drug would be used in human beings for longer periods, a study of chronic use for 2 years may be required.

Studies of chronic exposure often are used to determine the carcinogenic potential of chemicals. These studies usually are performed in rats and mice for the average lifetime of the species. Other tests are designed to evaluate teratogenicity (congenital malformations), perinatal and postnatal toxicity, and effects on fertility. Teratogenicity studies usually are performed by administering drugs to pregnant rats and rabbits during the period of organogenesis. **As noted in Chapter 6, in silico** computational methods of chemical biology systems may soon contribute to such studies.

### TOXICOLOGY, SAFETY TESTING, AND CLINICAL TRIALS

Fewer than one-third of the drugs tested in clinical trials reach the marketplace. Federal law in the U.S. and ethical considerations require that the study of new drugs in humans be conducted in accordance with stringent guidelines. Such studies apply the principles of toxicology mentioned earlier.

Once a drug is judged ready to be studied in humans, a **Notice of Claimed Investigational Exemption for a New Drug (IND)** must be filed with the FDA. The IND includes: 1) information on the composition and source of the drug; 2) chemical and manufacturing information; 3) all data from animal studies; 4) proposed clinical plans and protocols; 5) the names and credentials of physicians who will conduct the clinical trials; and 6) a compilation of the key data relevant to study the drug in man made available to investigators and their institutional review boards (IRBs).

It often requires 4-6 years of clinical testing to accumulate and analyze all required data. Testing in humans is begun after sufficient acute and subacute animal toxicity studies have been completed. Chronic safety testing in animals, including carcinogenicity studies, is usually done concurrently with clinical trials. In each of the three formal phases of clinical trials, volunteers or patients must be informed of the investigational status of the drug as well as the possible risks and must be allowed to decline or to consent to participate and receive the drug. These regulations are based on the ethical principles set forth in the Declaration of Helsinki. In addition to the approval of the sponsoring organization and the FDA, an interdisciplinary IRB at the facility where the clinical drug trial will be conducted must review and approve the scientific and ethical plans for testing in humans.
In phase 1, the effects of the drug as a function of dosage are established in a small number (20–100) of healthy volunteers. Although a goal is to find the maximum tolerated dose, the study is designed to prevent severe toxicity. If the drug is expected to have significant toxicity, as may be the case in cancer and AIDS therapy, volunteer patients with the disease rather than disease-free volunteers are used in phase 1. Phase 1 trials are designed to determine the probable limits of the safe clinical dosage range. These trials may be non-blind or “open”; i.e., both the investigators and the subjects know what is being given. Alternatively, they may be “blinded” and/or placebo-controlled. The choice of design depends on the drug, disease, goals of investigators, and ethical considerations. Many predictable toxicities are detected in this phase. Pharmacokinetic measurements of absorption, $t_{1/2}$, and metabolism are often conducted. Phase 1 studies are usually performed in research centers by clinical pharmacologists.

In phase 2, the drug is studied in patients with the target disease to determine its efficacy ("proof of concept"), and the doses to be used in any follow-on trials. A modest number of patients (100–200) are studied in detail. A single-blind design may be used, with an inert placebo medication and an established active drug (positive control) in addition to the investigational agent. Phase 2 trials are usually done in special clinical centers (e.g., university hospitals). A broader range of toxicities may be detected in this phase. Phase 2 trials have the highest rate of drug failures, and only ~25% of drug candidates move on to phase 3.

In phase 3, the drug is evaluated in much larger numbers of patients with the target disease—usually thousands—to further establish and confirm safety and efficacy. Using information gathered in phases 1 and 2, phase 3 trials are designed to minimize errors caused by placebo effects, variable course of the disease, etc. Therefore, double-blind and crossover techniques are frequently used. Phase 3 trials are usually performed in settings similar to those anticipated for the ultimate use of the drug. Phase 3 studies can be difficult to design and execute and are usually expensive because of the large numbers of patients involved and the amount of data that must be collected and analyzed. The drug is formulated as intended for the market. The investigators are usually specialists in the disease being treated. Certain toxic effects, especially those caused by immunologic processes, may first become apparent in phase 3 trials.

If phase 3 results meet expectations, application is made to the FDA for permission to market the new agent. Marketing approval requires submission of a New Drug Application (NDA) (or for biologics, a Biological License Application [BLA]) to the FDA. Note that even at this point in the process, experience with the new drug is limited to information gathered from a few thousand patients. Thus, post-marketing surveillance is crucial in determining the actual toxicity of the drug as it is administered to a much larger population in which low-frequency adverse reactions will be noticeable.

### Epidemiology of Adverse Drug Responses and Pharmaceutical Poisoning

Poisoning can occur in many ways following both therapeutic and nontherapeutic drug or chemical exposures (Table 4–2). The incidence of serious and fatal adverse drug reactions in U.S. hospitals is extremely high (Institute of Medicine, 1999; Lazarou et al., 1998). It is estimated that ~2 million hospitalized patients have serious adverse drug reactions each year, and ~100,000 have fatal adverse drug reactions. Use of good principles of prescribing, as described in Appendix I and Table 4–6, can aid in avoiding such adverse outcomes.

Some toxicities of pharmaceuticals can be predicted based upon their known pharmacological mechanism; however, it is often not until the post-marketing period that the therapeutic toxicity profile of a drug becomes fully appreciated. In the U.S., the approval system for new drugs typically uses only 500 to 3000 exposed subjects. Such a system is likely to identify toxicities occurring in 1% or more of patients receiving a drug (Strom, 2004). The Adverse Event Reporting System of the FDA relies upon two signals to detect rarer adverse drug events. First, the FDA requires (Code of Federal Regulations, Title 21, Volume 5, Section 314.80) drug manufacturers to perform post-marketing surveillance of prescription drugs, and similar regulations exist for nonprescription products. Second, the FDA operates a voluntary reporting system (MedWatch, online at http://www.fda.gov/Safety/MedWatch/default.htm) available to both health professionals and consumers. Hospitals may also support adverse drug event committees to investigate potential adverse drug events, and these investigations may be made available to industry and the government. Unfortunately, any national dataset will significantly underestimate the morbidity and mortality attributable to adverse drug events because of under-reporting and because it is difficult to estimate the denominator of total patient exposures for each event reported once a drug is available on the open market.

As an example, post-marketing surveillance identified the toxicity associated with the serotonin receptor-modulating drug cisapride. This drug was known to enhance GI motility and was marketed in the U.S. as a treatment for gastroesophageal reflux. Post-marketing surveillance revealed that cisapride was associated with prolongation of the QT interval and predisposition to ventricular

arrhythmia. It was withdrawn from the market, and subsequent case-control studies demonstrated increased risk of arrhythmia (Hennessy et al., 2008). Cisapride is now limited in its distribution through an investigational access program managed by the manufacturer. In another instance, selective serotonin reuptake inhibitors (SSRIs, Chapter 15) are believed to be safer than monoamine oxidase inhibitors and tricyclic antidepressants, and are popularly prescribed for treatment of depression; however, current post-marketing studies are looking to see if the use of SSRIs may predispose adolescent and young adult patients to suicidality (Barbui et al., 2009). Thus, the determination of drug toxicity carries beyond the stages of drug development.

Therapeutic drug toxicity is only a subset of poisoning, as noted in Table 4–2. Misuse and abuse of both prescription and illicit drugs is a major public health problem. The incidence of unintentional, noniatrogenic poisoning is bimodal, primarily affecting exploratory young children, ages 1-5 years, and the elderly. *Intentional* overdose with pharmaceuticals is most common in adolescence and through adulthood. Fifty-one percent of poison exposures reported to the American Association of Poison Control Centers (AAPCC) involve children ≤5 years, but this group accounts for <3% of reported fatalities, demonstrating that intentional poisonings are inherently more dangerous than exploratory or inadvertent exposures (Bronstein et al., 2008).

Exact quantification of nontherapeutic poisoning occurrences remains elusive. The National Institute of Drug Abuse (NIDA) commissioned the University of Michigan to perform the “Monitoring the Future” survey of U.S. high school children regarding drug use patterns (NIDA, 2009). In 2008, 47% of surveyed high school seniors reported that they had previously used an illicit drug. Among pharmaceutical abuse, 13% reported having abused a non-heroin narcotic, 10% an amphetamine drug, 8.9% a benzodiazepine, antidepressant, or antipsychotic medicine, and 8.5% a barbiturate. NIDA also monitors emergency department (ED) visits through its Drug Abuse Warning Network (DAWN). In 2006, ~250 ED visits per 100,000 population were related to drug toxicity and 49% of these visits were related to the nonmedical use and abuse of pharmaceutical agents (U.S. DHHS). The top five drugs involved in drug-related deaths reported to DAWN-participating medical examiners’ offices in 2005 are presented in Table 4–3.

The AAPCC (www.aapcc.org) offers a toll-free poisoning information phone hotline throughout the U.S., and has been collecting voluntary reports of potential poison exposures for over 25 years. It currently has over 46 million human exposure case records in its database. In 2007, nearly 2.5 million cases, including 1239 fatal poisonings, were voluntarily reported to the AAPCC’s National Poison Data System (NPDS). Eighty-three percent of human poison exposures reported to the NPDS were unintentional, 13% were intentional, and 2.5% were adverse drug reactions (Bronstein et al., 2008). The substances most frequently involved in human exposures and fatalities are presented in Tables 4–4 and 4–5.

### PREVENTION OF POISONING

**Reduction of Medication Errors.** Over the past decade considerable attention has been given to the reduction of medication errors and adverse drug events (ADEs). Medication errors can occur in any part of the medication prescribing or use process, while ADEs are injuries related to the use or nonuse of medications. It is believed that medication errors are 50-100 times
more common than ADEs (Bates et al., 1995). Some ADEs, such as previously unknown allergies, are unpreventable, but most ADEs can be prevented. Traditionally, the “5 Rights” of safe medication administration have been taught on hospital wards:

Right drug, right patient, right dose, right route, right time.

However, accomplishing a reduction in medication errors involves scrutiny of the systems involved in prescribing, documenting, transcribing, dispensing, administering, and monitoring a therapy, as presented in Appendix I. Good medication use practices have mandatory and redundant checkpoints, such as having a pharmacist, a doctor, and a nurse all review and confirm that an ordered dose of a medication is appropriate for a patient prior to the drug’s administration. In such a system, medication errors occur only when several “holes” in the medication administration safeguards exist and are simultaneously aligned (Figure 4–7). Several practical strategies have been suggested to reduce medication errors within hospitals and other healthcare settings (Table 4–6), and these strategies are being constantly revised.

Poisoning Prevention in the Home. Table 4–2 demonstrates that there are several contexts into which poisoning prevention can be directed. Depression and suicidal ideation need to be identified and treated. Exposure to hazards in the home, outdoor, and work environments need to be reduced to reasonably achievable levels.

Poisoning prevention strategies may be categorized as being passive, requiring no behavior change on the part of the individual, or active, requiring sustained adaptation to be successful. Passive prevention strategies are the most effective, and several types of passive poisoning prevention are described in Table 4–7.

</tbody>
</table>
The incidence of poisoning in children has decreased dramatically over the past four decades. This favorable trend is largely due to improved safety packaging of drugs, drain cleaners, turpentine, and other household chemicals; improved medical training and care; and increased public awareness of potential poisons.

From 1958-1973, aspirin ingestion was a common cause of childhood poisoning death. In 1973, regulations were instituted requiring child-resistant packaging for aspirin consumer products, and this change in packaging was associated with a 34% reduction in the aspirin-related child mortality rate (Rodgers, 2002). In 2007, no aspirin deaths among children aged less than 6 years were reported to the AAPCC (Bronstein et al., 2008). From 1983-1990, iron was the single most frequent cause of unintentional pharmaceutical ingestion fatality in children younger than 6 years, and accounted for almost one-third of such deaths. In 1997, drug products with 30 mg or more of elemental iron per dosage unit were required to be placed into unit-dose packaging. This packaging change was associated with a decrease in mortality (odds ratio of 0.07; 95% confidence interval, 0.52–0.01) (Tenenbein, 2005).

**PRINCIPLES OF TREATMENT OF POISONING**

The majority of poisoning exposures reported to U.S. poison control centers are judged to be nontoxic or only minimally toxic (Bronstein et al., 2008). When toxicity is expected, or does occur, the priority of poisoning treatment is to support vital functions until the drug or chemical is eliminated from the body. Because of the acute onset of action and finite duration of action of most drugs, the treatment of poisoning must be prompt and goal-directed. The first goal is to maintain vital physiological functions from impairment. The second goal is to keep the concentration of poison in tissues as low as possible by preventing absorption and enhancing elimination. The third goal is to combat the toxicological effects of the poison at the effector sites.

**Initial Stabilization of the Poisoned Patient.** The “ABC” mnemonic of emergency care is popularly taught and applies to the treatment of acute poisoning (Table 4–8). In severe cases, endotracheal intubation, mechanical ventilation, pharmacological blood pressure support, and/or extracorporeal circulatory support may be necessary and appropriate.

**Identification of Clinical Patterns of Toxicity.** A carefully obtained medical history may allow for the creation of a list of available medications or chemicals that might be implicated in a poisoning event. Often, an observation of physical symptoms and signs may be the only additional clues to a poisoning diagnosis.

**Groups of physical signs and symptoms associated with specific poisoning syndromes are known as toxidromes** (Erickson, 2007; Osterhoudt, 2004). Table 4–9 describes commonly encountered toxidromes.

The most typically available urine drug toxicology test is an immunoassay designed to detect common drugs of abuse such as amphetamines, barbiturates, benzodiazepines, cannabis, cocaine, and opiates. Acute poisoning with these substances can usually be determined on clinical grounds, and the results of these assays are infrequently available fast enough to guide stabilization. Additionally, detection of drugs or their metabolites on a urine immunoassay does not mean that the detected drug is responsible for the currently observed poisoning illness. When ingestion of acetaminophen or aspirin cannot clearly be excluded via the exposure history, serum quantification of these drugs is recommended. An electrocardiogram (ECG) may be useful at detecting heart blocks, Na+ channel blockade, or K+ channel blockade associated with specific medication classes (Table 4–10). Further laboratory analysis, such as use of blood gas determinations, serum chemistries, complete blood counts, and other testing, should be tailored to the individual poisoning circumstance.

be washed copiously. Gastrointestinal decontamination is the process of preventing or reducing absorption of a substance after it has been ingested. The primary strategies for GI decontamination are gastric emptying, adsorption of poison, and catharsis. Minimal indications for considering GI decontamination include: 1) the poison must be potentially dangerous; 2) the poison must still be unabsorbed in the stomach or intestine, so it must be soon after ingestion; and 3) the procedure must be able to be performed safely and with proper technique. Gastric emptying is rarely recommended anymore, but the administration of activated charcoal and the performance of whole bowel irrigation remain therapeutic options.

Gastric emptying may be attempted by induced vomiting or by gastric lavage. Historically, pharmaceutical methods to stimulate vomiting included administration of potentially toxic doses of copper sulfate or apomorphine; more recently, syrup of ipecac took their place as the favored drug to induce emesis. Gastric emptying has been shown in volunteer studies to reduce drug absorption by ~one-third under optimal conditions (Tenebein, 1987). A randomized trial of gastric emptying for poisoned patients did not show improvement in clinical outcome (Pond et al., 1995), but the selection of subjects and timing of therapy may have biased the study toward the null hypothesis. Based upon review of existing evidence, the American Academy of Pediatrics no longer recommends syrup of ipecac as part of its childhood injury prevention program (AAP, 2003), and the American Academy of Clinical Toxicology dissuades routine use of gastric emptying in the poisoned patient (AACT, 2004; Manoguerra and Cobaugh, 2005). The declining role of syrup of ipecac in the treatment of poisoning is evident by its use in <0.1% of cases reported to the AAPCC in 2007, compared to ~10% in 1987 (Bronstein et al., 2008).

Syrup of Ipecac. The U.S. FDA approved syrup of ipecac for sale without a prescription in 1965. The alkaloids cephaeline and emetine within syrup of ipecac act as emetics because of both a local irritant effect on the enteric tract and a central effect on the chemoreceptor trigger zone in the area postrema of the medulla. Syrup of ipecac is available in 0.5- and 1-fluid ounce containers. Ipecac is given orally at a dose of 15 mL for children up to 12 years, and 30 mL for older children and adults. Administration of ipecac is typically followed by a drink of water, and reliably produces emesis in 15-30 minutes. Contraindications for syrup of ipecac administration include existing or impending CNS depression, ingestion of a corrosive or hydrocarbon drug (due to the emergence of chemical pneumonia), or presence of a medical condition that might be exacerbated by vomiting. Ipecac has been misused by bulimic patients; in cases of Munchausen syndrome by proxy and with chronic abuse, ipecac may cause serum electrolyte abnormalities, cardiomyopathy, ventricular arrhythmia, and death.

Gastric Lavage. The procedure for gastric lavage involves passing an orogastric tube (24-French for small children, up to 40-French for adults) into the stomach with the patient in the left-lateral decubitus position with head lower than feet. Preferably, the tube will have been designed for lavage purposes, and will have sizable side holes in the tubing. After withdrawing stomach contents, 10 to 15 mL/kg (up to 250 mL) of saline lavage fluid is administered and withdrawn. This process continues until the lavage fluid returns clear. Complications of the procedure include mechanical trauma to the stomach or esophagus, pulmonary aspiration of stomach contents, and vagus nerve stimulation.

Adsorption of a poison refers to the binding of a poison to the surface of another substance. An adsorbed poison may be less available for absorption into the body. It is well known that the fullness of the stomach from a meal affects a drug’s absorption kinetics. Fuller’s earth has been suggested as an adsorbent for paraquat, Prussian blue binds thallium and cesium, and sodium polystyrene can adsorb lithium. The most common adsorbent used in the treatment of acute drug overdose is activated charcoal.

Volunteer studies suggest that activated charcoal is more effective at reducing drug absorption than either induced emesis or gastric lavage (Tenebein, 1987). In a position paper of the American Academy of Clinical Toxicology on the use of single-dose activated charcoal, the opinion is given that single-dose charcoal should not be administered routinely in the management of poisoned patients, and that it should only be considered if a patient has ingested a potentially toxic amount of poison up to 1 hour before charcoal administration (AACT, 2005). In 2007, charcoal was used in 4.3% of cases reported to American poison control centers (Bronstein et al., 2008). Clinical evidence of improved patient parameters from treatment with activated charcoal are slowly emerging (Buckley et al., 1999; Isbister et al., 2007; Page et al., 2009), but good outcome data from clinical trials are still lacking.

Activated Charcoal. Charcoal is created through controlled pyrolysis of organic matter. and is activated through steam or chemical treatment that increases its internal pore structure and adsorptive surface capacity. The surface of activated charcoal contains carbon moieties, such as carbonyl and hydroxyl groups, that are capable of binding poisons. The recommended dose is typically 0.5-2 g/kg of body weight, up to a maximum tolerated dose of ~75-100 g. As a rough estimate, 10 g of activated charcoal is expected to bind ~1 g of drug. The efficacy of activated charcoal at adsorbing ingested drug diminishes over time. Alcohols, corrosives, hydrocarbons, and metals are not believed to be well adsorbed by charcoal.

Complications of activated charcoal therapy include vomiting, constipation, pulmonary aspiration, and death. Charcoal slurries are black and gritty; in a series of children offered charcoal in a pediatric emergency department, only 44% of the children <6 years accepted the agent orally (Osterhoudt et al., 2004a). Nasogastric administration of charcoal increases the incidence of vomiting (Osterhoudt et al., 2004b), and may increase the risk for pulmonary aspiration. Charcoal should not be given to patients with suspected GI perforation, or to patients who may be candidates for endoscopy.

Whole Bowel Irrigation. Whole bowel irrigation (WBI) involves the enteral administration of large amounts of a high molecular weight, iso-osmotic polyethylene glycol electrolyte solution with the goal of passing poison by the rectum before it can be absorbed. Potential candidates for WBI include: 1) “body-packers” with intestinal packets of illicit drugs; 2) patients with iron overdose; 3) patients who have ingested patch Pharmaceuticals; and 4) patients with overdoses of sustained-release or bezoar-forming drugs.

Polyethylene glycol electrolyte solution is typically administered at a rate of 25 to 40 mL/kg/h until the rectal effluent is clear and no more drug is being passed. To achieve these high
administration rates a nasogastric tube may be used. Large doses have been administered without adversely affecting serum electrolyte concentrations. WBI is contraindicated in the presence of bowel obstruction or perforation, and may be complicated by abdominal distention or pulmonary aspiration.

**Cathartics.** The two most common categories of simple cathartics are the magnesium salts, such as magnesium citrate and magnesium sulfate, and the nondigestible carbohydrates, such as sorbitol. The use of simple cathartics has been abandoned as a GI decontamination strategy, although sorbitol is sometimes administered with single-dose activated charcoal in an effort to add sweetness and reduce its predilection toward constipation.

**Enhancing the Elimination of Poisons.** Once absorbed, the deleterious toxicodynamic effects of some drugs may be reduced by methods that hasten their elimination from the body. Urinary excretion of some drugs may be enhanced by the process of ion-trapping in alkaline urine. Gastrointestinal excretion of some drugs may be enhanced through use of multiple doses of activated charcoal. Some drugs may be removed from the body by extracorporeal techniques such as peritoneal dialysis, hemodialysis, or hemoperfusion.

**Manipulating Urinary pH: Urinary Alkalinization.** Drugs subject to renal clearance are excreted into the urine by glomerular filtration and active tubular secretion (Chapter 2); non-ionized compounds may be reabsorbed far more rapidly than ionized polar molecules. Weakly acidic drugs are susceptible to “ion-trapping” in the urine. Aspirin is a weak acid with a $\text{pK}_a = 3.0$. As the pH of the urine increases, more salicylate is in its ionized form at equilibrium, and more salicylic acid is diffused into the tubular lumen of the kidney. Urinary alkalinization is also believed to speed clearance of phenobarbital, chlorpropamide, methotrexate, and chlorphenoxy herbicides. The American Academy of Clinical Toxicologists recommends urine alkalinization as first-line treatment only for moderately severe salicylate poisoning that does not meet criteria for hemodialysis (Proudfoot et al., 2004). To achieve alkalinization of the urine, 100-150 mEq of sodium bicarbonate in 1L of D5W is infused intravenously at twice the maintenance fluid requirements and then titrated to effect. Hypokalemia should be treated since it will hamper efforts to alkalinize the urine due to $\text{H}^+ - \text{K}^+$ exchange in the kidney. Urine alkalinization is contraindicated in the presence of renal failure, or when the fluid administration may worsen pulmonary edema or congestive heart failure. Acetazolamide is not used to alkalinize urine as it promotes acidemia.

**Multiple-Dose Activated Charcoal.** Activated charcoal adsorbs drug to its surface and promotes enteral elimination. Multiple doses of activated charcoal can speed elimination of absorbed drug by two mechanisms. Charcoal may interrupt enterohepatic circulation of hepatically metabolized drug excreted in the bile, and charcoal may create a diffusion gradient across the GI mucosa and promote movement of drug from the bloodstream onto the charcoal in the intestinal lumen. Activated charcoal may be administered in multiple doses, 12.5 g/h every 1, 2, or 4 hours (smaller doses may be used for children). Complications of therapy are similar to those listed for single-dose activated charcoal. Charcoal enhances the clearance of many drugs of low molecular weight, small volume of distribution, and long elimination $t_1/2$. In the absence of good clinical outcomes data, multiple-dose activated charcoal is believed to have the most potential utility in overdoses of carbamazepine, dapsone, phenobarbital, quinine, theophylline, and yellow oleaner (AACT, 1999; de Silva et al., 2003).

**Extracorporeal Drug Removal.** The ideal drug amenable to removal by hemodialysis has a low molecular weight, a low volume of distribution, high solubility in water, and minimal protein binding. Hemoperfusion involves passing blood through a cartridge containing adsorbent particles. The most common poisonings for which hemodialysis is sometimes used include salicylate, methanol, ethylene glycol, lithium, carbamazepine, and valproic acid. For a more exhaustive list of drugs amenable to hemodialysis or hemoperfusion, see Winchester (2002).

**Antidotal Therapies.** Antidotal therapy involves antagonism or chemical inactivation of an absorbed poison. The pharmacodynamics of a poison can be altered by competition at a receptor, as in the antagonism provided by naloxone therapy in the setting of heroin overdose. A physiological antidote may use a different cellular mechanism to overcome the effects of a poison, as in the use of glucagon to stimulate an alternative to the blocked $\beta$ adrenergic receptor and increase cellular cyclic AMP in the setting of propranolol overdose. Antivenoms and chelating agents bind and directly inactivate poisons. The biotransformation of a drug can also be altered by an antidote; for instance, fomepizole will inhibit alcohol dehydrogenase and stop the formation of toxic acid metabolites from ethylene glycol and methanol. Many drugs used in the supportive care of a poisoned patient (anticonvulsants, vasoconstricting agents, etc.) may be considered nonspecific functional antidotes.

The mainstay of therapy for poisoning is good support of the airway, breathing, circulation, and vital metabolic processes of the poisoned patient until the poison is eliminated from the body; specific antidotes are uncommonly needed. Among the most common specific antidotes used are $N$-acetyl-$L$-cysteine for acetaminophen poisoning, opioid antagonists for opioid overdose, and chelating agents for poisoning from certain metal ions. A listing of other commonly used antidotes is presented in Table 4–11.

**IMPORTANT RESOURCES FOR INFORMATION RELATED TO DRUG TOXICITY AND POISONING**

Pharmacology textbooks offer important information pertaining to the toxic nature of drugs, but they may lack
discussion of household, industrial, or environmental chemicals, and they may lack detailed discourse of prevention, identification, and treatment of overdose. Additional information on poisoning from drugs and chemicals can be found in many dedicated books of toxicology (Flomenbaum, 2006; Klaassen, 2007; Olson, 2007; Shannon et al., 2007). A popular computer database for information on toxic substances is POISINDEX (Micromedex, Inc., Denver, CO).

The National Library of Medicine offers information on toxicology and environmental health (http://sis.nlm.nih.gov/enviro.html), including a link to ToxNet (http://toxnet.nlm.nih.gov/), a cluster of full-text and bibliographic databases on toxicology, hazardous chemicals, and related areas.

Regional poison control centers are a resource for valuable poisoning information, and can be reached from anywhere within the U.S. through a national PoisonHelp hotline: 1-800-222-1222. Poison centers also collect epidemiological data regarding poisoning, perform all hazards surveillance, provide education, and work collaboratively with other agencies to effect poisoning prevention.

### BIBLIOGRAPHY

Transporters are membrane proteins that are present in all organisms. These proteins control the influx of essential nutrients and ions and the efflux of cellular waste, environmental toxins, drugs, and other xenobiotics. Consistent with their critical roles in cellular homeostasis, ~2000 genes in the human genome, ~7% of the total number of genes, code for transporters or transporter-related proteins. The functions of membrane transporters may be facilitated (equilibrative, not requiring energy) or active (requiring energy). In considering the transport of drugs, pharmacologists generally focus on transporters from two major superfamilies, ABC (ATP binding cassette) and SLC (solute carrier) transporters.

Most ABC proteins are primary active transporters, which rely on ATP hydrolysis to actively pump their substrates across membranes. There are 49 known genes for ABC proteins that can be grouped into seven subclasses or families (ABCA to ABCG) (Borst and Elferink, 2002). Among the best recognized transporters in the ABC superfamily are P-glycoprotein (P-gp, encoded by \( \text{ABCB1} \), also termed \( \text{MDR1} \)) and the cystic fibrosis transmembrane regulator (CFTR, encoded by \( \text{ABCC7} \)).

The SLC superfamily includes genes that encode facilitated transporters and ion-coupled secondary active transporters that reside in various cell membranes. Forty-eight SLC families with ~315 transporters have been identified in the human genome (Hediger, 2004). Many serve as drug targets or in drug absorption and disposition. Widely recognized SLC transporters include the serotonin (5-HT) and dopamine transporters (SERT, encoded by \( \text{SLC6A4} \); DAT, encoded by \( \text{SLC6A3} \)).

Analysis of physical chemical evidence suggests that the involvement of transporters in the passage of drugs across biological membranes may be more the rule than the exception (Dobson and Kell, 2008). Drug-transporting proteins operate in pharmacokinetic and pharmacodynamic pathways, including pathways involved in both therapeutic and adverse effects (Figure 5–1).

**MEMBRANE TRANSPORTERS IN THERAPEUTIC DRUG RESPONSES**

**Pharmacokinetics.** Transporters that are important in pharmacokinetics generally are located in intestinal, renal, and hepatic epithelia, where they function in the selective absorption and elimination of endogenous substances and xenobiotics, including drugs (Ciaramboli, 2008; El-Sheikh et al., 2008; Shitara et al., 2005; Srimaraoeng et al., 2008). Transporters work in concert with drug-metabolizing enzymes to eliminate drugs and their metabolites (Figure 5–2). In addition, transporters in various cell types mediate tissue-specific drug distribution (drug targeting). Conversely, transporters also may serve as protective barriers to particular organs and cell types. Access of solutes to several tissues such as the brain and testes is restricted by a capillary endothelial barrier (e.g., the blood-brain barrier), and the efflux transporters in these barrier endothelia may limit penetration of drugs. For example, P-glycoprotein in the blood-brain barrier protects the central nervous system (CNS) from a variety of structurally diverse drugs through its efflux mechanisms. Many of the transporters that are relevant to drug response control the tissue distribution as well as the absorption and elimination of drugs.

**Pharmacodynamics: Transporters as Drug Targets.** Membrane transporters are the targets of many clinically used drugs. For example, neurotransmitter
transporters are the targets for drugs used in the treatment of neuropsychiatric disorders (Murphy et al., 2004; Torres and Amara, 2007). SERT (SLC6A4) is a target for a major class of antidepressant drugs, the selective serotonin reuptake inhibitors (SSRIs). Other neurotransmitter reuptake transporters serve as drug targets for the tricyclic antidepressants, various amphetamines (including amphetamine-like drugs used in the treatment of attention deficit disorder in children), and anticonvulsants (Elliott and Beveridge,
Drug Resistance. Membrane transporters play critical roles in the development of resistance to anticancer drugs, antiviral agents, and anticonvulsants. Drug resistance, particularly to cytotoxic drugs, generally occurs by multiple mechanisms, two of which involve membrane transporters. Decreased uptake of drugs such as folate antagonists, nucleoside analogs, and platinum complexes, is mediated by reduced expression of influx transporters required for these drugs to access the tumor. Enhanced efflux of hydrophobic drugs is one of the most frequently encountered mechanisms of antitumor resistance in cellular assays of resistance. For example, P-glycoprotein is overexpressed in tumor cells after exposure to cytotoxic anticancer agents (Lin and Yamazaki, 2003; Leslie et al., 2005; Szakacs et al., 2006). P-glycoprotein pumps out the anticancer drugs, rendering cells resistant to their cytotoxic effects. Other efflux transporters, including breast cancer resistance protein (BCRP), and multidrug resistance-associated proteins (MRPs), also have been implicated in resistance to anticancer drugs (Clarke et al., 2002; Toyoda et al., 2008). The over-expression of multidrug resistance protein 4 (MRP4) is associated with resistance to antiviral nucleoside analogs (Imaoka et al., 2006; Schuetz et al., 1999).

MEMBRANE TRANSPORTERS AND ADVERSE DRUG RESPONSES

Through import and export mechanisms, transporters ultimately control the exposure of cells to chemical carcinogens, environmental toxins, and drugs. Thus, transporters play crucial roles in the cellular toxicities of these agents. Transporter-mediated adverse drug responses generally can be classified into three categories (Figure 5–3).

Transporters expressed in the liver and kidney, as well as metabolic enzymes, are key determinants of drug exposure in the circulating blood, thereby affecting exposure, and hence toxicity, in all organs (Figure 5–3, top panel) (Mizuno et al., 2003). For example, after oral administration of an HMG-CoA reductase inhibitor (e.g., pravastatin), the efficient first-pass hepatic uptake of the drug by the organic anion-transporting polypeptide OATP1B1 maximizes the effects of such drugs on hepatic HMG-CoA reductase. Uptake by OATP1B1 also minimizes the escape of these drugs into the systemic circulation, where they can cause adverse responses such as skeletal muscle myopathy.

Tumor resistance in cellular assays of resistance. For example, P-glycoprotein is overexpressed in tumor cells after exposure to cytotoxic anticancer agents (Lin and Yamazaki, 2003; Leslie et al., 2005; Szakacs et al., 2006). P-glycoprotein pumps out the anticancer drugs, rendering cells resistant to their cytotoxic effects. Other efflux transporters, including breast cancer resistance protein (BCRP), and multidrug resistance-associated proteins (MRPs), also have been implicated in resistance to anticancer drugs (Clarke et al., 2002; Toyoda et al., 2008). The over-expression of multidrug resistance protein 4 (MRP4) is associated with resistance to antiviral nucleoside analogs (Imaoka et al., 2006; Schuetz et al., 1999).

MEMBRANE TRANSPORTERS AND ADVERSE DRUG RESPONSES

Through import and export mechanisms, transporters ultimately control the exposure of cells to chemical carcinogens, environmental toxins, and drugs. Thus, transporters play crucial roles in the cellular toxicities of these agents. Transporter-mediated adverse drug responses generally can be classified into three categories (Figure 5–3).

Transporters expressed in the liver and kidney, as well as metabolic enzymes, are key determinants of drug exposure in the circulating blood, thereby affecting exposure, and hence toxicity, in all organs (Figure 5–3, top panel) (Mizuno et al., 2003). For example, after oral administration of an HMG-CoA reductase inhibitor (e.g., pravastatin), the efficient first-pass hepatic uptake of the drug by the organic anion-transporting polypeptide OATP1B1 maximizes the effects of such drugs on hepatic HMG-CoA reductase. Uptake by OATP1B1 also minimizes the escape of these drugs into the systemic circulation, where they can cause adverse responses such as skeletal muscle myopathy.

Transporters in toxicological target organs or at barriers to such organs affect exposure of the target organs to drugs. Transporters expressed in tissues that may be targets for drug toxicity (e.g., brain) or in barriers to such tissues (e.g., the blood-brain barrier [BBB]) can tightly control local drug concentrations and thus control the exposure of these tissues to the drug (Figure 5–3, middle panel). For example, to restrict the penetration of compounds into the brain, endothelial cells in the BBB are closely linked by tight junctions, and some efflux transporters are expressed on the blood-facing (luminal) side. The importance of the ABC transporter multidrug resistance protein (ABCB1; MDR1; P-glycoprotein, P-gp) in the BBB has been demonstrated in mdr1a knockout mice (Schinkel et al., 1994). The brain concentrations of many P-glycoprotein substrates, such as digoxin, used in the treatment of heart failure (Chapter 28), and cyclosporin A (Chapter 35), an immunosuppressant, are increased dramatically in mdr1a(--/-) mice, whereas their plasma concentrations are not changed significantly.

Another example of transporter control of drug exposure can be seen in the interactions of loperamide and quinidine. Loperamide is a peripheral opioid used in the treatment of diarrhea and is a substrate of P-glycoprotein. Co-administration of loperamide and the potent P-glycoprotein inhibitor quinidine results in significant respiratory depression, an adverse response to the loperamide (Sadeghi et al., 2000). Because plasma concentrations of loperamide are not changed in the presence of quinidine, it has been suggested that quinidine inhibits P-glycoprotein in the BBB, resulting in an increased exposure of the CNS to loperamide and bringing about the respiratory depression. Inhibition of P-glycoprotein-mediated efflux in the BBB thus would cause an increase in the concentration of substrates in the CNS and potentiate adverse effects.

The case of oseltamivir (the antiviral drug TAMIFLU) provides an example that dysfunction of an active barrier may cause a CNS effect. Abnormal behavior appears to be a rare adverse reaction of oseltamivir. Oseltamivir and its active form, Ro64-0802, undergo active efflux across the BBB by P-glycoprotein, organic anion transporter 3 (OAT3), and multidrug resistance-associated protein 4 (MRP4) (Ose et al., 2009). Decreased activities of these transporters at the BBB caused by concomitant drugs, ontagenetic and genetic factors, or disease may enhance the CNS exposure to oseltamivir and Ro64-0802, contributing to an adverse effect on the CNS.

Drug-induced toxicity sometimes is caused by the concentrative tissue distribution mediated by influx transporters. For example, biguanides (e.g., metformin and phenformin), widely used as oral
h hypoglycemic agents for the treatment of type II diabetes mellitus, can produce lactic acidosis, a lethal side effect. Phenformin was withdrawn from the market for this reason. Biguanides are substrates of the organic cation transporter OCT1, which is highly expressed in the liver. After oral administration of metformin, the distribution of the drug to the liver in oct1(−/−) mice is markedly reduced compared with the distribution in wild-type mice. Moreover, plasma lactic acid concentrations induced by metformin are reduced in oct1(−/−) mice.

Figure 5–3. Major mechanisms by which transporters mediate adverse drug responses. Three cases are given. The left panel of each case provides a cartoon representation of the mechanism; the right panel shows the resulting effect on drug levels. (Top panel) Increase in the plasma concentrations of drug due to a decrease in the uptake and/or secretion in clearance organs such as the liver and kidney. (Middle panel) Increase in the concentration of drug in toxicological target organs due either to the enhanced uptake or to reduced efflux of the drug. (Bottom panel) Increase in the plasma concentration of an endogenous compound (e.g., a bile acid) due to a drug’s inhibiting the influx of the endogenous compound in its eliminating or target organ. The diagram also may represent an increase in the concentration of the endogenous compound in the target organ owing to drug-inhibited efflux of the endogenous compound.
compared with wild-type mice, although the plasma concentrations of metformin are similar in the wild-type and knockout mice. These results indicate that the OCT1-mediated hepatic uptake of biguanides plays an important role in lactic acidosis (Wang et al., 2003).

The organic anion transporter 1 (OAT1) and organic cation transporters (OCT1 and OCT2) provide other examples of transporter-related toxicity. OCT1 is expressed mainly in the kidney and is responsible for the renal tubular secretion of anionic compounds. Substrates of OAT1, such as cephaloridine (a β-lactam antibiotic), and adefovir and cidofovir (antiviral drugs), reportedly cause nephrotoxicity. In vitro experiments suggest that cephaloridine, adefovir, and cidofovir are substrates of OAT1 and that OAT1-expressing cells are more susceptible to the toxicity of these drugs than control cells (Ho et al., 2000; Takeda et al., 1999). Exogenous expression of OCT1 and OCT2 enhances the sensitivities of tumor cells to the cytotoxic effect of oxaliplatin for OCT1, and cisplatin and oxaliplatin for OCT2 (Zhang et al., 2006b).

Drugs may modulate transporters for endogenous ligands and thereby exert adverse effects (Figure 5–3, bottom panel). For example, bile acids are taken up mainly by the bile salt export pump (BSEP, ABCB11) (Gerloff et al., 1998). Bilirubin is taken up by OATP1B1 and conjugated with glucuronic acid, and bilirubin glucuronide is excreted by the multidrug resistance-associated protein (MRP2, ABCC2). Inhibition of these transporters by drugs may cause cholestasis or hyperbilirubinemia. Troglitazone, a thiazolidinedione insulin-sensitizing drug used for the treatment of type II diabetes mellitus, was withdrawn from the market because it caused hepatotoxicity. The mechanism for this troglitazone-induced hepatotoxicity remains unclear. One hypothesis is that troglitazone and its sulfate conjugate induced cholestasis. Troglitazone sulfate potently inhibits the efflux of taurocholate (Ki ≈ 0.2 μM) mediated by the ABC transporter BSEP. These findings suggest that troglitazone sulfate induces cholestasis by inhibition of BSEP function. BSEP-mediated transport is also inhibited by other drugs, including cyclosporin A and the antibiotics rifampicin (Stieger et al., 2000).

Thus, uptake and efflux transporters determine the plasma and tissue concentrations of endogenous compounds and xenobiotics, and thereby can influence the systemic or site-specific toxicity of drugs.

BASIC MECHANISMS OF MEMBRANE TRANSPORT

Transporters Versus Channels. Both channels and transporters facilitate the membrane permeation of inorganic ions and organic compounds (Reuss, 2000). In general, channels have two primary states, open and closed, that are totally stochastic phenomena. Only in the open state do channels appear to act as pores for the selected ions, allowing their permeation across the plasma membrane. After opening, channels return to the closed state as a function of time. In contrast, a transporter forms an intermediate complex with the substrate (solute), and subsequently a conformational change in the transporter induces translocation of the substrates to the other side of the membrane. Therefore, there is a marked difference in turnover rates between channels and transporters. The turnover rate constants of typical channels are 10⁶ to 10⁷ s⁻¹, whereas those of transporters are, at most, 10¹ to 10³ s⁻¹. Because a particular transporter forms intermediate complexes with specific compounds (referred to as substrates), transporter-mediated membrane transport is characterized by saturability and inhibition by substrate analogs, as described in “Kinetics of Transport.”

The basic mechanisms involved in solute transport across biological membranes include passive diffusion, facilitated diffusion, and active transport. Active transport can be further subdivided into primary and secondary active transport. These mechanisms are depicted in Figure 5–4 and described in the next sections.

Passive Diffusion. Simple diffusion of a solute across the plasma membrane consists of three processes: partition from the aqueous to the lipid phase, diffusion across the lipid bilayer, and repartition into the aqueous phase on the opposite side. Diffusion of any solute (including drugs) occurs down an electrochemical potential gradient of the solute.

Such diffusion may be described by the equation:

\[ \Delta \mu = zEF + RT \ln \left( \frac{C_i}{C_o} \right) \]  
(Equation 5–1)

where \( \Delta \mu \) is the potential gradient, \( z \) is the charge valence of the solute, \( E_m \) is the membrane voltage, \( F \) is the Faraday constant, \( R \) is the gas constant, \( T \) is the absolute temperature, \( C \) is the concentration of the solute inside (\( i \)) and outside (\( o \)) of the plasma membrane. The first term on the right side in Equation (5–1) represents the electrical potential, and the second represents the chemical potential.

For non-ionized compounds, the flux \( J \) owing to simple diffusion is given by Fick’s first law (permeability multiplied by the concentration difference). For ionized compounds, the difference in electrical potential across the plasma membrane needs to be taken into consideration. Assuming that the electrical field is constant, the flux is given by the Goldman-Hodgkin-Katz equation:

\[ J = -P \frac{zE_m F}{RT} \left[ C_i - C_o \exp \left( \frac{E_m F}{RT} \right) \right] \left[ 1 - \exp \left( \frac{-E_m F}{RT} \right) \right] \]  
(Equation 5–2)

where \( P \) represents the permeability. The lipid and water solubility and the molecular weight and shape of the solute are determinants of
the flux in passive diffusion; they are incorporated in the permeability constant $P$. The permeability constant positively correlates with the lipophilicity, determined by the partition between water and organic solvents, such as octanol, and is also related to the inverse of the square root of the molecular weight of the solute. At steady state, the electrochemical potentials of all compounds become equal across the plasma membrane. In the case of non-ionized compounds, the steady-state concentrations are equal across the plasma membrane. For ionized compounds, however, the steady-state concentration ratio across the plasma membrane is affected by the membrane voltage and given by the Nernst equation:

$$\frac{C_i}{C_o} = \exp \left( \frac{-zE_m F}{RT} \right) \quad \text{(Equation 5–3)}$$

The membrane voltage is maintained by the ion gradients across the membrane.

**Facilitated Diffusion.** Diffusion of ions and organic compounds across the plasma membrane may be facilitated by a membrane transporter. Facilitated diffusion is a form of transporter-mediated membrane transport that does not require energy input. Just as in passive diffusion, the transport of ionized and non-ionized compounds across the plasma membrane occurs down their electrochemical potential gradient. Therefore, steady state will be achieved when the electrochemical potentials of the compound on both sides of the membrane become equal.

**Active Transport.** Active transport is the form of membrane transport that requires the input of energy. It is the transport of solutes against their electrochemical gradients, leading to the concentration of solutes on one side of the plasma membrane and the creation of potential energy in the electrochemical gradient formed. Active transport plays an important role in the uptake and efflux of drugs and other solutes. Depending on the driving force, active transport can be subdivided into primary and secondary active transport (Figure 5–4).

**Primary Active Transport.** Membrane transport that directly couples with ATP hydrolysis is called primary active transport. ABC transporters are examples of primary active transporters. They contain one or two ATP-binding cassettes that are highly conserved domains in the intracellular loop region and exhibit ATPase activity. In mammalian cells, ABC transporters mediate the unidirectional efflux of solutes across biological membranes. The molecular mechanism by which ATP hydrolysis is coupled to the active transport of substrates by ABC transporters is a subject of current investigation.

**Secondary Active Transport.** In secondary active transport, the transport across a biological membrane of one solute $S_1$ against its concentration gradient is energetically driven by the transport of another solute $S_2$ in

---

*Figure 5–4. Classification of membrane transport mechanisms. Red circles depict the substrate. Size of the circles is proportional to the concentration of the substrate. Arrows show the direction of flux. Black squares represent the ion that supplies the driving force for transport (size is proportional to the concentration of the ion). Blue ovals depict transport proteins.*
accordance with its concentration gradient. The driving force for this type of transport therefore is stored in the electrochemical potential created by the concentration difference of \( S_2 \) across the plasma membrane. For example, an inwardly directed Na\(^+\) concentration gradient across the plasma membrane is created by Na\(^+\), K\(^+\)-ATPase. Under these conditions, inward movement of Na\(^+\) produces the energy to drive the movement of a substrate \( S_1 \) against its concentration gradient by a secondary active transporter as in Na\(^+\)/Ca\(^{2+}\) exchange.

Depending on the transport direction of the solute, secondary active transporters are classified as either symporters or antiporters. Symporters, also termed co-transporters, transport \( S_2 \) and \( S_1 \) in the same direction, whereas antiporters, also termed exchangers, move their substrates in opposite directions (Figure 5–4). The free energy produced by one extracellular sodium ion (Na\(^+\)) is given by the difference in the electrochemical potential across the plasma membrane:

\[
\Delta \mu_{Na} = E_m F + RT \ln \left( \frac{C_{Na,i}}{C_{Na,o}} \right) \quad \text{(Equation 5–4)}
\]

The electrochemical potential of a non-ionized compound \( \Delta \mu_s \) acquired from one extracellular Na\(^+\) is less than this value:

\[
\Delta \mu_s + \Delta \mu_{Na} \leq 0 \quad \text{(Equation 5–5)}
\]

Therefore, the concentration ratio of the compound is given by the following equation:

\[
\frac{S_i}{S_o} \leq \left( \frac{C_{Na,o}}{C_{Na,i}} \right) \exp \left( \frac{-E_m F}{RT} \right) \quad \text{(Equation 5–6)}
\]

Involvement of multiple transporters with different \( K_m \) values gives an Eadie-Hofstee plot that is curved. In algebraic terms, the Eadie-Hofstee plot of kinetic data is equivalent to the Scatchard plot of equilibrium binding data. Transporter-mediated membrane transport of a substrate is also characterized by inhibition by other compounds. The manner of inhibition can be categorized as one of three types: competitive, noncompetitive, and uncompetitive.

**Competitive** inhibition occurs when substrates and inhibitors share a common binding site on the transporter, resulting in an increase in the apparent \( K_m \) value in the presence of inhibitor. The flux of a substrate in the presence of a competitive inhibitor is

\[
v = \frac{V_{max} C}{K_m (1 + I / K_i)} + C \quad \text{(Equation 5–10)}
\]

where \( I \) is the concentration of inhibitor, and \( K_i \) is the inhibition constant.
Noncompetitive inhibition assumes that the inhibitor has an allosteric effect on the transporter, does not inhibit the formation of an intermediate complex of substrate and transporter, but does inhibit the subsequent translocation process.

\[ v = \frac{V_{\text{max}}}{(1 + I / K_i) + C} \]  

(Equation 5–11)

Uncompetitive inhibition assumes that inhibitors can form a complex only with an intermediate complex of the substrate and transporter and inhibit subsequent translocation.

\[ v = \frac{V_{\text{max}}}{(1 + I / K_i) + C} \]  

(Equation 5–12)

VECTORIAL TRANSPORT

Asymmetrical transport across a monolayer of polarized cells, such as the epithelial and endothelial cells of brain capillaries, is called vectorial transport (Figure 5–5). Vectorial transport is important in the efficient transfer of solutes across epithelial or endothelial barriers. For example, vectorial transport is important for the absorption of nutrients and bile acids in the intestine. From the viewpoint of drug absorption and disposition, vectorial transport plays a major role in hepatobiliary and urinary excretion of drugs from the blood to the lumen and in the intestinal absorption of drugs. In addition, efflux of drugs from the brain via brain endothelial cells and brain choroid plexus epithelial cells involves vectorial transport. The ABC transporters mediate only unidirectional efflux, whereas SLC transporters mediate either drug uptake or efflux.

For lipophilic compounds that have sufficient membrane permeability, ABC transporters alone are able to achieve vectorial transport without the help of influx transporters (Horio et al., 1990). For relatively hydrophilic organic anions and cations, coordinated uptake and efflux transporters in the polarized plasma membranes are necessary to achieve the vectorial movement of solutes across an epithelium. Common substrates of coordinated transporters are transferred efficiently across the epithelial barrier (Cui et al., 2001; Sasaki et al., 2002).

In the liver, a number of transporters with different substrate specificities are localized on the sinusoidal membrane (facing blood). These transporters are involved in the uptake of bile acids, amphipathic organic anions, and hydrophilic organic cations into the hepatocytes. Similarly, ABC transporters on the canalicular membrane (facing bile) export such compounds into the bile. Multiple combinations of uptake (OATP1B1, OATP1B3, OATP2B1) and efflux transporters (MDR1, MRP2, and BCRP) are involved in the efficient transcellular transport of a wide variety of compounds in the liver by using a model cell system called “doubly transfected cells,” which express both uptake and efflux transporter on each side (Ishiguro et al., 2008; Kopplow et al., 2005; Matsushima et al., 2005). In many cases, overlapping substrate specificities between the uptake transporters (OATP family) and efflux transporters (MRP family) make the vectorial transport of organic anions highly efficient. Similar transport systems also are present in the intestine, renal tubules, and endothelial cells of the brain capillaries (Figure 5–5).

![Figure 5–5. Transepithelial or transendothelial flux. Transepithelial or transendothelial flux of drugs requires distinct transporters at the two surfaces of the epithelial or endothelial barriers. These are depicted diagrammatically for transport across the small intestine (absorption), the kidney and liver (elimination), and the brain capillaries that comprise the blood-brain barrier.](image-url)
Regulation of Transporter Expression. Transporter expression can be regulated transcriptionally in response to drug treatment and pathophysiological conditions, resulting in induction or down-regulation of transporter mRNAs. Recent studies have described important roles of type II nuclear receptors, which form heterodimers with the 9-cis-retinoic acid receptor (RXR), in regulating drug-metabolizing enzymes and transporters (see Table 6–4 and Figure 6–12) (Kullak-Ublick et al., 2004; Wang and LeCluyse, 2003). Such receptors include pregnane X receptor (PXR/NR1I2), constitutive androstane receptor (CAR/NR1I3), farnesoid X receptor (FXR/ NR1H4), PPARα (peroxisome proliferator-activated receptor α), and retinoic acid receptor (RAR). Except for CAR, these are ligand-activated nuclear receptors that, as heterodimers with RXR, bind specific elements in the enhancer regions of target genes. CAR has constitutive transcriptional activity that is antagonized by inverse agonists such as androstenol and androstanol and induced by barbiturates. PXR, also referred to as steroid X receptor (SXR) in humans, is activated by synthetic and endogenous steroids, bile acids, and drugs such as clotrimazole, phenobarbital, rifampicin, sulfipyrazone, ritonavir, carbamazepine, phenytoin, sulfadimidine, paclitaxel, and hyperforin (a constituent of St. John’s wort). Table 5–1 summarizes the effects of drug activation of type II nuclear receptors on expression of transporters. The potency of activators of PXR varies among species such that rodents are not necessarily a model for effects in humans. There is an overlap of substrates between CYP3A4 and P-glycoprotein, and PXR mediates coinduction of CYP3A4 and P-glycoprotein, supporting their synergy in efficient detoxification.

DNA methylation is one of the mechanisms underlying the epigenetic control of gene expression. Reportedly, the tissue-selective expression of transporters is achieved by DNA methylation (silencing in the transporter-negative tissues) as well as by transactivation in the transporter-positive tissues. Transporters subjected to epigenetic control include OAT3, URAT1, OCT2, Oatp1b2, Ntcp, and PEPT2 in the SLC families; and MDR1, BCRP, BSEP, and ABCG5/ABCG8 (Aoki et al., 2008; Imai et al., 2009; Kikuchi et al., 2006; Turner et al., 2006; Uchiumi et al., 1993).

**MOLECULAR STRUCTURES OF TRANSPORTERS**

Predictions of secondary structure of membrane transport proteins based on hydropathy analysis indicate that membrane transporters in the SLC and ABC superfamilies are multi-membrane-spanning proteins. A typical predicted secondary structure of the ABC transporter MRP2 (ABCC2) is shown in Figure 5–6. However, understanding the secondary structure of a membrane transporter provides little information on how the transporter functions to translocate its substrates. For this, information on the tertiary structure of the transporter is needed, along with complementary molecular information about the residues in the transporter that are involved in the recognition, association, and dissociation of its substrates. X-ray diffraction data on representative membrane transporters illustrate some basic structural properties of membrane transporters.

**ABC Transporter Crystal Structures.** To date, four full ABCs have been crystallographically characterized: three are importers and one is an exporter reminiscent of human ABC transporters (Figure 5–7). The importers are the vitamin B$_12$ transporter BtuCD from *E. coli* (Locher et al., 2002), the metal-chelate-type transporter HI1470/1 from *H. influenzae* (Pinkett et al., 2007), and the molybdate/tungstate transporter ModBC from *A. fulgidus* (Hollenstein et al., 2007). The exporter is Sav1866, a multidrug resistance transporter from *S. aureus* (Dawson et al., 2006, 2007). The nucleotide-binding domains (NBDs), which are present in the cytoplasm, are considered the motor domains of ABC transporters and contain conserved motifs (e.g., Walker-A motif, ABC signature motif) that participate in binding and hydrolysis of ATP. Crystal structures of all four full ABC transporters show two NBDs, which are in contact with each other, and a conserved fold. The transmembrane domains of Sav1866 serve as a good model for the basic architecture of human ABC transporters. Note how the transmembrane domains of Sav1866 extend into the cytoplasm and how in the observed crystal structure, the two major bundles are visible at the extracellular surface. The mechanism, shared by these ABC transporters, appears to involve binding of ATP to the NBDs, which subsequently triggers an outward-facing conformation of the transporters. Dissociation of the hydrolysis products of ATP appears to result in an inward-facing conformation. In the case of drug extrusion, when ATP binds, the transporters open to the outside, releasing their substrates to the extracellular media. Upon dissociation of the hydrolysis products, the transporters return to the inward-facing conformation, permitting the binding of ATP and substrate.

**Lactose Permease Symporter (LacY).** Lactose permease is a bacterial transporter that belongs to the major facilitator superfamily (MFS). This transporter is a proton-coupled symporter. A high-resolution X-ray crystal structure has been obtained for the protonated form of a mutant of LacY (C154G) (Abramson et al., 2003) (Figure 5–8). LacY consists of two units of six membrane-spanning α-helices. The crystal structure locates substrate at the interface of the two units and in the middle of the membrane. This location is consistent with an alternating-access transport mechanism in which the substrate recognition site is accessible to the cytosolic and then the extracellular surface but not to both simultaneously (Figure 5–9). Eight helices form the surface of the hydrophilic cavity, and each contains proline and glycine residues that result in kinks in the cavity. From LacY, we now know that, as in the case of MsbA, six membrane-spanning α-helices are critical structural units for transport by LacY.

Sodium Galactose Transporter (vSGLT). vSGLT is a sodium galactose transporter of *Vibrio parahaemolyticus*. vSGLT is a member of the solute sodium symporters (SSS). This bacterial transporter is ~30% homologous to the human SGLT1, an important transporter for the intestinal absorption of sugars. Crystal structure at ~3 Å resolution suggests that like LacY, vSGLT operates as an alternating-access transport mechanism (Faham et al., 2008). However, vSGLT operates as a gated pore rather than a rocker switch mechanism (Figure 5–9) (Kanner, 2008; Karpowich and Wang, 2008). The 12 transmembrane domains consist of two symmetrical halves (six domains each). Galactose and sodium are bound at the center of the membrane at two broken helices, one from each of the symmetrical halves. These broken helices appear to rotate to achieve alternating access of extracellular and intracellular sides. This mechanism, though similar to LacY, involves less molecular dynamic changes than LacY, which operates as a rocker switch. Figure 5–9 shows an alternating access model for SGLT (Karpowich and Wang, 2008).

In this model, a binding pocket faces the extracellular side. The substrate, glucose, is bound to this binding pocket. Movement of a bundle of helices, triggered by binding of glucose and sodium, simultaneously closes the access of the binding pocket to the extracellular face and opens the exit pathway to the intracellular spaces. The model is based on symmetrical arrangement of helices.

**TRANSPORTER SUPERFAMILIES IN THE HUMAN GENOME**

Two major gene superfamilies play critical roles in the transport of drugs across plasma and other biological membranes: the SLC and ABC superfamilies. Web sites that have information on these families include [http://nutrigene.4t.com/humanabc.htm](http://nutrigene.4t.com/humanabc.htm) (ABC superfamily),

The structures show the intracellular nucleotide binding domains (NBDs) along with the transmembrane alpha helices. Structure was reconstructed by Libusha Kelly using the coordinates deposited in the Protein Data Bank (PDB: http://www.rcsb.org/pdb/).
MEMBRANE TRANSPORTERS AND DRUG RESPONSE

CHAPTER 5

Transporters in the SLC superfamily transport diverse ionic and non-ionic endogenous compounds and xenobiotics. SLC superfamily transporters may be facilitated transporters or secondary active symporters or antiporters. The first SLC family transporter was cloned in 1987 by expression cloning in *Xenopus laevis* oocytes (Hediger et al., 1987). Since then, many transporters in the SLC superfamily have been cloned and characterized functionally. Predictive models defining important characteristics of substrate binding and knockout mouse models defining the *in vivo* role of specific transporters have been constructed for many SLC transporters (Chang et al., 2004; Ocheltree et al., 2004).

**ABC Superfamily.** ABC transporters can be divided into seven groups based on their sequence homology: ABCA (12 members), ABCB (11 members), ABCC (13 members), ABCD (4 members), ABCE (1 member), ABCF (3 members), and ABCG (5 members). ABC genes are essential for many cellular processes, and mutations in at least 13 of these genes cause or contribute to human genetic disorders (Table 5–3). In addition to conferring multidrug resistance (Sadee et al., 1995), an important pharmacological aspect of these transporters is xenobiotic export from healthy tissues. In particular, MDR1/ABCB1, MRP2/ABCC2, and BCRP/ABCG2 have been shown to be involved in overall drug disposition (Leslie et al., 2005). ABC transporters including MDR1, BCRP, and MRP4 play pivotal roles in the blood-tissue barriers in the brain, placenta, testis, and retina. Active efflux against concentration gradient in the blood-to-tissue direction on the blood-facing plasma membranes limits the tissue penetration from the blood.

**Gated Pore Mechanism**
- Na$^+$
- Glucose

**Rocker Switch Mechanism**
- Glucose

**Figure 5–9.** *Alternating access models of the transport function of two transporters.* The gated pore represents the model for SGLT in which the rotation of two broken helices facilitates alternating access of substrates to the intracellular and extracellular sides of the plasma membrane. The rocker switch represents the model by which MFS proteins, such as LacY, work. This example models a facilitated glucose transporter, GLUT2.

</table>
In 1976, Juliano and Ling reported that overexpression of a membrane protein in colchicine-resistant Chinese hamster ovary cells also resulted in acquired resistance to many structurally unrelated drugs (i.e., multidrug resistance) (Juliano and Ling, 1976). Since the cDNA cloning of this first mammalian ABC protein (P-glycoprotein/MDR1/ABCB1), knowledge of the ABC superfamily has grown to include 49 genes, each containing one or two conserved ABC regions (Borst and Elferink, 2002). The ABC region is a core catalytic domain of ATP hydrolysis and contains Walker A and B sequences and an ABC transporter-specific signature C sequence (Figure 5–6). The ABC regions of these proteins bind and hydrolyze ATP, and the proteins use the energy for uphill transport of their substrates across the membrane. Although some ABC superfamily transporters contain only a single ABC motif, they form homodimers (BCRP/ABCG2) or heterodimers (ABCG5 and ABCG8) that exhibit a transport function. ABC transporters (e.g., MsbA) (Figure 5–7) also are found in prokaryotes, where they are involved predominantly in the import of essential compounds that cannot be obtained by passive diffusion (sugars, vitamins, metals, etc.). By contrast, most ABC genes in eukaryotes transport compounds from the cytoplasm to the outside or into an intracellular compartment (endoplasmic reticulum, mitochondria, peroxisomes).

### Properties of ABC Transporters Related to Drug Action

The tissue distribution of drug-related ABC transporters in the body is summarized in Table 5–4 together with information about typical substrates.

#### Tissue Distribution of Drug-Related ABC Transporters

MDR1 (ABCB1), MRP2 (ABCC2), and BCRP (ABCG2) are all expressed in the apical side of the intestinal epithelia, where they serve to pump out xenobiotics, including many orally administered drugs. MRP3 (ABCC3) is expressed in the basal side of the epithelial cells.

The kidney and liver are major organs for overall systemic drug elimination from the body. The liver also plays a role in presystemic drug elimination. Key to the vectorial excretion of drugs into

The ATP Binding Cassette (ABC) Superfamily in the Human Genome and Linked Genetic Diseases

Urine or bile, ABC transporters are expressed in the polarized tissues of kidney and liver: MDR1, MRP2, and MRP4 (ABCC4) on the brush-border membrane of renal epithelia; MDR1, MRP2, and BCRP on the bile canicular membrane of hepatocytes; and MRP3 and MRP4 on the sinusoidal membrane of hepatocytes. Some ABC transporters are expressed specifically on the blood side of the endothelial or epithelial cells that form barriers to the free entrance of toxic compounds into tissues: the BBB (MDR1 and MRP4 on the luminal side of brain capillary endothelial cells), the blood-cerebrospinal fluid (CSF) barrier (MRP1 and MRP4 on the basolateral blood side of choroid plexus epithelia), the blood-testis barrier (MRP1 on the basolateral membrane of mouse Sertoli cells and MDR1 in several types of human testicular cells), and the blood-placenta barrier (MDR1, MRP2, and BCRP on the luminal maternal side and MRP1 on the anti-luminal fetal side of placental trophoblasts).

**Substrate Specificity of ABC Transporters.** MDR1/ABCB1 substrates tend to share a hydrophobic planar structure with positively charged or neutral moieties (see Table 5–4 and Ambudkar et al., 1998). These include structurally and pharmacologically unrelated compounds, many of which are also substrates of CYP3A4, a major drug-metabolizing enzyme in the human liver and GI tract. Such overlapping substrate specificity implies a synergistic role for MDR1 and CYP3A4 in protecting the body by reducing the intestinal absorption of xenobiotics (Zhang and Benet, 2001). After being taken up by enterocytes, some drug molecules are metabolized by CYP3A4. Drug molecules that escape metabolic conversion are eliminated from the cells by MDR1 and then reenter the enterocytes. The intestinal residence time of the drug is prolonged with the aid of MDR1, thereby increasing the chance of local metabolic conversion by the CYP3A4 (see Chapter 6).

**MRP/ABCC Family.** The substrates of transporters in the MRP/ABCC family are mostly organic anions. The substrate specificities of MRP1 and MRP2 are similar: both accept glutathione and glucuronide conjugates, sulfated conjugates of bile salts, and non-conjugated organic anions of an amphipathic nature (at least one negative charge and some degree of hydrophobicity). They also transport neutral or cationic anticancer drugs, such as vinca alkaloids and anthracyclines, possibly by means of a cotransport or symport mechanism with reduced glutathione (GSH).

MRP3 also has a substrate specificity that is similar to that of MRP2 but with a lower transport affinity for glutathione conjugates compared with MRP1 and MRP2. Most characteristic MRP3 substrates are monovalent bile salts, which are never transported by MRP1 and MRP2. Because MRP3 is expressed on the sinusoidal side of hepatocytes and is induced under cholestatic conditions, backflux of toxic bile salts and bilirubin glucuronides into the blood circulation is considered to be its physiological function.

Anticancer drugs: etoposide, methotrexate  
Glutathione conjugates: leukotriene C₄, glutathione conjugate of 15-deoxy-delta prostaglandin J2  
Glucuronide conjugates: estradiol-17-β-glucuronide, etoposide glucuronide, morphine-3-glucuronide, morphine-6-glucuronide, acetaminophen glucuronide, hycromone glucuronide, and harmol glucuronide  
Sulfate conjugates of bile salts: taurolithocholate sulfate  
Bile salts: glycocholate, taurocholate  
Others: folate, leucovorin |

| **MRP4** (ABCC4) | Ubiquitous (Kidney, Prostate, Lung, Muscle, Pancreas, Testis, Ovary, Bladder, Gallbladder, BBB, BCSFB) | ? | **Characteristics:** Nucleotide analogs  
**Anticancer drugs:** 6-mercaptopurine, methotrexate  
**Glucuronide conjugates:** estradiol-17-D-glucuronide  
**Sulfate conjugates:** dehydroepiandrosterone sulfate  
**Cyclic nucleotides:** cAMP, cGMP  
**Diuretics:** furosemide, trichlorothiazide  
**Antiviral drugs:** adefovir, tenofovir  
**Antibiotics:** cefazolin, ceftizoxime  
**Others:** folate, leucovorin, taurocholate (with GSH) |
| **MRP5** (ABCC5) | Ubiquitous | ? | **Characteristics:** Nucleotide analogs  
**Anticancer drugs:** 6-mercaptopurine  
**Cyclic nucleotides:** cAMP, cGMP  
**HIV protease inhibitors:** adefovir |
| **MRP6** (ABCC6) | Liver | ? | **Characteristics:** Nucleotide analogs  
**Anticancer drugs:** doxorubicin*, etoposide*  
**Glutathione conjugates:** leukotriene C4  
**Other:** BQ-123 (cyclic peptide) |
| **BCRP** (MXR) (ABCG2) | Liver Kidney | Normal heme metabolism/ transport during maturation of erythrocytes? | **Glucuronide conjugates:** 4-methylumbelliferone glucuronide, estradiol-17-D-glucuronide  
**Sulfate conjugates:** dehydroepiandrosterone sulfate, estrone-3-sulfate  
**Antibiotics:** nitrofurantoin, fluoroquinolones  
**Statins:** pitavastatin, rosuvastatin  
**Others:** cholesterol, estradiol, dantrolene, prazosin, sulfasalazine, phytoestrogens, PhIP, pheophorbide A |
| **MDR3** (ABCB4) | Liver | Excretion of phospholipids into bile | **Characteristics:** Phospholipids |
| **BSEP** (ABCB11) ABCG5 and ABCG8 | Liver Intestine | Excretion of bile salts into bile  
Excretion of plant sterols into bile and intestinal lumen | **Characteristics:** Bile salts  
**Characteristics:** Plant sterols |

Representative substrates and cytotoxic drugs with increased resistance (*) are included in this table (cytotoxicity with increased resistance is usually caused by the decreased accumulation of the drugs). Although MDR3 (ABCB4), BSEP (ABCB11), ABCG5 and ABCG8 are not directly involved in drug disposition, inhibition of these physiologically important ABC transporters will lead to unfavorable side effects. BBB, blood-brain barrier; BTB, blood-testis barrier; BPB, blood-placental barrier; BCSFB, blood-cerebrospinal fluid barrier.

MRP4 accepts negatively charged molecules, including cytotoxic compounds (e.g., 6-mercaptopurine and methotrexate), cyclic nucleotides, antiviral drugs (e.g., adefovir and tenofovir), diuretics (e.g., furosemide and trichlorothiazide), and cephalosporins (e.g., ceftizoxime and cefazolin). Glutathione enables MRP4 to accept taurocholate and leukotriene B4.

MRP5 has a narrower substrate specificity and accepts nucleotide analog and clinically important anti–human immunodeficiency virus (HIV) drugs. Although some transport substrates have been identified for MRP6, no physiologically important endogenous substrates have been identified that explain the mechanism of the MRP6-associated disease, pseudoxanthoma.
BCRP/ABCG2. BCRP accepts both neutral and negatively charged molecules, including cytotoxic compounds (e.g., topotecan, flavopiridol, and methotrexate), sulfated conjugates of therapeutic drugs and hormones (e.g., estrogen sulfate), antibiotics (e.g., nitrofurantoin and fluoroquinolones), statins (e.g., pitavastatin and rosuvastatin), and toxic compounds found in normal food [phytoestrogens, 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) and pheophorbide A, a chlorophyll catabolite].

Physiological Roles of ABC Transporters. The physiological significance of the ABC transporters is illustrated by studies involving knockout animals or patients with genetic defects in these transporters.

Mice deficient in MDR1 function are viable and fertile and do not display obvious phenotypic abnormalities other than hypersensitivity to toxic drugs, including the neurotoxic pesticide ivermectin (100-fold) and the cytotoxic drug vinblastine (3-fold) (Schinkel et al., 1994). Mrp1 (–/–) mice are also viable and fertile without any obvious difference in litter size. However, these mice are hypersensitive to the anticancer drug etoposide. Damage is especially severe in the testis, kidney, and oophorohyalge mucosa, where MRP1 is expressed on the basolateral membrane. Moreover, these mice have an impaired response to an arachidonic acid–induced inflammatory stimulus, which is likely due to a reduced secretion of leukotriene C4, from mast cells, macrophages, and granulocytes. MRP2-deficient rats (TR– and EHBR) and Dubin-Johnson syndrome patients are normal in appearance except for mild jaundice owing to impaired biliary excretion of bilirubin glucuronide (Büchler M et al., 1996; Ito et al., 1997; Paulusma et al., 1996). Mrp4 (–/–) mice are hypersensitive to adefovir and thiopurine. Damage induced by adefovir is especially severe in the bone marrow, thymus, spleen, and intestine, and that by thiopurine is in the myeloid progenitor cells (Belinsky et al., 2007; Krishnamurthy et al., 2008; Takenaka et al., 2007). MRP4 modulates the signal transduction by active efflux of cAMP and cGMP across the plasma membrane. Mrp4 (–/–) mice are sensitive to CFTR-mediated secretory diarrhea (Li et al., 2007), and exhibit an increase in inflammatory pain threshold. In addition, MRP4 is associated with proliferation of smooth muscle through modulation of cAMP/cGMP signaling (Sassi et al., 2008).

BCRP (–/–) mice are viable but highly sensitive to the dietary chlorophyll catabolite phenolphorbide, which induces photosensitivity (Jonker et al., 2002). These mice also exhibit protoporphyria, with a 10-fold increase in protoporphyrin IX accumulation in erythrocytes, resulting in photosensitivity. This protoporphyria is caused by the impaired function of BCRP in bone marrow: knockout mice transplanted with bone marrow from wild-type mice become normal with respect to protoporphyrin IX level in the erythrocytes and photosensitivity.

BSEP has a narrower substrate specificity. It accepts bile acids (Gerloff et al., 1998) and its physiological role is to provide the osmotic driving force for bile flow by biliary excretion of bile acids in an ATP-dependent manner. Hereditary functional defect of this transporter results in the acquisition of progressive familial intrahepatic cholestasis (PFIC2), a fatal liver disease (Strautnieks et al., 1998). In addition, several drugs such as cyclosporin A inhibit the transport function of BSEP at clinically relevant concentrations, thereby causing the disruption of bile formation usually called drug-induced cholestasis (Stieger et al., 2000).

As described earlier, complete absence of these drug-related ABC transporters is not lethal and can remain unrecognized in the absence of exogenous perturbations due to food, drugs, or toxins. Thus, inhibition of physiologically important ABC transporters (especially those related directly to the genetic diseases described in Table 5–3) by drugs should be avoided to reduce the incidence of drug-induced side effects.

ABC Transporters in Drug Absorption and Elimination. With respect to clinical medicine, MDR1 is the most important ABC transporter yet identified, and digoxin is one of the most widely studied of its substrates. The systemic exposure to orally administered digoxin (as assessed by the area under the plasma digoxin concentration–time curve) is decreased by coadministration of rifampin (an MDR1 inducer) and is negatively correlated with the MDR1 protein expression in the human intestine. MDR1 is also expressed on the brush-border membrane of renal epithelia, and its function can be monitored using digoxin as a probe. Digoxin undergoes very little degradation in the liver, and renal excretion is the major elimination pathway (>70%) in humans. Several studies in healthy subjects have been performed with MDR1 inhibitors (e.g., quinidine, verapamil, vasopar, spironolactone, clarklythromycin, and ritonavir) with digoxin as a probe drug, and all resulted in a marked reduction in the renal excretion of digoxin.

The intestinal absorption of cyclosporine is also related mainly to the MDR1 level rather than to the CYP3A4 level, although cyclosporine is a substrate of both CYP3A4 and MDR1. Alteration of MDR1 activity by inhibitors (drug-drug interactions) affects oral absorption and renal clearance. Drugs with narrow therapeutic windows (such as the cardiac glycoside digoxin and the immunosuppressants cyclosporine and tacrolimus) should be used with great care if MDR1-based drug-drug interactions are likely.

Despite the broad substrate specificity and distinct localization of MR2 and BCRP in drug-handling tissues (both are expressed on the canalicular membrane of hepatocytes and the brush-border membrane of enterocytes), there has been little integration of clinically relevant information. Part of the problem lies in distinguishing the biliary transport activities of MR2 and BCRP from the contribution of the hepatic uptake transporters of the OATP family. Most MR2 or BCRP substrates also can be transported by the OATP family transporters on the sinusoidal membrane. The rate-limiting process for systemic elimination is uptake in most cases. Under such conditions, the effect of drug-drug interactions (or genetic variants) in these biliary transporters may be difficult to identify. Despite such practical difficulties, there is a steady increase in the information about genetic variants and their effects on transporter expression and activity in vitro. Variants of BCRP with high allele frequencies (0.184 for V12M and 0.239 for Q141K) have been found to alter the protein expression in cellular assays. One variant is associated with greater oral availability of rosuvastatin and sulfasalazine following oral administration although the impact of the variant on the intestinal absorption and biliary excretion has not been separately evaluated (Yamasaki et al., 2008; Zhang et al., 2006c).

MRP3 is characterized by its localization in the plasma membrane of epithelial cells facing blood (basolateral membrane in the intestine epithelial cells, and sinusoidal membrane in the liver).
In the intestine, MRP3 can mediate the intestinal absorption in conjunction with uptake transporters. MRP3 mediates sinusoidal efflux in the liver, decreasing the efficacy of the biliary excretion from the blood, and excretion of intracellularly formed metabolites, particularly, glucuronide conjugates. Thus, dysfunction of MRP3 results in a shortening of the elimination half-life (Kitamura et al., 2008; Zelcer et al., 2005).

MRP4 substrates also can be transported by the OAT family transporters (OAT1 and OAT3) on the basolateral membrane of the epithelial cells in the kidney. MRP4 is involved in the directional transport in conjunction with OAT1 and/or OAT3 in the kidney (Hasegawa et al., 2007). The rate-limiting process in renal tubular secretion is likely the uptake process at the basolateral surface. Dysfunction of MRP4 enhances the renal concentration, but has limited impact on the blood concentration.

**GENETIC VARIATION IN MEMBRANE TRANSPORTERS: IMPLICATIONS FOR clinICAL DRUG RESPONSE**

Inherited defects in membrane transport have been known for many years, and the genes associated with several inherited disorders of membrane transport have been identified [Tables 5–2 (SLC) and 5–3 (ABC)]. Reports of polymorphisms in membrane transporters that play a role in drug response have appeared only recently, but the field is growing rapidly. Cellular studies have focused on genetic variation in only a few drug transporters, but progress has been made in characterizing the functional impact of variants in these transporters, including characterization of the effects of single-nucleotide polymorphisms (SNPs) (Burman et al., 2004; Gray et al., 2004; Leabman et al., 2003; Osato et al., 2003; Shu et al., 2003; see also Chapter 7).

The clinical impact of membrane transporter variants on drug response has been studied only recently. Clinical studies have focused on a limited number of transporters, relating genetic variation in membrane transporters to drug disposition and response. For example, two common SNPs in *SLCO1B1* (OATP1B1) have been associated with elevated plasma levels of pravastatin, a widely used drug for the treatment of hypercholesterolemia (Mwinyi et al., 2004; Niemi et al., 2004) (see Chapter 31). Recent studies using genome-wide association methods have determined that genetic variants in *SLCO1B1* (OATP1B1) predispose patients to risk for muscle toxicity associated with use of simvastatin (Search Collaborative Group, 2008). Other studies indicate that genetic variants in transporters in the SLC22A family associate with variation in renal clearance and response to various drugs including the anti-diabetic drug, metformin (Shu et al., 2007; Song et al., 2008; Wang et al., 2008). Further genetic variants in MRP2 and MRP4 have been associated with various drug related phenotypes (Han et al., 2007; Kiser et al., 2008; Naesens et al., 2006). Chapter 7 presents a more thorough discussion of the effects of genetic variation in membrane transporters on drug disposition and response.

**TRANSPORTERS INVOLVED IN PHARMACOKINETICS**

Drug transporters play a prominent role in pharmacokinetics (Figure 5–1). Transporters in the liver and kidney have important roles in removal of drugs from the blood and hence in metabolism and excretion.

**Hepatic Transporters**

Hepatic uptake of organic anions (e.g., drugs, leukotrienes, and bilirubin), cations, and bile salts is mediated by SLC-type transporters in the basolateral (sinusoidal) membrane of hepatocytes: OATPs (SLCO) (Abe et al., 1999; Konig et al., 2000) and OATs (SLC22) (Sekine et al., 1998), OCTs (SLC22) (Koepsell, 1998), and NTCP (SLC10A1) (Hagenbuch et al., 1991), respectively. These transporters mediate uptake by either facilitated or secondary active mechanisms.

ABC transporters such as MRP2, MDR1, BCRP, BSEP, and MDR2 in the bile canalicular membrane of hepatocytes mediate the efflux (excretion) of drugs and their metabolites, bile salts, and phospholipids against a steep concentration gradient from liver to bile. This primary active transport is driven by ATP hydrolysis. Moreover, SLC type transporter, MATE1 (SLC47A1), is also located on the canalicular membrane of hepatocytes. As a cation-proton antiporter, it works as an efflux transporter of organic cations, though its role in the biliary excretion of drugs has not been clearly demonstrated so far.

Some ABC transporters are also present in the basolateral membrane of hepatocytes and may play a role in the efflux of drugs back into the blood, although their physiological role remains to be elucidated. Drug uptake followed by metabolism and excretion in the liver is a major determinant of the systemic clearance of many drugs. Since clearance ultimately determines systemic blood levels, transporters in the liver play key roles in setting drug levels.

Vectorial transport of drugs from the circulating blood to the bile using an uptake transporter (OATP family) and an efflux transporter (MRP2) is important
for determining drug exposure in the circulating blood and liver. Moreover, there are many other uptake and efflux transporters in the liver (Figures 5–10 and 5–11). The following examples illustrate the importance of vectorial transport in determining drug exposure in the circulating blood and liver.

**HMG-CoA Reductase Inhibitors.** Statins are cholesterol-lowering agents that reversibly inhibit HMG-CoA reductase, which catalyzes a rate-limiting step in cholesterol biosynthesis (see Chapter 31). Statins affect serum cholesterol by inhibiting cholesterol biosynthesis in the liver, and this organ is their main target. On the other hand, exposure of extrahepatic cells in smooth muscle to these drugs may cause adverse effects. Among the statins, pravastatin, fluvastatin, cerivastatin, atorvastatin, rosuvastatin, and pitavastatin are given in a biologically active open-acid form, whereas simvastatin and lovastatin are administered as inactive prodrugs with lactone rings. The open-acid statins are relatively hydrophilic and have low membrane permeabilities. However, most of the statins in the acid form are substrates of uptake transporters, so they are taken up efficiently by the liver and undergo enterohepatic circulation (Figures 5–5 and 5–11). In this process, hepatic uptake transporters such as OATP1B1 and efflux transporters such as MRP2 act cooperatively to produce vectorial trans-cellular transport of bisubstrates in the liver. The efficient first-pass hepatic uptake of these statins by OATP1B1 after their oral administration helps to exert the pharmacological effect and also minimizes the escape of drug molecules into the circulating blood, thereby minimizing the exposure in a target of adverse response, smooth muscle. Recent studies indicate that the genetic polymorphism of OATP1B1 also affects the function of this transporter (Tirona et al., 2001).

**Temocapril.** Temocapril is an ACE inhibitor (see Chapter 26). Its active metabolite, temocaprilat, is excreted both in the bile and in
the urine by the liver and kidney, respectively, whereas other ACE inhibitors are excreted mainly by the kidney. The special feature of temocapril among ACE inhibitors is that the plasma concentration of temocapril remains relatively unchanged even in patients with renal failure. However, the plasma area under the curve (AUC) of enalaprilat and other ACE inhibitors is markedly increased in patients with renal disorders. Temocapril is a bisubstrate of the OATP family and MRP2, whereas other ACE inhibitors are not good substrates of MRP2 (although they are taken up into the liver by the OATP family). Taking these findings into consideration, the affinity for MRP2 may dominate in determining the biliary excretion of any series of ACE inhibitors. Drugs that are excreted into both the bile and urine to the same degree thus are expected to exhibit minimum inter-individual differences in their pharmacokinetics.

**Irinotecan (CPT-11).** Irinotecan hydrochloride (CPT-11) is a potent anticancer drug, but late-onset gastrointestinal toxic effects, such as severe diarrhea, make it difficult to use CPT-11 safely. After intravenous administration, CPT-11 is converted to SN-38, an active metabolite, by carboxylesterase. SN-38 is subsequently conjugated with glucuronic acid in the liver. SN-38 and SN-38 glucuronide are then excreted into the bile by MRP2. The inhibition of MRP2-mediated biliary excretion of SN-38 and its glucuronide by co-administration of probenecid reduces the drug-induced diarrhea, at least in rats. For additional details, see Figures 6–5 and 6–7.

**Angiotensin II Receptor Antagonists.** Angiotensin II receptor antagonists are used for the treatment of hypertension, acting on AT₁ receptors expressed in vascular smooth muscle, proximal tubule, and adrenal medullary cells, and elsewhere. For most of these drugs, hepatic uptake and biliary excretion are important factors for their pharmacokinetics as well as pharmacological effects. Telmisartan is taken up into human hepatocytes in a saturable manner, predominantly via OATP1B3 (Ishiguro et al., 2006). On the other hand, both OATPs 1B1 and 1B3 are responsible for the hepatic uptake of valsartan and olmesartan, although the relative contributions of these transporters are unclear. Studies using doubly transfected cells with hepatic uptake transporters and biliary excretion transporters have clarified that MRP2 plays the most important role in the biliary excretion of valsartan and olmesartan.

**Repaglinide and Nateglinide.** Repaglinide is a meglitinide analog antidiabetic drug. Although it is eliminated almost completely by the metabolism mediated by CYPs 2C8 and 3A4, transporter-mediated hepatic uptake is one of the determinants of its elimination rate. In subjects with SLCO1B1 (gene code for OATP1B1) 521CC genotype, a significant change in the pharmacokinetics of repaglinide was observed (Niemi et al., 2005). Genetic polymorphism in SLCO1B1 521T>C results in altered pharmacokinetics of nateglinide, suggesting OATP1B1 is a determinant of its elimination, although it is subsequently metabolized by CYPs 2C9, 3A4, and 2D6 (Zhang et al., 2006a).

**Fexofenadine.** Fexofenadine, a histamine H₁ receptor antagonist, is taken up in the liver by OATP1B1 and OATP1B3 and excreted in the bile via transporters including MRP2 and BSEP (Matsushima et al., 2008). Patients with genetic polymorphism in SLCO1B1 521T>C, show altered pharmacokinetics.

**Bosentan.** Bosentan is an endothelin antagonist used to treat pulmonary arterial hypertension. It is taken up in the liver by OATP1B1 and OATP1B3, and subsequently metabolized by CYP2C9 and CYP3A4 (Treiber et al., 2007). Transporter-mediated hepatic uptake can be a determinant of elimination of bosentan, and the inhibition of hepatic uptake by cyclosporin A, rifampicin, and sildenafil can affect its pharmacokinetics.

**Drug-Drug Interactions Involving Transporter-Mediated Hepatic Uptake.** Since drug transporters are determinants of the elimination rate of drugs from the body, transporter-mediated hepatic uptake can be the cause of drug-drug interactions involving drugs that are actively taken up into the liver and metabolized and/or excreted in the bile.

Cerivastatin (currently withdrawn), an HMG-CoA reductase inhibitor, is taken up into the liver via transporters (especially OATP1B1) and subsequently metabolized by CYPs 2C8 and 3A4. Its plasma concentration is increased 1-5 fold when co-administered with cyclosporin A. Transport studies using cryopreserved human hepatocytes and OATP1B1-expressing cells suggest that this drug-drug interaction is caused by inhibition of OATP1B1-mediated hepatic uptake (Shitara et al., 2003). However, cyclosporin A inhibits the metabolism of cerivastatin only to a limited extent, suggesting a low possibility of serious drug-drug interactions involving the inhibition of metabolism. Cyclosporin A also increases the plasma concentrations of other HMG-CoA reductase inhibitors. It markedly increases the plasma AUC of pravastatin, pitavastatin, and rosuvastatin, which are minimally metabolized and eliminated from the body by transporter-mediated mechanisms. Therefore, these pharmacokinetic interactions also may be due to transporter-mediated hepatic uptake. However, the interactions of cyclosporin A with pro-drug statins (lactone form) such as simvastatin and lovastatin are mediated by CYP3A4.

Gemfibrozil is another cholesterol-lowering agent that acts by a different mechanism and also causes a severe pharmacokinetic interaction with cerivastatin. Gemfibrozil glucuronide inhibits the CYP2C8-mediated metabolism and OATP1B1-mediated uptake of cerivastatin more potently than does gemfibrozil. Laboratory data show that the glucuronide is highly concentrated in the liver versus plasma probably owing to transporter-mediated active uptake and intracellular formation of the conjugate. Therefore, it may be that gemfibrozil glucuronide, concentrated in the hepatocytes, inhibits the CYP2C8-mediated metabolism of cerivastatin. In addition, gemfibrozil glucuronide is an inhibitor of CYP2C8. Gemfibrozil markedly (4-5 fold) increases the plasma concentration of cerivastatin but does not greatly increase (1.3-2 times) that of unmetabolized statins pravastatin, pitavastatin, and rosuvastatin, a result that also suggests that this interaction is caused by inhibition of metabolism. Thus, when an inhibitor of drug-metabolizing enzymes is highly concentrated in hepatocytes by active transport, extensive inhibition of the drug-metabolizing enzymes may be observed because of the high concentration of the inhibitor in the vicinity of the drug-metabolizing enzymes.

**The Contribution of Specific Transporters to the Hepatic Uptake of Drugs.** Estimating the contribution of transporters to the total hepatic uptake is necessary for understanding their importance in drug disposition.
This estimate can help to predict the extent to which a drug-drug interaction or a genetic polymorphism of a transporter may affect drug concentrations in plasma and liver. The contribution to hepatic uptake has been estimated successfully for CYP-mediated metabolism by using neutralizing antibody and specific chemical inhibitors. Unfortunately, specific inhibitors or antibodies for important transporters have not been identified yet, although some relatively specific inhibitors have been discovered.

The contribution of transporters to hepatic uptake can be estimated from in vitro studies. Injection of cRNA results in transporter expression on the plasma membrane of Xenopus laevis oocytes (Hagenbuch et al., 1996). Subsequent hybridization of the cRNA with its antisense oligonucleotide specifically reduces its expression. Comparison of the drug uptake into cRNA-injected oocytes in the presence and absence of antisense oligonucleotides clarifies the contribution of a specific transporter. Second, a method using reference compounds for specific transporters has been proposed. The reference compounds should be specific substrates for a particular transporter. The contribution of a specific transporter can be calculated from the uptake of test compounds and reference compounds into hepatocytes and transporter-expressing systems (Hirano et al., 2004):

\[
\text{Contribution} = \frac{CL_{\text{hep,ref}} \times CL_{\text{exp,test}}}{CL_{\text{hep,test}} \times CL_{\text{exp,ref}}} \quad (\text{Equation 5–13})
\]

where \(CL_{\text{hep,ref}}\) and \(CL_{\text{exp,ref}}\) represent the uptake of reference compounds into hepatocytes and transporter-expressing cells, respectively, and \(CL_{\text{hep,test}}\) and \(CL_{\text{exp,test}}\) represent the uptake of test compounds into the corresponding systems. For example, the contributions of OATP1B1 and OATP1B3 to the hepatic uptake of pitavastatin have been estimated using estrone-3-sulfate and cholecystokinin octapeptide (CCK8) as reference compounds for OATP1B1 and OATP1B3, respectively. However, for many transporters, reference compounds specific to the transporter are not available. Another approach to estimate the relative contribution of OATP1B1 and OATP1B3 is to use estrone-3-sulfate as a selective inhibitor for OATP1B1 (Ishiguro et al., 2006). The difference in uptake clearance of test compound in human hepatocytes in the absence and presence of estrone-3-sulfate represents OATP1B1-mediated hepatic uptake.

### Renal Transporters

Secretion in the kidney of structurally diverse molecules including many drugs, environmental toxins, and carcinogens is critical in the body’s defense against foreign substances. The specificity of secretory pathways in the nephron for two distinct classes of substrates, organic anions and cations, was first described decades ago, and these pathways were well characterized using a variety of physiological techniques including isolated perfused nephrons and kidneys, micro-puncture techniques, cell culture methods, and isolated renal plasma membrane vesicles. More recently, molecular studies have identified and characterized the renal transporters that play a role in drug elimination, toxicity, and response.

Although the pharmacological focus is often on the kidney, there is useful information on the tissue distribution of these transporters. Molecular studies using site-directed mutagenesis have identified substrate-recognition and other functional domains of the transporters, and genetic studies of knockout mouse models have been used to characterize the physiological roles of individual transporters. Recently, studies have identified and functionally analyzed genetic polymorphisms and haplotypes of the relevant transporters in humans. In some cases, transporters that are considered organic anion or organic cation transporters have dual specificity for anions and cations. The following section summarizes recent work on transporters in humans and other mammals. For more detail, refer to recent reviews of renal organic cation and anion transport (Ciarimboli, 2008; El-Sheikh et al., 2008; Koepsell et al., 2007; Srimaroeng et al., 2008; Wright and Dantzler, 2004).

### Organic Cation Transport

Structurally diverse organic cations are secreted in the proximal tubule (Ciarimboli, 2008; Koepsell et al., 2007; Wright and Dantzler, 2004). Many secreted organic cations are endogenous compounds (e.g., choline, N-methyl nicotinamide, and dopamine), and renal secretion appears to be important in eliminating excess concentrations of these substances. However, a primary function of organic cation secretion is ridding the body of xenobiotics, including many positively charged drugs and their metabolites (e.g., cimetidine, ranitidine, metformin, procainamide, and N-acetylprocainamide) and toxins from the environment (e.g., nicotine). Organic cations that are secreted by the kidney may be either hydrophobic or hydrophilic. Hydrophilic organic drug cations generally have molecular weights < 400 daltons; a current model for their secretion in the proximal tubule of the nephron is shown in Figure 5–12.

For the transepithelial flux of a compound (e.g., secretion), the compound must traverse two membranes sequentially, the basolateral membrane facing the blood side and the apical membrane facing the tubular lumen. Distinct transporters on each membrane mediate each step of transport. Organic cations appear to cross the basolateral membrane in human proximal tubule by two distinct transporters in the SLC family 22 (SCL22):
OCT2 (SLC22A2) and OCT3 (SLC22A3). Organic cations are transported across this membrane down an electrochemical gradient. Previous studies in isolated basolateral membrane vesicles demonstrate the presence of a potential-sensitive mechanism for organic cations. The cloned transporters OCT2 and OCT3 are potential sensitive and mechanistically coincide with previous studies of isolated basolateral membrane vesicles.

Transport of organic cations from cell to tubular lumen across the apical membrane occurs via an electroneutral proton–organic cation exchange mechanism in a variety of species, including human, dog, rabbit, and cat. The recent discovery of a new transporter family, SLC47A, multidrug and toxin extrusion family (MATEs), has provided the molecular identities of the previously characterized electroneutral proton–organic cation antiport mechanism (Otsuka et al., 2005; Tanihara et al., 2007). Transporters in the MATE family, assigned to the apical membrane of the proximal tubule, appear to play a key role in moving hydrophilic organic cations from tubule cell to lumen. In addition, novel organic cation transporters (OCTNs), located on the apical membrane, appear to contribute to organic cation flux across the proximal tubule. In humans, these include OCTN1 (SLC22A4) and OCTN2 (SLC22A5). These bifunctional transporters are involved not only in organic cation secretion but also in carnitine reabsorption. In the uptake mode, the transporters function as Na⁺ co-transporters, relying on the inwardly driven Na⁺ gradient created by Na⁺,K⁺-ATPase to move carnitine from tubular lumen to cell. In the secretory mode, the transporters appear to function as proton–organic cation exchangers. That is, protons move from tubular lumen to cell interior in exchange for organic cations, which move from cytosol to tubular lumen. The inwardly directed proton gradient (from tubular lumen to cytosol) is maintained by transporters in the SLC9 family, which are Na⁺/H⁺ exchangers (NHEs, antiporters). Of the two steps involved in secretory transport, transport across the luminal membrane appears to be rate-limiting.

OCT2 (SLC22A2). OCT2 (SLC22A2) was first cloned from a rat kidney cDNA library in 1996 (Okuda et al., 1996). Human, rabbit, mouse, and pig orthologs have all been cloned. Mammalian orthologs range in length from 553 through 555 amino acids. OCT2 is predicted to have 12 transmembrane domains, including one N-linked glycosylation site. OCT2 is located adjacent to OCT1 on chromosome 6 (6q26). A single splice variant of human OCT2, termed OCT2-A, has been identified in human kidney. OCT2-A, which is a truncated form of OCT2, appears to have a lower $K_{m}$ (or greater affinity) for substrates than OCT2, although a lower affinity has been observed for some inhibitors (Urakami et al., 2002). Human, mouse, and rat orthologs of OCT2 are expressed in abundance in human kidney and to some extent in neuronal tissue such as choroid plexus. In the kidney, OCT2 is localized to the proximal tubule and to distal tubules and collecting ducts. In the proximal tubule, OCT2 is restricted to the basolateral membrane. OCT2 mammalian species orthologs are > 80% identical, whereas the OCT2 paralog found primarily in the liver, OCT1, is ~70% identical to OCT2. OCT2-mediated transport of model organic cations MPP⁺ and TEA is electrogenic, and both OCT2 and OCT1 can support organic cation–organic cation exchange (Koepsell et al., 2007). OCT2 generally accepts a wide array of monovalent organic cations with molecular weights < 400 daltons (Ciarimboli, 2008; Koepsell et al., 2007). The apparent affinities of the human paralogs, OCT1 and OCT2, for some organic cation substrates and inhibitors are different in side-by-side comparison studies. Isoform-specific inhibitors of the OCTs are needed to determine the relative importance of OCT2 and OCT1 in the renal clearance of compounds in rodents, in which both isoforms are present in kidney. OCT2 is also present in neuronal tissues; however, monoamine neurotransmitters have low affinities for OCT2. OCT2 may play a housekeeping role in neurons, taking up only excess concentrations of neurotransmitters. OCT2 also may be involved in recycling of neurotransmitters by taking up breakdown products, which in turn enter monoamine synthetic pathways.

OCT3 (SLC22A3). OCT3 (SLC22A3) was cloned initially from rat placenta (Kekuda et al., 1998). Human and mouse orthologs have also been cloned. OCT3 consists of 551 amino acids and is predicted to have 12 transmembrane domains, including three N-linked glycosylation sites. hOCT3 is located in tandem with OCT1 and OCT2 on chromosome 6. Tissue distribution studies suggest that human OCT3 is expressed in liver, kidney, intestine, and placenta, although it appears to be expressed in considerably less abundance than OCT2 in the kidney. Like OCT1 and OCT2, OCT3 appears to support electronegenic potential-sensitive organic cation transport. Although the specificity of OCT3 is similar to that of OCT1 and OCT2, it appears to have quantitative differences in its affinities for many organic cations. Some studies have suggested that OCT3 is the extraneuronal monoamine transporter based on its substrate specificity and potency of interaction with monoamine neurotransmitters. Because of its relatively low abundance in the kidney (in the basolateral membrane of the proximal tubule (Koepsell et al., 2007)), OCT3 may play only a limited role in renal drug elimination.
**OCT1 (SLC22A4).** OCT1, cloned originally from human fetal liver, is expressed in the adult kidney, trachea, and bone marrow (Tamai et al., 1997). The functional characteristics of OCT1 suggest that it operates as an organic cation–proton exchanger. OCT1-mediated influx of model organic cations is enhanced at alkaline pH, whereas efflux is increased by an inwardly directed proton gradient. OCT1 contains a nucleotide-binding sequence motif, and transport of its substrates appears to be stimulated by cellular ATP. OCT1 also can function as an organic cation–organic cation exchanger. Although the subcellular localization of OCT1 has not been demonstrated clearly, available data collectively suggest that OCT1 functions as a bidirectional pH- and ATP-dependent transporter at the apical membrane in renal tubular epithelial cells. OCT1 appears to transport the anti-epileptic agent, gabapentin, in the kidney (Urban et al., 2007).

**OCTN2 (SLC22A5).** OCTN2 was first cloned from human kidney and determined to be the transporter responsible for systemic carnitine deficiency (Tamai et al., 1998). Rat OCTN2 mRNA is expressed predominantly in the cortex, with very little expression in the medulla, and is localized to the apical membrane of the proximal tubule.

OCTN2 is a bifunctional transporter, i.e., it transports L-carnitine with high affinity in an Na⁺-dependent manner, whereas, Na⁺ does not influence OCTN2-mediated transport of organic cations such as TEA. Thus, OCTN2 is thought to function as both an Na⁺-dependent carnitine transporter and an Na⁺-independent organic cation transporter. Similar to OCT1, OCTN2 transport of organic cations is sensitive to pH, suggesting that OCTN2 may function as an organic cation exchanger. The transport of L-carnitine by OCTN2 is a Na⁺-dependent electrogenic process, and mutations in OCTN2 appear to be the cause of primary systemic carnitine deficiency (Nezu et al., 1999).

**MATE1 and MATE2-K (SLC47A1 and SLC47A2).** Database searches for human orthologs of bacterial multidrug resistance transporters have identified two genes in the human genome that code for membrane transporters (Otsuka et al., 2005). Multidrug and toxin extrusion family members MATE1 (SLC47A1) and MATE2-K (SLC47A2) interact with structurally diverse hydrophilic organic cations including the anti-diabetic drug metformin, the H₂ antagonist cimetidine, and the anticancer drug, topotecan (Tanihara et al., 2007). In addition to cationic compounds, the transporters also recognize some anions, including the antiviral agents acyclovir and ganciclovir. The zwiterioncephalin and cephradine are specific substrates of MATE1, but not MATE2-K. The herbicide paraquat, a bisquaternary ammonium compound, which is nephrotoxic in humans, is a potent substrate of MATE1 (Chen et al., 2007). Both MATE1 and MATE2-K have been localized to the apical membrane of the proximal tubule (Tanihara et al., 2007). MATE1, but not MATE2-K, is also expressed on the canalicular membrane of the hepatocyte. These transporters appear to be the long-searched-for organic cation proton antiporters on the apical membrane of the proximal tubule, i.e., an oppositely directed proton gradient can drive the movement of organic cations via MATE1 or MATE2-K. The antibiotics, levofloxacin and ciprofloxacin, though potent inhibitors, are not translocated by either MATE1 or MATE2-K.

**Polymorphisms of OCTs.** Polymorphisms of OCTs have been identified in large post–human genome SNP discovery projects (Kerb et al., 2002; Leabman et al., 2003; Shu et al., 2003). OCT1 exhibits the greatest number of amino acid polymorphisms, followed by OCT2 and then OCT3. Furthermore, allele frequencies of OCT1 amino acid variants in human populations generally are greater than those of OCT2 and OCT3 amino acid variants. Functional studies of OCT1 and OCT2 polymorphisms have been performed. OCT1 exhibits five variants with reduced function. These variants may have important implications clinically in terms of hepatic drug disposition and targeting of OCT1 substrates. In particular, individuals with OCT1 variants may have reduced liver uptake of OCT1 substrates and therefore reduced metabolism. Recent studies suggest that genetic variants of OCT1 and OCT2 are associated with alterations in the renal elimination and response to the anti-diabetic drug, metformin (Shu et al., 2007; Song et al., 2008; Wang et al., 2008).

**Organic Anion Transport.** Myriad structurally diverse organic anions are secreted in the proximal tubule (Burckhardt and Burckhardt, 2003; El-Sheikh et al., 2008; Srimaroeng et al., 2008; Wright and Dantzler, 2004). As with organic cation transport, the primary function of organic anion secretion appears to be the removal from the body of xenobiotics, including many weakly acidic drugs [e.g., pravastatin, captopril, p-aminohippurate (PAH), and penicillins] and toxins (e.g., ochratoxin). Organic anion transporters move both hydrophobic and hydrophilic anions but also may interact with cations and neutral compounds.

A current model for the transepithelial flux of organic anions in the proximal tubule is shown in Figure 5–13. Two primary transporters on the basolateral membrane mediate the flux of organic anions from interstitial fluid to tubule cell: OAT1 (SLC22A6) and OAT3 (SLC22A8). Energetically, hydrophilic organic anions are...
transported across the basolateral membrane against an electrochemical gradient in exchange with intracellular α-ketoglutarate, which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α-ketoglutarate is maintained at least in part by a basolateral Na\(^+\)-dicarboxylate transporter (NaDC3). The Na\(^+\) gradient that drives NaDC3 is maintained by Na\(^+\),K\(^+\)-ATPase. Transport of small-molecular-weight organic anions by the cloned transporters OAT1 and OAT3 can be driven by α-ketoglutarate; coupled transport of α-ketoglutarate and small-molecular-weight organic anions (e.g., p-aminobenzoate) occurs in isolated basolateral membrane vesicles. The molecular pharmacology and molecular biology of OATs have recently been reviewed (El-Sheikh et al., 2008; Srimaroeng et al., 2008).

The mechanism responsible for the apical membrane transport of organic anions from tubule cell cytosol to tubular lumen remains controversial. Some studies suggest that OAT4 may serve as the luminal membrane transporter for organic anions. However, recent studies show that the movement of substrates via this transporter can be driven by exchange with α-ketoglutarate, suggesting that OAT4 may function in the reabsorptive, rather than secretory, flux of organic anions. Other studies have suggested that in the pig kidney, OATV1 serves as an electrogenic facilitated transporter on the apical membrane (Jutabha et al., 2003). The human ortholog of OAT1, OATV1 is NPT1, or NaPi-1, originally cloned as a phosphate transporter. NPT1 can support the low-affinity transport of hydrophilic organic anions such as PAH. Other transporters that may play a role in transport across the apical membrane include MRP2 and MRP4, multidrug-resistance transporters in the ATP binding cassette family C (ABCC). Both transporters interact with some organic anions and may actively pump their substrates from tubule cell cytosol to tubular lumen.

**OAT1 (SLC22A6).** OAT1 was cloned from rat kidney (Sekine et al., 1997; Sweet et al., 1997). This transporter is >30% identical to OCTs in the SLC22 family. Mouse, human, pig, and rabbit orthologs have been cloned and are ~80% identical to human OAT1. Mammalian isoforms of OAT1 vary in length from 545-551 amino acids. The gene for the human OAT1 is mapped to chromosome 11 and is found in an SLC22 cluster that includes OAT3 and OAT4. There are four splice variants in human tissues, termed OAT1-1, OAT1-2, OAT1-3, and OAT1-4. OAT1-2, which includes a 13-amino-acid deletion, transports PAH at a rate comparable with OAT1-1. These two splice variants use the alternative 5′-splice sites in exon 9. OAT1-3 and OAT1-4, which result from a 132-bp (44-amino-acid) deletion near the carboxyl terminus of OAT1, do not transport PAH. In humans, rat, and mouse, OAT1 is expressed primarily in the kidney, with some expression in brain and skeletal muscle.

Immunohistochemical studies suggest that OAT1 is expressed on the basolateral membrane of the proximal tubule in human and rat, with highest expression in the middle segment, S2. Based on quantitative PCR, OAT1 is expressed at a third of the level of OAT3. OAT1 exhibits saturable transport of organic anions such as PAH. This transport is trans-stimulated by other organic anions, including α-ketoglutarate. Thus, the inside negative-potential difference drives the efflux of the dicarboxylate α-ketoglutarate, which, in turn, supports the influx of monocarboxylates such as PAH. Regulation of expression levels of OAT1 in the kidney appears to be controlled by sex steroids.

OAT1 generally transports small-molecular-weight organic anions that may be endogenous (e.g., PGE\(_2\), and urate) or ingested drugs and toxins. Some neutral compounds are also transported by OAT1 at a lower affinity (e.g., cimetidine). Key residues that contribute to transport by OAT1 include the conserved K394 and R478, which are involved in the PAH-glutarate exchange mechanism.

**OAT2 (SLC22A7).** OAT2 was cloned first from rat liver (and named NLT at the time) (Sekine et al., 1998; Simonson et al., 1994). OAT2 is present in both kidney and liver. In the kidney, the transporter is localized to the basolateral membrane of the proximal tubule, and appears to function as a transporter for nucleotides, particularly guanine nucleotides such as cyclic GMP (Cropp et al., 2008). Cellular studies suggest that OAT2 functions in both the influx and efflux of guanine nucleotides. Organic anions such as PAH and methotrexate are also transported with low affinity by OAT2, which transports PGE\(_2\), with a high affinity.

**OAT3 (SLC22A8).** OAT3 (SLC22A8) was cloned originally from rat kidney (Kusuhara et al., 1999). Human OAT3 consists of two variants, one of which transports a wide variety of organic anions, including model compounds, PAH and estrone sulfate, as well as many drug products (e.g., pravastatin, cetirizine, 6-mercaptopurine, and methotrexate) (Srimaroeng et al., 2008). The longer OAT3 in humans, a 568-amino-acid protein, does not support transport. It is likely that the two OAT3 variants are splice variants. Human OAT3 is confined to the basolateral membrane of the proximal tubule.

OAT3 clearly has overlapping specificities with OAT1, although kinetic parameters differ. For example, estrone sulfate is transported by both OAT1 and OAT3, but OAT3 has a much higher affinity in comparison with OAT1. The weak base cimetidine (an H\(_2\) receptor antagonist) is transported with high affinity by OAT1, whereas the cation TEA is not transported.

**OAT4 (SLC22A9).** OAT4 (SLC22A9) was cloned from a human kidney cDNA library (Cha et al., 2000). OAT4 is expressed in human kidney and placenta; in human kidney, OAT4 is present on the luminal membrane of the proximal tubule. At first, OAT4 was thought to be involved in the second step of secretion of organic anions, i.e., transport across the apical membrane from cell to tubular lumen. However, studies demonstrate that organic anion transport by OAT4 can be stimulated by transgradients of α-ketoglutarate (Ekaratanawong et al., 2004), suggesting that OAT4 may be involved in the reabsorption of organic anions from tubular lumen into cell. The specificity of OAT4 includes the model compounds estrone sulfate and PAH, as well as zidovudine, tetracycline, and methotrexate (El-Sheikh et al., 2008; Srimaroeng et al., 2008). Interestingly, the affinity for PAH is low (>1 mM). Collectively, emerging studies suggest that OAT4 may be involved not in secretory flux of organic anions but in reabsorption instead.

**Other Anion Transporters.** URAT1 (SLC22A12), first cloned from human kidney, is a kidney-specific transporter confined to the apical membrane of the proximal tubule (Enomoto et al., 2002). Data suggest that URAT1 is primarily responsible for urate reabsorption, mediating electroneutral urate transport that can be trans-stimulated by Cl\(^-\) gradients. The mouse ortholog of URAT1 is involved in the renal secretory flux of organic anions including benzylpenicillin and urate.
NPT1 (SLC17A1), cloned originally as a phosphate transporter in humans, is expressed in abundance on the luminal membrane of the proximal tubule as well as in the brain (Werner et al., 1991). NPT1 transports PAH, probenecid, and penicillin G. It appears to be part of the system involved in organic anion efflux from tubule cell to lumen.

MRP2 (ABCC2), an ABC transporter, initially called the GS-X pump (El-Sheikh et al., 2008; Ishikawa et al., 1990; Toyoda et al., 2008), has been considered to be the primary transporter involved in efflux of many drug conjugates such as glutathione conjugates across the canalicular membrane of the hepatocyte. However, MRP2 is also found on the apical membrane of the proximal tubule, where it is thought to play a role in the efflux of organic anions into the tubular lumen. Its role in the kidney may be to secrete glutathione conjugates of drugs, but it also may support the translocation (with glutathione) of various non-conjugated substrates. In general, MRP2 transports larger, bulkier compounds than do most of the organic anion transporters in the SLC22 family.

MRP4 (ABCC4) is found on the apical membrane of the proximal tubule and transports a wide array of conjugated anions, including glucuronide and glutathione conjugates (El-Sheikh et al., 2008; Toyoda et al., 2008). However, unlike MRP2, MRP4 appears to interact with various drugs, including methotrexate, cyclic nucleotide analogs, and antiviral nucleoside analogs. Recent studies in Mrp4 knockout mice suggest that the transporter is involved in the renal elimination of the antiviral drugs adeovir and tenofovir (Imaoka et al., 2006). Other MRP efflux transporters also have been identified in human kidney, including MRP3 and MRP6, both on the basolateral membrane. Their roles in the kidney are not yet known.

Polymorphisms of OATs. Polymorphisms in OAT1 and OAT3 have been identified in ethnically diverse human populations (Leabman et al., 2003; Srimaroeng et al., 2008). Two amino acid polymorphisms (allele frequencies >1%) in OAT1 have been identified in African-American populations. Three amino acid polymorphisms and seven rare amino acid variants in OAT3 have been identified in ethnically diverse U.S. populations (see www.pharmgkb.org).

TRANSPORTERS INVOLVED IN PHARMACODYNAMICS: DRUG ACTION IN THE BRAIN

Neurotransmitters are packaged in vesicles in presynaptic neurons, released in the synapse by fusion of the vesicles with the plasma membrane, and, excepting acetylcholine, are then taken back into the presynaptic neurons or postsynaptic cells (see Chapter 8). Transports involved in the neuronal reuptake of the neurotransmitters and the regulation of their levels in the synaptic cleft belong to two major superfamilies, SLC1 and SLC6. Transports in both families play roles in reuptake of γ-aminobutyric acid (GABA), glutamate, and the monoamine neurotransmitters norepinephrine, serotonin, and dopamine. These transporters may serve as pharmacologic targets for neuropsychiatric drugs (Gether et al., 2006; Hog et al., 2006; Schousboe et al., 2004).

SLC6 family members localized in the brain and involved in the reuptake of neurotransmitters into presynaptic neurons include the norepinephrine transporters (NET, SLC6A2), the dopamine transporter (DAT, SLC6A3), the serotonin transporter (SERT, SLC6A4), and several GABA reuptake transporters (GAT1, GAT2, and GAT3) (Chen et al., 2004; Elliott and Beveridge, 2005; Hediger, 2004). Each of these transporters appears to have 12 transmembrane secondary structures and a large extracellular loop with glycosylation sites between transmembrane domains 3 and 4. These proteins are typically ~600 amino acids in length. SLC6 family members depend on the Na+ gradient to actively transport their substrates into cells. Cl– is also required, although to a variable extent depending on the family member. Residues and domains that form the substrate recognition and permeation pathways are currently being identified.

Through reuptake mechanisms, the neurotransmitter transporters in the SLC6A family regulate the concentrations and dwell times of neurotransmitters in the synaptic cleft; the extent of transmitter uptake also influences subsequent vesicular storage of transporters. Many of these transporters are present in other tissues (e.g., kidney and platelets) and may serve other roles. Further, the transporters can function in the reverse direction. That is, the transporters can export neurotransmitters in an Na+-independent fashion. The characteristics of each member of the SLC6A family of transporters that play a role in reuptake of monoamine neurotransmitters and GABA merit a brief description.

SLC6A1 (GAT1), SLC6A11 (GAT3), and SLC6A13 (GAT2). GAT1 (599 amino acids) is the most important GABA transporter in the brain, expressed in GABAergic neurons and found largely on presynaptic neurons (Høg et al., 2006; Schousboe et al., 2004). GAT1 is found in abundance in the neocortex, cerebellum, basal ganglia, brainstem, spinal cord, retina, and olfactory bulb. GAT3 is found only in the brain, largely in glial cells. GAT2 is found in peripheral tissues, including the kidney and liver, and within the CNS in the choroid plexus and meninges.

GAT1, GAT2, and GAT3 are ~50% identical in amino acid sequence. Functional analysis indicates that GAT1 transports GABA with a 2:1 Na+:GABA stoichiometry. Cl– is required. Residues and domains responsible for the recognition of GABA and subsequent translocation have been identified. Physiologically, GAT1 appears to be responsible for regulating the interaction of GABA at receptors. The presence of GAT2 in the choroid plexus and its absence in presynaptic neurons suggest that this transporter may play a primary role in maintaining the homeostasis of GABA in the CSF. GAT1 and GAT3 are drug targets (Schousboe et al., 2004). GAT1 is the target of the anti-epileptic drug tiagabine, which presumably acts to...
increase GABA levels in the synaptic cleft of GABAergic neurons by inhibiting the reuptake of GABA. GAT3 is the target for the nipecotic acid derivatives that are anticonvulsants.

**SLC6A2 (NET).** NET (617 amino acids) is found in central and peripheral nervous tissues as well as in adrenal chromaffin tissue (Hahn and Blakely, 2007). In the brain, NET co-localizes with neuronal markers, consistent with a role in reuptake of monoamine neurotransmitters. The transporter functions in the Na⁺-dependent reuptake of norepinephrine and dopamine and as a higher-capacity norepinephrine channel. A major role of NET is to limit the synaptic dwell time of norepinephrine and to terminate its actions, salvaging norepinephrine for subsequent repackaging. NET knockout mice exhibit a prolonged synaptic half-life of norepinephrine (Xu et al., 2000). Ultimately, through its reuptake function, NET participates in the regulation of many neurological functions, including memory and mood. NET serves as a drug target: the antidepressant desipramine is considered a selective inhibitor of NET. Other drugs that interact with NET include other tricyclic antidepressants and cocaine. Orthostatic intolerance, a rare familial disorder characterized by an abnormal blood pressure and heart rate response to changes in posture, has been associated with a mutation in NET.

**SLC6A3 (DAT).** DAT is located primarily in the brain in dopaminergic neurons. Although present on presynaptic neurons at the neurosynaptic junction, DAT is also present in abundance along the neurons, away from the synaptic cleft. This distribution suggests that DAT may play a role in clearance of excess dopamine in the vicinity of neurons. The primary function of DAT is the reuptake dopamine, terminating its actions, although DAT also weakly interacts with norepinephrine. Physiologically, DAT is involved in the various functions that are attributed to the dopaminergic system, including mood, behavior, reward, and cognition. The half-life of dopamine in the extracellular spaces of the brain is prolonged considerably in DAT knockout mice (Uhl, 2003), which are hyperactive and have sleep disorders. Drugs that interact with DAT include cocaine and its analogs, amphetamines, and the neurotoxin MPTP.

**SLC6A4 (SERT).** SERT is located in peripheral tissues and in the brain along extrasynaptic axonal membranes (Chen et al., 2004; Olivier et al., 2000). SERT clearly plays a role in the reuptake and clearance of serotonin in the brain. Like the other SLC6A family members, SERT transports its substrates in an Na⁺-dependent fashion and is dependent on Cl⁻ and possibly on the countertransport of K⁺. Substrates of SERT include serotonin (5-HT), various tryptamine derivatives, and neurotoxins such as 3,4-methylenedioxyamphetamine (MDMA; ecstasy) and fenfluramine. The serotonin transporter has been one of the most widely studied proteins in the human genome. First, it is the specific target of the antidepressants in the selective serotonin reuptake inhibitor class (e.g., fluoxetine and paroxetine) and one of several targets of tricyclic antidepressants (e.g., amitriptyline). Further, because of the important role of serotonin in neurological function and behavior, genetic variants of SERT have been associated with an array of behavioral and neurological disorders. In particular, a common promoter region variant that alters the length of the upstream region of SLC6A4 has been the subject of many studies (Hahn and Blakely, 2007). The short form of the variant results in a reduced rate of transcription of SERT in comparison with the long form. These differences in the rates of transcription alter the quantity of mRNA and, ultimately, the expression and activity of SERT. The short form has been associated with a variety of neuropsychiatric disorders (Lesch et al., 1996). The precise mechanism by which a reduced activity of SERT, caused by either a genetic variant or an antidepressant, ultimately affects behavior, including depression, is not known.

**BLOOD-BRAIN BARRIER AND BLOOD-CSF BARRIER**

Drugs acting in the CNS have to cross the BBB or blood-CSF barrier. These two barriers are formed by brain capillary endothelial cells and epithelial cells of the choroid plexus, respectively. These are not static anatomical barriers but dynamic ones in which efflux transporters play a role (Begley and Brightman, 2003; Sun et al., 2003). P-glycoprotein is a well-characterized efflux transporter that extrudes its substrate drugs on the luminal membrane of the brain capillary endothelial cells into the blood, thereby, limiting the brain penetration. Thus, recognition by P-glycoprotein as a substrate is a major disadvantage for drugs used to treat CNS diseases.

In addition to P-glycoprotein, there is accumulating evidence for the roles of BCRP and MRp4 in limiting the brain penetration of drugs at the BBB (Belinsky et al., 2007; Breedveld, et al., 2005; Enokizono et al., 2007; Leggas et al., 2004; Ose et al., 2009). Furthermore, because of overlapped substrate specificities of P-glycoprotein and BCRP, they act as active barrier cooperatively in the BBB (Enokizono et al., 2008). Thus, dysfunction of both P-glycoprotein and BCRP exhibits synergy on the increase in the brain-to-plasma concentration ratio of the common substrates compared with that observed when either P-glycoprotein or BCRP is dysfunctional (Oostendorp et al., 2009; Polli et al., 2009).

The transporters involved in the efflux of organic anions from the CNS are being identified in the BBB and the blood-CSF barrier and include the members of organic anion transporting polypeptide (OATP1A4 and OATP1A5) and organic anion transporter (OAT3) families (Kikuchi et al., 2004; Mori et al., 2003). They mediate the uptake of organic compounds such as β-lactam antibiotics, statins, p-aminobiphenyl, H₂ receptor antagonists, and bile acids on the plasma membrane facing the brain-CSF in the net efflux across the endothelial and epithelial cells. The transporters mediating the efflux on the membranes that face the blood, have not been fully elucidated both in the BBB and blood-CSF barrier. MRp4 has been shown to mediate luminal efflux in the directional transport on an anionic drug, Ro64-0802 (an active form of oseutilimivir), across the BBB in which the abluminal uptake is mediated by OAT3 (Ose et al., 2009). Members of the organic anion transporting polypeptide family also mediate uptake from the blood on the plasma membrane facing blood. Further clarification of influx and efflux transporters in the barriers will enable delivery of CNS drugs efficiently into the brain while avoiding undesirable CNS side effects and help to define the mechanisms of drug-drug interactions and interindividual differences in the therapeutic CNS effects.

COPING WITH EXPOSURE TO XENOBIOTICS

Humans come into contact with thousands of foreign chemicals, medicines, or xenobiotics (substances foreign to the body) through intentional exposure, accidental exposure to environmental contaminants, as well as through diet. Fortunately, humans have developed a means to rapidly eliminate xenobiotics so that they do not accumulate in the tissues and cause harm. The ability of humans to metabolize and clear drugs is a natural process that involves the same enzymatic pathways and transport systems that are used for normal metabolism of dietary constituents. In fact, plants are a common source of xenobiotics in the diet, contributing many structurally diverse chemicals, some of which are associated with pigment production and others of which are toxins (called phytoalexins) that protect plants against predators. For example, poisonous mushrooms produce toxins that are lethal to mammals, including amanitin, gyromitrin, orellanine, muscarine, ibotenic acid, muscimol, psilocybin, and coprine. Animals must be able to metabolize and eliminate such chemicals in order to consume vegetation.

Drugs are considered xenobiotics and most are extensively metabolized in humans. Many drugs are derived from chemicals found in plants, some of which have been used in Chinese herbal medicines for thousands of years. Thus, it is not surprising that humans also metabolize synthetic drugs by pathways that mimic the disposition of chemicals found in the diet. This capacity to metabolize xenobiotics, while mostly beneficial, has made development of drugs very time consuming and costly due in large part to:

- Inter-individual variations in the capacity of humans to metabolize drugs
- Drug-drug interactions
- Metabolic activation of chemicals to toxic and carcinogenic derivatives
- Species differences in expression of enzymes that metabolize drugs, thereby limiting the use of animal models for drug testing to predict effects in humans

A large number of diverse enzymes have evolved in animals that apparently function only to metabolize foreign chemicals. As will be discussed later, there are such large differences among species in the ability to metabolize xenobiotics, that animal models cannot be solely relied upon to predict how humans will metabolize a drug. Enzymes that metabolize xenobiotics have historically been called drug-metabolizing enzymes, although they are involved in the metabolism of many foreign chemicals to which humans are exposed. Thus, a more appropriate name would be xenobiotic-metabolizing enzymes. Dietary differences among species during the course of evolution could account for the marked species variation in the complexity of the drug-metabolizing enzymes. Additional diversity within these enzyme systems has also derived from the necessity to detoxify a host of endogenous chemicals that would otherwise prove harmful to the organism, such as bilirubin, steroid hormones, and catecholamines. Many of these compounds are detoxified by the same or closely related xenobiotic-metabolizing enzymes.

Xenobiotics to which humans are exposed come from sources that include environmental pollution, food additives, cosmetic products, agrochemicals, processed foods, and drugs. In general, most xenobiotics are lipophilic chemicals that, in the absence of metabolism, would not be efficiently eliminated, and thus would accumulate in the body, potentially resulting in toxicity. With very few exceptions, xenobiotics are subjected to one or multiple enzymatic pathways that
constitute **phase 1 oxidation** and **phase 2 conjugation**. As a general paradigm, metabolism serves to convert these hydrophobic chemicals into more hydrophilic derivatives that can easily be eliminated from the body through the urine or the bile.

In order to be accessible to cells and reach their sites of action, drugs generally must possess physical properties that allow them to move down a concentration gradient into the cell. Many drugs are hydrophobic, a property that allows entry through the lipid bilayers into cells where the agents can interact with their target receptors or proteins. With some compounds, entry into cells is facilitated by a large number of transporters on the plasma membrane (see Chapter 5). This property of hydrophobicity renders drugs difficult to eliminate, since in the absence of metabolism, they accumulate in fat and cellular phospholipid bilayers in cells. The xenobiotic-metabolizing enzymes serve to convert drugs and other xenobiotics into derivatives that are more hydrophilic and thus easily eliminated through excretion into the aqueous compartments of the tissues.

The process of drug metabolism that leads to elimination also plays a major role in diminishing the biological activity of a drug. For example, (S)-phenytoin, an anticonvulsant used in the treatment of epilepsy, is virtually insoluble in water. Metabolism by the phase 1 cytochromes P450 (CYPs) followed by phase 2 uridine diphosphate-glucuronosyltransferases (UGTs) produces a metabolite that is highly water soluble and readily eliminated from the body (Figure 6–1). Metabolism also terminates the biological activity of the drug. Since conjugates are generally hydrophobic, elimination via the bile and/or urine is dependent on the actions of many efflux transporters (see Chapter 5).

While xenobiotic-metabolizing enzymes are responsible for facilitating the elimination of chemicals from the body, paradoxically these same enzymes can also convert certain chemicals to highly reactive, toxic, and carcinogenic metabolites. This occurs when an unstable intermediate is formed that has reactivity toward other cellular constituents. Chemicals that can be converted by xenobiotic metabolism to cancer-causing derivatives are called **carcinogens**. Depending on the structure of the chemical substrate, xenobiotic-metabolizing enzymes can produce electrophilic metabolites that react with nucleophilic cellular macromolecules such as DNA, RNA, and protein. This can cause cell death and organ toxicity. Reaction of these electrophiles with DNA can sometimes result in cancer through the mutation of genes, such as oncogenes or tumor suppressor genes. It is generally believed that most human cancers are due to exposure to chemical carcinogens. This potential for carcinogenic activity makes testing the safety of drug candidates of vital importance. Testing for potential cancer-causing activity is particularly critical for drugs that will be used for the treatment of chronic diseases. Since each species has evolved a unique combination of xenobiotic-metabolizing enzymes, non-primate rodent models cannot be the only animal models used for testing the safety of new drug candidates targeted for human diseases. Nevertheless, testing in rodent models, such as mice and rats, can usually identify potential carcinogens. If a drug tests negative for carcinogenicity in rodents, it is unlikely to cause cancer in humans, albeit some rodent carcinogens are not associated with human cancer. However, many cytotoxic cancer drugs have the potential to cause cancer; this risk potential is minimized by their time-limited use in cancer therapy.

### THE PHASES OF DRUG METABOLISM

Xenobiotic metabolizing enzymes have historically been grouped into those that carry out **phase 1 reactions**, which include oxidation, reduction, or hydrolytic reactions, and the **phase 2 reactions**, in which enzymes catalyze the conjugation of the substrate (the phase 1 product) with a second molecule (Table 6–1). The phase 1
enzymes lead to the introduction of functional groups such as –OH, –COOH, –SH, –O–, or NH₂. The addition of functional groups does little to increase the water solubility of the drug, but can dramatically alter the biological properties of the drug. Reactions carried out by phase 1 enzymes usually lead to the inactivation of a drug. However, in certain instances, metabolism, usually the hydrolysis of an ester or amide linkage, results in bioactivation of a drug. Inactive drugs that undergo metabolism to an active drug are called prodrugs. Examples are the anti-tumor drug cyclophosphamide, which is bioactivated to a cell-killing electrophilic derivative (see Chapter 61); and clofibrate, which is converted in the cell from an ester to an active acidic metabolite. Phase 2 enzymes facilitate the elimination of drugs and the inactivation of electrophilic and potentially toxic metabolites produced by oxidation. While many phase 1 reactions result in the biological inactivation of the drug, phase 2 reactions produce a metabolite with improved water solubility, a change that facilitates the elimination of the drug from the tissue, normally via efflux transporters.

Superfamilies of evolutionarily related enzymes and receptors are common in the mammalian genome; the enzyme systems responsible for drug metabolism are good examples. The phase 1 oxidation reactions are carried out by CYPs, flavin-containing monooxygenases (FMO), and epoxide hydrolases (EH). The CYPs and FMOs are composed of superfamilies of enzymes. Each superfamily contains multiple genes. The phase 2 enzymes include several superfamilies of conjugating enzymes. Among the more important are the glutathione-S-transferases (GST), UDP-glucuronosyltransferases (UGT), sulfotransferases (SULT), N-acetyltransferases (NAT), and methyltransferases (MT). These conjugation reactions usually require the substrate to have oxygen (hydroxyl or epoxide groups), nitrogen, or sulfur atoms that serve as acceptor sites for a hydrophilic moiety, such as glutathione, glucuronic acid, sulfate, or an acetyl group. The example of phase 1 and phase 2 metabolism of phenytoin is shown in Figure 6–1. The oxidation by phase 1 enzymes either adds or exposes a functional group, permitting the products of phase 1 metabolism to serve as substrates for the phase 2 conjugating or synthetic enzymes. In the case of the UGTs, glucuronic acid is delivered to the functional group, forming a glucuronide metabolite that is more water soluble and is targeted for excretion either in the urine or bile. When the substrate is a drug, these reactions usually convert the original drug to a form that is not able to bind to its target receptor, thus attenuating the biological response to the drug.

**SITES OF DRUG METABOLISM**

Xenobiotic metabolizing enzymes are found in most tissues in the body with the highest levels located in the GI tract (liver, small and large intestines). Drugs that are

mEH and sEH are microsomal and soluble epoxide hydrolase. UDP, uridine diphosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate.
orally administered, absorbed by the gut, and taken to the liver, can be extensively metabolized. The liver is considered the major “metabolic clearing house” for both endogenous chemicals (e.g., cholesterol, steroid hormones, fatty acids, and proteins) and xenobiotics. The small intestine plays a crucial role in drug metabolism since drugs that are orally administered are absorbed by the gut and taken to the liver through the portal vein. The xenobiotic-metabolizing enzymes located in the epithelial cells of the GI tract are responsible for the initial metabolic processing of most oral medications. This should be considered the initial site of drug metabolism. The absorbed drug then enters the portal circulation for its first pass through the liver, where it can undergo significant metabolism. While a portion of active drug escapes metabolism in the GI tract and liver, subsequent passes through the liver result in more metabolism of the parent drug until the agent is eliminated. Thus, drugs that are poorly metabolized remain in the body for longer periods of time and their pharmacokinetic profiles show much longer elimination half-lives than drugs that are rapidly metabolized. Other organs that contain significant xenobiotic-metabolizing enzymes include tissues of the nasal mucosa and lung, which play important roles in the metabolism of drugs that are administered through aerosol sprays. These tissues are also the first line of contact with hazardous chemicals that are airborne.

Within the cell, xenobiotic-metabolizing enzymes are found in the intracellular membranes and in the cytosol. The phase 1 CYPs, FMOs, and EHs, and some phase 2 conjugating enzymes, notably the UGTs, are all located in the endoplasmic reticulum of the cell (Figure 6-2). The endoplasmic reticulum consists of phospholipid bilayers, organized as tubes and sheets throughout the cytoplasm, forming a network that has an inner lumen that is physically distinct from the rest of the cytosolic components of the cell and has connections to the plasma membrane and nuclear envelope. This membrane localization is ideally suited for the metabolic function of these enzymes: hydrophobic molecules enter the cell and become embedded in the lipid bilayer, where they come into direct contact with the

---

**Figure 6-2. Location of CYPs in the cell.** The figure shows increasingly microscopic levels of detail, sequentially expanding the areas within the black boxes. CYPs are embedded in the phospholipid bilayer of the endoplasmic reticulum (ER). Most of the enzyme is located on the cytosolic surface of the ER. A second enzyme, NADPH-cytochrome P₄₅₀ oxidoreductase, transfers electrons to the CYP where it can, in the presence of O₂, oxidize xenobiotic substrates, many of which are hydrophobic and dissolved in the ER. A single NADPH-CYP oxidoreductase species transfers electrons to all CYP isoforms in the ER. Each CYP contains a molecule of iron-protoporphyrin IX that functions to bind and activate O₂. Substituents on the porphyrin ring are methyl (M), propionyl (P), and vinyl (V) groups.
PHASE 1 REACTIONS

The Cytochrome P-450 Superfamily: the CYPs

The CYPs are a superfamily of enzymes, all of which contain a molecule of heme that is non-covalently bound to the polypeptide chain (Figure 6–2). Many other enzymes that use O₂ as a substrate for their reactions also contain heme. Heme is the oxygen-binding moiety found in hemoglobin, where it functions in the binding and transport of molecular oxygen from the lung to other tissues. Heme contains one atom of iron in a hydrocarbon cage that functions to bind oxygen in the CYP active site as part of the catalytic cycle of these enzymes. CYPs use O₂, plus H⁺ derived from the cofactor-reduced nicotinamide adenine dinucleotide phosphate (NADPH), to carry out the oxidation of substrates. The H⁺ is supplied through the enzyme NADPH-cytochrome P450 oxidoreductase. Metabolism of a substrate by a CYP consumes one molecule of molecular oxygen and produces an oxidized substrate and a molecule of water as a by-product. However, for most CYPs, depending on the nature of the substrate, the reaction is “uncoupled,” consuming more O₂ than substrate metabolized and producing what is called activated oxygen or O₂⁻. The O₂⁻ is usually converted to water by the enzyme superoxide dismutase. Elevated O₂⁻, a reactive oxygen species (ROS), can give rise to oxidative stress that is detrimental to cellular physiology and associated with diseases including hepatic cirrhosis.

Among the diverse reactions carried out by mammalian CYPs are N-dealkylation, O-dealkylation, aromatic hydroxylation, N-oxidation, S-oxidation, deamination, and dehalogenation (Table 6–2). More than 50 individual CYPs have been identified in humans. As a family of enzymes, CYPs are involved in the metabolism of dietary and xenobiotic chemicals, as well as the synthesis of endogenous compounds (e.g., steroids; fatty acid-derived signaling molecules, such as epoxyeicosatrienoic acids). CYPs also participate in the production of bile acids from cholesterol.

In contrast to the drug-metabolizing CYPs, the CYPs that catalyze steroid and bile acid synthesis have very specific substrate preferences. For example, the CYP that produces estrogen from testosterone, CYP19 or aromatase, can metabolize only testosterone or androstenedione and does not metabolize xenobiotics. Specific inhibitors for aromatase, such as anastrozole, have been developed for use in the treatment of estrogen-dependent tumors (see Chapters 40 and 60-63). The synthesis of bile acids from cholesterol occurs in the liver, where, subsequent to CYP-catalyzed oxidation, the bile acids are conjugated with amino acids and transported through the bile duct and gallbladder into the small intestine. Bile acids are emulsifiers that facilitate the elimination of conjugated drugs from the liver and the absorption of fatty acids and vitamins from the diet. In this capacity, > 90% of bile acids are reabsorbed by the gut and transported back to the hepatocytes. Similar to the steroid biosynthetic CYPs, CYPs involved in bile acid production have strict substrate requirements and do not participate in xenobiotic or drug metabolism.

The CYPs that carry out xenobiotic metabolism have the capacity to metabolize diverse chemicals. This is due both to multiple forms of CYPs and to the capacity of a single CYP to metabolize many structurally distinct chemicals. There is also significant overlapping substrate specificity amongst CYPs; a single compound can also be metabolized, albeit at different rates, by different CYPs. Additionally, CYPs can metabolize a single compound at different positions on the molecule. In contrast to most enzymes in the body that carry out highly specific reactions involved in the biosynthesis and degradation of important cellular constituents in which there is a single substrate and one or more products, or two simultaneous substrates, the CYPs are promiscuous in their capacity to bind and metabolize multiple substrates (Table 6–2). This property, which is due to large and fluid substrate binding sites in the CYP, sacrifices metabolic turnover rates; CYPs metabolize substrates at a fraction of the rate of more typical enzymes involved in intermediary metabolism and mitochondrial electron transfer. As a result, drugs have, in general, half-lives in the range of 3-30 hours, while endogenous compounds have half-lives of the order of seconds or minutes (e.g., dopamine and insulin). Even though CYPs have slow catalytic rates, their activities are sufficient to metabolize drugs that are administered at high concentrations in the body. This unusual feature of extensive overlapping substrate specificities by the CYPs is one of the underlying reasons for the predominance of drug-drug interactions. When two co-administered drugs are both metabolized by a single CYP, they compete for binding to the enzyme’s active site. This can result in the inhibition of metabolism of one or both of the drugs, leading to elevated plasma levels. If there is a narrow therapeutic index for the drugs, the elevated serum levels may elicit unwanted toxicities. Drug-drug interactions are among the leading causes of adverse drug reactions (ADRs).

The Naming of CYPs. The CYPs are the most actively studied of the xenobiotic metabolizing enzymes since they are responsible for metabolizing the vast majority of therapeutic drugs. Genome sequencing has revealed the existence of 102 putatively functional

PAPS, 3′-phosphoadenosine-5′-phosphosulfate; PAP 3′-phosphoadenosine-5′-phosphate.
genes and 88 pseudogenes in the mouse, and 57 putatively functional genes and 58 pseudogenes in humans. These genes are grouped, based on amino acid sequence similarity, into a superfamily composed of families and subfamilies with increasing sequence similarity. CYPs are named with the root CYP followed by a number designating the family, a letter denoting the sub-family, and another number designating the CYP form. Thus, *CYP3A4* is family 3, sub-family A, and gene number 4.

**A Dozen CYPs Suffice for Metabolism of Most Drugs.** While several CYP families are involved in the synthesis of steroid hormones and bile acids, and the metabolism of retinoic acid and fatty acids (including prostaglandins and eicosanoids), a limited number of CYPs that fall into families 1 to 3 are primarily involved in xenobiotic metabolism. Since a single CYP can metabolize myriad structurally diverse compounds, these enzymes can collectively metabolize scores of chemicals found in the diet and environment, and administered as drugs. In humans, 12 CYPs (*CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5*) are known to be important for metabolism of xenobiotics. The liver contains the greatest abundance of xenobiotic-metabolizing CYPs, thus ensuring efficient first-pass metabolism of drugs. CYPs are also expressed throughout the GI tract, and in lower amounts in lung, kidney, and even in the CNS. The expression of the different CYPs can differ markedly as a result of dietary and environmental exposure to inducers, or through inter-individual changes resulting from heritable polymorphic differences in gene structure; tissue-specific expression patterns can affect overall drug metabolism and clearance. The most active CYPs for drug metabolism are those in the CYP2C, CYP2D, and CYP3A sub-families. CYP3A4, the most abundantly expressed in liver, is involved in the metabolism of over 50% of clinically used drugs (Figure 6–3A). The CYP1A1, CYP1B1, CYP2A, CYP2B, and CYP2E subfamilies are not significantly involved in the metabolism of therapeutic drugs, but they do catalyze the metabolic activation of many protoxins and procarcinogens to their ultimate reactive metabolites.

There are large differences in levels of expression of each CYP amongst individuals as assessed both by clinical pharmacological studies and by analysis of expression in human liver samples. This large inter-individual variability in CYP expression is due to the presence of genetic polymorphisms and differences in gene regulation (see following discussion). Several human CYP genes exhibit polymorphisms, including *CYP2A6, CYP2C9, CYP2C19,* and *CYP2D6*. Allelic variants have been found in the *CYP1B1* and *CYP3A4* genes, but they are present at low frequencies in humans and appear not to have a major role in inter-individual levels of expression of these enzymes. However, homozygous mutations in the *CYP1B1* gene are associated with primary congenital glaucoma.

**CYPs and Drug-Drug Interactions.** Differences in the rate of metabolism of a drug can be due to drug interactions. Most commonly, this occurs when two drugs (e.g., a statin and a macrolide antibiotic or antifungal agent) are co-administered and subjected to metabolism by the same enzyme. Thus, it is important to determine the identity of the CYP that metabolizes a particular drug and to avoid co-administering drugs that are metabolized by the same enzyme. Some drugs can also inhibit CYPs independently of being substrates for a CYP. For example, the common antifungal agent, ketoconazole (*NIZORAL*), is a potent inhibitor of *CYP3A4* and other CYPs, and co-administration of ketoconazole with an anti-HIV viral protease inhibitor reduces the clearance of the protease inhibitor and increases its plasma concentration and the risk of toxicity. For most drugs, information found on the package insert lists the CYP that metabolizes the drug and determines the potential for drug interactions. Some drugs are CYP inducers that can increase not only their own rates of metabolism, but also induce metabolism of other
co-administered drugs (see later discussion and Figure 6–12). For example, steroid hormones and herbal products such as St. John’s wort can increase hepatic levels of CYP3A4, thereby increasing the metabolism of many orally administered drugs. Indeed, St. John’s wort can induce hepatic metabolism of the steroid components of birth control pills, rendering the standard dose ineffective in preventing pregnancy. Drug metabolism can also be influenced by diet. CYP inhibitors and inducers are commonly found in foods and in some cases these can influence the toxicity and efficacy of a drug. Components found in grapefruit juice (e.g., naringin, furanocoumarins) are potent inhibitors of CYP3A4, and thus some drug inserts recommend not taking medication with grapefruit juice because it could increase the bioavailability of the drug.

Terfenadine, a once popular antihistamine, was removed from the market because its metabolism was inhibited by CYP3A4 substrates such as erythromycin and grapefruit juice. Terfenadine was actually a prodrug that required oxidation by CYP3A4 to its active metabolite, and at high doses the parent compound caused the potentially fatal arrhythmia torsades de pointes. Thus, as a result of CYP3A4 inhibition by a co-administered agent, plasma levels of the parent drug could become dangerously elevated, causing ventricular tachycardia in some individuals; this led to terfenadine’s withdrawal from the market. Subsequently, the metabolite was developed as a drug, fexofenadine, which retains the therapeutic properties of the parent compound but avoids the step involving CYP3A4.

In addition, inter-individual differences in drug metabolism are significantly influenced by polymorphisms in CYPs. The CYP2D6 polymorphism has led to the withdrawal of several clinically used drugs (e.g., debrisoquine and perhexiline) and the cautious use of others that are known CYP2D6 substrates (e.g., encainide and flecainide [anti-arrhythmics], desipramine and nortriptyline [antidepressants], and codeine).

FLAVIN-CONTAINING MONOOXYGENASES (FMOs)

The FMOs are another superfamily of phase 1 enzymes involved in drug metabolism. Similar to CYPs, the FMOs are expressed at high levels in the liver and are bound to the endoplasmic reticulum, a site that favors interaction with and metabolism of hydrophobic drug substrates. There are six families of FMOs, with FMO3 being the most abundant in liver. FMO3 is able to metabolize nicotine, as well as H₂ receptor antagonists (cimetidine and ranitidine), antipsychotics (clozapine), and anti-emetics (itopride). A genetic deficiency in this enzyme causes the fish-odor syndrome due to a lack of metabolism of trimethylamine N-oxide (TMAO) to trimethylamine (TMA); in the absence of this enzyme, TMAO accumulates in the body and causes a socially offensive fish odor. TMAO is found at high concentrations, up to 15% by weight, in marine animals, where it acts as an osmotic regulator. FMOs are considered minor contributors to drug metabolism and they almost always produce benign metabolites. In addition, FMOs are not induced by any of the xenobiotic receptors (see below) or easily inhibited; thus, in contrast to CYPs, FMOs would not be expected to be involved in drug-drug interactions. In fact, this has been demonstrated by comparing the pathways of metabolism of two drugs used in the control of gastric motility, itopride, and cisapride. Itopride is metabolized by FMO3 while cisapride is metabolized by CYP3A4; thus, itopride is less likely to be involved in drug-drug interactions than is cisapride. CYP3A4 participates in drug-drug interactions through induction and inhibition of metabolism, whereas FMO3 is not induced or inhibited by any clinically used drugs. FMOs could be of importance in the development of new drugs. A candidate drug could be designed by introducing a site for FMO oxidation with the knowledge that favorable metabolism and pharmacokinetic properties could be accurately predicted.

HYDROLYTIC ENZYMES

Two forms of epoxide hydrolase carry out hydrolysis of epoxides, most of which are produced by CYPs. The soluble epoxide hydrolase (sEH) is expressed in the cytosol while the microsomal epoxide hydrolase (mEH) is localized to the membrane of the endoplasmic reticulum. Epoxides are highly reactive electrophiles that can bind to cellular nucleophiles found in protein, RNA, and DNA, resulting in cell toxicity and transformation. Thus, epoxide hydrolases participate in the deactivation of potentially toxic metabolites generated by CYPs. There are a few examples of the influence of mEH on drug metabolism. The anti-epileptic drug carbamazepine is a prodrug that is converted to its pharmacologically active derivative, carbamazepine-10, 11-epoxide by a CYP. This metabolite is efficiently hydrolyzed to a dihydriodiol by mEH, resulting in inactivation of the drug (Figure 6–4). Inhibition of mEH can cause an elevation in plasma concentrations of the active metabolite, causing side effects. The tranquilizer valnoctamide and anticonvulsant valproic acid inhibit mEH, resulting in clinically significant drug interactions with carbamazepine. This has led to efforts to develop new anti-epileptic drugs such as gabapentin and levetiracetam that are metabolized by CYPs and not by EHs.
more pharmacologically active than the parent. The contributions of different phase 2 reactions to drug metabolism are shown in Figure 6–3B. Two of the phase 2 reactions, glucuronidation and sulfation, result in the formation of metabolites with a significantly increased water-to-lipid partition coefficient, resulting in hydrophilicity and facilitating metabolite accumulation in the aqueous compartments of the cell and the body. While sulfation and acetylation terminate the biological activity of drugs, the solubility properties of these metabolites are altered through minor changes in the overall charge of the molecule. Characteristic of the phase 2 reactions is the dependency on the catalytic
reactions for cofactors, (or more correctly, co-substrates) such as UDP-glucuronic acid (UDP-GA) and 3'-phosphadenosine-5'-phosphosulfate (PAPS), for UDP-glucuronosyltransferases (UGT) and sulfotransferases (SULT), respectively, which react with available functional groups on the substrates. The reactive functional groups are often generated by the phase 1 CYPs, although there are many drugs (e.g., acetaminophen) where glucuronidation and/or sulfation occur directly without prior oxidative metabolism. All of the phase 2 reactions are carried out in the cytosol of the cell, with the exception of glucuronidation, which is localized to the luminal side of the endoplasmic reticulum. The catalytic rates of phase 2 reactions are significantly faster than the rates of the CYPs. Thus, if a drug is targeted for phase 1 oxidation through the CYPs, followed by a phase 2 conjugation reaction, usually the rate of elimination will depend upon the initial (phase 1) oxidation reaction. Since the rate of conjugation is faster and the process leads to an increase in hydrophilicity of the drug, phase 2 reactions are generally considered to assure the efficient elimination and detoxification of most drugs.

Glucuronidation. Among the more important of the phase 2 reactions in the metabolism of drugs is that catalyzed by UDP-glucuronosyltransferases (UGTs) (Figure 6–3B). These enzymes catalyze the transfer of glucuronic acid from the cofactor UDP-glucuronic acid to a substrate to form β-D-glucopyranosiduronic acids (glucuronides), metabolites that are sensitive to cleavage by β-glucuronidase. The generation of glucuronides can be formed through alcoholic and phenolic hydroxyl groups, carboxyl, sulfuryl, and carbonyl moieties, as well as through primary, secondary, and tertiary amine linkages. Examples of glucuronidation reactions are shown in Table 6–2 and Figure 6–5. The structural diversity in the many different types of drugs and xenobiotics that are processed through glucuronidation assures that most clinically efficacious therapeutic agents will be excreted as glucuronides.

There are 19 human genes that encode the UGT proteins. Nine are encoded by the UGT1 locus and 10 are encoded by the UGT2 family of genes. Both families of proteins are involved in the metabolism of drugs and xenobiotics, while the UGT2 family of proteins appears to have greater specificity for the glucuronidation of endogenous substances such as steroids. The UGT2 proteins are encoded by unique genes on chromosome 4 and the structure of each gene includes six exons. The clustering of the UGT2 genes on the same chromosome, with a comparable organization of the regions encoding the open reading frames, is evidence that gene duplication has occurred, a process of natural selection that has resulted in the multiplication and eventual diversification of the potential to detoxify the plethora of compounds that are targeted for glucuronidation.

The nine functional UGT1 proteins are all encoded by the UGT1 locus (Figure 6–6), which is located on chromosome 2. The UGT1 locus spans nearly 200 kb, with over 150 kb of a tandem array of cassette exonic regions that encode ~280 amino acids of the amino terminal portion of the UGT1A proteins. Four exons are located at the 3’ end of the locus that encode the carboxyl 245 amino acids that combine with one of the consecutively numbered array of first exons to form the individual UGT1 gene products. Since exons 2-5 encode the same sequence for each UGT1A protein, the variability in substrate specificity for each of the UGT1A proteins results from the significant divergence in sequence encoded by the exon 1 regions. The 5’ flank region of each first-exon cassette contains a fully functional promoter capable of initiating transcription in an inducible and tissue-specific manner.

From a clinical perspective, the expression of UGT1A1 assumes an important role in drug metabolism, since the glucuronidation of bilirubin by UGT1A1 is the rate-limiting step in assuring efficient bilirubin clearance, and this rate can be affected by both genetic variation and competing substrates (drugs). Bilirubin is the breakdown product of heme, 80% of which originates from circulating hemoglobin and 20% from other heme-containing proteins such as the CYPs. Bilirubin is hydrophobic, associates with serum albumin, and must be metabolized further by glucuronidation to assure its elimination. The failure to efficiently metabolize bilirubin by glucuronidation leads to elevated serum levels and a clinical symptom called hyperbilirubinemia or jaundice. There are >50 genetic lesions in the UGT1A1 gene that can lead to inheritable unconjugated
hyperbilirubinemia. Crigler-Najjar syndrome type I is diagnosed as a complete lack of bilirubin glucuronidation; Crigler-Najjar syndrome type II is differentiated by the detection of low amounts of bilirubin glucurononides in duodenal secretions. Types I and II Crigler-Najjar syndrome are rare, and result from genetic polymorphisms in the open reading frames of the \textit{UGT1A1} gene, resulting in abolished or highly diminished levels of functional protein.

Gilbert’s syndrome is a generally benign condition that is present in up to 10% of the population; it is diagnosed clinically because circulating bilirubin levels are 60-70% higher than those seen in normal subjects. The most common genetic polymorphism associated with Gilbert’s syndrome is a mutation in the \textit{UGT1A1} gene promoter, identified as the \textit{UGT1A1*28} allele, which leads to reduced expression levels of \textit{UGT1A1}. Subjects diagnosed with Gilbert’s syndrome may be predisposed to ADRs (Table 6-3) that result from a reduced capacity of \textit{UGT1A1} to metabolize drugs. If a drug undergoes selective metabolism by \textit{UGT1A1}, competition for drug metabolism with bilirubin glucuronidation will exist, resulting in pronounced hyperbilirubinemia as well as reduced clearance of the metabolized drug. Tranilast \([N-(3'-demethoxyxaminomethyl)-antranilic acid] \) is an investigational drug used for the prevention of restenosis in patients who have undergone transluminal coronary revascularization (intracoronary stents). Tranilast therapy in patients with Gilbert’s syndrome can lead to hyperbilirubinemia, as well as hepatic complications resulting from elevated levels of tranilast.

Gilbert’s syndrome also alters patient responses to irinotecan. Irinotecan, a prodrug used in chemotherapy of solid tumors (see Chapter 61), is metabolized to its active form, SN-38, by serum carboxylesterases (Figure 6–5). SN-38, a potent topoisomerase inhibitor, is inactivated by \textit{UGT1A1} and excreted in the bile (Figures 6–7 and 6–8). Once in the lumen of the intestine, the SN-38 glucuronide undergoes cleavage by bacterial \(\beta\)-glucuronidase and reenters the circulation through intestinal absorption. Elevated levels of SN-38 in the blood lead to bone marrow toxicities characterized by leukopenia and neutropenia, as well as damage to the intestinal epithelial cells (Figure 6–8), resulting in acute and life-threatening diarrhea. Patients with Gilbert’s syndrome who are receiving irinotecan therapy are predisposed to the hematological and GI toxicities resulting from elevated serum levels of SN-38.

While most of the drugs that are metabolized by \textit{UGT1A1} compete for glucuronidation with bilirubin, Gilbert’s patients who are HIV-positive and on protease inhibitor therapy with atazanavir (\textit{REY ATAZ}) develop hyperbilirubinemia because the drug inhibits \textit{UGT1A1} function. Although atazanavir is not a substrate for glucuronidation, severe hyperbilirubinemia can develop in Gilbert’s patients who have inactivating mutations in their \textit{UGT1A3} and \textit{UGT1A7} genes. Clearly, drug-induced side effects attributed to the inhibition of the UGT enzymes can be a significant concern and can be complicated in the presence of gene inactivating polymorphisms.

The UGTs are expressed in a tissue-specific and often inducible fashion in most human tissues, with the highest concentration of enzymes found in the GI tract and liver. Based upon their physicochemical properties, glucuronides are excreted by the kidneys into the urine or through active transport processes through the apical surface of the liver hepatocytes into the bile ducts where they are transported to the duodenum for excretion with components of the bile. Most of the bile acids that are conjugated are reabsorbed from the gut back to the liver via \textit{enterohepatic recirculation}; many drugs that are glucuronidated and excreted in the bile can re-enter the circulation by this same process. The \(\beta\)-D-glucopyranosiduronic acids are targets for \(\beta\)-glucuronidase activity found in resident strains of bacteria that are common in the lower GI tract, thus liberating the free drug into the intestinal lumen. As water is reabsorbed into the large intestine, the free drug can then be transported by passive diffusion or through apical transporters back into the intestinal epithelial cells, from which the drug can then re-enter the circulation. Through portal venous return from the large intestine to the liver, the reabsorption process allows for the reentry of drug into the systemic circulation (Figures 3–7 and 3–8).

**Sulfation.** The sulfotransferases (SULTs) are cytosolic and conjugate sulfate derived from \(3’\)-phosphoadenosine-5’-phosphosulfate (PAPS) to the hydroxyl and, less frequently, amine groups of aromatic and aliphatic compounds. Like all of the xenobiotic metabolizing enzymes, the SULTs metabolize a wide variety of endogenous and exogenous substrates.

In humans, 13 SULT isoforms have been identified, and based on sequence comparisons, have been classified into the SULT1 (SULT1A1, SULT1A2, SULT1A3/4, SULT1B1, SULT1C1, SULT1C2, SULT1C4, SULT1E1), SULT2 (SULT2A1, SULT2B1a, SULT2B1b), SULT4 (SULT4A1), and SULT6 (SULT6A1) families. SULTs play an important role in normal human homeostasis. For example, SULT2B1b...
is a predominant form expressed in skin, carrying out the catalysis of cholesterol. Cholesterol sulfate is an essential metabolite in regulating keratinocyte differentiation and skin development. SULT2A1 is very highly expressed in the fetal adrenal gland, where it produces the large quantities of dehydroepiandrosterone sulfate that are required for placental estrogen biosynthesis during the second half of pregnancy. SULT1A3 is highly selective for catecholamines, while estrogens (in particular 17β-estradiol) are sulfated by SULT1E1. In humans, significant

Figure 6–7. Routes of SN-38 transport and exposure to intestinal epithelial cells. SN-38 is transported into the bile following glucuronidation by liver UGT1A1 and extrahepatic UGT1A7. Following cleavage of luminal SN-38 glucuronide (SN-38G) by bacterial β-glucuronidase, reabsorption into epithelial cells can occur by passive diffusion (indicated by the dashed arrows entering the cell) as well as by apical transporters. Movement into epithelial cells may also occur from the blood by basolateral transporters. Intestinal SN-38 can efflux into the lumen through P-glycoprotein (P-gp) and multidrug resistance protein 2 (MRP2) and into the blood by means of MRP1. Excessive accumulation of the SN-38 in intestinal epithelial cells and bone marrow, resulting from reduced glucuronidation, can lead to the cellular damage and toxicity depicted in Figure 6–8 (Reproduced with permission from Tukey RH et al. Pharmacogenetics of human UDP-glucuronosyltransferases and irinotecan toxicity. Mol Pharmacol, 2002, 62:446–450. Copyright © 2002 The American Society for Pharmacology and Experimental Therapeutics.).
fractions of circulating catecholamines, estrogens, iodothyronines, and DHEA exist in the sulfated form. Some human SULTs display great fidelity to unique substrate specificities; other SULTs are shockingly promiscuous in their activities. The SULT1 family isoforms are considered to be the major forms involved in xenobiotic metabolism, with SULT1A1 being quantitatively and qualitatively the most important in the liver. It displays extensive diversity in its capacity to catalyze the sulfation of a wide variety of structurally heterogeneous xenobiotics with high affinity. SULT1 isoforms have been recognized as phenol SULTs, since they catalyze the sulfation of phenolic molecules such as acetaminophen, minoxidil, and 17α-ethyl estradiol. SULT1B1 is similar to SULT1A1 in that it can sulfate a very wide range of compounds, although it is much more abundant in the intestine than the liver. While three SULT1C isoforms exist in humans, little is known about their substrate specificity toward drugs or other compounds. In rodents, SULT1C enzymes are capable of sulfating the hepatic carcinogen N-OH-2-acetylaminofluorene, and are responsible for the bioactivation of this and related carcinogens. Their role in this pathway in humans is not clear. SULT1C enzymes are expressed abundantly in human fetal tissues, yet decline in abundance in adults. SULT1E catalyzes the sulfation of endogenous and exogenous steroids, and has been found localized in liver, as well as in hormone-responsive tissues such as the testis, breast, adrenal gland, and placenta. In the upper GI tract, SULT1A3 and SULT1B1 are particularly abundant.

The conjugation of drugs and xenobiotics is considered primarily a detoxification step, assuring that these compounds enter the aqueous compartments of the body and are targeted for elimination. However, drug metabolism through sulfation often leads to the generation of chemically reactive metabolites, where the sulfate is electron withdrawing and may be heterolytically cleaved, leading to the formation of an electrophilic cation. Most examples of the generation by sulfation of a carcinogenic or toxic response in animal or test mutagenicity assays have been documented with chemicals derived from the environment or from heterocyclic arylamine food mutagens generated from well-cooked meat. Thus, it is important to understand whether genetic linkages can be made by associating known human SULT polymorphisms to cancers that are believed to originate from environmental sources. Since SULT1A1 is the most abundant SULT form in human tissues and displays broad substrate specificity, the polymorphic profiles associated with this gene and their associations with various human cancers is of considerable interest. Recently, gene copy number polymorphisms within the SULT1A1, SULT1A3, and SULT1A4 genes have been indentified, which may help explain much of the interindividual variation in the expression and activity of these enzymes. Knowledge of the structure, activities, regulation, and polymorphisms of the SULT superfamily will aid in understanding of the linkages between sulfation and cancer susceptibility, reproduction, and development. Sulfation is a major xenobiotic metabolizing system during human development, with levels of many enzymes higher in the fetus than the adult.

The SULTs from the SULT1 and SULT2 families were among the first xenobiotic-metabolizing enzymes to be crystallized, and the data indicated a highly conserved catalytic core (Negishi et al., 2001). Crystal structures of the different SULTs indicate that while conservation in the PAPS binding region is maintained, the organization of the substrate binding region differs, helping to explain the observed differences in catalytic potential displayed with the different SULTs.

**Glutathione Conjugation.** The glutathione-S-transferases (GSTs) catalyze the transfer of glutathione to reactive electrophiles, a function that serves to protect cellular macromolecules from interacting with electrophiles that contain electrophilic heteroatoms (-O, -N, and -S) and in turn protects the cellular environment from damage (Hayes et al., 2005). The co-substrate in the reaction is the tripeptide glutathione, which is synthesized from γ-glutamatic acid, cysteine, and glycine (Figure 6–9). Glutathione exists in the cell as oxidized (GSSG) or reduced (GSH) forms, and the ratio of GSH:GSSG is critical in maintaining a cellular environment in the reduced state. In addition to affecting xenobiotic conjugation with GSH, a severe reduction in GSH content can predispose cells to oxidative damage, a state that has been linked to a number of human health issues.

In the formation of glutathione conjugates, the reaction generates a thioether linkage with drug or xenobiotic to the cysteine moiety of the tripeptide. Characteristically, all GST substrates contain an electrophilic atom and are hydrophobic, and by nature will associate with cellular proteins. Since the concentration of glutathione in cells is usually very high, typically ~7 μmol/g of liver, or in the 10 mM range, many drugs and xenobiotics can react non-enzymatically with glutathione. However, the GSTs have been found to occupy up to 10% of the total cellular protein concentration, a property that assures efficient conjugation of glutathione to reactive electrophiles. The high concentration of GSTs also provides the cells with a sink of cytosolic protein, a property that facilitates
non-covalent and sometimes covalent interactions with compounds that are not substrates for glutathione conjugation. The cytosolic pool of GSTs, once identified as ligandin, has been shown to bind steroids, bile acids, bilirubin, cellular hormones, and environmental toxicants, in addition to complexing with other cellular proteins.

Over 20 human GSTs have been identified and divided into two subfamilies: the cytosolic and the microsomal forms. The major differences in function between the microsomal and cytosolic GSTs reside in the selection of substrates for conjugation; the cytosolic forms have more importance in the metabolism of drugs and xenobiotics, whereas the microsomal GSTs are important in the endogenous metabolism of leukotrienes and prostaglandins. The cytosolic GSTs are divided into seven classes termed alpha (GSTA1 and 2), mu (GSTM1 through 5), omega (GSTO1), pi (GSTP1), sigma (GSTS1), theta (GSTT1 and 2), and zeta (GSTZ1). Those in the alpha and mu classes can form heterodimers, allowing for a large number of active transferases to form. The cytosolic forms of GST catalyze conjugation, reduction, and isomerization reactions.

The high concentrations of GSH in the cell and the plenitude of GSTs mean that few reactive molecules escape detoxification. However, while there appears to be an overcapacity of enzyme and reducing equivalents, there is always concern that some reactive intermediates will escape detoxification, and by nature of their electrophilicity, will bind to cellular components, and cause toxicity. The potential for such an occurrence is heightened if GSH is depleted or if a specific form of GST is polymorphic. While it is difficult to deplete cellular GSH levels, reactive therapeutic agents that require large doses for clinical efficacy have the greatest potential to lower cellular GSH levels. Acetaminophen, which is normally metabolized by glucuronidation and sulfation, is also a substrate for oxidative metabolism by CYP2E1 and CYP3A4, which generate the toxic metabolite N-acetyl-\(p\)-benzoquinone imine (NAPQI) that, under normal dosing, is readily neutralized through conjugation with GSH. However, an overdose of acetaminophen can lead to depletion of cellular GSH levels, thereby increasing the potential for NAPQI to interact with other cellular components resulting in toxicity and cell death (see Figure 4–5). Acetaminophen toxicity is associated with increased levels of NAPQI and hepatic necrosis.

Like many of the enzymes involved in drug and xenobiotic metabolism, all of the GSTs have been shown to be polymorphic. The mu (GSTM1*0) and theta (GSTT1*0) genotypes express a null phenotype; thus, individuals that are polymorphic at these loci are predisposed to toxicities by agents that are selective substrates for these GSTs. For example, the mutant GSTM1*0 allele is observed in 50% of the Caucasian population and has been linked genetically to human malignancies of the lung, colon, and bladder. Null activity in the GSTT1 gene has been associated with adverse side effects and toxicity in cancer chemotherapy with cytostatic drugs; the toxicities result from insufficient clearance of the drugs by GSH conjugation. Expression of the null genotype can be as high as 60% in Chinese and Korean populations. GST polymorphisms may influence efficacies and severity of adverse side effects of drugs.

While the GSTs play an important role in cellular detoxification, their activities in cancerous tissues have been linked to the development of drug resistance toward chemotherapeutic agents that are both substrates and nonsubstrates for the GSTs. Many anticancer drugs are effective because they initiate cell death or apoptosis, which is linked to the activation of mitogen-activated protein (MAP) kinases such as JNK and p38. Investigational studies have demonstrated that overexpression of GSTs is associated with resistance to apoptosis and the inhibition of MAP kinase activity. In a variety of tumors, GSTs are overexpressed, leading to a reduction in MAP kinase activity and reduced efficacy of chemotherapy. Taking advantage of the relatively high levels of GST in tumor cells, inhibition of GST activity has been exploited as a therapeutic strategy to modulate drug resistance by sensitizing tumors to anticancer drugs. TLK199, a glutathione analog, serves as a prodrug that undergoes activation by plasma esterases to a GST inhibitor, TLK117, which potentiates the toxicity of different anticancer agents (Figure 6–10). Alternatively, the elevated GST activity in cancer cells has been utilized to develop pro-drugs that can be activated by the GSTs to form electrophilic intermediates. For example, TLK286 is a substrate for GST that undergoes a β-elimination reaction, forming a glutathione conjugate and a nitrogen mustard (Figure 6–11) capable of alkylating cellular nucleophiles, resulting in anti-tumor activity.

**N-Acetylation.** The cytosolic N-acetyltransferases (NATs) are responsible for the metabolism of drugs and environmental agents that contain an aromatic amine or hydrazine group. The addition of the acetyl group from the cofactor acetyl-coenzyme A often leads to a metabolite that is less water soluble because the potential

![Figure 6-10. Activation of TLK199 by cellular esterases to the glutathione-S-transferase (GST) inhibitor TLK117. (For additional information, see Townsend and Tew, 2003.)](image-url)
ionizable amine is neutralized by the covalent addition of the acetyl group. NATs are among the most polymorphic of all the human xenobiotic drug-metabolizing enzymes.

The characterization of an acetylator phenotype in humans was one of the first hereditary traits identified, and was responsible for the development of the field of pharmacogenetics (see Chapter 7). Following the discovery that isonicotinic acid hydrazide (isoniazid, INH) could be used in the cure of tuberculosis, a significant proportion of the patients (5-15%) experienced toxicities that ranged from numbness and tingling in their fingers to CNS damage. After finding that isoniazid was metabolized by acetylation and excreted in the urine, researchers noted that individuals suffering from the toxic effects of the drug excreted the largest amount of unchanged drug and the least amount of acetylated isoniazid. Pharmacogenetic studies led to the classification of “rapid” and “slow” acetylators, with the “slow” phenotype being predisposed to toxicity. Purification and characterization of N-acetyltransferase and the eventual cloning of its RNA provided sequence characterization of the gene, revealing polymorphisms that correspond to the “slow” acetylator phenotype. There are two functional NAT genes in humans, NAT1 and NAT2. Over 25 allelic variants of NAT1 and NAT2 have been characterized, and in individuals in whom acetylation of drugs is compromised, homozygous genotypes for at least two variant alleles are required to predispose a patient to lowered drug metabolism. Polymorphism in the NAT2 gene, and its association with the slow acetylation of isoniazid, was one of the first completely characterized genotypes shown to affect drug metabolism, thereby linking pharmacogenetic phenotype to a genetic polymorphism. Although nearly as many mutations have been identified in the NAT1 gene as the NAT2 gene, the frequency of the slow acetylation patterns are attributed mostly to the polymorphism in the NAT2 gene.

Drugs that are subject to acetylation and their known toxicities are listed in Table 6–4. The therapeutic relevance of NAT polymorphisms is in avoiding drug-induced toxicities. The adverse drug response in a slow acetylator resembles a drug overdose; thus, reducing the dose or increasing the dosing interval is recommended. Aromatic amine or a hydrazine groups exist in many classes of clinically used drugs, and if a drug is

![Figure 6-11. Generation of the reactive alkylating agent following the conjugation of glutathione to TLK286. GST interacts with the prodrug and GSH analog, TLK286, via a tyrosine in the active site of GST. GSH portion is shown in red. The interaction promotes β-elimination and cleavage of the prodrug to a vinyl sulfone and an active alkylating fragment. (See Townsend and Tew, 2003.)](image-url)
known to be metabolized through acetylation, determining an individual’s phenotype can be important in maximizing outcome in subsequent therapy. For example, hydralazine, a once popular orally active antihypertensive (vasodilator) drug, is metabolized by NAT2; the administration of therapeutic doses of hydralazine to a slow acetylator can result in extreme hypotension and tachycardia. Several drugs, such as the sulfonamides, that are known targets for acetylation have been implicated in idiosyncratic hypersensitivity reactions; in such instances, an appreciation of a patient’s acetylating phenotype is particularly important. Sulfonamides are transformed into hydroxylamines that interact with cellular proteins, generating haptens that can elicit autoimmune responses. Individuals who are slow acetylators are predisposed to drug-induced autoimmune disorders.

Tissue-specific expression patterns of NAT1 and NAT2 have a significant impact on the fate of drug metabolism and the potential for eliciting a toxic episode. NAT1 is ubiquitously expressed among most human tissues, whereas NAT2 is found predominantly in liver and the GI tract. Both NAT1 and NAT2 can form N-hydroxy–acetylated metabolites from bicyclic aromatic hydrocarbons, a reaction that leads to the non-enzymatic release of the acetyl group and the generation of highly reactive nitrenium ions. Thus, N-hydroxy acetylation is thought to activate certain environmental toxicants. In contrast, direct N-acetylation of bicyclic aromatic amines is stable and leads to detoxification. Individuals who are NAT2 fast acetylators are able to efficiently metabolize and detoxify bicyclic aromatic amines through liver-dependent acetylation. Slow acetylators (NAT2 deficient), however, accumulate bicyclic aromatic amines, which then become substrates for CYP-dependent N-oxidation. These N-OH metabolites are eliminated in the urine. In tissues such as bladder epithelium, NAT1 is highly expressed and can efficiently catalyze the N-hydroxy acetylation of bicyclic aromatic amines, a process that leads to de-acetylation and the formation of the mutagenic nitrenium ion, especially in NAT2-deficient subjects. Epidemiological studies have shown that slow acetylators are predisposed to bladder cancer if exposed environmentally to bicyclic aromatic amines.

**Methylation.** In humans, drugs and xenobiotics can undergo O-, N-, and S-methylation. The identification of the individual methyltransferase (MT) is based on the substrate and methyl conjugate. Humans express three N-methyltransferases, one catechol-O-methyltransferase (COMT), a phenol-O-methyltransferase (POMT), a thiorpurne S-methyltransferase (TPMT), and a thiol methyltransferase (TMT). These MTs exist as monomers and use S-adenosyl-methionine (SAM;
AdoMet) as the methyl donor. With the exception of a signature sequence that is conserved among the MTs, there is limited conservation in sequence, indicating that each MT has evolved to display a unique catalytic function. Although the common theme among the MTs is the generation of a methylated product, substrate specificity is high and distinguishes the individual enzymes.

Nicotinamide N-methyltransferase (NNMT) methylates serotonin and tryptophan as well as pyridine-containing compounds such as nicotinamide and nicotine. Phenylethanolamine N-methyltransferase (PNMT) is responsible for the methylation of the neurotransmitter norepinephrine, forming epinephrine; the histamine N-methyltransferase (HNMT) metabolizes drugs containing an imidazole ring such as that found in histamine. COMT methylates the ring hydroxyl groups of neurotransmitters containing a catechol moiety, such as dopamine and norepinephrine, in addition to drugs such as methyldopa and drugs of abuse such as ecstasy (MDMA; 3,4-methylenedioxymethamphetamine).

From a clinical perspective, the most important MT may be thiopurine S-methyltransferase (TPMT), which catalyzes the S-methylation of aromatic and heterocyclic sulfhydryl compounds, including the thiopurine drugs azathioprine (AZA), 6-mercaptopurine (6-MP); and thioguanine. AZA and 6-MP are used for the management of inflammatory bowel disease (see Chapter 47), as well as autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis. Thioguanine is used in the treatment of acute myeloid leukemia, and 6-MP is used worldwide for the treatment of childhood acute lymphoblastic leukemia (see Chapters 61-63). Because TPMT is responsible for the detoxification of 6-MP, a genetic deficiency in TPMT can result in severe toxicities in patients taking these drugs. When given orally at clinically established doses, 6-MP serves as a prodrug that is metabolized by hypoxanthine guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides (6-TGNs), which become incorporated into DNA and RNA, resulting in arrest of DNA replication and cytotoxicity. The toxic side effects arise when a lack of 6-MP methylation by TPMT causes a buildup of 6-MP, resulting in the generation of toxic levels of 6-TGNs. The identification of the inactive TPMT alleles and the development of a genotyping test to identify homozygous carriers of the defective allele have now made it possible to identify individuals who may be predisposed to the toxic side effects of 6-MP therapy. Simple adjustments in the patient’s dosage regimen have been shown to be a life-saving intervention for those with TPMT deficiencies.

**ROLE OF XENOBIOTIC METABOLISM IN THE SAFE AND EFFECTIVE USE OF DRUGS**

Any xenobiotics entering the body must be eliminated through metabolism and excretion in the urine or feces. This mechanism keeps foreign compounds from accumulating in the body and possibly causing toxicity. In the case of drugs, metabolism normally results in the inactivation of their therapeutic effectiveness and facilitates their elimination. The extent of metabolism can determine the efficacy and toxicity of a drug by controlling its biological t_{1/2}. Among the most serious considerations in the clinical use of drugs are ADRs. If a drug is metabolized too quickly, it rapidly loses its therapeutic efficacy. This can occur if specific enzymes involved in metabolism are naturally overly active or are induced by dietary or environmental factors. If a drug is metabolized too slowly, the drug can accumulate in the bloodstream; as a consequence, the pharmacokinetic parameter AUC (area under the plasma concentration-time curve) is elevated and the plasma clearance of the drug is decreased. This increase in AUC can lead to overstimulation or excessive inhibition of some target receptors or undesired binding to other cellular macromolecules. An increase in AUC often results when specific xenobiotic-metabolizing enzymes are inhibited, which can occur when an individual is taking a combination of different therapeutic agents and one of those drugs targets the enzyme involved in drug metabolism. For example, the consumption of grapefruit juice with drugs taken orally can inhibit intestinal CYP3A4, blocking the metabolism of many of these drugs. The inhibition of specific CYPs in the gut by dietary consumption of grapefruit juice alters the oral bioavailability of many classes of drugs, such as certain antihypertensives, immunosuppressants, antidepressants, antihistamines, and statins, to name a few. Among the components of grapefruit juice that inhibit CYP3A4 are naringin and furanocoumarins.

While environmental factors can alter the steady-state levels of specific enzymes or inhibit their catalytic potential, these phenotypic changes in drug metabolism are also observed clinically in groups of individuals that are genetically predisposed to adverse drug reactions because of pharmacogenetic differences in the expression of xenobiotic-metabolizing enzymes (see Chapter 7). Most of the xenobiotic-metabolizing enzymes display polymorphic differences in their expression, resulting from heritable changes in the structure of the genes. For example, as discussed earlier, a significant population was found to be hyperbilirubinemic, resulting from a reduction in the ability to glucuronidate circulating bilirubin due to a lowered expression of the UGT1A1 gene (Gilbert’s syndrome). Drugs that are subject to glucuronidation by UGT1A1, such as the topoisomerase inhibitor SN-38 (Figures 6–5, 6–7, and 6–8), will display an increased AUC because individuals with Gilbert’s
syndrome are unable to detoxify these drugs. Since most cancer chemotherapeutic agents have a very narrow therapeutic index, increases in the circulating levels of the active form can result in significant toxicities. There are a number of genetic differences in CYPs that can have a major impact on drug therapy.

Nearly every class of therapeutic agent has been reported to initiate an adverse drug response (ADR). In the U.S., the annual costs of ADRs have been estimated at over 100,000 deaths and $100 billion. It has been estimated that 56% of drugs that are associated with adverse responses are subjected to metabolism by the xenobiotic-metabolizing enzymes, notably the CYPs and UGTs. Since many of the CYPs and UGTs are subject to induction as well as inhibition by drugs, dietary factors, and other environmental agents, these enzymes play an important role in most ADRs. Thus, before a new drug application (NDA) is filed with the Food and Drug Administration, the route of metabolism and the enzymes involved in the metabolism must be known. As a result, it is now routine practice in the pharmaceutical industry to establish which enzymes are involved in metabolism of a drug candidate and to identify the metabolites and determine their potential toxicity.

**Induction of Drug Metabolism**

Xenobiotics can influence the extent of drug metabolism by activating transcription and inducing the expression of genes encoding drug-metabolizing enzymes. Thus, a foreign compound may induce its own metabolism, as may certain drugs. One potential consequence of this is a decrease in plasma drug concentration over the course of treatment, resulting in loss of efficacy, as the auto-induced metabolism of the drug exceeds the rate at which new drug enters the body. Many ligands and receptors participate in this way to induce drug metabolism (Table 6–5). A particular receptor, when activated by a ligand, can induce the transcription of a battery of target genes. Among these target genes are certain CYPs and drug transporters. Thus, any drug that is a ligand for a receptor that induces CYPs and transporters could lead to drug interactions. Figure 6–12 shows the scheme by which a drug may interact with nuclear receptors to induce its own metabolism.

The aryl hydrocarbon receptor (AHR) is a member of a superfamily of transcription factors with diverse roles in mammals, such as a regulatory role in the development of the mammalian CNS and modulating the response to chemical and oxidative stress. This superfamily of transcription factors includes Period (Per) and Simpleminded (Sim), two transcription factors involved in development of the CNS, and the HIF (hypoxia-inducible factor) family of transcription factors that activate genes in response to low cellular O2 levels. The AHR induces expression of genes encoding CYP1A1, CYP1A2, and CYP1B1, three CYPs that are able to metabolically activate chemical carcinogens, including environmental contaminants and carcinogens derived from food. Many of these substances are inert unless metabolized by CYPs. Thus, induction of these CYPs by a drug could potentially result in an increase in the toxicity and carcinogenicity of procarcinogens. For example, omeprazole, a proton pump inhibitor used to treat gastric and duodenal ulcers (see Chapter 45), is a ligand for the AHR and can induce CYP1A1 and CYP1A2, with the possible consequences of toxin/carcinogen activation as well as drug-drug interactions in patients receiving agents that are substrates for either of these CYPs.

Another important induction mechanism is due to type 2 nuclear receptors that are in the same superfamily as the steroid hormone receptors. Many of these receptors, identified on the basis of their structural similarity to steroid hormone receptors, were originally termed “orphan receptors,” because no endogenous ligands were known to interact with them. Subsequent studies revealed that some of these receptors are activated by xenobiotics, including drugs. The type 2 nuclear receptors of most importance to drug metabolism and drug therapy include the pregnane X receptor (PXR), constitutive androstane receptor (CAR), and the peroxisome proliferator activated receptors (PPARs). PXR, discovered because it is activated by the synthetic steroid pregnenolone-16α-carbonitrile, is also activated by a number of other drugs including, antibiotics (rifampicin and troleandomycin), Ca2+ channel blockers (nifedipine), statins (mevastatin), anti-diabetic drugs

HIV protease inhibitors (ritonavir), and anticancer drugs (paclitaxel). Hyperforin, a component of St. John’s wort, an over-the-counter herbal remedy used for depression, also activates PXR. This activation is thought to be the basis for the increase in failure of oral contraceptives in individuals taking St. John’s wort: Activated PXR is an inducer of CYP3A4, which can metabolize the atorvastatin and decrease its cellular concentration. Thus, atorvastatin induces its own metabolism. Atorvastatin undergoes both ortho and para hydroxylation. (See Handschin and Meyer, 2003.)

The nuclear receptor CAR was discovered based on its ability to activate genes in the absence of ligand. Steroids such as androstanol, the antifungal agent clotrimazole, and the anti-emetic meclizine are inverse agonists that inhibit gene activation by CAR, while the pesticide 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene, the steroid 5-β-pregnane-3,20-dione, and probably other endogenous compounds, are agonists that activate gene expression when bound to CAR. Genes induced by CAR include those encoding several CYPs (CYP2B6, CYP2C9, and CYP3A4), various phase 2 enzymes (including GSTs, UGTs, and SULTs), and drug and endobiotic transporters. CYP3A4 is induced by both PXR and CAR and thus its level is highly influenced by a number of drugs and other xenobiotics. In addition to a potential role in inducing the degradation of drugs including the over-the-counter analgesic acetaminophen, this receptor may function in the control of bilirubin degradation, the process by which the liver decomposes heme.

Clearly, PXR and CAR have a capacity for binding a great variety of ligands. As with the xenobiotic-metabolizing enzymes, species differences also exist in the ligand specificities of these receptors. For example, rifampin activates human PXR, but not mouse or rat PXR, while pregnenolone-16α-carbonitrile preferentially activates the mouse and rat PXR. Paradoxically, meclizine activates mouse CAR, but inhibits gene induction by human CAR. These findings further underscore that data from rodent model systems do not always reflect the response of humans to drugs.

Members of a receptor family do not always show similar activities toward xenobiotics. The peroxisome proliferator activated receptor (PPAR) family has three members, α, β, and γ. PPARα is...
Role of Drug Metabolism in the Drug Development Process. There are two key elements associated with successful drug development: efficacy and safety. Both depend on drug metabolism. It is necessary to determine which enzymes metabolize a potential new drug candidate in order to predict whether the compound may cause drug-drug interactions or be susceptible to marked inter-individual variation in metabolism due to genetic polymorphisms. Computational chemical systems biology and metabolomic approaches could enhance this process.

Historically, drug candidates have been administered to rodents at doses well above the human target dose in order to predict acute toxicity. For drug candidates to be used chronically in humans, such as for lowering serum triglycerides and cholesterol or for treatment of type 2 diabetes, long-term carcinogenicity studies are carried out in rodent models. For determination of metabolism, the compound is subjected to analysis by human liver cells or extracts from these cells that contain the drug-metabolizing enzymes. Such studies determine how humans will metabolize a particular drug, and to a limited extent, predict the rate of metabolism. If a CYP is involved, a panel of recombinant CYPs can be used to determine which CYP predominates in the metabolism of the drug. If a single CYP, such as CYP3A4, is found to be the sole CYP that metabolizes a drug candidate, then a decision can be made about the likelihood of drug interactions. Interactions become a problem when multiple drugs are simultaneously administered, e.g., in elderly patients, who on a daily basis may take prescribed anti-inflammatory drugs, one or two cholesterol-lowering drugs, several classes of blood pressure medications, a gastric acid suppressant, an anticoagulant, and a number of over-the-counter medications. Ideally, the best drug candidate would be metabolized by several CYPs, so that variability in expression levels of one CYP or drug-drug interactions would not alter its metabolism and pharmacokinetics.

Similar studies can be carried out with phase 2 enzymes and drug transporters in order to predict the metabolic fate of a drug. In addition to the use of recombinant human xenobiotic-metabolizing enzymes in predicting drug metabolism, human receptor-based (PXR and CAR) systems or cell lines expressing these receptors are used to determine whether a particular drug candidate could be a ligand of or activator of PXR, CAR, or PPAR. For example, a drug that activates PXR may result in rapid clearance of other drugs that are CYP3A4 substrates, thus decreasing their bioavailability and efficacy.

Computer-based computational (in silico) prediction of drug metabolism is a not-so-distant prospect, as is the structural modeling of the regulation of CYP expression via activation of nuclear receptors. Currently, chemical systems biology approaches are being applied on a proteome-wide scale to discover novel drug leads (Kinnings et al., 2009). The large size of the CYP active sites, which permits them to metabolize many different compounds, also renders them difficult to model. However, with refinement of structures and more powerful modeling software, in silico drug metabolism may become a useful adjunct to experimentation.

Determining the potential for a drug candidate to produce toxicity in pre-clinical studies is vital and routine in the drug development process. Historically, this is typically done by administering the drug candidate to rodents at escalating doses, usually above the predicted therapeutic dose that will be used in humans. Signs of toxicity are monitored and organ damage assessed by postmortem examination. This process is not high throughput and can be a bottleneck in the drug development process of lead compound optimization. A new technology of high-throughput screening for biomarkers of toxicity is being adopted for drug development using metabolomics. Metabolomics is the systematic identification and quantification of all metabolites in a given organism or biological sample. Analytical platforms such as 1H-NMR and liquid or gas chromatography coupled to mass spectrometry, in conjunction with chemometric and multivariate data analysis, allow the simultaneous determination and comparison of thousands of chemicals in biological fluids such as serum and urine, as well as the chemical constituents of cells and tissues. This technology can be used to monitor for drug toxicity in whole animal systems during pre-clinical drug development and can obviate the need for time-consuming and expensive postmortem analyses on thousands of animals. Using metabolomics, test animals can be analyzed for the presence of one or more metabolites in urine that correlate with drug efficacy or toxicity. Urine metabolites that are fingerprints for liver, kidney and CNS toxicity have been identified using known chemical toxicants. Metabolic fingerprints of specific compounds that are elevated in urine can be used to determine, in dose escalation studies, whether a particular drug causes toxicity, and can also be employed in early clinical trials to monitor for potential toxicities. Metabolomics can be used to find biomarkers for drug efficacy and toxicity that can be of value in clinical trials to identify responders and nonresponders. Drug metabolism can be studied in whole animal model systems and in humans to determine the metabolites of a drug or indicate the presence of a polymorphism in drug metabolism that might signal an adverse clinical outcome. Finally, biomarkers developed from experimental metabolomics could eventually be developed for routine monitoring of patients for signs of drug toxicity.

Pharmacogenetics is the study of the genetic basis for variation in drug response. In this broadest sense, pharmacogenetics encompasses pharmacogenomics, which employs tools for surveying the entire genome to assess multigenic determinants of drug response. Prior to the technical advances in genomics of the last decade, pharmacogenetics proceeded using a forward genetic, phenotype-to-genotype approach. Drug response outliers were compared to individuals with “normal” drug response to identify the pharmacologic basis of altered response. An inherited component to response was demonstrated using family studies or imputed through intra- vs. intersubject reproducibility studies. With the explosion of technology in genomics, a reverse genetic, genotype-to-phenotype approach is feasible whereby genomic polymorphisms can serve as the starting point to assess whether genomic variability translates into phenotypic variability.

Individuals differ from each other approximately every 300-1000 nucleotides, with an estimated total of 10 million single nucleotide polymorphisms (SNPs; single base pair substitutions found at frequencies ≥1% in a population) and thousands of copy number variations in the genome (International HapMap et al., 2007; Redon et al., 2006; Stranger et al., 2007). Identifying which of these variants or combinations of variants have functional consequence for drug effects is the task of modern pharmacogenetics.

Historical Context. In the pre-genomics era, the frequency of genetic variation was hypothesized to be relatively uncommon, and the demonstration of inherited drug-response traits applied to a relatively small number of drugs and pathways (Eichelbaum and Gross, 1990; Evans and Relling, 2004; Johnson and Lima, 2003). Historically, uncommon severe drug-induced phenotypes served as the triggers to investigate and document pharmacogenetic phenotypes. Prolonged neuromuscular blockade following normal doses of succinylcholine, neurotoxicity following isoniazid therapy (Hughes et al., 1954), and methemoglobinemia in glucose-6-phosphate dehydrogenase (G6PD) deficiency (Alving et al., 1956) were discovered to have a genetic basis in the first half of the 20th century. In the 1970s and 1980s, debrisoquine hydroxylation and exaggerated hypotensive effects from that drug were related to an autosomal recessive inherited deficiency in the cytochrome P450 isoenzyme 2D6 (CYP2D6) (Evans and Relling, 2004). Since the elucidation of the molecular basis of the phenotypic polymorphism in CYP2D6 (Gonzalez et al., 1988), the molecular bases of many other monogenic pharmacogenetic traits have been identified (Meyer and Zanger, 1997).

Importance of Pharmacogenetics to Variability in Drug Response

Drug response is considered to be a gene-by-environment phenotype. That is, an individual’s response to a drug depends on the complex interplay between environmental factors and genetic factors (Figure 7–1). Variation in drug response therefore may be explained by variation in environmental and genetic factors, alone or in combination. What proportion of drug-response variability is likely to be genetically determined? Classical family studies provide some information (Weinshilboum and Wang, 2004).

Because estimating the fraction of phenotypic variability that is attributable to genetic factors in pharmacogenetics usually requires administration of a drug to twins or trios of family members, data are somewhat limited. Twin studies have shown that drug metabolism is highly heritable, with genetic factors accounting for most of the variation in metabolic rates for many drugs (Vesell, 2000). Results from a twin study in which the t1/2 of antipyrine was measured are typical (Figure 7–2). Antipyrine, a pyrazolone analgesic, is eliminated exclusively by metabolism and is a substrate for multiple CYPs. There is considerably greater concordance in the t1/2 of antipyrine between the monozygotic (identical) twin pairs in comparison to the dizygotic (fraternal) twin pairs. Comparison of intra-twin vs. inter-pair variability suggests that ~75-85% of the variability in pharmacokinetic half-lives for drugs that are eliminated by metabolism is heritable (Penno et al., 1981). It has also been proposed that heritability can be estimated by comparing intra-subject vs. inter-subject variability in drug response or disposition in unrelated individuals (Kalow et al., 1998), with the assumption that high intra-subject reproducibility translates into high heritability; the validity of this method across pharmacologic phenotypes remains to be established. In any case, such studies provide only an estimate of
the overall contribution of inheritance to the phenotype; because multiple gene products contribute to antipyrine disposition, most of which have unelucidated mechanisms of genetic variability, the predictability of antipyrine disposition based on known genetic variability is poor.

Extended kindreds may be used to estimate heritability. This approach to estimating the degree of heritability of a pharmacogenetic phenotype uses \textit{ex vivo} experiments with cell lines derived from related individuals from extended multigenerational families. Inter- vs. intrafamily variability and relationships among members of a kindred are used to estimate heritability. Using this approach with lymphoblastoid cells, cytotoxicity from chemotherapeutic agents was shown to be heritable, with \( \sim 20\%-70\% \) of the variability in sensitivity to 5-fluorouracil, cisplatin, docetaxel and other anticancer agents estimated as inherited (Hartford and Dolan, 2007; Watters et al., 2004).

For the “monogenic” phenotypic traits of G6PD deficiency, CYP2D6, or thiopurine methyltransferase (TPMT) metabolism, it is often possible to predict phenotype based on genotype. Several genetic polymorphisms of drug metabolizing enzymes result in monogenic traits. Based on a retrospective study, 49\% of adverse drug reactions were associated with drugs that are substrates for polymorphic drug metabolizing enzymes, a proportion larger than estimated for all drugs (22\%) or for top-selling drugs (7\%) (Phillips et al., 2001). Prospective genotype determinations may result in the ability to prevent adverse drug reactions.

Defining multigenic contributors to drug response will be much more challenging. For some multigenic phenotypes, such as response to antihypertensives, the large numbers of candidate genes will necessitate a large patient sample size to produce the statistical power required to solve the “multigene” problem.

**GENOMIC BASIS OF PHARMACOGENETICS**

**Phenotype-Driven Terminology**

Because initial discoveries in pharmacogenetics were driven by variable phenotypes and defined by family and twin studies, the classic genetic terms for monogenic traits apply to some pharmacogenetic polymorphisms. A trait (e.g., CYP2D6 “poor metabolism”) is deemed autosomal recessive if the responsible gene is located on an autosome (i.e., it is not sex-linked) and a distinct

![Figure 7–1. Exogenous and endogenous factors contribute to variation in drug response. (Reproduced with permission from Vesell, 1991. Copyright © Elsevier.]

![Figure 7–2. Pharmacogenetic contribution to pharmacokinetic parameters. \( t_{1/2} \) of antipyrine is more concordant in identical in comparison to fraternal twin pairs. Bars show the \( t_{1/2} \) of antipyrine in identical (monozygotic) and fraternal (dizygotic) twin pairs. (Redrawn from data in Vesell and Page, 1968.)

phenotype is evident only with nonfunctional alleles on both the maternal and paternal chromosomes. An autosomal recessive trait does not appear in heterozygotes. A trait is deemed codominant if heterozygotes exhibit a phenotype that is intermediate to that of homozygotes for the common allele and homozygotes for the variant allele. For example, TPMT catabolism of thiopurines exhibits three relatively distinct phenotypes, and thus was deemed codominant even in the pre-molecular era. With the advances in molecular characterization of polymorphisms and a genotype-to-phenotype approach, many polymorphic traits (e.g., CYP2C19 metabolism of drugs such as mephenytoin and omeprazole) are now recognized to exhibit some degree of codominance. Some pharmacogenetic traits, such as the long QT syndrome, segregate as dominant traits; the long QT syndrome is associated with heterozygous loss-of-function mutations of ion channels. A prolonged QT interval is seen on the electrocardiogram, either basally or in the presence of certain drugs, and individuals with prolonged QT intervals are predisposed to cardiac arrhythmias (see Chapter 29).

In an era of detailed molecular characterization, two major factors complicate the historical designation of recessive, co-dominant, and dominant traits. First, even within a single gene, a vast array of polymorphisms (promoter, coding, noncoding, completely inactivating, or modestly modifying) are possible. Each polymorphism may produce a different effect on gene function and therefore differentially affect a measured trait. For example, the effect of a polymorphism with only a modest effect on the function of an enzyme will only be observed in individuals who are homozygous for the polymorphism. Heterozygotes will not exhibit any measurable changes in enzyme activity. In contrast, the effect of a polymorphism that exhibits complete loss of function of the enzyme will be large and may be observed phenotypically in heterozygotes. Secondly, most traits (pharmacogenetic and otherwise) are multigenic, not monogenic. Thus, even if the designations of recessive, co-dominant, and dominant are informative for a given gene, their utility in describing the genetic variability that underlies variability in drug response phenotype is diminished, because most phenotypic variability is likely to be multigenic.

**Types of Genetic Variants**

A polymorphism is a variation in the DNA sequence that is present at an allele frequency of 1% or greater in a population. Two major types of sequence variation have been associated with variation in human phenotype: single nucleotide polymorphisms (SNPs) and insertions/deletions (indels) (Figure 7–3). In comparison to base pair

**Figure 7–3. Molecular mechanisms of genetic polymorphisms.**

The most common genetic variants are single nucleotide polymorphism substitutions (SNPs). Coding non-synonymous SNPs result in a nucleotide substitution that changes the amino acid codon (here proline to glutamine), which could change protein structure, stability, substrate affinities, or introduce a stop codon. Coding synonymous SNPs do not change the amino acid codon, but may have functional consequences (transcript stability, splicing). Noncoding SNPs may be in promoters, introns, or other regulatory regions that may affect transcription factor binding, enhancers, transcript stability, or splicing. The second major type of polymorphism is indels (insertion/deletions). SNP indels can have any of the same effects as SNP substitutions: short repeats in the promoter (which can affect transcript amount), or insertions/deletions that add or subtract amino acids. Copy number variations (CNVs) involve large segments of genomic DNA that may involve gene duplications (stably transmitted inherited germline gene replication that causes increased protein expression and activity), gene deletions that result in the complete lack of protein production, or inversions of genes that may disrupt gene function. All of these mechanisms have been implicated in common germline pharmacogenetic polymorphisms. TPMT, thiopurine methyltransferase; ABCB1, the multidrug resistance transporter (P-glycoprotein); CYP, cytochrome P450; CBS, cystathionine β-synthase; UGT, UDP-glucuronyl transferase; GST, glutathione-S-transferase.
substitutions, indels are much less frequent in the genome and are of particularly low frequency in coding regions of genes (Cargill et al., 1999; Stephens et al., 2001). Single base pair substitutions that are present at frequencies ≥1% in a population are termed single nucleotide polymorphisms (SNPs) and are present in the human genome at ~1 SNP every few hundred to a thousand base pairs, depending on the gene region (Stephens et al., 2001).

SNPs in the coding region are termed cSNPs, and are further classified as non-synonymous (or missense) if the base pair change results in an amino acid substitution, or synonymous (or sense) if the base pair substitution within a codon does not alter the encoded amino acid. Typically, substitutions of the third base pair, termed the wobble position, in a three base pair codon, such as the G to A substitution in proline shown in Figure 7–3, do not alter the encoded amino acid. Base pair substitutions that lead to a stop codon are termed nonsense mutations. In addition, ~10% of SNPs can have more than two possible alleles (e.g., a C can be replaced by either an A or G), so that the same polymorphic site can be associated with amino acid substitutions in some alleles but not others.

Synonymous polymorphisms have sometimes been found to contribute directly to a phenotypic trait. One of the most notable examples is a polymorphism in ABCB1, which encodes P-glycoprotein, an efflux pump that interacts with many clinically used drugs. The synonymous polymorphism, C3435T, is associated with various phenotypes and has been the subject of numerous studies (Hoffmeyer et al., 2000; Kim et al., 2006; Sills et al., 2005; Turgut et al., 2007). This synonymous polymorphism results in a change from a preferred codon for isoleucine to a less preferred codon. Presumably, the less preferred codon is translated at a slower rate, which apparently changes the folding of the protein, its insertion into the membrane, and its interaction with drugs (Kimchi-Sarfaty et al., 2007).

Polymorphisms in noncoding regions of genes may occur in the 3’ and 5’ untranslated regions, in promoter or enhancer regions, in intronic regions, or in large regions between genes, intergenic regions (Figure 7–4). Polymorphisms in introns found near exon-intron boundaries are often treated as a separate category from other intronic polymorphisms since these may affect splicing, and thereby affect function. Noncoding SNPs in promoters or enhancers may alter cis- or trans-acting elements that regulate gene transcription or transcript stability. Noncoding SNPs in introns or exons may create alternative exon splicing sites, and the altered transcript may have fewer or more exons, or shorter or larger exons, than the wild-type transcript. Introduction or deletion of exonic sequence can cause a frame shift in the translated protein and thereby change protein structure or function, or result in an early stop codon, which makes an unstable or nonfunctional protein. Because 95% of the genome is intergenic, most polymorphisms are unlikely to directly affect the encoded transcript or protein. However, intergenic polymorphisms may have biological consequences by affecting DNA tertiary structure, interaction with chromatin and topoisomerases, or DNA replication. Thus, intergenic polymorphisms cannot be assumed to be without pharmacogenetic importance.

A remarkable degree of diversity in the types of insertions/deletions that are tolerated as germline polymorphisms is evident. A common glutathione-S-transferase M1 (GSTM1) polymorphism is caused by a 50-kilobase (kb) germline deletion, and the null allele has a population frequency of 0.3–0.5, depending on race/ethnicity. Biochemical studies indicate that livers from homozygous null individuals have only ~50% of the glutathione conjugating capacity of those with at least one copy of the GSTM1 gene (Townsend and Kew, 2003). The number of TA repeats in the UGT1A1 promoter affects the quantitative expression of this crucial glucuronosyl transferase in liver; although 4-9 TA repeats exist in germline-inherited alleles, 6 or 7 repeats constitute the most common alleles (Monaghan et al., 1996). Cystathionine β-synthase has a common 68 base pair insertion/deletion polymorphism that has been linked to folate levels (Kraus et al., 1998). Some deletion and duplication polymorphisms can be seen as a special case of copy number variations (CNVs) (Beckmann et al., 2007; Redon et al., 2006; Stranger et al., 2007). A CNV is a segment of DNA in which a variable number of that segment has been found in one or more populations. CNVs, which range in size from 1 kb to many megabases, are caused by genomic rearrangements including duplications, deletions, and inversions. CNVs appear to occur in ~10% of the human genome and in one study accounted for ~18% of the detected genetic variation in expression of around 15,000 genes in lymphoblastoid cell lines (Stranger et al., 2007). Because of their size, CNVs are likely to affect phenotype. There are notable examples of CNVs in pharmacogenetics; gene duplications of CYP2D6 are associated with an ultra-rapid metabolizer phenotype.

A haplotype, which is defined as a series of alleles found at a linked locus on a chromosome, specifies the DNA sequence variation...
In a gene or a gene region on one chromosome. For example, consider two SNPs in *ABCB1*, which encodes for the multidrug resistance protein, P-glycoprotein. One SNP is a T to A base pair substitution at position 3421 and the other is a C to T change at position 3435. Possible haplotypes would be T\textsubscript{3421}C\textsubscript{3435}, T\textsubscript{3421}T\textsubscript{3435}, A\textsubscript{3421}C\textsubscript{3435}, and A\textsubscript{3421}T\textsubscript{3435}. For any gene, individuals will have two haplotypes, one maternal and one paternal in origin, which may or may not be identical. Haplotypes are important because they are the functional unit of the gene. That is, a haplotype represents the constellation of variants that occur together for the gene on each chromosome. In some cases, this constellation of variants, rather than the individual variant or allele, may be functionally important. In others, however, a single mutation may be functionally important regardless of other linked variants within the haplotype(s).

Two terms are useful in describing the relationship of genotypes at two loci: linkage equilibrium and linkage disequilibrium. Linkage equilibrium occurs when the genotype present at one locus is independent of the genotype at the second locus. Linkage disequilibrium occurs when the genotypes at the two loci are not independent of one another. In complete linkage disequilibrium, genotypes at two loci always occur together. As recombination occurs then linkage disequilibrium between two alleles will decay and linkage equilibrium will result. Over many generations, with many recombination events, linkage disequilibrium will be eliminated. Patterns of linkage disequilibrium are population specific. For any gene region, linkage disequilibrium among individuals between SNPs in that region may be viewed using a software tool such as Haplovview (Barrett et al., 2005) (Figure 7–5).

![Figure 7–5. Haplotype blocks in UGT1A1 generated by Haploview version 4.1. Linkage disequilibrium between SNPs in UGT1A1 in Europeans is shown. SNPs present at allele frequencies of 20% or greater are included and identified by rs numbers. The r\textsuperscript{2} values indicating linkage disequilibrium values between any two SNPs are shown in the blocks below as whole numbers (e.g., 86 = r\textsuperscript{2} of 0.86 between SNPs at rs4148328 and rs8330. Those that are dark blue without numbers have an r\textsuperscript{2} = 1.0. The relationships among the SNP genotypes in this population for this gene indicate that there are three primary linkage disequilibrium blocks (Block 1, Block 2, and Block 3), which in this case, were generated by the Haploview program. (Source: Broad Institute, http://www.broad.mit.edu/haploview/haploview.)
**Ethnic Diversity**

Polymorphisms differ in their frequencies within human populations (Burchard et al., 2003; Rosenberg et al., 2002, 2003). Frequencies of polymorphisms in ethnically or racially diverse human populations have been examined in whole genome scanning studies (Cargill et al., 1999; Stephens et al., 2001). In these studies, polymorphisms have been classified as either cosmopolitan or population (or race and ethnic) specific. Cosmopolitan polymorphisms are those polymorphisms present in all ethnic groups, although frequencies may differ among ethnic groups. Cosmopolitan polymorphisms are usually found at higher allele frequencies in comparison to population-specific polymorphisms. Likely to have arisen before migrations of humans from Africa, cosmopolitan polymorphisms are generally older than population-specific polymorphisms.

The presence of ethnic and race-specific polymorphisms is consistent with geographical isolation of human populations (Xie et al., 2001). These polymorphisms probably arose in isolated populations and then reached a certain frequency because they are advantageous (positive selection) or more likely, neutral, conferring no advantage or disadvantage to a population. Large-scale sequence studies in ethnically diverse populations in the U.S. demonstrate that African Americans have the highest number of population-specific polymorphisms in comparison to European Americans, Mexican Americans, and Asian Americans (Leabman et al., 2003; Stephens et al., 2001). Africans are believed to be the oldest population and therefore have both recently derived, population-specific polymorphisms, and a large number of older polymorphisms that occurred before migrations out of Africa.

Consider the coding region variants of two membrane transporters identified in 247 ethnically diverse DNA samples (Figure 7–6).

---

**Figure 7–6. Coding region polymorphisms in two membrane transporters.** Shown are the dopamine transporter, DAT (encoded by SLC6A3) and multidrug resistance associated protein, MRP2 (encoded by ABCC2). Coding region variants were identified in 247 ethnically diverse DNA samples (100 African Americans, 100 European Americans, 30 Asians, 10 Mexicans, and 7 Pacific islanders). Shown in blue circles are synonymous variants, and in red circles, non-synonymous variants.
modest effects by comparison. Transcription factors and drug-metabolizing genes have a mental" effect that polymorphisms in the affected genes, are part of a large array of multigenic factors that polymorphisms have a modest impact on the affected gene activity). For example, phenobarbital induction of metabolism may be such an overwhelming "environmental" effect that polymorphisms in the affected gene activity, drug or metabolite levels in plasma or urine, blood pressure or lipid lowering produced by a drug, and drug-induced gene expression patterns are examples of pharmacogenetic traits. Directly measuring a trait (e.g., enzyme activity) has the advantage that the net effect of the contributions of all genes that influence the trait is reflected in the phenotypic measure. However, it has the disadvantage that it is also reflective of nongenetic influences (e.g., diet, drug interactions, diurnal or hormonal fluctuation) and thus, may be “unstable.”

For CYP2D6, if a patient is given an oral dose of dextromethorphan, and the urinary ratio of parent drug to metabolite is assessed, the phenotype is reflective of the genotype for CYP2D6 (Meyer and Zanger, 1997). However, if dextromethorphan is given with quinidine, a potent inhibitor of CYP2D6, the phenotype may be consistent with a poor metabolizer genotype, even though the subject carries wild-type CYP2D6 alleles. In this case, quinidine administration results in a drug-induced haploinsufficiency, and the assignment of a CYP2D6 poor metabolizer phenotype would not be accurate for that subject in the absence of quinidine. If a phenotypic measure, such as the erythromycin breath test (for CYP3A), is not stable within a subject, this is an indication that the phenotype is highly influenced by nongenetic factors, and may indicate a multigenic or weakly penetrant effect of a monogenic trait.

Because most pharmacogenetic traits are multigenic rather than monogenic (Figure 7–7), considerable effort is being made to identify the important genes and their polymorphisms that influence variability in drug response.

Genetic Testing. Most genotyping methods use constitutional or germline DNA, i.e., DNA extracted from any somatic, diploid cells, usually white blood cells or buccal cells (due to their ready accessibility). DNA is extremely stable if appropriately extracted and stored, and unlike many laboratory tests, genotyping need to be performed only once, because DNA sequence is generally invariant throughout an individual’s lifetime. Progress continues in moving genotyping tests from research laboratories into patient care. Because genotyping tests are directed at specific known polymorphic sites using a variety of strategies, and not all known functional polymorphisms are likely to be known for any particular gene, it is critical that the methodology for interrogating the polymorphic sites be understood, so that the probability of a negative genotyping test being falsely negative can be estimated.
One method to assess the reliability of any specific genotype determination in a group of individuals is to assess whether the relative number of homozygotes to heterozygotes is consistent with the overall allele frequency at each polymorphic site. Hardy-Weinberg equilibrium is maintained when mating within a population is random and there is no natural selection effect on the variant. Such assumptions are described mathematically when the proportions of the population that are observed to be homozygous for the variant genotype \( q^2 \), homozygous for the wild-type genotype \( p^2 \), and heterozygous \( 2pq \) are not significantly different from that predicted from the overall allele frequencies (\( p = \) frequency of wild-type allele; \( q = \) frequency of variant allele) in the population. Proportions of the observed three genotypes must add up to one; significant differences from those predicted may indicate a genotyping error.

### Candidate Gene Versus Genome-Wide Approaches

Because pathways involved in drug response are often known or at least partially known, pharmacogenetic studies are highly amenable to candidate gene association studies. After genes in drug response pathways are identified, the next step in the design of a candidate gene association pharmacogenetic study is to identify the genetic polymorphisms that are likely to contribute to the therapeutic and/or adverse responses to the drug. There are several databases that contain information on polymorphisms and mutations in human genes (Table 7–1); these databases allow the investigator to search by gene for reported polymorphisms. Some of the databases, such as the Pharmacogenetics and Pharmacogenomics Knowledge Base (PharmGKB), include phenotypic as well as genotypic data.

In candidate gene association studies, specific genes are prioritized as playing a role in response or adverse response to a drug, it is important to select polymorphisms in those genes for association studies. For this purpose, there are two categories of polymorphisms. The first are polymorphisms that do not, in and of themselves, cause altered function or expression level of the encoded protein (e.g., an enzyme that metabolizes the drug or the drug receptor). Rather, these polymorphisms are linked to the variant allele(s) that produces the altered function. These polymorphisms serve as biomarkers for drug-response phenotype. One way to select SNPs in each gene is to use a tag SNP approach. That is, all SNPs in a gene including SNPs in and around the gene (e.g., 25 kb upstream and downstream of the

**Figure 7–7. Monogenic versus multigenic pharmacogenetic traits.** Possible alleles for a monogenic trait (upper left), in which a single gene has a low-activity (1a) and a high-activity (1b) allele. The population frequency distribution of a monogenic trait (bottom left), here depicted as enzyme activity, may exhibit a trimodal frequency distribution with relatively distinct separation among low activity (homozygosity for 1a), intermediate activity (heterozygote for 1a and 1b), and high activity (homozygosity for 1b). This is contrasted with multigenic traits (e.g., an activity influenced by up to four different genes, genes 2 through 5), each of which has 2, 3, or 4 alleles (a through d). The population histogram for activity is unimodal-skewed, with no distinct differences among the genotypic groups. Multiple combinations of alleles coding for low activity and high activity at several of the genes can translate into low-, medium-, and high-activity phenotypes.
Gene) are identified from SNP databases (e.g., HapMap Database: http://www.hapmap.org). SNPs with allele frequencies equal to or greater than a target allele frequency are selected. From this set of SNPs, tag SNPs are selected to serve as representatives of multiple SNPs that tend to be in linkage disequilibrium. These tag SNPs are then genotyped in the candidate gene studies.

The second type of polymorphism is the causative polymorphism, which directly precipitates the phenotype. For example, a causative SNP may change an amino acid residue at a site that is highly conserved throughout evolution. This substitution may result in a protein that is nonfunctional or has reduced function. If biological information indicates that a particular polymorphism alters function, e.g., in cellular assays of non-synonymous variants, this polymorphism is an excellent candidate to use in an association study. When causative SNPs are unknown, tag SNPs can be typed to represent important, relatively common blocks of variation within a gene. Once a tag SNP is found to associate with a drug response phenotype, the causative variant or variants, which may be in linkage with the tag SNP, should be identified. Because the causative variant may be an unknown variant, sequencing the gene may be necessary to identify potential causative variants. These additional causative variants may be uncovered by further deep resequencing of the gene.

**Genome-Wide and Alternative Large-Scale Approaches.** A potential drawback of the candidate gene approach is that the wrong genes may be studied. Genome-wide approaches, using gene expression arrays, genome-wide scans, or proteomics, can complement and feed into the candidate gene approach by providing a relatively unbiased survey of the genome to identify previously unrecognized candidate genes. For example, RNA, DNA, or protein from patients who have unacceptable toxicity from a drug can be compared with identical material from identically treated patients who did not have such toxicity. Differences in gene expression, DNA polymorphisms, or relative amounts of proteins can be ascertained using computational tools, to identify genes, genomic regions, or proteins that can be further assessed for germline polymorphisms differentiating the phenotype. Gene expression and proteomic approaches have the advantage that the abundance of signal may itself directly reflect some of the relevant genetic variation; however, both types of expression are highly influenced by choice of tissue type, which may not be available from the relevant tissue; e.g., it may not be feasible to obtain biopsies of brain tissue for studies on CNS toxicity. DNA has the advantage that it is readily available and independent of tissue type, but the vast majority of genomic variation is not in genes, and the large number of polymorphisms presents the danger of type I error (finding differences in genome-wide surveys that are false positives). Current research challenges include prioritizing among the many possible differentiating variations in genome-wide surveys of RNA, DNA, and protein to focus on those that hold the most promise for future pharmacogenomic utility.

**Functional Studies of Polymorphisms**

For most polymorphisms, functional information is not available. Therefore, to select polymorphisms that are

**GeneExpression**

Gene expression data for human genes in multiple tissues and cell lines.
likely to be causative, it is important to predict whether a polymorphism may result in a change in expression level of a protein or a change in protein function, stability, or subcellular localization. One way to gain an understanding of the functional effects of various types of genomic variations is to survey the mutations that have been associated with human Mendelian disease. The greatest numbers of DNA variations associated with Mendelian diseases or traits are missense and nonsense mutations, followed by deletions. Further studies suggest that among amino acid replacements associated with human disease, there is a high representation at residues that are most evolutionarily conserved (Miller and Kumar, 2001; Ng and Henikoff, 2003).

These data have been supplemented by a large survey of genetic variation in membrane transporters important in drug response (Leabman et al., 2003). That survey shows that nonsynonymous SNPs that alter evolutionarily conserved amino acids are present at lower allele frequencies on average than those that alter residues that are not conserved across species. A functional genomics study of almost 90 variants in membrane transporters demonstrated that the variants that altered function were likely to change an evolutionarily conserved amino acid residue and to be at low allele frequencies (Urban et al., 2006; SEARCH Group et al., 2008). These data indicate that SNPs that alter evolutionarily conserved residues are most deleterious. The nature of chemical change of an amino acid substitution determines the functional effect of an amino acid variant. More radical changes in amino acids are more likely to be associated with disease than more conservative changes. For example, substitution of a charged amino acid (Arg) for a nonpolar, uncharged amino acid (Cys) is more likely to affect function than substitution of residues that are more chemically similar (e.g., Arg to Lys). The data also suggest that rare SNPs, at least in the coding region, are likely to alter function. New sequencing methods to identify SNPs in pharmacogenetic studies will likely uncover many new rare SNPs which cause variation in drug response.

Among the first pharmacogenetic examples to be discovered was glucose-6-phosphate dehydrogenase (G6PD) deficiency, an X-linked monogenic trait that results in severe hemolytic anemia in individuals after ingestion of fava beans or various drugs, including many antimalarial agents (Alving et al., 1956). G6PD is normally present in red blood cells and helps to regulate levels of glutathione (GSH), an antioxidant. Antimalarials such as primaquine increase red blood cell fragility in individuals with G6PD deficiency, leading to profound hemolytic anemia. Interestingly, the severity of the deficiency syndrome varies among individuals and is related to the amino acid variant in G6PD. The severe form of G6PD deficiency is associated with changes at residues that are highly conserved across evolutionary history. Chemical change is also more radical on average in mutations associated with severe G6PD deficiency in comparison to mutations associated with milder forms of the syndrome. Collectively, studies of Mendelian traits and polymorphisms suggest that nonsynonymous SNPs that alter residues that are highly conserved among species and those that result in more radical changes in the nature of the amino acid are likely to be the best candidates for causing functional changes. The information in Table 7–2 (categories of polymorphisms and the likelihood of each polymorphism to alter function) can be used as a guide for prioritizing polymorphisms in candidate gene association studies.

With the increasing number of SNPs that have been identified in large-scale SNP discovery projects, it is clear that computational methods are needed to predict the functional consequences of SNPs. To this end, predictive algorithms have been developed to identify potentially deleterious amino acid substitutions. These methods can be classified into two groups. The first group relies on sequence comparisons alone to identify and score substitutions according to their degree of conservation across multiple species; different scoring matrices have been used (e.g., BLOSUM62, SIFT and PolyPhen) (Henikoff and Henikoff, 1992; Ng and Henikoff, 2003; Ramensky, 2002). The second group of methods relies on mapping of SNPs onto protein structures, in addition to sequence comparisons (Mirkovic et al., 2004). For example, rules have been developed that classify SNPs in terms of their impact on folding and stability of the native protein structure as well as shapes of its binding sites. Such rules depend on the structural context in which SNPs occur (e.g., buried in the core of the fold or exposed to the solvent, in the binding site or not), and are inferred by machine learning methods from many functionally annotated SNPs in test proteins.

Functional activity of amino acid variants for many proteins can be studied in cellular assays. An initial step in characterizing the function of a non-synonymous variant would be to isolate the variant gene or construct the variant by site-directed mutagenesis, express it in cells, and compare its functional activity to that of the reference or most common form of the protein. Large-scale functional analyses have been performed on genetic variants in membrane transporters and phase II enzymes. Figure 7–8 shows the function of all non-synonymous variants and coding region insertions and deletions of two membrane transporters, the organic cation transporter, OCT1 (encoded by SLC22A1) and the nucleoside transporter, CNT3 (encoded by SLC28A3). Most of the naturally occurring variants have functional activity similar to that of the reference transporters. However, several variants exhibit reduced function; in the case of OCT1, a gain–of–function variant is also present. Results such as these indicate heterogeneity exists in the functionality of natural amino acid variants in normal healthy human populations.

For many proteins, including enzymes, transporters, and receptors, the mechanisms by which amino acid substitutions alter function have been characterized in kinetic studies. Figure 7–9 shows simulated curves depicting the rate of metabolism of a substrate by two amino acid variants of an enzyme and the most common genetic form of the enzyme. The kinetics of metabolism of substrate by one variant enzyme, Variant A, are characterized by an...
increased \( K_m \). Such an effect can occur if the amino acid substitution alters the binding site of the enzyme leading to a decrease in its affinity for the substrate. An amino acid variant may also alter the maximum rate of metabolism (\( V_{\text{max}} \)) of substrate by the enzyme, as exemplified by Variant B. The mechanisms for a reduced \( V_{\text{max}} \) are generally related to a reduced expression level of the enzyme, which may occur because of decreased stability of the protein or changes in protein trafficking or recycling (Shu et al., 2003; Tirona et al., 2001; Xu et al., 2002).

In contrast to the studies with SNPs in coding regions, we know much less about noncoding region SNPs. The principles of evolutionary conservation that have been shown to be important in predicting the function of non-synonymous variants in the coding region need to be refined and tested as predictors of function of SNPs in noncoding regions. New methods in comparative genomics are being refined to identify conserved elements in non-coding regions of genes that may be functionally important (Bejerano et al., 2004; Boffelli et al., 2004; Brudno et al., 2003). SNPs identified in genome-wide association studies as being associated with clinical phenotypes including drug response phenotypes have largely been in noncoding regions, either intergenic or intronic regions, of the genome (Figure 7–10). It is a challenge in human genetics and pharmacogenetics to understand the functional effects of noncoding region variants. Such variants may be in potential enhancer regions of the genome and may enhance (or repress) gene transcription.

Data adapted from Tabor et al., 2002.
An example of profound functional effect of a noncoding SNP is provided by CYP3A5; a common noncoding intronic SNP in CYP3A5 accounts for its polymorphic expression in humans. It was well known that only ~10% of whites but a higher percentage of blacks expressed CYP3A5. The SNP accounting for variation in CYP3A5 protein lies in intron 3, 1618 nucleotides 3’ from exon 3 and 377 nucleotides 5’ of exon 4. This SNP creates an alternative splice site, resulting in a transcript with a larger exon 3 but also the introduction of an early stop codon in this 13 exon transcript (Figure 7–11). The resultant protein, in the majority of whites who are homozygous for the *3 nonfunctional allele, is thus truncated so early that the protein is completely non-detectable. Thus, even SNPs quite distant from intron/exon borders can profoundly affect splicing and thus affect protein function (Kuehl et al., 2001).

**Pharmacogenetic Phenotypes**

Candidate genes for therapeutic and adverse response can be divided into three categories: *pharmacokinetic*, receptor/target, and disease modifying.

**Pharmacokinetics.** Germline variability in genes that encode determinants of the pharmacokinetics of a drug, in particular metabolizing enzymes and transporters, affect drug concentrations, and are therefore major determinants of therapeutic and adverse drug response (Table 7–3; Nebert et al., 1996). Multiple enzymes and transporters may be involved in the pharmacokinetics of a single drug. Several polymorphisms in drug metabolizing enzymes were discovered as monogenic phenotypic trait variations, and thus may be referenced using their phenotypic designations (e.g., slow vs. fast acetylation, extensive vs. poor metabolizers of debrisoquine or sparteine) rather than their genotypic designations that reference the polymorphic gene (NAT2 and CYP2D6, respectively) (Grant et al., 1990). CYP2D6 is now known to catabolize the two initial probe drugs (sparteine and debrisoquine), each of which was associated with exaggerated responses in 5-10% of treated
individuals. The exaggerated responses are an inherited trait (Eichelbaum et al., 1975; Mahgoub et al., 1977). At present, a very large number of medications (estimated at 15-25% of all medicines in use) have been shown to be substrates for CYP2D6 (Table 7–3 and Figure 6–3A). The molecular and phenotypic characterization of multiple racial and ethnic groups has shown that seven variant alleles account for well over 90% of the “poor metabolizer” low-activity alleles for this gene in most racial groups; that the frequency of variant alleles varies with geographic origin; and that a small percentage of individuals carry stable duplications of CYP2D6, with “ultra-rapid” metabolizers having up to 13 copies of the active gene (Ingelman-Sundberg and Evans, 2001). Phenotypic consequences of the deficient CYP2D6 phenotype (Table 7–3) include increased risk of toxicity of antidepressants or antipsychotics (catabolized by the enzyme), lack of analgesic effects of codeine (anabolized by the enzyme), and lack of activation of tamoxifen, leading to a greater risk of relapse or recurrence in breast cancer (Borges et al., 2006; Goetz et al., 2008; Ingle, 2008). Conversely, the ultra-rapid phenotype is associated with extremely rapid clearance and thus inefficacy of antidepressants (Kirchheiner et al., 2001).

A promoter region variant in the enzyme UGT1A1, UGT1A1*28, which has an additional TA in comparison to the more common form of the gene, has been associated with a reduced transcription rate of UGT1A1 and lower glucuronidation activity of the enzyme. This reduced activity has been associated with higher levels of the active metabolite of the cancer chemotherapeutic agent irinotecan (see Chapters 6). The metabolite, SN38, which is eliminated by glucuronidation, is associated with the risk of toxicity (Iyer et al., 2002; Rosner and Panetta, 2008), which will be more severe in individuals with genetically lower UGT1A1 activity (see Figures 6–5, 6–7, and 6–8).

CYP2C19, historically termed mephenytoin hydroxylase, displays penetrant pharmacogenetic variability, with just a few SNPs accounting for the majority of the deficient, poor metabolizer phenotype (Mallal et al., 2002). The deficient phenotype is much more common in Chinese and Japanese populations. Several proton pump inhibitors, including omeprazole and lansoprazole, are inactivated by CYP2C19. Thus, the deficient patients have higher exposure to active parent drug, a greater pharmacodynamic effect (higher gastric pH), and a higher probability of ulcer cure than heterozygotes or homozygous wild-type individuals (Figure 7–12).

Both pharmacokinetic and pharmacodynamic polymorphisms affect warfarin dosing. The anticoagulant warfarin is catabolized by CYP2C9, and its action is partly dependent upon the baseline level of reduced vitamin K (catalyzed by vitamin K epoxide reductase; Figures 7–13 and 30–7). Inactivating polymorphisms in CYP2C9 are common (Goldstein, 2001), with 2-10% of most populations being homozygous for low-activity variants, and are associated with lower warfarin clearance, a higher risk of bleeding complications, and lower dose requirements (see Table 30–2 and Aithal et al., 1999). Combined with
Figure 7–11. An intronic SNP can affect splicing and account for polymorphic expression of CYP3A5. A common polymorphism (A>G) in intron 3 of CYP3A5 defines the genotypes associated with the wild-type CYP3A5*1 allele, or the variant nonfunctional CYP3A5*3 allele. This intronic SNP creates an alternative splice site that results in the production of an alternative CYP3A5 transcript carrying an additional intron 3B (panel B), with an accompanying early stop codon and truncated CYP3A5 protein. Whereas the wild-type gene (more common in African than Caucasian or Asian populations) results in production of active CYP3A5 protein (panel A), the *3 variant results in a truncated and inactive CYP3A5 protein. Thus, metabolism of CYP3A5 substrates is diminished in vitro (panel C, shown for midazolam) and blood concentrations of such medications are higher in vivo (panel D, shown for tacrolimus) for these with the *3 than the *1 allele. (Based on data from Haufroid et al., 2004; Kuehl et al., 2001; Lin et al., 2002.)

genotyping for a common polymorphism in VKORC1, inherited variation in these two genes account for 20-60% of the variability in warfarin doses needed to achieve the desired INR, and use of these tests in the clinic can result in fewer bleeding complications and shorter time of trial-and-error to achieve the desired steady state level of anticoagulation. (Caraco et al., 2008; Lesko, 2008; Schwarz et al., 2008).

Thiopurine methyltransferase (TPMT) methylates thiopurines such as mercaptopurine (an anti-leukemic drug that is also the product of azathioprine metabolism; Figure 47–5). One in 300 individuals is homozygous deficient, 10% are heterozygotes, and ~90% are homozygous for the wild-type alleles for TPMT (Weinshilboum and Sladek, 1980). Three SNPs account for over 90% of the inactivating alleles (Yates et al., 1997). Because methylation of mercaptopurine competes with activation of the drug to thioguanine nucleotides, the concentration of the active (but also toxic) thioguanine metabolites is inversely related to

* Information on genetics-based dosing, adverse events, or testing added to FDA-approved drug label (Grossman, 2007).

*TPMT* activity and directly related to the probability of pharmacologic effects. Dose reductions (from the “average” population dose) may be required to avoid myelosuppression in 100% of homozygous deficient patients, 35% of heterozygotes, and only 7-8% of those with homozygous wild-type activity (Relling et al., 1999). The rare homozygous deficient patients can tolerate 10% or less of the mercaptopurine doses tolerated by the homozygous wild-type patients, with heterozygotes often requiring an intermediate dose. Conversely, homozygous wild-type patients show less anti-leukemic response to a short course of mercaptopurine than

![Figure 7–12. Effect of CYP2C19 genotype on proton pump inhibitor (PPI) pharmacokinetics (AUC), gastric pH, and ulcer cure rates. those with at least one inactive TPMT allele (Stanulla et al., 2005). Mercaptopurine has a narrow therapeutic range, and dosing by trial and error can place patients at higher risk of toxicity; thus, prospective adjustment of thiopurine doses based on TPMT genotype has been suggested (Lesko and Woodcock, 2004). Life-threatening toxicity has also been reported when thiopurines have been given to patients with nonmalignant conditions (such as Crohn’s disease, arthritis, or for prevention of solid organ transplant rejection) (Evans and Johnson, 2001; Evans and Relling, 2004; Weinshilboum, 2003).

**Pharmacogenetics and Drug Receptors/Targets.** Gene products that are direct targets for drugs have an important role in pharmacogenetics (Johnson and Lima, 2003). Whereas highly penetrant variants with profound functional consequences in some genes may cause disease phenotypes that confer negative selective pressure, more subtle variations in the same genes can be maintained in the population without causing disease, but nonetheless causing variation in drug response. For example, complete inactivation by means of rare point mutations in methylenetetrahydrofolate reductase (MTHFR) causes severe mental retardation, cardiovascular disease, and a shortened lifespan (Goyette et al., 1994). MTHFR reduces 5,10-CH₂ to 5-CH₃ tetrahydrofolate, and thereby interacts with folate-dependent one-carbon synthesis reactions, including homocysteine/methionine metabolism and pyrimidine/purine synthesis (see Chapter 61). This pathway is the target of several antifolate drugs. For details, see the methotrexate pathway at www.pharmGKB.org.

Whereas rare inactivating variants in MTHFR may result in early death, the 677C→T SNP causes an amino acid substitution that is maintained in the population at a high frequency (variant allele, q, frequency in most white populations = 0.4). This variant is associated with modestly lower MTHFR activity (~30% less than the 677C allele) and modest but significantly elevated plasma homocysteine concentrations (about 25% higher) (Klerk et al., 2002). This polymorphism does not alter drug pharmacokinetics, but does appear to modulate pharmacodynamics by predisposing to GI toxicity to the antifolate drug methotrexate in stem cell transplant recipients. Following prophylactic treatment with methotrexate for graft-versus-host disease, mucositis was three times more common among patients homozygous for the 677T allele than those homozygous for the 677C allele (Ulrich et al., 2001).

**Factors Modifying Methotrexate Action.** The methotrexate pathway involves metabolism, transport, drug modifier, and drug target polymorphisms. Methotrexate is a substrate for transporters and anabolizing enzymes that affect its intracellular pharmacokinetics and that are subject to common polymorphisms (see methotrexate pathway at www.pharmGKB.org). Several of the direct targets (dihydrofolate reductase, purine transformylases, and thymidylate synthase [TYMS]) are also subject to common polymorphisms.
A polymorphic indel in TYMS (two vs. three repeats of a 28-base pair repeat in the enhancer) affects the amount of enzyme expression in both normal and tumor cells. The polymorphism is quite common, with alleles equally split between the lower-expression two-repeat and the higher-expression three-repeat alleles. The TYMS polymorphism can affect both toxicity and efficacy of anticancer agents (e.g., fluorouracil and methotrexate) that target TYMS (Krajinovic et al., 2002). Thus, the genetic contribution to variability in the pharmacokinetics and pharmacodynamics of methotrexate cannot be understood without assessing genotypes at a number of different loci.

Other Examples of Drug Target Polymorphisms. Many drug target polymorphisms have been shown to predict responsiveness to drugs (Table 7–3). Serotonin receptor polymorphisms predict not only the responsiveness to antidepressants, but also the overall risk of depression (Murphy et al., 2003). β-Adrenergic receptor polymorphisms have been linked to asthma responsiveness (degree of change in 1-second forced expiratory volume after use of a β agonist) (Tan et al., 1997), renal function following angiotensin-converting enzyme (ACE) inhibitors (Essen et al., 1996), and heart rate following β blockers (Taylor and Kennedy, 2001). Polymorphisms in 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase have been linked to the degree of lipid lowering following statins, which are HMG-CoA reductase inhibitors (see Chapter 31), and to the degree of positive effects on high-density lipoproteins among women on estrogen replacement therapy (Herrington et al., 2002). Ion channel polymorphisms have been linked to a risk of cardiac arrhythmias in the presence and absence of drug triggers (Roden, 2004).

Polymorphism-Modifying Diseases and Drug Responses. Some genes may be involved in an underlying disease being treated, but do not directly interact with the drug. Modifier polymorphisms are important for the de novo risk of some events and for the risk of drug-induced events. The MTHFR polymorphism, e.g., is linked to homocysteinemia, which in turn affects thrombosis risk (den Heijer, 2003). The risk of a drug-induced thrombosis is dependent not only on the use of prothrombotic drugs, but on environmental and genetic predisposition to thrombosis, which may be affected by germline polymorphisms in MTHFR, factor V, and prothrombin (Chanock, 2003). These polymorphisms do not directly act on the pharmacokinetics or pharmacodynamics of prothrombotic drugs, such as glucocorticoids, estrogens, and asparaginase, but may modify the risk of the phenotypic event (thrombosis) in the presence of the drug.

Likewise, polymorphisms in ion channels (e.g., HERG, KvLQT1, Mink, and MiRPl) may affect the overall risk of cardiac dysrhythmias, which may be accentuated in the presence of a drug that can prolong the QT interval in some circumstances (e.g., macrolide antibiotics, antihistamines) (Roden, 2003). These modifier polymorphisms may impact on the risk of “disease” phenotypes even in the absence of drug challenges; in the presence of drug, the “disease” phenotype may be elicited.

Cancer As a Special Case. Cancer pharmacogenetics have an unusual aspect in that tumors exhibit somatically acquired mutations in addition to the underlying germline variation of the host. Thus, the efficacy of some anticancer drugs depends on the genetics of both the host and the tumor. For example, non-small-cell lung cancer is treated with an inhibitor of epidermal growth factor receptor (EGFR), gefitinib. Patients whose tumors have activating mutations in the tyrosine kinase domain of EGFR appear to respond better to gefitinib than those without the mutations (Lynch et al., 2004). Thus, the receptor is altered, and at the same time, individuals with the activating mutations may be considered to have a distinct category of non-small-cell lung cancer. Breast cancer patients with expression of the Her2 antigen (as an acquired genetic changes) are more likely to benefit from the antibody trastuzumab than are those who are negative for Her2 expression, and this results in a common tailoring of anticancer therapy in patients with breast cancer based on tumor genetics. As an example of a gene that affects both tumor and host, the presence of two instead of three copies of a TYMS enhancer repeat polymorphism increases the risk of host toxicity but also increases the chance of tumor susceptibility to thymidylate synthase inhibitors (Evans, and McLeod, 2003; Relling and Dervieux, 2001; Villafranca et al., 2001).

Pharmacogenetics and Drug Development

Pharmacogenetics will likely impact drug regulatory considerations in several ways (Evans and Relling, 2004; Lesko and Woodcock, 2004; Weinshilboum and Wang, 2004). Genome-wide approaches hold promise for identification of new drug targets and therefore new drugs. In addition, accounting for genetic/genomic inter-individual variability may lead to genotype-specific development of new drugs, and to genotype-specific dosing regimens. Recently, the U.S. Food and Drug Administration (FDA) altered the labels of several drugs in clinical use to indicate a pharmacogenetic issue (Table 7–3). With time and study, other drug labels will likely be changed as well.

Pharmacogenomics can identify new targets. For example, genome-wide assessments using microarray technology could identify genes whose expression differentiates inflammatory processes; a compound could be identified that changes expression of that gene; and then that compound could serve as a starting point for anti-inflammatory drug development. Proof of principle has been demonstrated for identification of anti-leukemic agents (Stegmaier et al., 2004) and antifungal drugs (Parsons et al., 2004), among others.

Pharmacogenetics may identify subsets of patients who will have a very high or a very low likelihood of responding to an agent. This will permit testing of the drug
in a selected population that is more likely to respond, minimizing the possibility of adverse events in patients who derive no benefit, and more tightly defining the parameters of response in the subset more likely to benefit. Somatic mutations in the EGFR gene strongly identify patients with lung cancer who are likely to respond to the tyrosine kinase inhibitor gefitinib (Lynch et al., 2004); germline variations in 5-lipoxygenase (ALOX5) determine which asthma patients are likely to respond to ALOX inhibitors (Drazen et al., 1999); and vasodilation in response to β2 agonists has been linked to β2 adrenergic receptor polymorphisms (Johnson and Lima, 2003).

A related role for pharmacogenomics in drug development is to identify which genetic subset of patients is at highest risk for a serious adverse drug effect, and to avoid testing the drug in that subset of patients (Lesko and Woodcock, 2004). For example, the identification of HLA subtypes associated with hypersensitivity to the HIV-1 reverse transcriptase inhibitor abacavir (Mallal et al., 2002, 2008) identifies a subset of patients who should receive alternative antiretroviral therapy, and this has been shown to decrease the frequency of hypersensitivity as an adverse effect of this agent. Children with acute myeloid leukemia who are homozygous for germline deletions in GSH transferase (GSTT1) are almost three times as likely to die of toxicity as those patients who have at least one wild-type copy of GSTT1 following intensively timed antileukemic therapy but not after “usual” doses of antileukemic therapy (Davies et al., 2001). These latter results suggest an important principle: pharmacogenetic testing may help to identify patients who require altered dosages of medications, but will not necessarily preclude the use of the agents completely.

Pharmacogenetics in Clinical Practice

Despite considerable research activity, pharmacogenetics are not yet widely utilized in clinical practice. There are three major types of evidence that should accumulate in order to implicate a polymorphism in clinical care (Figure 7–14):

- screens of tissues from multiple humans linking the polymorphism to a trait
- complementary preclinical functional studies indicating that the polymorphism is plausibly linked with the phenotype
- multiple supportive clinical phenotype/genotype association studies

Because of the high probability of type I error in genotype/phenotype association studies, replication of clinical findings will generally be necessary. Although the impact of the polymorphism in TPMT on mercaptopurine dosing in childhood leukemia is a good example of a polymorphism for which all three types of evidence are available, proactive individualized dosing of thiopurines based on genotype has not been widely incorporated into clinical practice (Lesko et al., 2004).

Most drug dosing relies on a population “average” dose of drug. Adjusting dosages for variables such as renal or liver dysfunction is often accepted in drug dosing, even in cases in which the clinical outcome of such adjustments has not been studied. Even though there are many examples of significant effects of polymorphisms on drug disposition (e.g., Table 7–3), there is much more hesitation from clinicians to adjust doses based on genetic testing than on indirect clinical measures of renal and liver function. Whether this hesitation reflects resistance to abandon the “trial-and-error” approach that has defined most drug dosing, concern about genetic discrimination, or unfamiliarity with the principles of genetics is not clear. Nonetheless, broad public initiatives, such as the NIH-funded Pharmacogenetics and Pharmacogenomics Knowledge Base (www.pharmGKB.org), provide useful resources to permit clinicians to access information on pharmacogenetics (see Table 7–1). The passage of laws to prevent genetic discrimination (Erwin, 2008) may also assuage concerns that genetic data placed in medical records could penalize those with “unfavorable” genotypes.

The fact that functionally important polymorphisms are so common means that complexity of dosing will be likely to increase substantially in the postgenomic era. Even if every drug has only one important polymorphism to consider when dosing, the scale of complexity could be large. Many individuals take multiple drugs simultaneously for different diseases, and many therapeutic regimens for a single disease consist of multiple agents. This situation translates into a large number of possible drug-dose combinations. Much of the excitement regarding the promise of human genomics has emphasized the hope of discovering individualized “magic bullets,” and ignored the reality of the added complexity of additional testing and need for interpretation of results to capitalize on individualized dosing. This is illustrated in a potential pharmacogenetic example in Figure 7–14. In this case, a traditional anticancer treatment approach is replaced with one that incorporates pharmacogenetic information with the stage of the cancer determined by a variety of standardized pathological criteria. Assuming just one important genetic polymorphism for each of the
three different anticancer drugs, 11 individual drug regimens can easily be generated.

Nonetheless, the potential utility of pharmacogenetics to optimize drug therapy is great. After adequate genotype/phenotype studies have been conducted, molecular diagnostic tests will be developed, and genetic tests have the advantage that they need only be conducted once during an individual’s lifetime. With continued incorporation of pharmacogenetics into clinical trials, the important genes and polymorphisms will be identified, and data will demonstrate whether dosage individualization can improve outcomes and decrease short- and long-term adverse effects. Significant covariates will be identified to allow refinement of dosing in the context of drug interactions and disease influences. Although the challenges are substantial, accounting for the genetic basis of variability in response to medications is already being used in specific pharmacotherapeutics decisions, and is likely to become a fundamental component of diagnosing any illness and guiding the choice and dosage of medications.

ANATOMY AND GENERAL FUNCTIONS

The autonomic nervous system, also called the visceral, vegetative, or involuntary nervous system, is distributed widely throughout the body and regulates autonomic functions that occur without conscious control. In the periphery, it consists of nerves, ganglia, and plexuses that innervate the heart, blood vessels, glands, other visceral organs, and smooth muscle in various tissues.

Differences Between Autonomic and Somatic Nerves. The efferent nerves of the involuntary system supply all innervated structures of the body except skeletal muscle, which is served by somatic nerves. The most distal synaptic junctions in the autonomic reflex arc occur in ganglia that are entirely outside the cerebrospinal axis. These ganglia are small but complex structures that contain axodendritic synapses between preganglionic and postganglionic neurons. Somatic nerves contain no peripheral ganglia, and the synapses are located entirely within the cerebrospinal axis. Many autonomic nerves form extensive peripheral plexuses, but such networks are absent from the somatic system. Whereas motor nerves to skeletal muscles are myelinated, postganglionic autonomic nerves generally are nonmyelinated. When the spinal efferent nerves are interrupted, the denervated skeletal muscles lack myogenic tone, are paralyzed, and atrophy, whereas smooth muscles and glands generally retain some level of spontaneous activity independent of intact innervation.

Visceral Afferent Fibers. The afferent fibers from visceral structures are the first link in the reflex arcs of the autonomic system. With certain exceptions, such as local axon reflexes, most visceral reflexes are mediated through the central nervous system (CNS).

Information on the status of the visceral organs is transmitted to the CNS through two main sensory systems: the cranial nerve (parasympathetic) visceral sensory system and the spinal (sympathetic) visceral afferent system (Saper, 2002). The cranial visceral sensory system carries mainly mechanoreceptor and chemosensory information, whereas the afferents of the spinal visceral system principally convey sensations related to temperature and tissue injury of mechanical, chemical, or thermal origin. Cranial visceral sensory information enters the CNS by four cranial nerves: the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus (X) nerves. These four cranial nerves transmit visceral sensory information from the internal face and head (V); tongue (taste, VII); hard palate and upper part of the oropharynx (IX); and carotid body, lower part of the oropharynx, larynx, trachea, esophagus, and thoracic and abdominal organs (X), with the exception of the pelvic viscera. The pelvic viscera are innervated by nerves from the second through fourth sacral spinal segments.

The visceral afferents from these four cranial nerves terminate topographically in the solitary tract nucleus (STN) (Altschuler et al., 1989). The most massive site for termination of the fibers from the STN is the parabrachial nucleus, which is thus the major relay station. The parabrachial nucleus consists of at least 13 separate subnuclei, which in turn project extensively to a wide range of sites in the brainstem, hypothalamus, basal forebrain, thalamus, and cerebral cortex. Other direct projections from the STN also innervate these brain structures.

Sensory afferents from visceral organs also enter the CNS from the spinal nerves. Those concerned with muscle chemosensation may arise at all spinal levels, whereas sympathetic visceral sensory afferents generally arise at the thoracic levels where sympathetic preganglionic neurons are found. Pelvic sensory afferents from spinal segments S2–S4 enter at that level and are important for the
regulation of sacral parasympathetic outflow. In general, visceral afferents that enter the spinal nerves convey information concerned with temperature as well as nociceptive visceral inputs related to mechanical, chemical, and thermal stimulation. The primary pathways taken by ascending spinal visceral afferents are complex and controversial (Saper, 2002). Most probably converge with muscular-skeletal and cutaneous afferents and ascend by the spinothalamic and spinoreticular tracts. Others ascend by the dorsal column. An important feature of the ascending pathways is that they provide collaterals that converge with the cranial visceral sensory pathway at virtually every level (Saper, 2000). At the brainstem level, collaterals from the spinal system converge with the cranial nerve sensory system in the STN, the ventrolateral medulla, and the parabrachial nucleus. At the level of the forebrain, the spinal system appears to form a posterolateral continuation of the cranial nerve visceral sensory thalamus and cortex (Saper, 2000).

The neurotransmitters that mediate transmission from sensory fibers have not been characterized unequivocally. Substance P and calcitonin gene–related peptide (CGRP), which are present in afferent sensory fibers, in the dorsal root ganglia, and in the dorsal horn of the spinal cord, are leading candidates for neurotransmitters that communicate nociceptive stimuli from the periphery to the spinal cord and higher structures. Other neuroactive peptides, including somatostatin, vasoactive intestinal polypeptide (VIP), and cholecystokinin, also have been found in sensory neurons (Hökfelt et al., 2000), and one or more such peptides may play a role in the transmission of afferent impulses from autonomic structures. ATP appears to be a neurotransmitter in certain sensory neurons, including those that innervate the urinary bladder. Enkephalins, present in interneurons in the dorsal spinal cord (within an area termed the substantia gelatinosa), have antinociceptive effects that appear to arise from presynaptic and postsynaptic actions to inhibit the release of substance P and diminish the activity of cells that project from the spinal cord to higher centers in the CNS. The excitatory amino acids glutamate and aspartate also play major roles in transmission of sensory responses to the spinal cord.

Central Autonomic Connections. There probably are no purely autonomic or somatic centers of integration, and extensive overlap occurs. Somatic responses always are accompanied by visceral responses, and vice versa. Autonomic reflexes can be elicited at the level of the spinal cord. They clearly are demonstrable in experimental animals or humans with spinal cord transection and are manifested by sweating, blood pressure alterations, vasomotor responses to temperature changes, and reflex emptying of the urinary bladder, rectum, and seminal vesicles. Extensive central ramifications of the autonomic nervous system exist above the level of the spinal cord. For example, integration of the control of respiration in the medulla oblongata is well known. The hypothalamus and the STN generally are regarded as principal loci of integration of autonomic nervous system functions, which include regulation of body temperature, water balance, carbohydrate and fat metabolism, blood pressure, emotions, sleep, respiration, and reproduction. Signals are received through ascending spinobulbar pathways, the limbic system, neostriatum, cortex, and to a lesser extent other higher brain centers. Stimulation of the STN and the hypothalamus activates bulbospinal pathways and hormonal output to mediate autonomic and motor responses (Andresen and Kunze, 1994; (see Chapter 14). The hypothalamic nuclei that lie posteriorly and laterally are sympathetic in their main connections, whereas parasympathetic functions evidently are integrated by the midline nuclei in the region of the tuber cinereum and by nuclei lying anteriorly.

The CNS can produce a wide range of patterned autonomic and somatic responses from discrete activation of sympathetic or parasympathetic neurons to more generalized activation of these nerves with highly integrated patterns of response. There are highly differentiated patterns of activity during a wide range of physiological conditions consistent with the need for modulation of different organ functions. There is evidence for organotropical organization of neuronal pools at multiple levels of the CNS that generate these various patterns of sympathetic and parasympathetic responses. The pattern generators at these different levels of the neuroaxis are often organized in a hierarchical manner that allows individual response or larger responses made up of multiple individual units.

Highly integrated patterns of response generally are organized at a hypothalamic level and involve autonomic, endocrine, and behavioral components. On the other hand, more limited patterned responses are organized at other levels of basal forebrain, brainstem, and spinal cord.

Divisions of the Peripheral Autonomic System. On the efferent side, the autonomic nervous system consists of two large divisions: (1) the sympathetic or thoracolumbar outflow and (2) the parasympathetic or craniosacral outflow. A brief outline of those anatomical features is necessary for an understanding of the actions of autonomic drugs.

The arrangement of the principal parts of the peripheral autonomic nervous system is presented schematically in Figure 8–1. The neurotransmitter of all preganglionic autonomic fibers, most postganglionic parasympathetic fibers, and a few postganglionic sympathetic fibers is acetylcholine (ACh). Some postganglionic parasympathetic nerves use nitric oxide (NO) as a neurotransmitter; nerves that release NO are referred to as nitrergic (Toda and Okamura, 2003). The adrenergic fibers comprise the majority of the postganglionic sympathetic fibers; here the primary transmitter is norepinephrine (NE, noradrenaline, levarterenol). The terms cholinergic and adrenergic were proposed originally by Dale to describe neurons that liberate ACh or noradrenaline, respectively. Not all the transmitter(s) of the primary afferent fibers, such as those from the mechano- and chemoreceptors of the carotid body and aortic arch, have been identified conclusively. Substance P and glutamate are thought to mediate many afferent impulses; both are present in high concentrations in the dorsal spinal cord.

Sympathetic Nervous System. The cells that give rise to the preganglionic fibers of this division lie mainly in the intermediolateral columns of the spinal cord and extend from the first thoracic to the second or
Figure 8–1. *The autonomic nervous system.* Schematic representation of the autonomic nerves and effector organs based on chemical mediation of nerve impulses. Yellow, cholinergic; red, adrenergic; dotted blue, visceral afferent; solid lines, preganglionic; broken lines, postganglionic. In the upper rectangle at the right are shown the finer details of the ramifications of adrenergic fibers at any one segment of the spinal cord, the path of the visceral afferent nerves, the cholinergic nature of somatic motor nerves to skeletal muscle, and the presumed cholinergic nature of the vasodilator fibers in the dorsal roots of the spinal nerves. The asterisk (*) indicates that it is not known whether these vasodilator fibers are motor or sensory or where their cell bodies are situated.
The axons from these cells are carried in the anterior (ventral) nerve roots and synapse, with neurons lying in sympathetic ganglia outside the cerebrospinal axis. Sympathetic ganglia are found in three locations: paravertebral, prevertebral, and terminal.

The 22 pairs of paravertebral sympathetic ganglia form the lateral chains on either side of the vertebral column. The ganglia are connected to each other by nerve trunks and to the spinal nerves by rami communicantes. The white rami are restricted to the segments of the thoracolumbar outflow; they carry the preganglionic myelinated fibers that exit the spinal cord by the anterior spinal roots. The gray rami arise from the ganglia and carry postganglionic fibers back to the spinal nerves for distribution to sweat glands and pilomotor muscles and to blood vessels of skeletal muscle and skin. The prevertebral ganglia lie in the abdomen and the pelvis near the ventral surface of the bony vertebral column and consist mainly of the celiac (solar), superior mesenteric, aorticorenal, and inferior mesenteric ganglia. The terminal ganglia are few in number, lie near the organs they innervate, and include ganglia connected with the urinary bladder and rectum and the cervical ganglia in the region of the neck. In addition, small intermediate ganglia lie outside the conventional vertebral chain, especially in the thoracolumbar region. They are variable in number and location but usually are in close proximity to the communicating rami and the anterior spinal nerve roots.

Preganglionic fibers issuing from the spinal cord may synapse with the neurons of more than one sympathetic ganglion. Their principal ganglia of termination need not correspond to the original level from which the preganglionic fiber exits the spinal cord. Many of the preganglionic fibers from the fifth to the last thoracic segment pass through the paravertebral ganglia to form the splanchnic nerves. Most of the splanchnic nerve fibers do not synapse until they reach the celiac ganglion; others directly innervate the adrenal medulla (see following discussion).

Postganglionic fibers arising from sympathetic ganglia innervate visceral structures of the thorax, abdomen, head, and neck. The trunk and the limbs are supplied by the sympathetic fibers in spinal nerves, as described earlier. The prevertebral ganglia contain cell bodies whose axons innervate the glands and smooth muscles of the abdominal and the pelvic viscera. Many of the upper thoracic sympathetic fibers from the vertebral ganglia form terminal plexuses, such as the cardiac, esophageal, and pulmonary plexuses. The sympathetic distribution to the head and the neck (vasomotor, pupillodilator, secretory, and pilomotor) is by means of the cervical sympathetic chain and its three ganglia. All postganglionic fibers in this chain arise from cell bodies located in these three ganglia; all preganglionic fibers arise from the upper thoracic segments of the spinal cord, there being no sympathetic fibers that leave the CNS above the first thoracic level.

The adrenal medulla and other chromaffin tissue are embryologically and anatomically similar to sympathetic ganglia; all are derived from the neural crest. The adrenal medulla in humans and many other species differs from sympathetic ganglia in that its principal catecholamine is epinephrine (adrenaline), whereas norepinephrine is released from postganglionic sympathetic fibers. The chromaffin cells in the adrenal medulla are innervated by typical preganglionic fibers that release ACh.

**Parasympathetic Nervous System.** The parasympathetic nervous system consists of preganglionic fibers that originate in the CNS and their postganglionic connections. The regions of central origin are the midbrain, the medulla oblongata, and the sacral part of the spinal cord. The midbrain, or tectal, outflow consists of fibers arising from the Edinger-Westphal nucleus of the third cranial nerve and going to the ciliary ganglion in the orbit. The medullary outflow consists of the parasympathetic components of the seventh, ninth, and tenth cranial nerves. The fibers in the seventh (facial) cranial nerve form the chorda tympani, which innervates the ganglia lying on the submaxillary and sublingual glands. They also form the greater superficial petrosal nerve, which innervates the sphenopalatine ganglion. The autonomic components of the ninth (glossopharyngeal) cranial nerve innervate the otic ganglia. Postganglionic parasympathetic fibers from these ganglia supply the sphincter of the iris (pupillary constrictor muscle), the ciliary muscle, the salivary and lacrimal glands, and the mucous glands of the nose, mouth, and pharynx. These fibers also include vasodilator nerves to these same organs. The tenth (vagus) cranial nerve arises in the medulla and contains preganglionic fibers, most of which do not synapse until they reach the many small ganglia lying directly on or in the viscera of the thorax and abdomen. In the intestinal wall, the vagal fibers terminate around ganglion cells in the myenteric and submucosal plexuses. Thus, in the parasympathetic branch of the autonomic nervous system, preganglionic fibers are very long, whereas postganglionic fibers are very short. The vagus nerve also carries a far greater
number of afferent fibers (but apparently no pain fibers) from the viscera into the medulla; the cell bodies of these fibers lie mainly in the nodose ganglion.

The parasympathetic sacral outflow consists of axons that arise from cells in the second, third, and fourth segments of the sacral cord and proceed as preganglionic fibers to form the pelvic nerves (*nervi erigentes*). They synapse in terminal ganglia lying near or within the bladder, rectum, and sexual organs. The vagal and sacral outflows provide motor and secretory fibers to thoracic, abdominal, and pelvic organs, as indicated in Figure 8–1.

**Enteric Nervous System.** The processes of mixing, propulsion, and absorption of nutrients in the GI tract are controlled locally through a restricted part of the peripheral nervous system called the *enteric nervous system* (ENS). The ENS is involved in sensorimotor control and thus consists of both afferent sensory neurons and a number of motor nerves and interneurons that are organized principally into two nerve plexuses: the myenteric (Auerbach’s) plexus and the submucosal (Meissner’s) plexus. The myenteric plexus, located between the longitudinal and circular muscle layers, plays an important role in the contraction and relaxation of GI smooth muscle (Kunze and Furness, 1999). The submucosal plexus is involved with secretory and absorptive functions of the GI epithelium, local blood flow, and neuroimmune activities (Cooke, 1998).

Although originally classified by Langley in the 1920s as a third division of the autonomic nervous system, the ENS is actually comprised of components of the sympathetic and parasympathetic nervous systems and has sensory nerve connections through the spinal and nodose ganglia (see Chapter 46).

Parasympathetic preganglionic inputs are provided to the GI tract via the vagus and pelvic nerves. Acetylcholine is released from preganglionic neurons and activates nicotinic acetylcholine receptors (nAChRs) on postganglionic neurons within the enteric ganglia. Excitatory preganglionic input activates both excitatory and inhibitory motor neurons that control processes such as muscle contraction and secretion/absorption. Postganglionic sympathetic nerves also synapse with intrinsic neurons and generally induce relaxation by inhibiting the release of ACh. Sympathetic input can also be excitatory at some sphincter muscles.

There are intrinsic primary afferent neurons with cell bodies in the enteric ganglia and processes that extend into the lamina propria of the mucosa. These neurons respond to luminal chemical stimuli, mechanical deformation of the mucosa, and to stretch (Costa et al., 2000). Nerve endings of the primary afferents can be activated by numerous endogenous substances, the most important of which is serotonin 5-hydroxy tryptamine, 5-HT, which is secreted from enterochromaffin cells within the mucosa. Enterochromaffin cells likely provide the primary sensory transduction mechanism that activates the afferent neurons.

Information from afferent and preganglionic neural inputs to the enteric ganglia is integrated and distributed by a network of interneurons. These cells provide both ascending and descending pathways within the enteric plexuses that are involved in generating stereotypical GI reflexes such as ascending inhibition and descending (receptive) relaxation. ACh is the primary neurotransmitter providing excitatory inputs between interneurons, but other substances such as ATP (via postjunctional P2X receptors), substance P (by NK1 receptors), and serotonin (using 5-HT3 receptors) are also important in mediating integrative processing via interneurons.

The muscle layers of the GI tract are dually innervated by excitatory and inhibitory motor neurons with cell bodies primarily in the myenteric ganglia (Kunze and Furness, 1999). ACh, in addition to being a neurotransmitter released from preganglionic neurons in ganglia, also serves as a primary excitatory motor neurotransmitter released from postganglionic neurons. ACh activates M3 and M4 receptors in postjunctional cells to elicit motor responses. Pharmacological blockade of muscarinic cholinergic (mAChRs) receptors does not block all excitatory neurotransmission, however, because neurokinins (neurokinin A and Substance P) are also stored and released by excitatory motor neurons and contribute to postjunctional excitation via NK1 and NK2 receptors (Costa et al., 1996).

Inhibitory motor neurons are also abundant in the GI tract and regulate important motility events such as accommodation, sphincter relaxation, and descending receptive relaxation. Inhibitory responses are elicited by at least two major transmitters, used to varying degrees depending upon the region of the gut and the species. A purine substance, either ATP or β-nicotinamide adenine dinucleotide (β-NAD) (Mutafowa-Yambolieva, 2007), elicits relaxation via postjunctional P2Y1 receptors. Nitric oxide is also an important transmitter that activates production of cyclic GMP and downstream effector phosphorylation by activation of PKG. Inhibitory neuropeptides, such as vasoactive intestinal polypeptide (VIP) and pituitary adenylyl cyclase-activating peptide (PACAP), may also be released from inhibitory motor neurons under conditions of strong stimulation (Kunze and Furness, 1999).

In general, motor neurons do not directly innervate smooth muscle cells in the GI tract. Nerve terminals make synaptic connections with interstitial cells of Cajal (ICCs), and these cells make electrical connections (gap junctions) with smooth muscle cells (Ward et al., 2000). Thus, the ICCs are the receptive, postjunctional transducers of inputs from enteric motor neurons, and loss of these cells has been associated with conditions that appear like neuropathies. ICCs have all of the major receptors and effectors necessary to transduce both excitatory and inhibitory neurotransmitters into postjunctional responses (Chen et al., 2007).

**Differences Among Sympathetic, Parasympathetic, and Motor Nerves.** The sympathetic system is distributed to effectors throughout the body, whereas parasympathetic distribution is much more limited. Furthermore, the sympathetic fibers ramify to a much greater extent. A preganglionic sympathetic fiber may traverse a considerable distance of the sympathetic chain and pass through several ganglia before it finally synapses with a postganglionic neuron; also, its terminals make contact with a large number of postganglionic neurons. In some
ganglia, the ratio of preganglionic axons to ganglion cells may be 1:20 or more. This organization permits a diffuse discharge of the sympathetic system. In addition, synaptic innervation overlaps, so one ganglion cell may be supplied by several preganglionic fibers.

The parasympathetic system, in contrast, has terminal ganglia very near or within the organs innervated and thus is more circumscribed in its influences. In some organs, a 1:1 relationship between the number of preganglionic and postganglionic fibers has been suggested, but the ratio of preganglionic vagal fibers to ganglion cells in the myenteric plexus has been estimated as 1:8000. Hence this distinction between the two systems does not apply to all sites.

The cell bodies of somatic motor neurons reside in the ventral horn of the spinal cord; the axon divides into many branches, each of which innervates a single muscle fiber, so more than 100 muscle fibers may be supplied by one motor neuron to form a motor unit. At each neuromuscular junction, the axonal terminal loses its myelin sheath and forms a terminal arborization that lies in apposition to a specialized surface of the muscle membrane, termed the motor end plate. Mitochondria and a collection of synaptic vesicles are concentrated at the nerve terminal. Through trophic influences of the nerve, those cell nuclei in the multinucleated skeletal muscle cell lying in close apposition to the synapse acquire the capacity to activate specific genes that express synapse-localized proteins (Sanes and Lichtman, 1999). Differences among somatic motor, sympathetic and parasympathetic nerves are shown schematically in Figure 8–2.

Details of Innervation. The terminations of the postganglionic autonomic fibers in smooth muscle and glands form a rich plexus, or terminal reticulum. The terminal reticulum (sometimes called the autonomic ground plexus) consists of the final ramifications of the postganglionic sympathetic, parasympathetic, and visceral afferent fibers, all of which are enclosed within a frequently interrupted sheath of satellite or Schwann cells. At these interruptions, varicosities packed with vesicles are seen in the efferent fibers. Such varicosities occur repeatedly but at variable distances along the course of the ramifications of the axon.

“Protoplasmic bridges” occur between the smooth muscle fibers themselves at points of contact between their plasma membranes. They are believed to permit the direct conduction of impulses from cell to cell without the need for chemical transmission. These structures have been termed nexuses, or tight junctions, and they enable the smooth muscle fibers to function as a syncytial unit.

Sympathetic ganglia are extremely complex anatomically and pharmacologically (see Chapter 11). The preganglionic fibers lose their myelin sheaths and divide repeatedly into a vast number of end fibers with diameters ranging from 0.1–0.3 μm; except at points of synaptic contact, they retain their satellite cell sheaths. The vast majority of synapses are axodendritic. Apparently, a given axonal terminal may synapse with one or more dendritic processes.

Responses of Effector Organs to Autonomic Nerve Impulses. From the responses of the various effector organs to autonomic nerve impulses and the knowledge of the intrinsic autonomic tone, one can predict the actions of drugs that mimic or inhibit the actions of these nerves. In most instances, the sympathetic and parasympathetic neurotransmitters can be viewed as physiological or functional antagonists. If one neurotransmitter inhibits a certain function, the other usually augments that function. Most viscera are innervated by both divisions of the autonomic nervous system, and the level of activity at any moment represents the integration of influences of the two components. Despite the conventional concept of antagonism between the two portions of the autonomic nervous system, their activities on specific structures may be either discrete and independent or integrated and interdependent. For example, the effects of sympathetic and parasympathetic stimulation of the heart and the iris show a pattern of functional antagonism in controlling heart rate and pupillary aperture, respectively, whereas their actions on male sexual organs are complementary and are integrated to promote sexual function. The control of peripheral vascular resistance is primarily, but not exclusively, due to sympathetic control of arteriolar resistance. The effects of stimulating the sympathetic and parasympathetic nerves to various organs, visceral structures, and effector cells are summarized in Table 8–1.

General Functions of the Autonomic Nervous System. The integrating action of the autonomic nervous system (ANS) is of vital importance for the well-being of the organism. In general, the ANS regulates the activities of structures that are not under voluntary control and that function below the level of consciousness. Thus, respiration, circulation, digestion, body temperature, metabolism, sweating, and the secretions of certain endocrine glands are regulated, in part or entirely, by the autonomic nervous system, making the ANS the primary regulator of the constancy of the internal environment of the organism.

The sympathetic system and its associated adrenal medulla are not essential to life in a controlled environment, but the lack of sympatho-adrenal functions becomes evident under circumstances of stress. Body temperature cannot be regulated when environmental temperature varies; the concentration of glucose in blood does not rise in response to urgent need; compensatory vascular responses to hemorrhage, oxygen deprivation, excitement, and exercise are lacking; resistance to fatigue is lessened; sympathetic
components of instinctive reactions to the external environment are lost; and other serious deficiencies in the protective forces of the body are discernible.

The sympathetic system normally is continuously active; the degree of activity varies from moment to moment and from organ to organ. In this manner, adjustments to a constantly changing environment are accomplished. The sympatho-adrenal system also can discharge as a unit. This occurs particularly during rage and fright, when sympathetically innervated structures...

over the entire body are affected simultaneously. Heart rate is accelerated; blood pressure rises; red blood cells are poured into the circulation from the spleen (in certain species); blood flow is shifted from the skin and splanchnic region to the skeletal muscles; blood glucose rises; the bronchioles and pupils dilate; and the organism is better prepared for “fight or flight.” Many of these effects result primarily from or are reinforced by the actions of epinephrine secreted by the adrenal medulla (described later). In addition, signals are received in higher brain centers to facilitate purposeful responses or to imprint the event in memory.

The parasympathetic system is organized mainly for discrete and localized discharge. Although it is concerned primarily with conservation of energy and maintenance of organ function during periods of minimal activity, its elimination is not compatible with life. Sectioning the vagus, e.g., soon gives rise to pulmonary infection because of the inability of cilia to remove irritant substances from the respiratory tract. The parasympathetic system slows the heart rate, lowers the blood pressure, stimulates GI movements and secretions, aids absorption of nutrients, protects the retina from excessive light, and empties the urinary

\(^a\)Responses are designated + to +++ to provide an approximate indication of the importance of sympathetic and parasympathetic nerve activity in the control of the various organs and functions listed.

\(^b\)Adrenergic receptors: $\alpha_{1}$, $\alpha_{2}$ and subtypes thereof; $\beta_1$, $\beta_2$, $\beta_3$. Cholinergic receptors: nicotinic (N); muscarinic (M), with subtypes 1–4. The receptor subtypes are described more fully in Chapters 9 and 12 and in Tables 8–2, 8–3, 8–6 and 8–7. When a designation of subtype is not provided, the nature of the subtype has not been determined, unequivocally. Only the principal receptor subtypes are shown. Transmitters other than ACh and NE contribute to many of the responses.

\(^c\)In the human heart, the ratio of $\beta_1$ to $\beta_2$ is about 3:2 in atria and 4:1 in ventricles. While $\beta_2$ receptors predominate, $\beta_4$ receptors are also present (Wang et al., 2004).

\(^d\)The predominant $\alpha_2$ receptor subtype in most blood vessels (both arteries and veins) is $\alpha_{1A}$, although other $\alpha_1$ subtypes are present in specific blood vessels. The $\alpha_{1A}$ is the predominant subtype in the aorta (Michelotti et al., 2000).

\(^e\)Dilation predominates in situ owing to metabolic autoregulatory mechanisms.

\(^f\)Over the usual concentration range of physiologically released circulating epinephrine, the $\beta$ receptor response (vasodilation) predominates in blood vessels of skeletal muscle and liver; $\beta$ receptor response (vasoconstriction) in blood vessels of other abdominal viscera. The renal and mesenteric vessels also contain specific dopaminergic receptors whose activation causes dilation.

\(^g\)Sympathetic cholinergic neurons cause vasodilation in skeletal muscle beds, but this is not involved in most physiological responses.

\(^h\)The endothelium of most blood vessels releases NO, which causes vasodilation in response to muscarinic stimuli. However, unlike the receptors innervated by sympathetic cholinergic fibers in skeletal muscle blood vessels, these muscarinic receptors are not innervated and respond only to exogenously added muscarinic agonists in the circulation.

\(^i\)While adrenergic fibers terminate at inhibitory $\beta$ receptors on smooth muscle fibers and at inhibitory $\beta$ receptors on parasympathetic (cholinergic) excitatory ganglion cells of the myenteric plexus, the primary inhibitory response is mediated via enteric neurons through NO, P2Y receptors, and peptide receptors.

\(^j\)Uterine responses depend on stages of menstrual cycle, amount of circulating estrogen and progesterone, and other factors.

\(^k\)Palms of hands and some other sites (“adrenergic sweating”).

\(^l\)There is significant variation among species in the receptor types that mediate certain metabolic responses. All three $\beta$ adrenergic receptors have been found in human fat cells. Activation of $\beta_3$ receptors produces a vigorous thermogenic response as well as lipolysis. The significance is unclear. Activation of $\beta$ receptors also inhibits leptin release from adipose tissue.
bladder and rectum. Many parasympathetic responses are rapid and reflexive in nature.

**NEUROTRANSMISSION**

Nerve impulses elicit responses in smooth, cardiac, and skeletal muscles, exocrine glands, and postsynaptic neurons by liberating specific chemical neurotransmitters. The processes are presented in some detail because an understanding of the chemical mediation of nerve impulses provides the framework for our knowledge of the mechanism of action of drugs at these sites.

**Historical Aspects.** The earliest concrete proposal of a neurohumoral mechanism was made shortly after the turn of the twentieth century. Lewandowsky and Langley independently noted the similarity between the effects of injection of extracts of the adrenal gland and stimulation of sympathetic nerves. In 1905, T. R. Elliott, while a student with Langley at Cambridge, postulated that sympathetic nerve impulses release minute amounts of an epinephrine-like substance in immediate contact with effector cells. He considered this substance to be the chemical step in the process of transmission. He also noted that long after sympathetic nerves had degenerated, the effector organs still responded characteristically to the hormone of the adrenal medulla. Langley suggested that effector cells have excitatory and inhibitory “receptive substances” and that the response to epinephrine depended on which type of substance was present. In 1907, Dixon, impressed by the correspondence between the effects of the alkaloid muscarine and the responses to vagal stimulation, advanced the concept that the vagus nerve liberates a muscarine-like substance that acts as a chemical transmitter of its impulses. In the same year, Reid Hunt described the actions of ACh and other choline esters. In 1914, Dale investigated the pharmacological properties of ACh and other choline esters and distinguished its nicotine-like and muscarine-like actions. Intrigued with the remarkable fidelity with which this drug reproduced the responses to stimulation of parasympathetic nerves, he introduced the term parasympathomimetic to characterize its effects. Dale also noted the brief duration of action of this chemical and proposed that an esterase in the tissues rapidly splits ACh to acetic acid and choline, thereby terminating its action.

The studies of Loewi, begun in 1921, provided the first direct evidence for the chemical mediation of nerve impulses by the release of specific chemical agents. Loewi stimulated the vagus nerve of a perfused (donor) frog heart and allowed the perfusion fluid to come in contact with a second (recipient) frog heart used as a test object. The recipient frog heart was found to respond, after a short lag, in the same way as the donor heart. It thus was evident that a substance was liberated from the first organ that slowed the rate of the second. Loewi referred to this chemical substance as Vagusstoff (“vagus substance,” “parasympathin”); subsequently, Loewi and Navratil presented evidence to identify it as ACh. Loewi also discovered that an accelerator substance similar to epinephrine and called Acceleranstoff was liberated into the perfusion fluid in summer, when the action of the sympathetic fibers in the frog’s vagus, a mixed nerve, predominated over that of the inhibitory fibers. Feldberg and Krayer demonstrated in 1933 that the cardiac “vagus substance” also is ACh in mammals.

In addition to its role as the transmitter of most postganglionic parasympathetic fibers and of a few postganglionic sympathetic fibers, ACh has been shown to function as a neurotransmitter in three additional classes of nerves: preganglionic fibers of both the sympathetic and the parasympathetic systems, motor nerves to skeletal muscle, and certain neurons within the CNS.

In the same year as Loewi’s discovery, Cannon and Urild reported that stimulation of the sympathetic hepatic nerves resulted in the release of an epinephrine-like substance that increased blood pressure and heart rate. Subsequent experiments firmly established that this substance is the chemical mediator liberated by sympathetic nerve impulses at neuroeffector junctions. Cannon called this substance “sympathin.” In many of its pharmacological and chemical properties, “sympathin” closely resembled epinephrine, but also differed in certain important respects. As early as 1910, Barger and Dale noted that the effects of sympathetic nerve stimulation were reproduced more closely by the injection of sympathomimetic primary amines than by that of epinephrine or other secondary amines. The possibility that demethylated epinephrine (norepinephrine) might be “sympathin” had been advanced repeatedly, but definitive evidence for its being the sympathetic nerve mediator was not obtained until specific assays were developed for the determination of sympathomimetic amines in extracts of tissues and body fluids. In 1946, von Euler found that the sympathomimetic substance in highly purified extracts of bovine splenic nerve resembled norepinephrine by all criteria used. Norepinephrine is the predominant sympathomimetic substance in the postganglionic sympathetic nerves of mammals and is the adrenergic mediator liberated by their stimulation. Norepinephrine, its immediate precursor dopamine, and epinephrine also are neurotransmitters in the CNS (see Chapter 14).

**Evidence for Neurohumoral Transmission**

The concept of neurohumoral transmission or chemical neurotransmission was developed primarily to explain observations relating to the transmission of impulses from postganglionic autonomic fibers to effector cells. Evidence supporting this concept includes:

- demonstration of the presence of a physiologically active compound and its biosynthetic enzymes at appropriate sites
- recovery of the compound from the perfusate of an innervated structure during periods of nerve stimulation but not (or in greatly reduced amounts) in the absence of stimulation
- demonstration that the compound is capable of producing responses identical to responses to nerve stimulation
- demonstration that the responses to nerve stimulation and to the administered compound are modified in the same manner by various drugs, usually competitive antagonists
While these criteria are applicable for most neurotransmitters, including norepinephrine and ACh, there are now exceptions to these general rules. For instance, NO has been found to be a neurotransmitter, in a few postganglionic parasympathetic nerves, in nonadrenergic, noncholinergic (NANC) neurons in the periphery, in the ENS, and in the CNS. However, NO is not stored in neurons and released by exocytosis. Rather, it is synthesized when needed and readily diffuses across membranes.

Chemical rather than electrogenic transmission at autonomic ganglia and the neuromuscular junction of skeletal muscle was not generally accepted for a considerable period because techniques were limited in time and chemical resolution. Techniques of intracellular recording and microiontophoretic application of drugs, as well as sensitive analytical assays, have overcome these limitations.

Neurotransmission in the peripheral and central nervous systems once was believed to conform to the hypothesis that each neuron contains only one transmitter substance. However, peptides such as enkephalin, substance P, neuropeptide Y, VIP, and somatostatin; purines such as ATP and adenosine; and small molecules such as NO have been found in nerve endings. These substances can depolarize or hyperpolarize nerve terminals or postsynaptic cells. Furthermore, results of histochemical, immunocytochemical, and autoradiographic studies have demonstrated that one or more of these substances is present in the same neurons that contain one of the classical biogenic amine neurotransmitters. For example, enkephalins are found in postganglionic sympathetic neurons and adrenal medullary chromaffin cells. VIP is localized selectively in peripheral cholinergic neurons that innervate exocrine glands, and neuropeptide Y is found in sympathetic nerve endings. These observations suggest that synaptic transmission in many instances may be mediated by the release of more than one neurotransmitter (see the next section).

Steps Involved in Neurotransmission

The sequence of events involved in neurotransmission is of particular importance because pharmacologically active agents modulate the individual steps.

The term conduction is reserved for the passage of an impulse along an axon or muscle fiber; transmission refers to the passage of an impulse across a synaptic or neuromuscular junction. With the exception of the local anesthetics, very few drugs modify axonal conduction in the doses employed therapeutically. Hence this process is described only briefly.

Axonal Conduction. At rest, the interior of the typical mammalian axon is ~70 mV negative to the exterior. The resting potential is essentially a diffusion potential based chiefly on the 40 times higher concentration of K+ in the axoplasm as compared with the extracellular fluid and the relatively high permeability of the resting axonal membrane to K+. Na+ and Cl– are present in higher concentrations in the extracellular fluid than in the axoplasm, but the axonal membrane at rest is considerably less permeable to these ions; hence their contribution to the resting potential is small. These ionic gradients are maintained by an energy-dependent active transport mechanism, the Na+, K+-ATPase (Hille, 1992).

In response to depolarization to a threshold level, an action potential or nerve impulse is initiated at a local region of the membrane. The action potential consists of two phases. Following a small gating current resulting from depolarization inducing an open conformation of the channel, the initial phase is caused by a rapid increase in the permeability of Na+ through voltage-sensitive Na+ channels. The result is inward movement of Na+ and a rapid depolarization from the resting potential, which continues to a positive overshoot. The second phase results from the rapid inactivation of the Na+ channel and the delayed opening of a K+ channel, which permits outward movement of K+ to terminate the depolarization. Inactivation appears to involve a voltage-sensitive conformational change in which a hydrophobic peptide loop physically occludes the open channel at the cytoplasmic side. Although not important in axonal conduction, Ca2+ channels in other tissues (e.g., L-type Ca2+channels in heart) contribute to the action potential by prolonging depolarization by an inward movement of Ca2+. This influx of Ca2+ also serves as a stimulus to initiate intracellular events (Catterall, 2000; Hille, 1992), and Ca2+ influx is important in excitation-exocytosis coupling (transmitter release).

The transmembrane ionic currents produce local circuit currents around the axon. As a result of such localized changes in membrane potential, adjacent resting channels in the axon are activated, and excitation of an adjacent portion of the axonal membrane occurs. This brings about propagation of the action potential without decrement along the axon. The region that has undergone depolarization remains momentarily in a refractory state. In myelinated fibers, permeability changes occur only at the nodes of Ranvier, thus causing a rapidly progressing type of jumping, or saltatory, conduction.

The puffer fish poison, tetrodotoxin, and a close congener found in some shellfish, saxitoxin, selectively
block axonal conduction; they do so by blocking the voltage-sensitive Na\(^+\) channel and preventing the increase in Na\(^+\) permeability associated with the rising phase of the action potential. In contrast, batrachotoxin, an extremely potent steroidal alkaloid secreted by a South American frog, produces paralysis through a selective increase in permeability of the Na\(^+\) channel, which induces a persistent depolarization. Scorpion toxins are peptides that also cause persistent depolarization, but they do so by inhibiting the inactivation process (Catterall, 2000). Na\(^+\) and Ca\(^{2+}\) channels are discussed in more detail in Chapters 11, 14, and 20.

**Junctional Transmission.** The arrival of the action potential at the axonal terminals initiates a series of events that trigger transmission of an excitatory or inhibitory impulse across the synapse or neuroeffector junction. These events, diagrammed in Figure 8–3, are:

1. **Storage and release of the transmitter.** The non-peptide (small molecule) neurotransmitters are largely synthesized in the region of the axonal terminals and stored there in synaptic vesicles. Peptide neurotransmitters (or precursor peptides) are found in large dense-core vesicles that are transported down the axon from their site of synthesis in the cell body. During the resting state, there is a continual slow release of isolated quanta of the neurotransmitter; these produce electrical responses at the postjunctional membrane (minature end-plate potentials (mepps)) that are associated with the maintenance of physiological responsiveness of the effector organ. A low level of spontaneous activity within the motor units of skeletal muscle is particularly important because skeletal muscle lacks inherent tone. The action potential causes the synchronous release of several hundred quanta of neurotransmitter. Depolarization of the axonal terminal triggers this process; a critical step in most nerve endings is the influx of Ca\(^{2+}\), which enters the axonal cytoplasm and promotes fusion between the axoplasmic membrane and

![Figure 8–3. Steps involved in excitatory and inhibitory neurotransmission.](image-url)}
those vesicles in close proximity to it (Meir et al., 1999). The contents of the vesicles, including enzymes and other proteins, then are discharged to the exterior by a process termed exocytosis. Synaptic vesicles may either fully exocytose with complete fusion and subsequent endocytosis or form a transient pore that closes after transmitter has escaped (Murthy and Stevens, 1998).

Synaptic vesicles are clustered in discrete areas underlying the presynaptic plasma membrane, termed active zones; they often are aligned with the tips of postsynaptic folds. Some 20–40 proteins, playing distinct roles as transporter or trafficking proteins, are found in the vesicle. Neurotransmitter transport into the vesicle is driven by an electrochemical gradient generated by the vacuolar proton pump.

The vesicle protein synaptobrevin (VAMP) assembles with the plasma membrane proteins SNAP-25 and syntaxin 1 to form a core complex that initiates or drives the vesicle–plasma membrane fusion process (Jahn et al., 2003). The submillisecond triggering of exocytosis by Ca\(^{2+}\) appears to be mediated by a separate family of proteins, the synaptotagmins. GTP-binding proteins of the Rab 3 family regulate the fusion. Several other regulatory proteins of less well-defined function—synapsin, synaptophysin, and synapticynin—also play a role in fusion and exocytosis, as do proteins such as RIM and neurexin that are found on the active zones of the plasma membrane. Many of the trafficking proteins are homologous to those used in vesicular transport in yeast.

An extensive variety of receptors has been identified on soma, dendrites, and axons of neurons, where they respond to neurotransmitters or modulators released from the same neuron or from adja-

cent neurons or cells (Miller, 1998; Westfall, 2004). Soma–dendritic receptors are those receptors located on or near the cell body and dendrites; when activated, they primarily modify functions of the soma–dendritic region such as protein synthesis and generation of action potentials. Presynaptic receptors are those presumed to be located on, in, or near axon terminals or varicosities; when activated, they modify functions of the terminal region such as synthesis and release of transmitters. Two main classes of presynaptic receptors have been identified on most neurons, including sympathetic and parasympathetic terminals. Heteroreceptors are presynaptic receptors that respond to neurotransmitters, neuromodulators, or neurohormones released from adjacent neurons or cells. For example, NE can influence the release of ACh from parasympathetic neurons by acting on α\(_{2A}\), α\(_{2B}\), and α\(_{2C}\) receptors, whereas ACh can influence the release of NE from sympathetic neurons by acting on M\(_2\) and M\(_4\) receptors (described later in the chapter). The other class of presynaptic receptors consists of autoreceptors, which are receptors located on or close to those axon terminals of a neuron through which the neuron’s own transmitter can modify transmitter synthesis and release. For example, NE released from sympathetic neurons may interact with α\(_{2A}\) and α\(_{2C}\) receptors to inhibit neurally released NE. Similarly, ACh released from parasympathetic neurons may interact with M\(_2\) and M\(_4\) receptors to inhibit neurally released ACh.

Presynaptic nicotinic receptors enhance transmitter release in motor neurons (Bowman et al., 1990) and in a variety of other central and peripheral synapses (MacDermott et al., 1999).

2. Combination of the transmitter with postjunctional receptors and production of the postjunctional potential. The transmitter diffuses across the synaptic or junctional cleft and combines with specialized receptors on the postjunctional membrane; this often results in a localized increase in the ionic permeability, or conductance, of the membrane. With certain exceptions (noted in the following discussion), one of three types of permeability change can occur:

- a generalized increase in the permeability to cations (notably Na\(^{+}\) but occasionally Ca\(^{2+}\)), resulting in a localized depolarization of the membrane, that is, an excitatory postsynaptic potential (EPSP)
- a selective increase in permeability to anions, usually Cl\(^{-}\), resulting in stabilization or actual hyperpolarization of the membrane, which constitutes an inhibitory postsynaptic potential (IPSP)
- an increased permeability to K\(^{+}\). Because the K\(^{+}\) gradient is directed out of the cell, hyperpolarization and stabilization of the membrane potential occur (an IPSP)

The potential changes associated with the EPSP and IPSP at most sites are the results of passive fluxes of ions down their concentration gradients. The changes in channel permeability that cause these potential changes are specifically regulated by the specialized postjunctional receptors for the neurotransmitter that initiates the response (see Figures 8–4, 8–5 11–5, and Chapter 14). These receptors may be clustered on the effector cell surface, as seen at the neuromuscular junctions of skeletal muscle and other discrete synapses, or distributed more uniformly, as observed in smooth muscle.

By using microelectrodes that form high-resistance seals on the surface of cells, electrical events associated with a single neurotransmitter-gated channel can be recorded (Hille, 1992). In the presence of an appropriate neurotransmitter, the channel opens rapidly to a high-conductance state, remains open for about a millisecond, and then closes. A short square-wave pulse of current is observed as a result of the channel’s opening and closing. The summation of these microscopic events gives rise to the EPSP. The graded response to a neurotransmitter usually is related to the frequency of opening events rather than to the extent of opening or the duration of opening. High-conductance ligand-gated ion channels usually permit passage of Na\(^{+}\) or Cl\(^{-}\); K\(^{+}\) and Ca\(^{2+}\) are involved less...
frequently. The preceding ligand-gated channels belong to a large superfamily of ionotropic receptor proteins that includes the nicotinic, glutamate, and certain serotonin (5-HT₃) and purine receptors, which conduct primarily Na⁺, cause depolarization, and are excitatory; and GABA and glycine receptors, which conduct Cl⁻, cause hyperpolarization, and are inhibitory. The nicotinic, GABA, glycine, and 5-HT₃ receptors are closely related, whereas the glutamate and purinergic ionotropic receptors have distinct structures (Karlin and Akabas, 1995). Neurotransmitters also can modulate the permeability of K⁺ and Ca²⁺ channels indirectly. In these cases, the receptor and channel are separate proteins, and information is conveyed between them by G proteins. Other receptors for neurotransmitters act by influencing the synthesis of intracellular second messengers and do not necessarily cause a change in membrane potential. The most widely documented examples of receptor regulation of second-messenger systems are the activation or inhibition of adenyl cyclase to modulate cellular cyclic AMP concentrations and the increase in cytosolic concentrations of Ca²⁺ that results from release of the ion from internal stores by inositol trisphosphate (see Chapter 3).

3. **Initiation of postjunctional activity.** If an EPSP exceeds a certain threshold value, it initiates a propagated action potential in a postsynaptic neuron or a muscle action potential in skeletal or cardiac muscle by activating voltage-sensitive channels in the immediate vicinity. In certain smooth muscle types in which propagated impulses are minimal, an EPSP may increase the rate of spontaneous depolarization, cause Ca²⁺ release, and enhance muscle tone; in gland cells, the EPSP initiates secretion through Ca²⁺ mobilization. An IPSP, which is found in neurons and smooth muscle but not in skeletal muscle, will tend to oppose excitatory potentials simultaneously initiated by other neuronal sources. Whether a propagated impulse or other response ensues depends on the summation of all the potentials.

4. **Destruction or dissipation of the transmitter.** When impulses can be transmitted across junctions at frequencies up to several hundred per second, there must be an efficient means of disposing of the transmitter following each impulse. At cholinergic synapses involved in rapid neurotransmission, high and localized concentrations of acetylcholinesterase (AChE) are available for this purpose. When AChE activity is inhibited, removal of the transmitter is accomplished principally by diffusion. Under these circumstances, the effects of released ACh are potentiated and prolonged (see Chapter 10).

Rapid termination of NE occurs by a combination of simple diffusion and reuptake by the axonal terminals of most of the released norepinephrine. Termination of the action of amino acid transmitters results from their active transport into neurons and surrounding glia. Peptide neurotransmitters are hydrolyzed by various peptidases and dissipated by diffusion; specific uptake mechanisms have not been demonstrated for these substances.

5. **Non-electrogenic functions.** The continual quantal release of neurotransmitters in amounts insufficient to elicit a postjunctional response probably is important in the transsynaptic control of neurotransmitter action. The activity and turnover of enzymes involved in the synthesis and inactivation of neurotransmitters, the density of presynaptic and postsynaptic receptors, and other characteristics of synapses probably are controlled by trophic actions of neurotransmitters or other trophic factors released by the neuron or the target cells (Sanes and Lichtman, 1999).

### Cholinergic Transmission

The synthesis, storage, and release of ACh follow a similar life cycle in all cholinergic synapses, including those at skeletal neuromuscular junctions, preganglionic sympathetic and parasympathetic terminals, postganglionic parasympathetic varicosities, postganglionic sympathetic varicosities innervating sweat glands in the skin, and in the CNS. The neurochemical events that underlie cholinergic neurotransmission are summarized in Figure 8–4. Two enzymes, choline acetyltransferase and AChE, are involved in ACh synthesis and degradation, respectively.

**Choline Acetyltransferase.** Choline acetyltransferase catalyzes the final step in the synthesis of ACh—the acetylation of choline with acetyl coenzyme A (CoA) (Wu and Hersh, 1994). The primary structure of choline acetyltransferase is known from molecular cloning, and its immunocytochemical localization has proven useful for identification of cholinergic axons and nerve cell bodies.

Acetyl CoA for this reaction is derived from pyruvate via the multistep pyruvate dehydrogenase reaction or is synthesized by acetate thiokinase, which catalyzes the reaction of acetate with ATP to form an enzyme-bound acyladenylate (acetyl AMP). In the presence of CoA, transacetylation and synthesis of acetyl CoA proceed.

Choline acetyltransferase, like other protein constituents of the neuron, is synthesized within the perikaryon and then is transported along the length of the axon to its terminal. Axonal terminals contain a large number of mitochondria, where acetyl CoA is synthesized. Choline is taken up from the extracellular fluid into the axoplasm by active transport. The final step in the synthesis occurs within the cytoplasm, following which most of the ACh is
sequestered within synaptic vesicles. Although moderately potent inhibitors of choline acetyltransferase exist, they have no therapeutic utility, in part because the uptake of choline is the rate-limiting step in ACh biosynthesis.

**Choline and Choline Transport.** The availability of choline is critical to the synthesis of acetylcholine and is provided from the diet as there is little de novo synthesis of choline in cholinergic neurons. Choline is also an essential component for the normal function of all cells, necessary for the structural integrity and signaling functions for cell membranes. Choline is taken up from the extracellular space by two transport systems: a ubiquitous low affinity, Na⁺-independent transport system that is inhibited by hemicholinium-3 with a \( K_i \) of \( \sim 50 \mu \text{M} \), and high affinity Na⁺- and Cl⁻-dependent choline transport system that is also sensitive to inhibition by hemicholinium-3 (\( K_i = 10-100 \text{ nM} \)). This second transport system is found predominantly in cholinergic neurons.

---

**Figure 8–4.** A cholinergic neuroeffector junction showing features of the synthesis, storage, and release of acetylcholine (ACh) and receptors on which ACh acts. The synthesis of ACh in the varicosity depends on the uptake of choline via a sodium-dependent carrier. This uptake can be blocked by hemicholinium. Choline and the acetyl moiety of acetyl coenzyme A, derived from mitochondria, form ACh, a process catalyzed by the enzyme choline acetyl transferase (ChAT). ACh is transported into the storage vesicle by another carrier that can be inhibited by vesamicol. ACh is stored in vesicles along with other potential cotransmitters (Co-T) such as ATP and VIP at certain neuroeffector junctions. Release of ACh and the Co-T occurs on depolarization of the varicosity, which allows the entry of Ca²⁺ through voltage-dependent Ca²⁺ channels. Elevated [Ca²⁺]ₐₚₚ promotes fusion of the vesicular membrane with the cell membrane, and exocytosis of the transmitters occurs. This fusion process involves the interaction of specialized proteins associated with the vesicular membrane (VAMPs, vesicle-associated membrane proteins) and the membrane of the varicosity (SNAPs, synaptosome-associated proteins). The exocytotic release of ACh can be blocked by botulinum toxin. Once released, ACh can interact with the muscarinic receptors (M), which are GPCRs, or nicotinic receptors (N), which are ligand-gated ion channels, to produce the characteristic response of the effector. ACh also can act on presynaptic mAChRs or nAChRs to modify its own release. The action of ACh is terminated by metabolism to choline and acetate by acetylcholinesterase (AChE), which is associated with synaptic membranes.
and is responsible for providing choline for ACh synthesis. Once ACh is released from cholinergic neurons following the arrival of action potentials, ACh is hydrolyzed by acetylcholine esterase (AChE) to acetate and choline. Choline is recycled after reuptake into the nerve terminal of cholinergic cells and reused for ACh synthesis. Under many circumstances this reuptake and availability of choline appear to serve as the rate limiting step in acetylcholine synthesis.

The gene for the high-affinity choline transporter (CHT1) has been cloned from a variety of species including human and it is homologous to the Na+-dependent glucose transport family. The location of CHT1 is in intracellular vesicular structures rather than the nerve terminal plasma membrane and co-localizes with synaptic vesicle markers such as vesicle-associated membrane protein 2 (VAMP2) and vesicular ACh transporter (VACHT). Although the details are incomplete there is evidence that in response to the cascade of events that culminate in transmitter release, there is also increased trafficking of CHT1 to the plasma membrane, where it functions to take up choline after hydrolysis of acetylcholine. Since choline transport is rate limiting for acetylcholine synthesis, increased availability of choline via its transport by CHT1 would favor an increase in ACh stores to maintain high levels of transmitter release during neuronal stimulation. This also suggests that the availability of CHT1 at the cell surface is dynamically regulated in a manner very similar to the regulation of the exocytosis of synaptic vesicles. The precise mechanisms involved in maintaining the distribution of CHT1 predominantly in intracellular vesicles rather than at the terminal surface like other neurotransmitter transporters are unclear (Ferguson and Blakely, 2004; Chaudhry et al. 2008).

Storage of Acetylcholine. Following the synthesis of acetylcholine, which takes place in the cytoplasm of the nerve terminal, ACh is transported into synaptic vesicles by VACHT using a proton electrochemical gradient to move ACh to the inside of the organelle. VACHT is thought to be a protein comprising 12 transmembrane domains with hydrophilic N- and C-termini in the cytoplasm. By sequence homology, VACHT appears to be a member of a family of transport proteins that includes two vesicular monoamine transporters. Transport of protons out of the vesicle is coupled to uptake of ACh into the vesicle and against a concentration gradient via the acetylcholine antiporter.

There appear to be two types of vesicles in cholinergic terminals: electron-lucent vesicles (40-50 nm in diameter) and dense-cored vesicles (80-150 nm). The core of the vesicles contains both ACh and ATP, at an estimated ratio of 10:1, which are dissolved in the fluid phase with metal ions (Ca\(^{2+}\) and Mg\(^{2+}\)) and a proteoglycan called vesiculin. Vesiculin is negatively charged and is thought to sequester the Ca\(^{2+}\) or ACh. It is bound within the vesicle, with the protein moiety anchoring it to the vesicular membrane. In some cholinergic terminals there are peptides, such as VIP, that act as co-transmitters at some junctions. The peptides usually are located in the dense-cored vesicles. Vesicular membranes are rich in lipids, primarily cholesterol and phospholipids, as well as protein. The proteins include ATPase, which is ouabain-sensitive and thought to be involved in proton pumping and in vesicular inward transport of Ca\(^{2+}\). Other proteins include protein kinases (involved in phosphorylation mechanisms of Ca\(^{2+}\) uptake), calmodulin, atractylside-binding protein (which acts as an ATP carrier), and synapsin (which is thought to be involved with exocytosis).

The vesicular transporter allows for the uptake of ACh into the vesicle, has considerable concentrating power, is saturable, and is ATPase-dependent. The process is inhibited by vesamicol (Figure 8–4). Inhibition by vesamicol is noncompetitive and reversible and does not affect the vesicular ATPase. The gene for choline acetyltransferase and the vesicular transporter are found at the same locus, with the transporter gene positioned in the first intron of the transferase gene. Hence a common promoter regulates the expression of both genes (Eiden, 1998).

Estimates of the ACh content of synaptic vesicles range from 1000 to over 50,000 molecules per vesicle, and it has been calculated that a single motor nerve terminal contains 300,000 or more vesicles. In addition, an uncertain but possibly significant amount of ACh is present in the extravesicular cytoplasm. Recording the electrical events associated with the opening of single channels at the motor end plate during continuous application of ACh has permitted estimation of the potential change induced by a single molecule of ACh (3 × 10\(^{-7}\) V); from such calculations it is evident that even the lower estimate of the ACh content per vesicle (1000 molecules) is sufficient to account for the magnitude of the mepps.

Release of Acetylcholine. Release of acetylcholine and co-transmitters (e.g., ATP and VIP or in some neurons, NO) occurs on depolarization of the nerve terminals and takes place by exocytosis. Depolarization of the terminals allows the entry of Ca\(^{2+}\) through voltage-gated Ca\(^{2+}\) channels. Elevated Ca\(^{2+}\) concentration promotes fusion of the vesicular membrane with the plasma membrane, allowing exocytosis to occur.

The molecular mechanisms involved in the release and regulation of release are not completely understood (Südhof, 2004). ACh, like other neurotransmitters, is stored in vesicles located at special release sites, close to presynaptic membranes and ready for release following the appropriate stimulus. The vesicles initially dock and are primed for release. A multiprotein complex appears to form and attach the vesicle to the plasma membrane close to other signaling elements. The complex involves proteins from the vesicular membrane and the presynaptic neuronal membrane, as well as other components that help link them together. Various synaptic proteins, including the plasma membrane protein syntaxin and synaptosomal protein 25 kDa (SNAP-25), and the vesicular membrane protein, synaptobrevin, form a complex. This complex interacts in an ATP-dependent manner with soluble N-ethylmaleimide-sensitive fusion protein and soluble SNAPs. The ability of synaptobrevin, syntaxin, and SNAP-25 to bind SNAPs has led to their designation as SNAP regulators (SNARES). It has been hypothesized that most, if not all, intracellular fusion events are mediated by SNARE interactions. Important evidence supporting the involvement of SNARE proteins
in transmitter release comes from the fact that botulinum neurotoxins and tetanus toxin, which block neurotransmitter release, proteolyze these three proteins (Südhof, 2004).

Two pools of acetylcholine appear to exist. One pool, the “depot” or “readily releasable” pool, consists of vesicles located near the plasma membrane of the nerve terminals; these vesicles contain newly synthesized transmitter. Depolarization of the terminals causes these vesicles to release ACh rapidly or readily. The other pool, the “reserve pool,” seems to replenish the readily releasable pool and may be required to sustain ACh release during periods of prolonged or intense nerve stimulation.

Acetylcholinesterase (AChE). For ACh to serve as a neurotransmitter in the motor system and at other neuronal synapses, it must be removed or inactivated within the time limits imposed by the response characteristics of the synapse. At the neuromuscular junction, immediate removal is required to prevent lateral diffusion and sequential activation of adjacent receptors. Modern biophysical methods have revealed that the time required for hydrolysis of ACh at the neuromuscular junction is less than a millisecond. The $K_m$ of AChE for ACh is $\sim 50-100$ $\mu$M. Choline has only $10^{-3}$ to $10^{-5}$ the potency of ACh at the neuromuscular junction.

While AChE is found in cholinergic neurons (dendrites, perikarya, and axons), it is distributed more widely than cholinergic synapses. It is highly concentrated at the postsynaptic end plate of the neuromuscular junction. Butyrylcholinesterase (BuChE; also known as pseudocholinesterase) is present in low abundance in glial or satellite cells but is virtually absent in neuronal elements of the central and peripheral nervous systems. BuChE is synthesized primarily in the liver and is found in liver and plasma; its likely physiological function is the hydrolysis of ingested esters from plant sources. AChE and BuChE are typically distinguished by the relative rates of ACh and butyrylcholine hydrolysis and by effects of selective inhibitors (Chapter 10). Almost all pharmacological effects of the anti-ChE agents are due to the inhibition of AChE, with the consequent accumulation of endogenous ACh in the vicinity of the nerve terminal. Distinct but single genes encode AChE and BuChE in mammals; the diversity of molecular structure of AChE arises from alternative mRNA processing (Taylor et al., 2000).

Numerous reports suggest that AChE plays other roles in addition to its classical function in terminating impulse transmission at cholinergic synapses. Non-classical functions of AChE might include hydrolysis of ACh in a non-synaptic context, action as an adhesion protein involved in synaptic development and maintenance, as a bone matrix protein, involvement in neurite outgrowth, and acceleration of the assembly of Aβ peptide into amyloid fibrils (Silman and Sussman, 2005).

Characteristics of Cholinergic Transmission at Various Sites. There are marked differences among various sites of cholinergic transmission with respect to architecture and fine structure, the distributions of AChE and receptors, and the temporal factors involved in normal function.

In skeletal muscle, e.g., the junctional sites occupy a small, discrete portion of the surface of the individual fibers and are relatively isolated from those of adjacent fibers; in the superior cervical ganglion, $\sim 100,000$ ganglion cells are packed within a volume of a few cubic millimeters, and both the presynaptic and postsynaptic neuronal processes form complex networks.

**Skeletal Muscle.** Stimulation of a motor nerve results in the release of ACh from perfused muscle; close intra-arterial injection of ACh produces muscular contraction similar to that elicited by stimulation of the motor nerve. The amount of ACh ($10^{-12}$mol) required to elicit an end-plate potential (EPP) following its microiontophoretic application to the motor end plate of a rat diaphragm muscle fiber is equivalent to that recovered from each fiber following stimulation of the phrenic nerve.

The combination of ACh with nicotinic ACh receptors at the external surface of the postsynaptic membrane induces an immediate, marked increase in cation permeability. On receptor activation by ACh, its intrinsic channel opens for $\sim 1$ ns; during this interval, $\sim 50,000$ Na$^+$ ions traverse the channel. The channel-opening process is the basis for the localized depolarizing EPP within the end plate, which triggers the muscle AP. The latter, in turn, leads to contraction.

Following section and degeneration of the motor nerve to skeletal muscle or of the postganglionic fibers to autonomic effectors, there is a marked reduction in the threshold doses of the transmitters and of certain other drugs required to elicit a response; that is, denervation supersensitivity occurs. In skeletal muscle, this change is accompanied by a spread of the receptor molecules from the end-plate region to the adjacent portions of the sarcoplasmic membrane, which eventually involves the entire muscle surface. Embryonic muscle also exhibits this uniform sensitivity to ACh prior to innervation. Hence, innervation represses the expression of the receptor gene by the nuclei that lie in extrajunctional regions of the muscle fiber and directs the subsynaptic nuclei to express the structural and functional proteins of the synapse (Sanes and Lichtman, 1999).

**Autonomic Effector Cells.** Stimulation or inhibition of autonomic effector cells occurs on activation of muscarinic acetylcholine receptors (discussed later in the chapter). In this case, the effector is coupled to the receptor by a G protein (Chapter 3). In contrast to skeletal muscle and neurons, smooth muscle and the cardiac conduction system [sinoatrial (SA) node, atrium, atrioventricular (AV) node, and the His-Purkinje system] normally exhibit intrinsic activity, both electrical and mechanical, that is modulated but not initiated by nerve impulses.

In the basal condition, unitary smooth muscle exhibits waves of depolarization and/or spikes that are propagated from cell to cell at rates considerably slower than the AP of axons or skeletal muscle. The spikes apparently are initiated by rhythmic fluctuations in the membrane resting potential. Application of ACh (0.1 to 1 $\mu$M) to isolated intestinal muscle causes a decrease in the resting potential (i.e., the membrane potential becomes less negative) and an increase in the frequency of spike production, accompanied by a rise in tension. A primary action of ACh in initiating these effects through muscarinic receptors is probably partial depolarization of the cell membrane brought about by an increase in Na$^+$ and, in some instances, Ca$^{2+}$ conductance. ACh also can produce contraction of
some smooth muscles when the membrane has been depolarized completely by high concentrations of K⁺, provided that Ca²⁺ is present. Hence, ACh stimulates ion fluxes across membranes and/or mobilizes intracellular Ca²⁺ to cause contraction.

In the heart, spontaneous depolarizations normally arise from the SA node. In the cardiac conduction system, particularly in the SA and AV nodes, stimulation of the cholinergic innervation or the direct application of ACh causes inhibition, associated with hyperpolarization of the membrane and a marked decrease in the rate of depolarization. These effects are due, at least in part, to a selective increase in permeability to K⁺ (Hille, 1992).

**Autonomic Ganglia.** The primary pathway of cholinergic transmission in autonomic ganglia is similar to that at the neuromuscular junction of skeletal muscle. Ganglion cells can be discharged by injecting very small amounts of ACh into the ganglion. The initial depolarization is the result of activation of nicotinic ACh receptors, which are ligand-gated cation channels with properties similar to those found at the neuromuscular junction. Several secondary transmitters or modulators either enhance or diminish the sensitivity of the postganglionic cell to ACh. This sensitivity appears to be related to the membrane potential of the postsynaptic nerve cell body or its dendritic branches. Ganglionic transmission is discussed in more detail in Chapter 11.

**Prejunctional Sites.** As described earlier, both cholinergic and adrenergic nerve terminal varicosities contain autoreceptors and heteroreceptors. ACh release therefore is subject to complex regulation by mediators, including ACh itself acting on M₁ and M₄ autoreceptors, and other transmitters (e.g., NE acting on α₂A and α₂C adrenergic receptors) (Philipp and Hein, 2004; Wess, 2004) or substances produced locally in tissues (e.g., NO). ACh-mediated inhibition of ACh release following activation of M₁ and M₄ autoreceptors is thought to represent a physiological negative-feedback control mechanism. At some neuroeffector junctions such as the myenteric plexus in the GI tract or the SA node in the heart, sympathetic and parasympathetic nerve terminals often lie juxtaposed to each other. The opposing effects of norepinephrine and ACh, therefore, result not only from the opposite effects of the two transmitters on the smooth muscle or cardiac cells but also from the inhibition of ACh release by NE or inhibition of NE release by ACh acting on heteroreceptors on parasympathetic or sympathetic terminals. The muscarinic autoreceptors and heteroreceptors also represent drug targets for both agonists and antagonists. Muscarinic agonists can inhibit the electrically induced release of ACh, whereas antagonists will enhance the evoked release of transmitter. The parasympathetic nerve terminal varicosities also may contain additional heteroreceptors that could respond by inhibition or enhancement of ACh release by locally formed autacoids, hormones, or administered drugs. In addition to α₂A and α₂C adrenergic receptors, other inhibitory heteroreceptors on parasympathetic terminals include adenosine A₁ receptors, histamine H₁ receptors, and opioid receptors. Evidence also exists for β₁-adrenergic facilitatory receptors.

**Extraneuronal Sites.** A large body of evidence now indicates that all elements of the cholinergic system including the enzyme ChAT, ACh synthesis, ACh release mechanisms, and both mAChRs and nAChRs, are functionally expressed independently of cholinergic innervation in numerous non-neuronal cells including those of humans. These non-neuronal cholinergic systems can both modify and control phenotypic cell functions such as proliferation, differentiation, formation of physical barriers, migration, and ion and water movements. The widespread synthesis of ACh in non-neuronal cells has changed the thinking that ACh acts only as a neurotransmitter. Each component of the cholinergic system in non-neuronal cells can be affected by pathophysiological conditions or secondary to disease states. For instance, blockade of mAChRs and nAChRs on non-neuronal cells can cause cellular dysfunction and cell death. Moreover, dysfunctions of non-neuronal cholinergic systems may be involved in the pathogenesis of diseases (e.g., inflammatory processes) (Kalamida et al., 2007; Wessler and Kirkpatrick, 2008).

### Cholinergic Receptors and Signal Transduction

Sir Henry Dale noted that the various esters of choline elicited responses that were similar to those of either nicotine or muscarine depending on the pharmacological preparation. A similarity in response also was noted between muscarine and nerve stimulation in those organs innervated by the craniosacral divisions of the autonomic nervous system. Thus, Dale suggested that ACh or another ester of choline was a neurotransmitter in the autonomic nervous system; he also stated that the compound had dual actions, which he termed a “nicotine action” (nicotinic) and a “muscarine action” (muscarinic).

The capacities of tubocurarine and atropine to block nicotinic and muscarinic effects of ACh, respectively, provided further support for the proposal of two distinct types of cholinergic receptors. Although Dale had access only to crude plant alkaloids of then unknown structure from *Amanita muscaria* and *Nicotiana tabacum*, this classification remains as the primary subdivision of cholinergic receptors. Its utility has survived the discovery of several distinct subtypes of nicotinic and muscarinic receptors.

Although ACh and certain other compounds stimulate both muscarinic and nicotinic cholinergic receptors, several other agonists and antagonists are selective for one of the two major types of receptors. ACh is a flexible molecule, and indirect evidence suggests that the conformations of the neurotransmitter are distinct when it is bound to nicotinic or muscarinic cholinergic receptors.

Nicotinic receptors are ligand-gated ion channels whose activation always causes a rapid (millisecond) increase in cellular permeability to Na⁺ and Ca²⁺, depolarization, and excitation. By contrast, muscarinic receptors are G protein–coupled receptors (GPCRs). Responses to muscarinic agonists are slower; they may be either excitatory or inhibitory, and they are not necessarily linked to changes in ion permeability.

The primary structures of various species of nicotinic receptors (Changeux and Edelstein, 1998; Numa et al., 1983) and muscarinic receptors (Bonner, 1989; Caulfield and Birdsall, 1998) have been deduced from the sequences of their respective genes. That these two types of receptors belong to distinct families of proteins is not surprising, retrospectively, in view of their distinct differences in chemical specificity and function.
**Subtypes of Nicotinic Acetylcholine Receptors.** The nicotinic ACh receptors (nAChRs) are members of a superfamily of ligand-gated ion channels. The receptors exist at the skeletal neuromuscular junction, autonomic ganglia, adrenal medulla, the CNS and in non-neuronal tissues. The nAChRs are composed of five homologous subunits organized around a central pore (see Chapter 11). In general the nAChRs are further divided into two groups:

- **muscle type**, found in vertebrate skeletal muscle, where they mediate transmission at the neuromuscular junction (NMJ)
- **neuronal type**, found mainly throughout the peripheral nervous system, central nervous system, and also in non-neuronal tissues

Both the mAChRs and nAChRs are the natural targets of ACh, synthesized, stored, and released from cholinergic neurons as well as through pharmacologically administered drugs (agonists and antagonists), including the alkaloïds muscarine and nicotine.

cDNAs for 17 types of nAChRs subunits have been cloned from several species. These consist of α subunits (α1–α10) that compose the main ligand binding sites, β (β1–4), γ, δ, and ε subunits. The nAChRs have been further divided into two main types based on different binding properties to the toxin α-bungarotoxin (αβgtx): 1) the αβgtx binding nAChRs, which can be either homopentamers of α7, α8, or α9 subunits or heteropentamers (e.g., α2βεγδ); and 2) nAChRs that do not bind αβgtx. These contain the α2-α6 and β2-β4 subunits, exist only as heteropentamers, and bind agonists with high affinity (Albuquerque et al., 2009).

**Muscle-Type nAChRs.** In fetal muscle prior to innervation, in adult muscle after denervation, and in fish electric organs, the nAChR subunit stoichiometry is (α1)1β1γδε, whereas in adult muscle the γ subunit is replaced by ε to give the (α1)1β1ε6 stoichiometry (Table 8–2). The γε and δ subunits are involved together with the α1 subunits in forming the ligand-binding sites and in the maintenance of cooperative interactions between the α1 subunit. Different affinities to the two binding sites are conferred by the presence of different non-α subunits. Binding of ACh to the α7γε and α7δ sites is thought to induce a conformational change predominantly in the α1 subunits which interacts with the transmembrane region to cause channel opening.

**Neuronal-Type nAChRs.** Neuronal nAChRs are widely expressed in peripheral ganglia, the adrenal medulla, numerous areas of the brain, and non-neuronal cells such as epithelial cells and cells of the immune system. To date, nine α (α2–α10) and three β (β2–β4) subunit genes have been cloned. The α2–α10, β2–β4 subunits are found either as homopentamers (of five αs, αs, and αs subunits) or as heteropentamers of α7, α8, and αs/α10. By contrast, the α2–α6 and β2–β4 subunits form heteropentamers usually with (αααβγδ) stoichiometry. The α and β subunits do not appear to be able to form functional receptors when expressed alone or in paired combinations with α or β subunits, respectively (Kalamida et al., 2007).

The precise function of many of the neuronal nAChRs in the brain is not known; presumably, the considerable molecular diversity of the subunits can result in numerous nAChRs being formed with different physiological properties. There are few examples of neuronal nAChRs in the CNS mediating fast signaling propagation in a manner similar to that at the NMJ, and it is thought that they act more as synaptic modulators. Neuronal nAChRs are widely distributed in the CNS and are found at presynaptic, perisynaptic, and postsynaptic sites. At pre- and perisynaptic sites, nAChRs appear to act as autoreceptors or heteroreceptors to regulate the release of several neurotransmitters (ACh, DA, NE, glutamate, and 5-HT) at several diverse sites throughout the brain (Exley and Cragg, 2008). The synaptic release of a particular neurotransmitter can be regulated by different neuronal type nAChR subtypes in different CNS regions. For instance, DA release from striatal and thalamic dopamine neurons can be controlled by the αβ3 subtype or both αβ2 and αβ2β3 subtypes, respectively. In contrast, glutamatergic neurotransmission is regulated everywhere by α7 nAChRs (Kalamida et al., 2007).

**Subtypes of Muscarinic Receptors.** In mammals, five distinct subtypes of muscarinic ACh receptors (mAChRs) have been identified, each produced by a different gene. Like the different forms of nicotinic receptors, these variants have distinct anatomic locations in the periphery and CNS and differing chemical specificities. The mAChRs are GPCRs (see Table 8–3 for characteristics of the mAChRs and Chapter 9 for further details).

Different experimental approaches including immunohistochemical and mRNA hybridization studies have shown that mAChRs are present in virtually all organs, tissues, and cell types (Table 8–3). Although most cell types have multiple mAChR subtypes, certain subtypes often predominate in specific sites. For example, the M1 receptor is the predominant subtype in the heart and in CNS neurons is mostly located presynaptically, whereas the M4 receptor is the predominant subtype in the detrusor muscle of the bladder (Dhein et al., 2001; Fetscher et al., 2002) (see Table 8–3). M1, M4, and M5 receptors are richly expressed in the CNS, whereas the M2 and M4 receptor subtypes are widely distributed both in the CNS and peripheral tissue (Wess et al., 2007). M1 receptors are widely distributed in the periphery, and although they are also widely distributed in the CNS, they are at lower levels than other subtypes.

In the periphery, mAChRs mediate the classical muscarinic actions of ACh in organs and tissues innervated by parasympathetic nerves, although receptors may be present at sites that lack parasympathetic innervation (e.g., most blood vessels). In the CNS, mAChRs are involved in regulating a large number of cognitive, behavioral, sensory, motor, and autonomic functions. Owing to the lack of specific muscarinic agonists and antagonists that demonstrate selectivity for individual mAChRs and the fact that most organs and tissues express multiple mAChRs, it has been a challenge to assign specific pharmacological functions to distinct mAChRs. The development of gene-targeting techniques in mice has been very helpful in defining specific functions (Table 8–3) (Wess, 2004).

The basic functions of muscarinic cholinergic receptors are mediated by interactions with G proteins
and by G protein–induced changes in the function of distinct member-bound effector molecules. The M1, M3, and M5 subtypes couple through the pertussis toxin–insensitive Gq/11 responsible for stimulation of phospholipase C (PLC) activity. The immediate result is hydrolysis of membrane phosphatidylinositol 4,5 diphosphate to form inositol polyphosphates. Inositol trisphosphate (IP3) causes release of intracellular Ca2+ from the endoplasmic reticulum, with activation of Ca2+-dependent phenomena such as contraction of smooth muscle and secretion (Chapter 3). The second product of the PLC reaction, diacylglycerol, activates PKC (in conjunction with Ca2+ and phosphatidylserine). This arm of the pathway plays a role in the phosphorylation of numerous proteins, leading to various physiological responses. Activation of M1, M3, and M5 receptors can also cause the activation of phospholipase A2, leading to the release of arachidonic acid and consequent eicosanoid synthesis, resulting in autocrine/paracrine stimulation of adenylyl cyclase and

<sup>a</sup>Most organs, tissues, and cells express multiple mAChRs.
<sup>b</sup>M<sub>1</sub>, M<sub>3</sub>, and M<sub>5</sub> mAChRs appear to couple to the same G proteins and signal through similar pathways. Likewise, M<sub>2</sub> and M<sub>4</sub> mAChRs couple through similar G proteins and signal through similar pathways.
<sup>c</sup>Despite the fact that in many tissues, organs, and cells multiple subtypes of mAChRs coexist, one subtype may predominate in producing a particular function; in others, there may be equal predominance.

and inhibition of excitable membranes. These are most clear in myocardium, where inhibition of adenylyl cyclase and activation of K+ conductances account for the negative inotropic and chronotropic effects of ACh. The specificity is not absolute, however, and depends on proper trafficking of the G protein subunits within the cell; consequently, heterologous systems may exhibit alternative interactions between mAChRs and G–protein coupled pathways (Nathanson, 2008). In addition, there are numerous reports suggesting the differential subcellular location of specific mAChR subtypes in a variety of cell types in the nervous system and in a variety of non-neuronal polarized cells.

Following activation by classical or allosteric agonists, mAChRs can be phosphorylated by a variety of receptor kinases and second-messenger regulated kinases; the phosphorylated mAChR subtypes then can interact with β-arrestin and possibly other adaptors. As a result, mAChR signaling pathways may be differentially altered. Agonist activation of mAChRs also may induce receptor internalization and down-regulation (van Koppen and Kaiser, 2003). Muscarinic AChRs can also regulate other signal transduction pathways that have diverse effects on cell growth, survival, and physiology, such as the MAP kinase, phosphoinositide-3-kinase, RhoA, and Rac1 (Nathanson, 2008).

Changes in mAChR levels and activity have been implicated in the pathophysiology of numerous major diseases in the CNS and in the autonomic nervous system (Table 8–3). Phenotypic analysis of mAChR-mutant mice as well as the development of selective agonists and antagonists has led to a wealth of new information regarding the physiological and potential pathophysiological roles of the individual mAChR subtype (Langmead et al., 2008; Wess et al., 2007).

**Adrenergic Transmission**

Under this general heading are norepinephrine (NE), the principal transmitter of most sympathetic postganglionic fibers and of certain tracts in the CNS; dopamine (DA), the predominant transmitter of the mammalian extrapyramidal system and of several mesocortical and mesolimbic neuronal pathways; and epinephrine, the major hormone of the adrenal medulla. Collectively, these three amines are called catecholamines.

A tremendous amount of information about catecholamines and related compounds has accumulated in recent years partly because of the importance of interactions between the endogenous catecholamines and many of the drugs used in the treatment of hypertension, mental disorders, and a variety of other conditions. The details of these interactions and of the pharmacology of the sympathomimetic amines themselves will be found in subsequent chapters. The basic physiological, biochemical, and pharmacological features are presented here.

**Synthesis of Catecholamines.** The steps in the synthesis of DA, NE (noradrenaline), and epinephrine (adrenaline) are shown in Figure 8–5. Tyrosine is sequentially 3-hydroxylated and decarboxylated to form dopamine. Dopamine is β-hydroxylated to yield norepinephrine, which is N-methylated in chromaffin tissue to give epinephrine. The enzymes involved have been identified.

![Figure 8–5. Steps in the enzymatic synthesis of dopamine, norepinephrine and epinephrine.](image-url)
cloned, and characterized (Nagatsu, 1991). Table 8–4 summarizes some of the important characteristics of the four enzymes. These enzymes are not completely specific; consequently, other endogenous substances, as well as certain drugs, are also substrates. For example, 5-hydroxytryptamine (5-HT, serotonin) can be produced from 5-hydroxy-L-tryptophan by aromatic L-amino acid decarboxylase (or dopa decarboxylase). Dopa decarboxylase also converts dopa into DA (Chapter 13) and methyldopa to α-methyldopamine, which in turn is converted by dopamine β-hydroxylase (DβH) to methylnor-epinephrine.

The hydroxylation of tyrosine by tyrosine hydroxylase (TH) generally is regarded as the rate-limiting step in the biosynthesis of catecholamines (Zigmond et al., 1989); this enzyme is activated following stimulation of sympathetic nerves or the adrenal medulla. The enzyme is a substrate for PKA, PKC, and CaM kinase; phosphorylation is associated with increased hydroxylase activity. This is an important acute mechanism for increasing catecholamine synthesis in response to elevated nerve stimulation. In addition, there is a delayed increase in TH gene expression after nerve stimulation. This increased expression can occur at multiple levels of regulation, including transcription, RNA processing, regulation of RNA stability, translation, and enzyme stability (Kumer and Vrana, 1996). These mechanisms serve to maintain the content of catecholamines in response to increased transmitter release. In addition, TH is subject to feedback inhibition by catechol compounds, which allosterically modulate enzyme activity.

TH deficiency has been reported in humans and is characterized by generalized rigidity, hypokinesia, and low cerebrospinal fluid (CSF) levels of NE and DA metabolites homovanillic acid and 3-methoxy-4-hydroxyphenylethylene glycol (Wevers et al., 1999). TH knockout is embryonically lethal in mice, presumably because the loss of catecholamines results in altered cardiac function. Interestingly, residual levels of DA are present in these mice. It has been suggested that tyrosinase may be an alternate source for catecholamines, although tyrosinase-derived catecholamines are clearly not sufficient for survival (Carson and Robertson, 2002).

DβH deficiency in humans is characterized by orthostatic hypotension, ptosis of the eyelids, retrograde ejaculation, and elevated plasma levels of dopamine. In the case of DβH-deficient mice, there is ~90% embryonic mortality (Carson and Robertson, 2002).

Our understanding of the cellular sites and mechanisms of synthesis, storage, and release of catecholamines derives from studies of sympathetically innervated organs and the adrenal medulla. Nearly all the NE content of innervated organs is confined to the postganglionic sympathetic fibers; it disappears within a few days after section of the nerves. In the adrenal medulla, catecholamines are stored in chromaffin granules (Aunis, 1998). These vesicles contain extremely high concentrations of catecholamines (~21% dry weight), ascorbic acid, and ATP, as well as specific proteins such as chromogranins, DβH, and peptides including enkephalin and neuropeptide Y. Vasostatin-1, the N-terminal fragment of chromogranin A, has been found to have antibacterial and antifungal activity (Lugardon et al., 2000), as have other chromogranin A fragments such as chromofungin, vasostatin II, prochromacin, and chromacins I and II (Taupenot et al., 2003). Two types of storage vesicles are found in sympathetic nerve terminals: large dense-core vesicles

corresponding to chromaffin granules; and small dense-core vesicles containing NE, ATP, and membrane-bound DβH.

The main features of the mechanisms of synthesis, storage, and release of catecholamines and their modifications by drugs are summarized in Figure 8–6. In the case of adrenergic neurons, the enzymes that participate in the formation of NE are synthesized in the cell bodies of the neurons and then are transported along the axons to their terminals. In the course of synthesis (Figure 8–6), the hydroxylation of tyrosine to dopa and the decarboxylation of dopa to dopamine take place in the cytoplasm. DA formed in the cytoplasm then is actively transported into the DβH-containing storage vesicles, where it is converted to NE. About 90% of the dopamine is converted to NE by DβH in sympathetic nerves; the remainder is metabolized. DA is converted by MAO to a aldehyde intermediate DOPAL, and then mainly converted to 3,4-dihydroxyphenyl acetic acid (DOPAC) by aldehyde dehydrogenase and to a minor extent 3,4-dihydroxyphenylethanol (DOPET) by aldehyde reductase. DOPAC is further converted to homovanillic acid (HVA) by o-methylation in non-neuronal sites.

The adrenal medulla has two distinct catecholamine-containing cell types: those with NE and those with primarily epinephrine. The latter cell population contains the enzyme phenylethanolamine-N-methyltransferase (PNMT). In these cells, the NE formed in the granules leaves these structures, presumably by diffusion, and is methylated in the cytoplasm to epinephrine. Epinephrine then reenters the chromaffin granules, where it is stored until released. In adults, epinephrine accounts for ~80% of the catecholamines of the adrenal medulla, with NE making up most of the remainder.

A major factor that controls the rate of synthesis of epinephrine, and hence the size of the store available for release from the adrenal medulla, is the level of glucocorticoids secreted by the adrenal cortex. The intra-adrenal portal vascular system carries the corticosteroids directly to the adrenal medullary chromaffin cells, where they induce the synthesis of PNMT (Figure 8–5). The activities of both TH and DβH also are increased in the adrenal medulla when the secretion of glucocorticoids is stimulated (Viskupic et al., 1994). Thus, any stress that persists sufficiently to evoke an enhanced secretion of corticotropin mobilizes the appropriate hormones of both the adrenal cortex (predominantly cortisol in humans) and medulla (epinephrine). This remarkable relationship is present only in certain mammals, including humans, in which the adrenal chromaffin cells are enveloped entirely by steroid-secreting cortical cells. In the dogfish, e.g., where the chromaffin cells and steroid-secreting cells are located in independent, noncontiguous glands, epinephrine is not formed. Nonetheless, there is evidence indicating that PNMT is expressed in mammalian tissues such as brain, heart, and lung, leading to extra-adrenal epinephrine synthesis (Kennedy et al., 1993).

In addition to de novo synthesis, NE stores in the terminal portions of the adrenergic fibers are also replenished by reuptake and restorage of NE following its release. At least two distinct carrier-mediated transport systems are involved: one across the axoplasmic membrane from the extracellular fluid to the cytoplasm (NET, the norepinephrine transporter, previously called uptake 1); and the other from the cytoplasm into the storage vesicles (VMAT2, the vesicular monoamine transporter) (Chandhry et al., 2008). A third transporter, ENT (the extraneuronal transporter, also called uptake 2), is responsible for the facilitated entry of catecholamines into non-neuronal cells.

For norepinephrine released by neurons, uptake by NET is more important than extraneuronal uptake and metabolism of norepinephrine. Sympathetic nerves as a whole remove ~87% of released norepinephrine by NET, compared with 5% by extraneuronal uptake (ENT) and 8% by diffusion to the circulation. In contrast, clearance of circulating catecholamines is primarily by non-neuronal mechanisms, with liver and kidney accounting for over 60% of the clearance of circulating catecholamines. Because the VMAT2 has a much higher affinity for norepinephrine than does monoamine oxidase (MAO), over 70% of recaptured norepinephrine is sequestered into storage vesicles (Eisenhofer, 2001).

Storage of Catecholamines. Catecholamines are stored in vesicles, ensuring their regulated release; this storage decreases intraneuronal metabolism of these transmitters and their leakage outside the cell. The vesicular amine transporter (VMAT2) appears to be driven by pH and potential gradients that are established by an ATP-dependent proton translocase. For every molecule of amine taken up, two H+ ions are extruded (Brownstein and Hoffman, 1994). Monoamine transporters are relatively promiscuous and transport DA, NE, epinephrine, and 5-HT, e.g., as well as meta-iodobenzylguanidine, which can be used to image chromaffin cell tumors (Schuldiner, 1994). Reserpine inhibits monoamine transport into storage vesicles and ultimately leads to depletion of catecholamine from sympathetic nerve endings and in the brain. Several vesicular transport cDNAs have been cloned; these cDNAs reveal open reading frames predictive of proteins with 12 transmembrane domains (Chapter 5). Regulation of the expression of these various transporters may be important in the regulation of synaptic transmission (Varoqui and Erickson, 1997).

NET is Na+-dependent and is blocked selectively by a number of drugs, including cocaine and tricyclic antidepressants such as imipramine. This transporter has a high affinity for NE and a somewhat lower affinity for epinephrine (Table 8–5); the synthetic β adrenergic
Figure 8–6. An adrenergic neuroeffector junction showing features of the synthesis, storage, release, and receptors for norepinephrine (NE), the cotransmitters neuropeptide Y (NPY), and ATP. Tyrosine is transported into the varicosity and is converted to DOPA by tyrosine hydroxylase (TH) and DOPA to dopamine (DA) by the action of aromatic L-amino acid decarboxylase (AAADC). Dopamine is taken up into the vesicles of the varicosity by a transporter, VMAT2, that can be blocked by reserpine. Cytoplasmic NE also can be taken up by this transporter. Dopamine is converted to NE within the vesicle via the action of dopamine-β-hydroxylase (DβH). NE is stored in vesicles along with other cotransmitters, NPY and ATP, depending on the particular neuroeffector junction. Release of the transmitters occurs upon depolarization of the varicosity, which allows entry of Ca\(^{2+}\) through voltage-dependent Ca\(^{2+}\) channels. Elevated levels of Ca\(^{2+}\) promote the fusion of the vesicular membrane with the membrane of the varicosity, with subsequent exocytosis of transmitters. This fusion process involves the interaction of specialized proteins associated with the vesicular membrane (VAMPS, vesicle-associated membrane proteins) and the membrane of the varicosity (SNAPs, synaptosome-associated proteins). In this schematic representation, NE, NPY, and ATP are stored in the same vesicles. Different populations of vesicles, however, may preferentially store different proportions of the cotransmitters. Once in the synapse, NE can interact with \(\alpha\) and \(\beta\) adrenergic receptors to produce the characteristic response of the effector. The adrenergic receptors are GPCRs. \(\alpha\) and \(\beta\) Receptors also can be located presynaptically where NE can either diminish (\(\alpha_2\)), or facilitate (\(\beta\)) its own release and that of the cotransmitters. The principal mechanism by which NE is cleared from the synapse is via a cocaine-sensitive neuronal uptake transporter, NET. Once transported into the cytosol, NE can be re-stored in the vesicle or metabolized by monoamine oxidase (MAO). NPY produces its effects by activating NPY receptors, of which there are at least five types (Y\(_1\) through Y\(_2\)). NPY receptors are GPCRs. NPY can modify its own release and that of the other transmitters via presynaptic receptors of the Y\(_2\) type. NPY is removed from the synapse by metabolic breakdown by peptidases. ATP produces its effects by activating P2X receptors or P2Y receptors. P2X receptors are ligand-gated ion channels; P2Y receptors are GPCRs. There are multiple subtypes of both P2X and P2Y receptors. As with the other cotransmitters, ATP can act prejunctionally to modify its own release via receptors for ATP or via its metabolic breakdown to adenosine that acts on P1 (adenosine) receptors. ATP is cleared from the synapse primarily by releasable nucleotidases (rNTPase) and by cell-fixed ectonucleotidases.
receptor agonist isoproterenol is not a substrate for this system.

There are actually two neuronal membrane transporters for catecholamines, the NE transporter (NET) mentioned above and the DA transporter (DAT); their characteristics are depicted in Table 8–5.

The NET is also present in the adrenal medulla, the liver, and the placenta, whereas the DAT is present in the stomach, pancreas, and kidney (Eisenhofer, 2001). NET and DAT are members of an extended family of biogenic amine and amino acid neurotransmitter transporters. Members share common structural motifs, particularly the putative 12-transmembrane helices. These plasma membrane transporters appear to have greater substrate specificity than do vesicular transporters and are targets for specific drugs such as cocaine (catecholamine transporters) and fluoxetine (serotonin transporter).

Certain sympathomimetic drugs (e.g., ephedrine and tyramine) produce some of their effects indirectly by displacing NE from the nerve terminals to the extracellular fluid, where it then acts at receptor sites of the effector cells. The mechanisms by which these drugs release NE from nerve endings are complex. All such agents are substrates for NET. As a result of their transport across the neuronal membrane and release into the axoplasm, they make carrier available at the inner surface of the membrane for the outward transport of NE.

NET, norepinephrine transporter, originally known as uptake 1; DAT, dopamine transporter; ENT (OCT3), extraneuronal transporter, originally known as uptake 2; OCT 1, OCT 2, organic cation transporters; Epi, epinephrine; NE, norepinephrine; DA, dopamine.
nephrine over NE and DA, and shows a higher maximum rate of NET, ENT exhibits lower affinity for catecholamines, favors epinephrine results in rapidly decreasing effectiveness, whereas repeated administration of NE does not reduce effectiveness and, in fact, reverses the tachyphylaxis to tyramine. Although these phenomena have not been explained fully, several hypotheses have been proposed. One possible explanation is that the pool of neurotransmitter available for displacement by these drugs is small relative to the total amount stored in the sympathetic nerve ending. This pool is presumed to reside in close proximity to the plasma membrane, and the NE of such vesicles may be replaced by the less potent amine following repeated administration of the latter substance. In any case, neurotransmitter release by displacement is not associated with the release of DβH and does not require extracellular Ca²⁺; thus, it is presumed not to involve exocytosis.

There are also three extraneuronal transporters that handle a wide range of endogenous and exogenous substrates. The extraneuronal amine transporter (ENT), originally named uptake-2 and also designated OCT3, is an organic cation transporter. Relative to NET, ENT exhibits lower affinity for catecholamines, favors epinephrine over NE and DA, and shows a higher maximum rate of catecholamine uptake. The ENT is not Na⁺-dependent and displays a different profile of pharmacological inhibition. Other members of this family are the organic cation transporters OCT1 and OCT2 (Chapter 5). All three can transport catecholamines in addition to a wide variety of other organic acids, including 5-HT, histamine, choline, spermine, guanidine, and creatinine. The characteristics and location of the non-neuronal transporters are summarized in Table 8–5.

**Release of Catecholamines.** The full sequence of steps by which the nerve impulse effects the release of NE from sympathetic neurons is not known. In the adrenal medulla, the triggering event is the liberation of ACh by the preganglionic fibers and its interaction with nicotinic receptors on chromaffin cells to produce a localized depolarization; a subsequent step is the entrance of Ca²⁺ into these cells, which results in the extrusion by exocytosis of the granular contents, including epinephrine, ATP, some neuroactive peptides or their precursors, chromogranins, and DβH. Influx of Ca²⁺ likewise plays an essential role in coupling the nerve impulse, membrane depolarization, and opening of voltage-gated Ca²⁺ channels with the release of norepinephrine at sympathetic nerve terminals. Blockade of N-type Ca²⁺ channels leads to hypotension likely owing to inhibition of NE release. Ca²⁺-triggered secretion involves interaction of highly conserved molecular scaffolding proteins leading to docking of granules at the plasma membrane and ultimately leading to secretion (Aunis, 1998).

Reminiscent of the release of ACh at cholinergic terminals, various synaptic proteins, including the plasma membrane proteins syntaxin and SNAP-25, and the vesicle membrane protein synaptobrevin form a complex that interacts in an ATP-dependent manner with the soluble proteins N-ethylmaleimide-sensitive fusion protein (NSF) and soluble NSF attachment proteins (SNAPs). The ability of synaptobrevin, syntaxin, and SNAP-25 to bind SNAPs has led to their designation as SNAP receptors (SNAREs). It has been hypothesized that most, if not all, intracellular fusion events are mediated by SNARE interactions (Boehm and Kubista, 2002). As with cholinergic neurotransmission, important evidence supporting the involvement of SNARE proteins (e.g., SNAP-25, syntaxin, and synaptobrevin) in transmitter release comes from the fact that botulinum neurotoxins and tetanus toxin, which potently block neurotransmitter release, proteolyse these proteins.

Enhanced activity of the sympathetic nervous system is accompanied by an increased concentration of both DβH and chromogranins in the circulation, supporting the argument that the process of release following adrenergic nerve stimulation also involves exocytosis.

Adrenergic fibers can sustain the output of norepinephrine during prolonged periods of stimulation without exhausting their reserve supply, provided that synthesis and uptake of the transmitter are unimpaired. To meet increased needs for NE acute regulatory mechanisms are evoked involving activation of tyrosine hydroxylase and DβH (described earlier in the chapter).

**Prejunctional Regulation of Norepinephrine Release.** The release of the three sympathetic co-transmitters can be modulated by prejunctional autoreceptors and heteroreceptors. Following their release from sympathetic terminals, all three co-transmitters—NE, neuropeptide Y (NPY), and ATP—can feed back on prejunctional receptors to inhibit the release of each other (Westfall, 2004; Westfall et al., 2002). The most thoroughly studied have been prejunctional α₂ adrenergic receptors. The α₂A and α₂C adrenergic receptors are the principal prejunctional receptors that inhibit sympathetic neurotransmitter release, whereas the α₂B adrenergic receptors also may inhibit transmitter release at selected sites. Antagonists of this receptor, in turn, can enhance the electrically evoked release of sympathetic neurotransmitter. NPY, acting on Y₂ receptors, and ATP-derived adenosine, acting on P₁ receptors, also can inhibit sympathetic neurotransmitter release. Numerous heteroreceptors on sympathetic nerve varicosities also inhibit the release of sympathetic neurotransmitters; these include: M₁, M₄ muscarinic, 5-HT, PGE₂, histamine, enkephalin, and DA receptors. Enhancement of sympathetic neurotransmitter release can be produced...
Termination of the Actions of Catecholamines. The actions of NE and epinephrine are terminated by:

- reuptake into nerve terminals by NET
- dilution by diffusion out of the junctional cleft and uptake at extraneuronal sites by ENT, OCT 1, and OCT 2

Following uptake, catecholamines can be metabolized (in neuronal and non-neuronal cells) or re-stored in vesicles (in neurons). Two enzymes are important in the initial steps of metabolic transformation of catecholamines—monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT). In addition, catecholamines are metabolized by sulfotransferases (Dooley, 1998) (Chapter 6). However, termination of action by a powerful degradative enzymatic pathway, such as that provided by AChE at sites of cholinergic transmission, is absent from the adrenergic nervous system. The importance of neuronal reuptake of catecholamines is shown by observations that inhibitors of this process (e.g., cocaine and imipramine) potentiate the effects of the neurotransmitter; inhibitors of MAO and COMT have relatively little effect. However, MAO metabolizes transmitter that is released within the nerve terminal. COMT, particularly in the liver, plays a major role in the metabolism of endogenous circulating and administered catecholamines.

Both MAO and COMT are distributed widely throughout the body, including the brain; the highest concentrations of each are in the liver and the kidney. However, little or no COMT is found in sympathetic neurons. In the brain, there is also no significant COMT in presynaptic terminals, but it is found in some postsynaptic neurons and glial cells. In the kidney, COMT is localized in proximal tubular epithelial cells, where DA is synthesized, and is thought to exert local diuretic and natriuretic effects. The physiological substrates for COMT include L-dopa, all three endogenous catecholamines (DA, NE, and epinephrine), their hydroxylated metabolites, catecholestrogens, ascorbic acid, and dihydroxyindolic intermediates of melanin (Männistö and Kaakkola, 1999). There are distinct differences in the cytological locations of the two enzymes; MAO is associated chiefly with the outer surface of mitochondria, including those within the terminals of sympathetic or central noradrenergic neuronal fibers, whereas COMT is largely cytoplasmic except in the chromaffin cells of the adrenal medulla, where COMT is present as a membrane-bound form. These factors are of importance both in determining the primary metabolic pathways followed by catecholamines in various circumstances and in explaining the effects of certain drugs. Two different isoforms of MAO (MAO-A and MAO-B) are found in widely varying proportions in different cells in the CNS and in peripheral tissues. In the periphery, MAO-A is located in the syncytiotrophoblast layer of term placenta and liver, whereas MAO-B is located in platelets, lymphocytes, and liver. In the brain, MAO-A is located in all regions containing catecholamines, with the highest abundance in the locus ceruleus. MAO-B, on the other hand, is found primarily in regions that are known to synthesize and store 5-HT. MAO-B is most prominent in the nucleus raphe dorsalis but also in the posterior hypothalamus and in glial cells in regions known to contain nerve terminals. MAO-B is also present in osteocytes around blood vessels (Abell and Kwan, 2001). Selective inhibitors of these two isoforms are available (Chapter 15). Irreversible antagonists of MAO-A (e.g., phenelzine, tranylcypromine, and isocarboxazid) enhance the bioavailability of tyramine contained in many foods; tyramine-induced NE release from sympathetic neurons may lead to markedly increased blood pressure (hypertensive crisis). Selective MAO-B inhibitors (e.g., selegiline) or reversible MAO-A–selective inhibitors (e.g., moclobemide) are less likely to cause this potential interaction (Volz and Geiter, 1998; Wouters, 1998). MAO inhibitors are useful in the treatment of Parkinson’s disease and mental depression (Chapters 15 and 22).

Inhibitors of MAO (e.g., pargyline and nialamide) can cause an increase in the concentration of NE, DA, and 5-HT in the brain and other tissues accompanied by a variety of pharmacological effects. No striking pharmacological action in the periphery can be attributed to the inhibition of COMT. However, the COMT inhibitors entacapone and tolcapone have been found to be efficacious in the therapy of Parkinson’s disease (Chong and Mersfelder, 2000) (Chapter 22).

There is ongoing passive leakage of catecholamines from vesicular storage granules of sympathetic neurons and adrenal medullary chromaffin cells. As a consequence, most metabolism of catecholamines takes place in the same cells where the amines are synthesized and stored. VMAT2 effectively sequesters ~90% of the amines leaking into the cytoplasm back into storage vesicles; ~10% escapes sequestration and is metabolized (Eisenhofer et al., 2004). Sympathetic nerves contain MAO but not COMT, and this MAO catalyzes only the first step of a two-step reaction. MAO converts NE to epinephrine into a short-lived intermediate, DOPGAL, which undergoes further metabolism in a second step catalyzed by another group of enzymes forming more stable alcohol- or acid-deaminated metabolites. Aldehyde dehydrogenase metabolizes DOPGAL to 3,4-dihydroxyphenylacetic acid (DOPAC), while aldehyde reductase metabolizes DOPGAL to 3,4-dihydroxyphenyl glycol (DOPEG). In addition to aldehyde reductase, a related enzyme, aldose reductase, can also reduce a catecholamine to its corresponding alcohol. This latter enzyme is present in sympathetic neurons and adrenal chromaffin cells. Under normal circumstances, DOMA is an insignificant metabolite of NE and epinephrine, with DOPPEG being the main metabolite produced by deamination in sympathetic neurons and adrenal medullary chromaffin cells.

Once it leaves the sites of formation (sympathetic neurons, adrenal medulla), DOPEDG is converted to 3-methyl, 4-hydroxy phenylethylamine (DOPAC), which undergoes further metabolism in a second step catalyzed by another group of enzymes forming more stable alcohol- or acid-deaminated metabolites. Aldehyde dehydrogenase metabolizes DOPAC to 3,4-dihydroxyphenylacetic acid (DOPAC), while aldehyde reductase metabolizes DOPAC to 3,4-dihydroxyphenyl glycol (DOPPEG). In addition to aldehyde reductase, a related enzyme, aldose reductase, can also reduce a catecholamine to its corresponding alcohol. This latter enzyme is present in sympathetic neurons and adrenal chromaffin cells. Under normal circumstances, DOMA is an insignificant metabolite of NE and epinephrine, with DOPPEG being the main metabolite produced by deamination in sympathetic neurons and adrenal medullary chromaffin cells.
MOPGAL and then to VMA, with VMA being the major end product of NE and epinephrine metabolism. Another route for the formation of VMA is conversion of NE and epinephrine into normetanephrine and metanephrine, respectively, by COMT followed by deamination to MOPGAL and ultimately VMA. This is now thought to be only a minor pathway, as indicated by the size of the arrows on Figure 8–7.

In contrast to sympathetic neurons, adrenal medullary chromaffin cells contain both MAO and COMT. In chromaffin cells, the COMT is mainly present as the membrane-bound form of the enzyme in contrast to the form found in the cytoplasm of extra-neuronal tissue. This isoform of COMT has a higher affinity for catecholamines than does the soluble form found in most other tissues (e.g., liver and kidney). In adrenal medullary chromaffin cells, leakage of NE and epinephrine from storage vesicles leads to substantial intracellular production of the O-methylated metabolites normetanephrine and metanephrine. It is estimated that in humans, over 90% of circulating metanephrine and 25–40% of circulating normetanephrine are derived from catecholamines metabolized within adrenal chromaffin cells.

The sequence of cellular uptake and metabolism of catecholamines in extraneuronal tissues contributes very little (~25%) to the total metabolism of endogenously produced NE in sympathetic neurons or the adrenal medulla. However, extraneuronal metabolism is an important mechanism for the clearance of circulating and exogenously administered catecholamines.

**Classification of Adrenergic Receptors.** Crucial to understanding the remarkably diverse effects of the catecholamines and related sympathomimetic agents is an understanding of the classification and properties of the different types of adrenergic receptors (or adrenoceptors). Elucidation of the characteristics of these receptors and the biochemical and physiological pathways they regulate has increased our understanding of the seemingly contradictory and variable effects of catecholamines on various organ systems. Although structurally related (discussed later), different receptors regulate distinct physiological processes by controlling the synthesis or release of a variety of second messengers (Table 8–6).

Based on studies of the abilities of epinephrine, norepinephrine, and other related agonists to regulate various physiological processes, Ahlquist first proposed the existence of more than one adrenergic receptor. It was known that these drugs could cause either contraction or relaxation of smooth muscle depending on the site, the dose, and the agent chosen. For example, NE was known to have potent excitatory effects on smooth muscle and correspondingly low activity as an inhibitor; isoproterenol displayed the opposite pattern of activity. Epinephrine could both excite and inhibit smooth muscle. Thus, Ahlquist proposed the designations α and β for receptors on smooth muscle where catecholamines produce excitatory and inhibitory responses, respectively. An exception is the gut, which generally is relaxed by activation of either α or β receptors. The rank order of potency of agonists is isoproterenol > epinephrine ≥ norepinephrine for β adrenergic receptors and epinephrine ≥ norepinephrine >> isoproterenol for α adrenergic receptors (Table 8–3).

This initial classification was corroborated by the finding that certain antagonists produce selective blockade of the effects of adrenergic nerve impulses and sympathomimetic agents at α receptors (e.g., phenoxybenzamine), whereas others produce selective β receptor blockade (e.g., propranolol).

β Receptors later were subdivided into β1 (e.g., those in the myocardium) and β2 (smooth muscle and most other sites) because epinephrine and norepinephrine essentially are equipotent at the former sites, whereas epinephrine is 10–50 times more potent than norepinephrine at the latter. Antagonists that discriminate between β1 and β2 receptors were subsequently developed (Chapter 12). A human gene that encodes a third β receptor (designated β3) has been isolated (Emorine et al., 1989). Since the β1 receptor is about tenfold more sensitive to norepinephrine than to epinephrine and is relatively resistant to blockade by antagonists such as propranolol, it may mediate responses to catecholamine at sites with “atypical” pharmacological characteristics (e.g., adipose tissue). Although the adipocytes are a major site of β3 adrenergic receptors, all three β adrenergic receptors are present in both white adipose tissue and brown adipose tissue. Animals treated with β1 receptor agonists exhibit a vigorous thermogenic response as well as lipolysis (Robidoux et al., 2004). Polymorphisms in the β3 receptor gene may be related to risk of obesity or type 2 diabetes in some populations (Arner and Hoffstedt, 1999). Also, there has been interest in the possibility that β3 receptor–selective agonists may be beneficial in treating these disorders (Weyer et al., 1999). The existence of a fourth type of βAR, β4AR, has been proposed. Despite intense efforts, β4AR, like α1AR, has not been cloned. Current thinking is that the β4AR represents an affinity state of β1AR rather than a discrete receptor (Hieble, 2007).

There is also heterogeneity among α adrenergic receptors. The initial distinction was based on functional and anatomic considerations when it was realized that NE and other α-adrenergic receptors could profoundly inhibit the release of norepinephrine from neurons (Westfall, 1977) (Figure 8–6). Indeed, when sympathetic nerves are stimulated in the presence of certain α receptor antagonists, the amount of NE liberated by each nerve impulse increases markedly. This
Figure 8-7. Steps in the metabolic disposition of catecholamines. Norepinephrine and epinephrine are first oxidatively deaminated to a short lived intermediate (DOPGAL) by monoamine oxidase (MAO). DOPGAL then undergoes further metabolism to more stable alcohol or acid deaminated metabolites. Aldehyde dehydrogenase (AD) metabolizes DOPGAL to 3,4-dihydroxymandelic acid (DOMA) while aldehyde reductase (AR) metabolizes DOPGAL to 3,4-dihydroxyphenyl glycol (DOPEG). Under normal circumstances DOMA is a minor metabolite with DOPEG being the major metabolite produced from norepinephrine and epinephrine. Once DOPEG leaves the major sites of its formation (sympathetic nerves; adrenal medulla), it is converted to 3-methoxy, 4-hydroxyphenyl glycol (MOPEG) by catechol-0-methyl transferase (COMT). MOPEG is then converted to the unstable aldehyde (MOPGAL) by alcohol dehydrogenase (ADH) and finally to vanillyl mandelic acid (VMA) by aldehyde dehydrogenase. VMA is the major end product of norepinephrine and epinephrine metabolism. Another route for the formation of VMA is conversion of norepinephrine or epinephrine into normetanephrine or metanephrine by COMT either in the adrenal medulla or extraneuronal sites, with subsequent metabolism to MOPGAL and thence to VMA.

\(^a\)At least three subtypes each of \( \alpha_1 \) and \( \alpha_2 \) adrenergic receptors are known, but distinctions in their mechanisms of action have not been clearly defined.

\(^b\)In some species (e.g., rat), metabolic responses in the liver are mediated by \( \alpha_1 \) adrenergic receptors, whereas in others (e.g., dog) \( \beta_2 \) adrenergic receptors are predominantly involved. Both types of receptors appear to contribute to responses in human beings.

\(^c\)Receptor coupling to cell signaling can be more complex. In addition to coupling to \( G_s \) to stimulate AC, \( \beta_2 \) receptors can activate signaling via a GRK/\( \beta \)-arrestin pathway (Violin and Lefkowitz, 2007). \( \beta_2 \) and \( \beta_3 \) receptors can couple to both \( G_s \) and \( G_i \) in a manner that may reflect agonist stereochemistry (Woo et al., 2009). See also Chapter 12.

\(^d\)Metabolic responses in adipocytes and certain other tissues with atypical pharmacological characteristics may be mediated by this subtype of receptor. Most \( \beta \) adrenergic receptor antagonists (including propranolol) do not block these responses.

AC, adenylyl cyclase; Epi, epinephrine; NE, norepinephrine; Iso, isoproterenol; GI, gastrointestinal; GU, genitourinary.

feedback-inhibitory effect of NE on its release from nerve terminals is mediated by \( \alpha \) receptors that are pharmacologically distinct from the classical postsynaptic \( \alpha \) receptors. Accordingly, these presynaptic \( \alpha \) adrenergic receptors were designated \( \alpha_2 \), whereas the postsynaptic “excitatory” \( \alpha \) receptors were designated \( \alpha_1 \) (Langer, 1997). Compounds such as clonidine are more potent agonists at \( \alpha_2 \) than at \( \alpha_1 \) receptors; by contrast, phenylephrine and methoxamine selectively activate postsynaptic \( \alpha_1 \) receptors. Although there is little evidence to suggest that \( \alpha_1 \) adrenergic receptors function presynaptically in the autonomic nervous system, it is now clear that \( \alpha_2 \) receptors also are present at postjunctional or nonjunctional sites in several tissues. For example, stimulation of postjunctional \( \alpha_2 \) receptors in the brain is associated with reduced sympathetic outflow from the CNS and appears to be responsible for a significant component of the antihypertensive effect of drugs such as clonidine (Chapter 12). Thus, the anatomic concept of prejunctional
α and postjunctional αβ adrenergic receptors has been abandoned in favor of a pharmacological and functional classification (Tables 8–6 and 8–7).

Cloning revealed additional heterogeneity of both α and αβ adrenergic receptors (Bylund, 1992). There are three pharmacologically defined α receptors (α1A, α1B, and α1D) with distinct sequences and tissue distributions, and three cloned subtypes of α receptors (α2A, α2B, and α2C) (Table 8–6). A fourth type of α receptor, α1LAR, has been defined on the basis of a low affinity for a number of selective antagonists including prazosin (Hieble, 2007). This phenotype could be of physiological significance since the α1L profile has been identified in a variety of tissues across a number of different species, where it appears to regulate smooth muscle contractility in the vasculature and lower urinary tract. It also appears (at least in the mouse prostate smooth muscle) to be dependent upon expression of the α1LAR gene product. Moreover, an intact cellular environment is important for the manifestation of the α1LAR phenotype in vivo. Despite intense efforts, α2AR has not been cloned and it is doubtful that α1LAR is a discrete AR (Hieble, 2007).

Owing to the lack of sufficiently subtype-selective ligands, the precise physiological function and therapeutic potential of the subtypes of adrenergic receptors have not been elucidated fully. Great advances in our understanding have been made through the use of genetic approaches using transgenic and receptor knockout experiments in mice (discussed later). These mouse models have been used to identify the particular receptor subtypes and pathophysiological relevance of individual adrenergic receptors subtypes (Philipp and Hein, 2004; Tanoue et al., 2002a, 2002b; Xiao et al., 2006).

**Molecular Basis of Adrenergic Receptor Function.** All of the adrenergic receptors are GPCRs that link to heterotrimeric G proteins. Each major type shows preference for a particular class of G proteins, i.e., α1 to Gq, α2 to Gi, and β to Gs (Table 8–6). The responses that follow activation of all types of adrenergic receptors result from G protein–mediated effects on the generation of second messengers and on the activity of ion channels, as discussed in Chapter 3. The pathways overlap broadly with those discussed for muscarinic acetylcholine receptors and are summarized in Table 8–6 (Drake et al., 2006; Park et al., 2008).

**Structure of Adrenergic Receptors.** Adrenergic receptors constitute a family of closely related proteins that are related both structurally and functionally to GPCRs for a wide variety of other hormones and neurotransmitters (see Chapter 3). Ligand binding, site-directed labeling, and mutagenesis have revealed that the conserved membrane-spanning regions are crucially involved in ligand binding (Hutchins, 1994; Strader et al., 1994). These regions appear to create a ligand-binding pocket analogous to that formed by the membrane-spanning regions of rhodopsin to accommodate the covalently attached chromophore, retinal, with molecular models placing catecholamines either horizontally (Strader et al., 1994) or perpendicularly (Hutchins, 1994) in the bilayer. The crystal structure of mammalian rhodopsin confirms a number of predictions about the structure of GPCRs (Palczewski et al., 2000).

**β Adrenergic Receptors.** The three β receptors share ~60% amino acid sequence identity within the presumed membrane-spanning domains where the ligand-binding pocket for epinephrine and norepinephrine is found. Based on results of site-directed mutagenesis, individual amino acids in the β2 receptor that interact with each of the functional groups on the catecholamine agonist molecule have been identified.

β Receptors regulate numerous functional responses, including heart rate and contractility, smooth muscle relaxation, and multiple metabolic events in numerous tissues including adipose and hepatic cells and skeletal muscle (Lynch and Ryall, 2008) (Table 8–1). All three of the β receptor subtypes (β1, β2, and β3) couple to Gi and activate adenyl cyclase (Table 8–7). However, recent data suggest differences in downstream signals and events activated by the three β receptors (Lefkowitz, 2000; Ma and Huang, 2002). Catecholamines promote β receptor feedback regulation, that is, desensitization and receptor down-regulation (Kohout and Lefkowitz, 2003). β Receptors differ in the extent to which they undergo such regulation, with the β1 receptor being the most susceptible. Stimulation of β adrenergic receptors leads to the accumulation of cyclic AMP, activation of the PKA, and altered function of numerous cellular proteins as a result of their phosphorylation (Chapter 3). In addition, Gs can enhance directly the activation of voltage-sensitive Ca2+ channels in the plasma membrane of skeletal and cardiac muscle.

Several reports demonstrate that β1, β2, and β3 receptors can differ in their intracellular signaling pathways and subcellular location (Brodde et al., 2006; Violin and Lefkowitz, 2007; Woo et al., 2009). While the positive chronotropic effects of β1 receptor activation are clearly mediated by Gi in myocytes, dual coupling of β2 receptors to Gi and Gs occurs in myocytes from newborn mice. Stimulation of β2 receptors caused a transient increase in heart rate that is followed by a prolonged decrease. Following pretreatment with pertussis toxin, which prevents activation of Gi, the negative chronotropic effect of β2 activation is abolished. It is thought that these specific signaling properties of β receptor subtypes are linked to subtype-selective association with intracellular scaffolding and signaling proteins (Bailie and Houslay, 2005). β3 Receptors normally are confined to caveolae in cardiac myocyte membranes. The activation

*At least five subtypes of muscarinic receptors exist. Agonists show little selectivity for subtypes whereas several antagonists show partial subtype selectivity (see Table 8–3).

Two subtypes of muscle acetylcholine nicotinic receptors and several subtypes of neuronal receptors have been identified (see Table 8–2). ACh, acetylcholine; AChE, acetylcholine esterase; COMT, catechol-O-methyl transferase; MAO, monoamine oxidase; NE, norepinephrine; j-g cells, renin-secreting cells in the juxta-glomerular complex of the kidney.

of PKA by cyclic AMP and the importance of compartmentation of components of the cyclic AMP pathway are discussed in Chapter 3. A representation of the general structure of adrenergic receptors is shown in Figure 8–8.

**\( \alpha \) Adrenergic Receptors.** The deduced amino acid sequences from the three \( \alpha_1 \) receptor genes (\( \alpha_{1A}, \alpha_{1B}, \) and \( \alpha_{1D} \)) and three \( \alpha_2 \) receptor genes (\( \alpha_{2A}, \alpha_{2B}, \) and \( \alpha_{2C} \)) conform to the well-established GPCR paradigm (Bylund, 1992; Zhong and Minneman, 1999). The general structural features of \( \alpha \) receptors and their relation to the functions of ligand binding and G protein activation appear to agree with those set forth in Chapter 3 and earlier in this chapter for the \( \beta \) receptors. Within the membrane-spanning domains, the three \( \alpha_1 \) adrenergic receptors share ~75% identity in amino acid residues, as do the three \( \alpha_2 \) receptors, but the \( \alpha_1 \) and \( \alpha_2 \) subtypes are no more similar than are the \( \alpha \) and \( \beta \) subtypes (~30-40%).

**\( \alpha_2 \) Adrenergic Receptors.** As shown in Table 8–6, \( \alpha_2 \) receptors couple to a variety of effectors (Aantaa et al., 1995; Bylund, 1992; Tan and Limbird, 2005). Inhibition of adenylyl cyclase activity was the first effect observed, but in some systems the enzyme actually is stimulated by \( \alpha_2 \) adrenergic receptors, either by \( G_i, G_j \) subunits or by weak direct stimulation of \( G_s \). The physiological significance of these latter processes is not currently clear. \( \alpha_2 \) Receptors activate G protein–gated \( K^+ \) channels, resulting in membrane hyperpolarization. In some cases (e.g., cholinergic neurons in the myenteric plexus) this may be \( Ca^{2+} \)-dependent, whereas in others (e.g., muscarinic ACh receptors in atrial myocytes) it results from direct interaction of \( \beta \gamma \) subunits with \( K^+ \) channels. \( \alpha_2 \) Receptors also can inhibit voltage-gated \( Ca^{2+} \) channels; this is mediated by \( G_o \). Other second-messenger systems linked to \( \alpha_2 \) receptor activation include acceleration of \( Na^+/H^+ \) exchange, stimulation of PLC\(_{12}\) activity and arachidonic acid mobilization, increased phosphoinositide hydrolysis, and increased intracellular availability of \( Ca^{2+} \). The latter is involved in the smooth muscle–contracting effect of
α<sub>2</sub> adrenergic receptor agonists. In addition, the α<sub>2</sub> receptors activate mitogen-activated protein kinases (MAPKs) likely by means of βγ subunits released from pertussis toxin–sensitive G proteins (Della Rocca et al., 1997; Richman and Regan, 1998). This and related pathways lead to activation of a variety of tyrosine kinase–mediated downstream events. These pathways are reminiscent of pathways activated by tyrosine kinase activities of growth factor receptors. Although α<sub>2</sub> receptors may activate several different signaling pathways, the exact contribution of each to many physiological processes is not clear. The α<sub>2A</sub> receptor plays a major role in inhibiting NE release from sympathetic nerve endings and suppressing sympathetic outflow from the brain, leading to hypotension (Kable et al., 2000).

In the CNS, α<sub>2A</sub> receptors, which appear to be the most dominant adrenergic receptor, probably produce the antinociceptive effects, sedation, hypothermia, hypotension, and behavioral actions of α<sub>2</sub> agonists (Lakhani et al., 1997). The α<sub>2C</sub> receptor occurs in the ventral and dorsal striatum and hippocampus. It appears to modulate dopamine neurotransmission and various behavioral responses. The α<sub>2B</sub> receptor is the main receptor mediating α<sub>2</sub>-induced vasoconstriction, whereas the α<sub>2C</sub> receptor is the predominant receptor inhibiting the release of catecholamines from the adrenal medulla and modulating dopamine neurotransmission in the brain.

α<sub>1</sub> Adrenergic Receptors. Stimulation of α<sub>1</sub> receptors results in the regulation of multiple effector systems. A primary mode of signal transduction involves activation of the G<sub>α</sub>-PLC<sub>β</sub>-IP<sub>3</sub>-Ca<sup>2+</sup> pathway and the activation of other Ca<sup>2+</sup> and calmodulin sensitive pathways such as CaM kinases (Chapter 3). For example, α<sub>1</sub> receptors regulate hepatic glycogenolysis in some animal species; this effect results from the activation of phosphorylase kinase by the mobilized Ca<sup>2+</sup>, aided by the inhibition of glycogen synthase caused by PKC-mediated phosphorylation. PKC phosphorylates many substrates, including membrane proteins such as channels, pumps, and ion-exchange proteins (e.g., Ca<sup>2+</sup>-transport ATPase). These effects presumably lead to regulation of various ion conductances.

α<sub>1</sub> Receptor stimulation of PLA<sub>2</sub> leads to the release of free arachidonate, which is then metabolized by the cyclooxygenase and lipoxygenase pathways to the bioactive prostaglandins and leukotrienes, respectively (Chapter 33). Stimulation of PLA<sub>2</sub> activity by various agonists (including epinephrine acting at α<sub>1</sub> receptors) is found in many tissues and cell lines, suggesting that this effector is physiologically important. PLD hydrolyzes phosphatidylcholine to yield phosphatidic acid (PA). Although PA itself may act as a second messenger by releasing Ca<sup>2+</sup> from intracellular stores, it also is metabolized to the second messenger DAG. PLD is an effector for ADP-ribosylating factor (ARF), suggesting that PLD may play a role in membrane trafficking. Finally, some evidence in vascular smooth muscle suggests that α<sub>1</sub> receptors are capable of regulating a Ca<sup>2+</sup> channel by means of a G protein.

In most smooth muscles, the increased concentration of intracellular Ca<sup>2+</sup> ultimately causes contraction as a result of activation of Ca<sup>2+</sup>-sensitive protein
kinases such as the calmodulin-dependent myosin light-chain kinase; phosphorylation of the light chain of myosin is associated with the development of tension (see Chapter 3). In contrast, the increased concentration of intracellular Ca\(^{2+}\) that result from stimulation of \(\alpha\) receptors in GI smooth muscle causes hyperpolarization and relaxation by activation of Ca\(^{2+}\)-dependent K\(^+\) channels (McDonald et al., 1994).

As with \(\alpha\) receptors, there is considerable evidence demonstrating that \(\alpha\) receptors activate MAPKs and other kinases such as PI3 kinase leading to important effects on cell growth and proliferation (Dorn and Brown, 1999; Gutkind, 1998). For example, prolonged stimulation of \(\alpha\) receptors promotes growth of cardiac myocytes and vascular smooth muscle cells. The \(\alpha\) receptor is the predominant receptor causing vasoconstriction in many vascular beds, including the following arteries: mammary, mesenteric, splenic, hepatic, omental, renal, pulmonary, and epicardial coronary. It is also the predominant subtype in the vena cava and the saphenous and pulmonary veins (Michelotti et al., 2001). Together with the \(\alpha\) receptor subtype, it promotes cardiac growth and structure. The \(\alpha\) receptor subtype is the most abundant subtype in the heart, whereas the \(\alpha\) receptor subtype is the predominant receptor causing vasoconstriction in the aorta. There is evidence to support the idea that \(\alpha\) receptors mediate behaviors such as reaction to novelty and exploration and are involved in behavioral sensitizations and in the vulnerability to addiction (see Chapter 24).

Adrenergic Receptor Polymorphism. Numerous polymorphisms and splice variants of adrenergic receptors continue to be identified. Receptors \(\alpha\), \(\alpha\) and \(\beta\) are polymorphic. Such polymorphisms in these adrenergic receptors could result in altered physiological responses to activation of the sympathetic nervous system, contribute to disease states and alter the responses to adrenergic agonists and/or antagonists (Brodde, 2008). Knowledge of the functional consequences of specific polymorphisms could theoretically result in the individualization of drug therapy based on a patient’s genetic makeup and could explain marked inter-individual variability within the human population.

Localization of Adrenergic Receptors. Presynaptically located \(\alpha\) and \(\beta\) receptors fulfill important roles in the regulation of neurotransmitter release from sympathetic nerve endings. Presynaptic \(\alpha\) receptors also may mediate inhibition of release of neurotransmitters other than norepinephrine in the central and peripheral nervous systems. Both \(\alpha\) and \(\beta\) receptors are located at post-synaptic sites (Table 8–6), such as on many types of neurons in the brain. In peripheral tissues, postsynaptic \(\alpha\) receptors are found in vascular and other smooth muscle cells (where they mediate contraction), adipocytes, and many types of secretory epithelial cells (intestinal, renal, endocrine). Postsynaptic \(\beta\) receptors can be found in the myocardium (where they mediate contraction) as well as on vascular and other smooth muscle cells (where they mediate relaxation) and skeletal muscle (where they can mediate hypertrophy). Indeed, most normal human cell types express \(\beta\) receptors. Both \(\alpha\) and \(\beta\) receptors may be situated at sites that are relatively remote from nerve terminals releasing NE. Such extrajunctional receptors typically are found on vascular smooth muscle cells and blood elements (platelets and leukocytes) and may be activated preferentially by circulating catecholamines, particularly epinephrine.

In contrast, \(\alpha\) and \(\beta\) receptors appear to be located mainly in the immediate vicinity of sympathetic adrenergic nerve terminals in peripheral target organs, strategically placed to be activated during stimulation of these nerves. These receptors also are distributed widely in the mammalian brain (Table 8–6).

The cellular distributions of the three \(\alpha\) and three \(\beta\) receptor subtypes still are incompletely understood. \textit{In situ} hybridization of receptor mRNA and receptor subtype-specific antibodies indicates that \(\alpha\) receptors in the brain may be both pre- and postsynaptic. These findings and other studies indicate that this receptor subtype functions as a presynaptic autoreceptor in central noradrenergic neurons (Aantaa et al., 1995; Lakhlani et al., 1997). Using similar approaches, \(\alpha\) mRNA was found to be the dominant subtype message expressed in prostac smooth muscle (Walden et al., 1997).

Refractoriness to Catecholamines. Exposure of catecholamine-sensitive cells and tissues to adrenergic agonists causes a progressive diminution in their capacity to respond to such agents. This phenomenon, variously termed refractoriness, desensitization, or tachyphylaxis, can limit the therapeutic efficacy and duration of action of catecholamines and other agents (Chapter 3). The mechanisms are incompletely understood. They have been studied most extensively in cells that synthesize cyclic AMP in response to \(\beta\) receptor agonists.

Multiple mechanisms are involved in desensitization, including rapid events such as receptor phosphorylation by both G-protein receptor kinases (GRKs) and by signaling kinases such as PKA and PKC, receptor sequestration, uncoupling from G proteins, and activation of specific cyclic nucleotide phosphodiesterases. More slowly occurring events also are seen, such as receptor endocytosis, which decreases receptor number. An understanding of the mechanisms involved in regulation of GPCR desensitization has developed over the last few years (Kohout and Lefkowitz, 2003; Violin and Lefkowitz, 2007). Such regulation is very complex and exceeds the simplistic model of GPCR phosphorylation by GRKs followed by arrestin binding and
uncoupling of G-protein signaling. It is known that GRK activities are extensively regulated by numerous interactions with and modifications by other proteins. β-Arrestin, now recognized as a scaffolding protein, can physically interrupt signaling to the G proteins as well as to further enhance GPCR desensitization by causing translocation of cytosolic proteins to the receptor (e.g., phosphodiesterase and cSrc). These, in turn, can turn off signaling at its source by degrading cyclic AMP or phosphorylating GRK2 to enhance its activity toward the receptor (DeFea, 2008; DeWire et al., 2007; Hanyaloglu and VonZastrow, 2008).

**RELATIONSHIP BETWEEN THE NERVOUS AND ENDOCRINE SYSTEMS**

The theory of neurohumoral transmission by its very designation implies at least a superficial resemblance between the nervous and endocrine systems. It is now clear that the similarities extend considerably deeper, particularly with respect to the autonomic nervous system. In the regulation of homeostasis, the autonomic nervous system is responsible for rapid adjustments to changes in the environment, which it effects at both its ganglionic synapses and its postganglionic terminals by the liberation of chemical agents that act transiently at their immediate sites of release. The endocrine system, in contrast, regulates slower, more generalized adaptations by releasing hormones into the systemic circulation to act at distant, widespread sites over periods of minutes to hours or days. Both systems have major central representations in the hypothalamus, where they are integrated with each other and with subcortical, cortical, and spinal influences. The neurohumoral theory provides a unitary concept of the functioning of the nervous and endocrine systems in which the differences largely relate to the distances over which the released mediators travel.

**PHARMACOLOGICAL CONSIDERATIONS**

The foregoing sections contain numerous references to the actions of drugs considered primarily as tools for the dissection and elucidation of physiological mechanisms. This section presents a classification of drugs that act on the peripheral nervous system and its effector organs at some stage of neurotransmission. In the subsequent four chapters, the systematic pharmacology of the important members of each of these classes is described.

Each step involved in neurotransmission (Figures 8–3, 8–4, and 8–6) represents a potential point of therapeutic intervention. This is depicted in the diagrams of the cholinergic and adrenergic terminals and their postjunctional sites (Figure 8–4 and 8–6). Drugs that affect processes involved in each step of transmission at both cholinergic and adrenergic junctions are summarized in Table 8–7, which lists representative agents that act through the mechanisms described next.

**Interference with the Synthesis or Release of the Transmitter**

**Cholinergic.** Hemicholinium (HC-3), a synthetic compound, blocks the transport system by which choline accumulates in the terminals of cholinergic fibers, thus limiting the synthesis of the ACh store available for release. Vesamicol blocks the transport of ACh into its storage vesicles, preventing its release. The site on the presynaptic nerve terminal for block of ACh release by botulinum toxin was discussed previously; death usually results from respiratory paralysis unless patients with respiratory failure receive artificial ventilation. Injected locally, botulinum toxin type A is used in the treatment of certain ophthalmological conditions associated with spasms of ocular muscles (e.g., strabismus and blepharospasm) (Chapter 64) and for a wide variety of unlabeled uses ranging from treatment of muscle dystonias and palsy (Chapter 11) to cosmetic erasure of facial lines and wrinkles (Chapter 65).

**Adrenergic.** α-Methyltyrosine (methyrosine) blocks the synthesis of NE by inhibiting TH, the enzyme that catalyzes the rate-limiting step in catecholamine synthesis. This drug occasionally may be useful in treating selected patients with pheochromocytoma. On the other hand, methyldopa, an inhibitor of aromatic L-amino acid decarboxylase, is—like dopa itself—successively decarboxylated and hydroxylated in its side chain to form the putative “false neurotransmitter” α-methylnorepinephrine. The use of methyldopa in the treatment of hypertension is discussed in Chapter 27. Bretylium, guanadrel, and guanethidine act by preventing the release of NE by the nerve impulse. However, such agents can transiently stimulate the release of NE because of their capacity to displace the amine from storage sites.

**Promotion of Release of the Transmitter**

**Cholinergic.** The ability of cholinergic agents to promote the release of ACh is limited presumably because ACh and other cholinomimetic agents are quaternary amines
and do not readily cross the axonal membrane into the nerve ending. The latrotoxins from black widow spider venom and stonefish are known to promote neuroexocytosis by binding to receptors on the neuronal membrane.

**Adrenergic.** Several drugs that promote the release of the adrenergic mediator already have been discussed. On the basis of the rate and duration of the drug-induced release of norepinephrine from adrenergic terminals, one of two opposing effects can predominate. Thus tyramine, ephedrine,amphetamine, and related drugs cause a relatively rapid, brief liberation of the transmitter and produce a sympathomimetic effect. On the other hand, reserpine, by blocking the vesicular amine transporter (VAMT2) uptake of amines, produces a slow, prolonged depletion of the adrenergic transmitter from adrenergic storage vesicles, where it is largely metabolized by intraneuronal MAO. The resulting depletion of transmitter produces the equivalent of adrenergic blockade. Reserpine also causes the depletion of 5-HT, DA, and possibly other, unidentified amines from central and peripheral sites, and many of its major effects may be a consequence of the depletion of transmitters other than NE.

As discussed earlier, deficiencies of tyrosine hydroxylase in humans cause a neurologic disorder (Carson and Robertson, 2002) that can be treated by supplementation with the dopamine precursor levodopa.

A syndrome caused by congenital DβH deficiency has been described; this syndrome is characterized by the absence of NE and epinephrine, elevated concentrations of DA, intact baroreflex afferent fibers and cholinergic innervation, and undetectable concentrations of plasma DβH activity (Carson and Robertson, 2002). Patients have severe orthostatic hypotension, ptosis of the eyelids, and retrograde ejaculations. Dihydroxyphenylserine (L-DOPS) has been shown to improve postural hypotension in this rare disorder. This therapeutic plasma L-DOPS, epinephrine levels are not restored, leading to speculations that PNMT may require DβH for appropriate functioning (Carson and Robertson, 2002).

**Agonist and Antagonist Actions at Receptors**

**Cholinergic.** The nicotinic receptors of autonomic ganglia and skeletal muscle are not identical; they respond differently to certain stimulating and blocking agents, and their pentameric structures contain different combinations of homologous subunits (Table 8–2). Dimethylphenylpiperazinium (DMPP) and phenyltrimethylammonium (PTMA) show some selectivity for stimulation of autonomic ganglion cells and end plates of skeletal muscle, respectively. Trimethaphan and hexamethonium are relatively selective competitive and noncompetitive ganglionic blocking agents. Although tubocurarine effectively blocks transmission at both motor end plates and autonomic ganglia, its action at the former site predominates. Succinylcholine, a depolarizing agent, produces selective neuromuscular blockade. Transmission at autonomic ganglia and the adrenal medulla is complicated further by the presence of muscarinic receptors in addition to the principal nicotinic receptors (see Chapter 12).

Various toxins in snake venoms exhibit a high degree of specificity toward cholinergic receptors. The α-neurotoxins from the Elapidae family interact with the agonist-binding site on the nicotinic receptor. α-Bungarotoxin is selective for the muscle receptor and interacts with only certain neuronal receptors, such as those containing α2 through α5 subunits. Neuronal bungarotoxin shows a wider range of inhibition of neuronal receptors. A second group of toxins, called the fasciculins, inhibits AChE. A third group of toxins, termed the muscarinic toxins (MT1 through MT2), includes partial agonists and antagonists for the muscarinic receptors. Venoms from the Viperidae family of snakes and the fish-hunting cone snails also have relatively selective toxins for nicotinic receptors.

Muscarinic ACh receptors, which mediate the effects of ACh at autonomic effector cells, now can be divided into five subclasses. Atropine blocks all the muscarinic responses to injected ACh and related cholinomimetic drugs whether they are excitatory, as in the intestine, or inhibitory, as in the heart. Newer muscarinic agonists, pirenzipine for M1, triptitramine for M2, and darifenacin for M3, show selectivity as muscarinic blocking agents. Several muscarinic antagonists show sufficient selectivity in the clinical setting to minimize the bothersome side effects seen with the nonselective agents at therapeutic doses (see Chapter 9).

**Adrenergic.** A vast number of synthetic compounds that bear structural resemblance to the naturally occurring catecholamines can interact with α and β adrenergic receptors to produce sympathomimetic effects (see Chapter 12). Phenylephrine acts selectively at α1 receptors, whereas clonidine is a selective α2 adrenergic agonist. Isoproterenol exhibits agonist activity at both β1 and β2 receptors. Preferential stimulation of cardiac β1 receptors follows the administration of dobutamine. Terbutaline is an example of a drug with relatively selective action on β2 receptors; it produces effective bronchodilation with minimal effects on the heart. The main features of adrenergic blockade, including the selectivity of various blocking agents for α and β adrenergic receptors, are considered in detail in Chapter 12. Partial dissociation of effects at β1 and β2 receptors has been achieved by subtype-selective antagonists, as exemplified by the β1 receptor antagonists metoprolol.
and atenolol, which antagonize the cardiac actions of catecholamines while causing somewhat less antagonism at bronchioles. Prazosin and yohimbine are representative of $\alpha_1$ and $\alpha_2$ receptor antagonists, respectively, although prazosin has a relatively high affinity at $\alpha_{2B}$ and $\alpha_{2C}$ subtypes compared with $\alpha_{2A}$ receptors. Several important drugs that promote the release of noradrenaline or deplete the transmitter resemble, in their effects, activators or blockers of postjunctional receptors (e.g., tyramine and reserpine, respectively).

**Interference with the Destruction of the Transmitter**

**Cholinergic.** The anti-ChE agents (see Chapter 10) constitute a chemically diverse group of compounds, the primary action of which is inhibition of AChE, with the consequent accumulation of endogenous ACh. At the neuromuscular junction, accumulation of ACh produces depolarization of end plates and flaccid paralysis. At postganglionic muscarinic effector sites, the response is either excessive stimulation resulting in contraction and secretion or an inhibitory response mediated by hyperpolarization. At ganglia, depolarization and enhanced transmission are observed.

**Adrenergic.** The reuptake of NE by the adrenergic nerve terminals by means of NET is the major mechanism for terminating its transmitter action. Interference with this process is the basis of the potentiating effect of cocaine on responses to adrenergic impulses and injected catecholamines. It also has been suggested that the antidepressant actions and some of the adverse effects of imipramine and related drugs are due to a similar action at adrenergic synapses in the CNS (Chapter 15).

Entacapone and tolcapone are nitro catechol-type COMT inhibitors. Entacapone is a peripherally acting COMT inhibitor, whereas tolcapone also inhibits COMT activity in the brain. COMT inhibition has been shown to attenuate levodopa toxicity on dopamine neurons and enhance dopamine action in the brain of patients with Parkinson disease (Chapter 22). On the other hand, nonselective MAO inhibitors, such as tranylcypromine, potentiate the effects of tyramine and may potentiate effects of neurotransmitters. While most MAO inhibitors used as antidepressants inhibit both MAO-A and MAO-B, selective MAO-A and MAO-B inhibitors are available. Selegiline is a selective and irreversible MAO-B inhibitor that also has been used as an adjunct in the treatment of Parkinson disease.

**OTHER AUTONOMIC NEUROTRANSMITTERS**

The vast majority of neurons in both the central and peripheral nervous systems contain more than one substance with potential or demonstrated activity at relevant postjunctional sites (see Chapter 14). In some cases, especially in peripheral structures, it has been possible to demonstrate that two or more such substances are contained within individual nerve terminals and are released simultaneously on nerve stimulation. Although the anatomic separation of the parasympathetic and sympathetic components of the autonomic nervous system and the actions of ACh and NE (their primary neurotransmitters) still provides the essential framework for studying autonomic function, a host of other chemical messengers such as purines, eicosanoids, NO, and peptides modulate or mediate responses that follow stimulation of the autonomic nervous system. An expanded view of autonomic neurotransmission has evolved to include instances where substances other than ACh or NE are released and may function as co-transmitters, neuromodulators, or even primary transmitters. For example, it appears that some postganglionic parasympathetic nerves utilize NO as a neurotransmitter (Toda and Okamura, 2003).

The evidence for co-transmission in the autonomic nervous system usually encompasses the following considerations:

- A portion of responses to stimulation of preganglionic or postganglionic nerves or to field stimulation of target structures persists in the presence of concentrations of muscarinic or adrenergic antagonists that completely block their respective agonists.
- The candidate substance can be detected within nerve fibers that course through target tissues.
- The substance can be recovered on microdialysis or in the venous or perfusion effluent following electrical stimulation; such release often can be blocked by tetrodotoxin.
- Effects of electrical stimulation are mimicked by the application of the substance and are inhibited in the presence of specific antagonists, neutralizing antibodies, or selective desensitization produced by prior exposure to the substance.

A more recent approach to this challenging problem is the use of knockout mice that do not express the putative co-transmitter.

A number of problems confound interpretation of such evidence. It is particularly difficult to establish that substances that fulfill all the listed criteria originate within the autonomic nervous system. In some instances, their origin can be traced to sensory fibers, to intrinsic neurons, or to nerves innervating blood vessels. Also, there may be marked synergism between the candidate substance...
and known or unknown transmitters. In knockout mice, compensatory mechanisms or transmitter redundancy may disguise even well-defined actions (Hökfelt et al., 2000). Finally, it should be recognized that the putative co-transmitter may have primarily a trophic function in maintaining synaptic connectivity or in expressing a particular receptor.

ATP and ACh coexist in cholinergic vesicles (Dowdall et al., 1974) and ATP, NPY, and catecholamine are found within storage granules in nerves and the adrenal medulla (see above). ATP is released along with the transmitters, and either it or its metabolites have a significant function in synaptic transmission in some circumstances (see below). Recently, attention has focused on the growing list of peptides that are found in the adrenal medulla, nerve fibers, or ganglia of the autonomic nervous system or in the structures that are innervated by the autonomic nervous system. This list includes the enkephalin, substance P and other tachykinins, somatostatin, gonadotropin-releasing hormone, cholecystokinin, calcitonin gene–related peptide, galanin, pituitary adenyl cyclase–activating peptide, VIP, chromogranins, and NPY (Hökfelt et al., 2000). Some of the orphan GPCRs discovered in the course of genome-sequencing projects may represent receptors for undiscovered peptides or other co-transmitters. The evidence for widespread transmitter function in the autonomic nervous system is substantial for VIP and NPY, and further discussion is confined to these peptides. The possibility that abnormalities in function of neuropeptide co-transmitters, in type 2 diabetes, e.g., contribute to disease pathogenesis remains of interest (Ahren, 2000).

Co-transmission in the Autonomic Nervous System. The evidence is substantial that ATP plays a role in sympathetic nerves as a co-transmitter with norepinephrine (Silinsky et al., 1998; Westfall et al., 1991, 2002). For example, the rodent vas deferens is supplied with a dense sympathetic innervation, and stimulation of the nerves results in a biphasic mechanical response that consists of an initial rapid twitch followed by a sustained contraction. The first phase of the response is mediated by ATP acting on postjunctional P2X receptors, whereas the second phase is mediated mainly by norepinephrine acting on \( \alpha_1 \) receptors (Sneddon and Westfall, 1984). The co-transmitters apparently are released from the same types of nerves because pretreatment with 6-hydroxydopamine, an agent that specifically destroys adrenergic nerves, abolishes both phases of the neurogenically induced biphasic contraction. It has been assumed that the sympathetic nerves store ATP and NE in the same synaptic vesicles, and therefore, on release, the two co-transmitters are released together (Stjärne, 1989). This may not always be the case, and ATP and NE may be released from separate subsets of vesicles and subject to differential regulation (Todorov et al., 1996).

While part of the metabolism of ATP, once released into the neuroeffector junction, is by extracellularly directed membrane-bound nucleotidases to ADP, AMP, and adenosine (Gordon, 1986), the majority of the metabolism occurs by the action of releasable nucleotidases. There is also evidence that ATP and its metabolites exert presynaptic modulatory effects on transmitter release by P2 receptors and receptors for adenosine. In addition to evidence showing that ATP is a co-transmitter with norepinephrine, there is also evidence that ATP may be a co-transmitter with ACh in certain postganglionic parasympathetic nerves, such as in the urinary bladder.

The NPY family of peptides is distributed widely in the central and peripheral nervous systems and consists of three members: NPY, pancreatic polypeptide, and peptide YY. NPY has been shown to be colocalized and core-leased with NE and ATP in most sympathetic nerves in the peripheral nervous system, especially those innervating blood vessels (Westfall, 2004). There is also convincing evidence that NPY exerts prejunctional modulatory effects on transmitter release and synthesis. Moreover, there are numerous examples of postjunctural interactions that are consistent with a co-transmitter role for NPY at various sympathetic neuroeffector junctions. Thus, it seems that NPY, together with NE and ATP, is the third sympathetic co-transmitter. The functions of NPY include 1) direct postjunctional contractile effects; 2) potentiation of the contractile effects of the other sympathetic co-transmitters; and 3) inhibitory modulation of the nerve stimulation–induced release of all three sympathetic co-transmitters.

Studies with selective NPY-1 antagonists provide evidence that the principal postjunctural receptor is of the Y1 subtype, although other receptors are also present at some sites and may exert physiological actions. Studies with selective NPY-1 antagonists suggest that the principal prejunctural receptor is of the Y2 subtype both in the periphery and in the CNS. Again, there is evidence for a role for other NPY receptors, and clarification awaits the further development of selective antagonists. NPY also can act prejuncturally to inhibit the release of ACh, CGRP, and substance P. In the CNS, NPY exists as a co-transmitter with catecholamine in some neurons and with peptides and mediators in others. A prominent action of NPY is the presynaptic inhibition of the release of various neurotransmitters, including NE, DA, GABA, glutamate, and 5-HT, as well as inhibition or stimulation of various neurohormones such as gonadotropin-releasing hormone, vasopressin, and oxytocin. Evidence also exists for stimulation of NE and DA release. NPY also acts on autoreceptors...
to inhibit its own release. NPY may use several mechanisms to produce its presynaptic effects, including: inhibition of Ca^{2+} channels, activation of K^+ channels, and perhaps regulation of the vesicle release complex at some point distal to Ca^{2+} entry. NPY also may play a role in several pathophysiological conditions. The further development of selective NPY agonists and antagonists should enhance understanding about the physiological and pathophysiological roles of NPY.

The pioneering studies of Hökfelt and coworkers, which demonstrated the existence of VIP and ACh in peripheral autonomic neurons, initiated interest in the possibility of peptidergic cotransmission in the autonomic nervous system. Subsequent work has confirmed the frequent association of these two substances in autonomic fibers, including parasympathetic fibers that innervate smooth muscle and exocrine glands and cholinergic sympathetic neurons that innervate sweat glands (Hökfelt et al., 2000).

The role of VIP in parasympathetic transmission has been studied most extensively in the regulation of salivary secretion. The evidence for co-transmission includes the release of VIP following stimulation of the chorda lingual nerve and the incomplete blockade by atropine of vasodilation when the frequency of stimulation is raised; the latter observation may indicate independent release of the two substances, which is consistent with histochemical evidence for storage of ACh and VIP in separate populations of vesicles. Synergism between ACh and VIP in stimulating vasodilation and secretion also has been described. VIP may be involved in parasympathetic responses in the GI tract, where it may facilitate sphincter relaxation, and the trachea.

**Nonadrenergic, Noncholinergic Transmission by Purines.**

The smooth muscle of many tissues that are innervated by the autonomic nervous system shows inhibitory junction potentials following stimulation by field electrodes. Since such responses frequently are undiminished in the presence of adrenergic and muscarinic cholinergic antagonists, these observations have been taken as evidence for the existence of nonadrenergic, noncholinergic (NANC) transmission in the autonomic nervous system.

Burnstock (1996) and colleagues have compiled compelling evidence for the existence of purinergic neurotransmission in the GI tract, genitourinary tract, and certain blood vessels; ATP has fulfilled all the criteria for a neurotransmitter listed earlier. However, in at least some circumstances, primary sensory axons may be an important source of ATP (Burnstock, 2000). Although adenosine is generated from the released ATP by ectoenzymes and releasable nucleotidases, its primary function appears to be modulatory by causing feedback inhibition of release of the transmitter.

Adenosine can be transported from the cell cytoplasm to activate extracellular receptors on adjacent cells. The efficient uptake of adenosine by cellular transporters and its rapid rate of metabolism to inosine or to adenine nucleotides contribute to its rapid turnover. Several inhibitors of adenosine transport and metabolism are known to influence extracellular adenosine and ATP concentrations (Sneddon et al., 1999).

The purinergic receptors found on the cell surface may be divided into the adenosine (P1) receptors and the receptors for ATP (P2X and P2Y receptors) (Fredholm et al., 2000). Both of the P1 and P2 receptors have various subtypes. Methylxanthines such as caffeine and theophylline preferentially block adenosine receptors (Chapter 36). There are four adenosine receptors (A_1, A_2A, A_2B, and A_3) and multiple sub-types of P2X and P2Y receptors throughout the body. The adenosine receptors and the P2Y receptors mediate their responses via G proteins, whereas the P2X receptors are a sub-family of ligand-gated ion channels (Burnstock, 2000).

**Modulation of Vascular Responses by Endothelium-Derived Factors; NO and Endothelin.**

Furchgott and colleagues demonstrated that an intact endothelium is necessary to achieve vascular relaxation in response to ACh (Furchgott, 1999). This inner cellular layer of the blood vessel now is known to modulate autonomic and hormonal effects on the contractility of blood vessels. In response to a variety of vasoactive agents and even physical stimuli, the endothelial cells release a short-lived vasodilator called endothelium-derived relaxing factor (EDRF), now known to be NO. Less commonly, an endothelium-derived hyperpolarizing factor (EDHF) and endothelium-derived contracting factor (EDCF) of as yet undefined compositions are released (Vanhoutte, 1996). EDCF formation depends on cyclooxygenase activity.

Products of inflammation and platelet aggregation (e.g., 5-HT, histamine, bradykinin, purines, and thrombin) exert all or part of their action by stimulating the production of NO. Endothelial cell–dependent mechanisms of relaxation are important in a variety of vascular beds, including the coronary circulation (Hobbs et al., 1999). Activation of specific GPCRs on endothelial cells promotes NO production. NO diffuses readily to the underlying smooth muscle and induces relaxation of vascular smooth muscle by activating the soluble form of guanylyl cyclase, which increases cyclic GMP concentrations. Nitrovasodilating drugs used to lower blood pressure or to treat ischemic heart disease probably act through conversion to or release of NO (Chapters 3 and 27). NO also has been shown to be released from certain nerves (nitrergic) innervating blood vessels and smooth muscles of the GI tract. NO has a negative inotropic action on the heart.

Alterations in the release or action of NO may affect a number of major clinical situations such as atherosclerosis (Hobbs et al., 1999; Ignarro et al., 1999). Furthermore, there is evidence suggesting that the hypotension of endotoxemia or that induced by cytokines is mediated by induction of enhanced production and release of NO; consequently, increased NO production may have pathological significance in septic shock.

Full contractile responses of cerebral arteries also require an intact endothelium. A family of peptides, termed endothelins, is stored in vascular endothelial cells. Their release onto smooth muscle promotes contraction by stimulation of endothelin receptors. Endothelins contribute to the maintenance of vascular homostasis by acting via multiple endothelin receptors (Sokolovsky, 1995) to reverse the response to NO (Rubanyi and Polokoff, 1994). In isolated cell systems, several G-protein-linked responses to endothelins are quasi-irreversible (Hilal-Dandan et al., 1997).

Muscarinic acetylcholine receptors in the peripheral nervous system occur primarily on autonomic effector cells innervated by postganglionic parasympathetic nerves. Muscarinic receptors are also present in autonomic ganglia and on some cells (e.g., vascular endothelial cells) that, paradoxically, receive little or no cholinergic innervation. Within the central nervous system (CNS), the hippocampus, cortex, and thalamus have high densities of muscarinic receptors.

Acetylcholine (ACh), the naturally occurring neurotransmitter for these receptors, has virtually no systemic therapeutic applications because its actions are diffuse, and its hydrolysis, catalyzed by both acetylcholinesterase (AChE) and plasma butyrylcholinesterase, is rapid. Muscarinic agonists mimic the effects of ACh at these sites. These agonists typically are longer-acting congeners of ACh or natural alkaloids, some of which stimulate nicotinic as well as muscarinic receptors.

The mechanisms of action of endogenous ACh at the postjunctional membranes of the effector cells and neurons that represent different types of cholinergic synapses are discussed in Chapter 8. To recapitulate, these synapses are found at: 1) autonomic effector sites innervated by postganglionic parasympathetic nerves (or, in the sweat glands, by postganglionic sympathetic nerves); 2) sympathetic and parasympathetic ganglia and the adrenal medulla, innervated by preganglionic autonomic nerves; 3) motor end plates on skeletal muscle, innervated by somatic motor nerves; and 4) certain synapses in the CNS (Krnjevic, 2004), where ACh can have either pre- or postsynaptic actions. When ACh is administered systemically, it can potentially act at all of these sites; however, as a quaternary ammonium compound, its penetration to the CNS is limited, and the amount of ACh that reaches peripheral areas with low blood flow is limited due to hydrolysis by plasma butyrylcholinesterase.

The actions of ACh and related drugs at autonomic effector sites are referred to as muscarinic, based on the observation that the alkaloid muscarine acts selectively at those sites and produces the same qualitative effects as ACh. The muscarinic, or parasympathomimetic, actions of the drugs considered in this chapter are practically equivalent to the parasympathetic effects of ACh listed in Table 8–1. Muscarinic receptors are present in autonomic ganglia and the adrenal medulla but primarily function to modulate the nicotinic actions of ACh at these sites (Chapter 11). In the CNS, muscarinic receptors are widely distributed and have a role in mediating many important responses. The differences between the actions of ACh and other muscarinic agonists are largely quantitative, with limited selectivity for one organ system or another. All of the actions of ACh and its congeners at muscarinic receptors can be blocked by atropine.

**Properties and Subtypes of Muscarinic Receptors**

Muscarinic receptors were characterized initially by analysis of the responses of cells and organ systems in the periphery and the CNS. For example, differential effects of two muscarinic agonists, bethanechol and McN-A-343, on the tone of the lower esophageal sphincter led to the initial designation of muscarinic receptors as M1 (ganglionic) and M2 (effector cell) (Goyal and Rattan, 1978). The cloning of the cDNAs that encode muscarinic receptors identified five distinct gene products (Bonner et al., 1987), now designated as...
M₁ through M₅ muscarinic receptors (Chapter 8). All of the known muscarinic receptors are G protein-coupled receptors that in turn couple to various cellular effectors (Chapter 3). Although selectivity is not absolute, stimulation of M₁, M₂, and M₃ receptors causes hydrolysis of polyphosphoinositides and mobilization of intracellular Ca²⁺ as a consequence of activation of the Gq-PLC pathway (Chapter 8), resulting in a variety of Ca²⁺-mediated responses. In contrast, M₂ and M₅ muscarinic receptors inhibit adenylyl cyclase and regulate specific ion channels via their coupling to the pertussis toxin–sensitive G proteins, G₁ and G₆ (Chapter 3).

The binding site for the endogenous agonist ACh, the orthosteric site (Neubig et al., 2003), is highly conserved among muscarinic receptor subtypes (Hulme et al., 2003). By analogy with the position of retinal in the orthosteric site of the mammalian rhodopsin receptor structure (Palczewski et al., 2000), the ACh orthosteric binding site is putatively located toward the extracellular regions of a cleft formed by several of the receptor’s seven transmembrane helices. An aspartic acid present in the N-terminal portion of the third transmembrane helix of all five muscarinic receptor subtypes is believed to form an ionic bond with the cationic quaternary nitrogen in ACh and the tertiary or quaternary nitrogen of antagonists (Caulfield and Birdsell, 1998; Wess, 1996).

The five muscarinic receptor subtypes are widely distributed in both the CNS and peripheral tissues; most cells express at least two subtypes (Abrams et al., 2006; Wess, 1996; Wess et al., 2007). Identifying the role of a specific subtype in mediating a particular muscarinic response to ACh has been difficult due to the lack of subtype-specific agonists and antagonists. More recently, gene-targeting techniques have been used to elucidate the functions of each subtype (Wess et al., 2007). These techniques have allowed the creation of mutant mice with null alleles for the genes of each of the muscarinic receptor subtypes (Gomez et al., 1999; Hamilton et al., 1997; Matsui et al., 2000; Wess, 2004; Yamada et al., 2001a, 2001b). All of these muscarinic receptor knockout mice are viable and fertile. The minimal phenotypic alteration that accompanies deletion of a single receptor subtype suggests functional redundancy between receptor subtypes in various tissues. For example, abolition of cholinergic bronchoconstriction, salivation, pupillary constriction, and bladder contraction generally requires deletion of more than a single receptor subtype. Such knockout mouse studies have resulted in an increased understanding of the physiological roles of the individual muscarinic receptor subtypes (Wess et al., 2007; Table 8–3); many of the findings are consistent with the results obtained from examining the localization of muscarinic receptor subtypes in human tissues (Abrams et al., 2006). Although there is functional redundancy, the M₁ receptor is the predominant subtype in the cholinergic control of the heart, while the M₅ receptor is the predominant subtype in the cholinergic control of smooth muscle, secretory glands, and the eye. The M₅ receptor has an important role in the modulation of nicotinic cholinergic transmission in ganglia.

Although antagonists that can discriminate between various muscarinic receptor subtypes have been identified, the development of selective agonists and antagonists has generally been difficult because of the high conservation of the orthosteric site across subtypes (Conn et al., 2009b). Muscarinic receptors seem to possess topographically distinct allosteric binding sites, with at least one being located in the extracellular loops and outermost segments of different transmembrane helices; these sites are less conserved across receptor subtypes than the orthosteric binding site and thus offer the potential for greater subtype-selective targeting (Birdsall and Lazareno, 2005; May et al., 2007). Ligands that bind to allosteric sites are called allosteric modulators, because they can change the conformation of the receptor to modulate the affinity or efficacy of the orthosteric ligand. Progress has been made in developing selective positive allosteric modulators (PAMs) as important candidates for drugs with muscarinic receptor subtype selectivity, especially in the CNS (Conn et al., 2009a, 2009b). Selective negative allosteric modulators (NAMs), which act at an allosteric site to reduce the responsiveness of specific muscarinic receptor subtype(s) to ACh, also may become important therapeutic agents in the future. In both instances, the modulators do not activate the receptor by themselves, but can potentiate (in the case of PAMs) or inhibit (in the case of NAMs) receptor activation by ACh at specific muscarinic receptor subtype(s). Allosteric agonists have also been identified that appear to mediate receptor activation through a distinct allosteric site even in the absence of an orthosteric agonist (Nawaratne et al., 2008). Another potential mechanism for achieving selectivity is through the development of hybrid, bitopic orthosteric/allosteric ligands, which interact with both the orthosteric site and an allosteric site, a mechanism recently demonstrated to explain the unique effects of the M₁ selective agonist McN-A-343 (Valant et al., 2008).

Pharmacological Effects of Acetylcholine

The influence of ACh and parasympathetic innervation on various organs and tissues was introduced in Chapter 8; a more detailed description of the effects of ACh is presented here as background for understanding the physiological basis for the therapeutic uses of the muscarinic receptor agonists and antagonists.

Cardiovascular System. ACh has four primary effects on the cardiovascular system:

- vasodilation
- decrease in heart rate (negative chronotropic effect)
- decrease in the conduction velocity in the atrioventricular (AV) node (negative dromotropic effect)
- decrease in the force of cardiac contraction (negative inotropic effect)

The last effect is of lesser significance in the ventricles than in the atria. Some of the above responses can be obscured by baroreceptor and other reflexes that dampen the direct responses to ACh.

Although ACh rarely is given systemically, its cardiac actions are important because the cardiac effects of cardiac glycosides, anti-arrhythmic agents, and many other drugs are at least partly due to changes in parasympathetic (vagal) stimulation of the heart; in addition, afferent
stimulation of the viscera during surgical interventions can reflexly increase the vagal stimulation of the heart.

The intravenous injection of a small dose of ACh produces a transient fall in blood pressure owing to generalized vasodilation (mediated by vascular endothelial NO), which is usually accompanied by reflex tachycardia. A considerably larger dose is required to see direct effects of ACh on the heart, such as eliciting bradycardia or AV nodal conduction block. The generalized vasodilation produced by exogenously administered ACh is due to the stimulation of muscarinic receptors, primarily of the M₂ subtype (Khurana et al., 2004; Lampe et al., 2004), located on vascular endothelial cells despite the apparent lack of cholinergic innervation. Occupation of the receptors by agonist activates the Gq – PLC – IP₃ pathway, leading to Ca²⁺-calmodulin-dependent activation of endothelial NO synthase and production of NO (endothelium-derived relaxing factor) (Moncada and Higgs, 1995), which diffuses to adjacent vascular smooth muscle cells and causes them to relax (Furchgott, 1999; Ignarro et al., 1999) (Chapters 3 and 8). If the endothelium is damaged, as occurs under various pathophysiological conditions, ACh acts predominantly on M₃ receptors located on vascular smooth muscle cells, causing vasoconstriction.

Although endogenous ACh does not have a significant role in the physiological regulation of peripheral vascular tone, there is evidence that baroreceptor or chemoreceptor reflexes or direct stimulation of the vagus can elicit parasympathetic coronary vasodilation mediated by ACh and the consequent production of NO by the endothelium (Feigl, 1998). However, neither parasympathetic vasodilator nor sympathetic vasoconstrictor tone plays a major role in the regulation of coronary blood flow relative to the effects of local oxygen tension, activation of K⁺ ATP channels, and autoregulatory metabolic factors such as adenosine (Berne and Levy, 2001).

ACh affects cardiac function directly and also indirectly through inhibition of the adrenergic stimulation of the heart. Cardiac effects of ACh are mediated primarily by M₂ muscarinic receptors (Stengel et al., 2000), which couple to Gq/G₁₆. The direct effects include an increase in the ACh-activated K⁺ current (Iₖ,ACh) due to activation of K-ACh channels, a decrease in the L-type Ca²⁺ current (Iₐᵥ) due to inhibition of L-type Ca²⁺ channels, and a decrease in the cardiac pacemaker current (Iₚ) due to inhibition of HCN (pacemaker) channels (DiFrancesco and Tromba, 1987). The indirect effects include a Gq-mediated decrease in cyclic AMP, which opposes and counteracts the β₂ adrenergic/G₁₆-mediated increase in cyclic AMP, and an inhibition of the release of norepinephrine from sympathetic nerve terminals. The inhibition of norepinephrine release is mediated by presynaptic M₂ and M₃ receptors, which are stimulated by ACh released from adjacent parasympathetic postganglionic nerve terminals (Trendelenburg et al., 2005). There are also presynaptic M₁ receptors that inhibit ACh release from parasympathetic postganglionic nerve terminals in the human heart (Oberhauser et al., 2001).

In the SA node, each normal cardiac impulse is initiated by the spontaneous depolarization of the pacemaker cells (Chapter 29). At a critical level (the threshold potential), this depolarization initiates an action potential. ACh slows the heart rate primarily by decreasing the rate of spontaneous depolarization; attainment of the threshold potential and the succeeding events in the cardiac cycle are therefore delayed. Until recently it was widely accepted that β-adrenergic and muscarinic cholinergic effects on heart rate resulted from regulation of the cardiac pacemaker current (Iₚ). Unexpected findings made through genetic deletion of HCN4 and pharmacological inhibition of Iₚ have generated an alternative, albeit controversial, theory involving a pacemaking function for an intracellular Ca²⁺ “clock” (Lakatta and DiFrancesco, 2009) that might mediate effects of ACh on heart rate (Lyashkov et al., 2009).

In the atria, ACh causes hyperpolarization and a decreased action potential duration by increasing Iₖ,ACh. ACh also inhibits cyclic AMP formation and norepinephrine release, decreasing atrial contractility. The rate of impulse conduction is either unaffected or may increase in response to ACh; the increase probably is due to the activation of additional Na⁺ channels in response to ACh-induced hyperpolarization. In contrast, in the AV node (which has Ca²⁺ channel-dependent action potentials; see Chapter 29), ACh slows conduction and increases the refractory period by inhibiting Iᵥ,ACh; the decrement in AV conduction is responsible for the complete heart block that may be observed when large quantities of cholinergic agonists are administered systemically. With an increase in parasympathetic (vagal) tone, such as is produced by the digitalis glycosides, the increased refractory period of the AV node can contribute to the reduction in the frequency with which aberrant atrial impulses are transmitted to the ventricles and thereby decrease the ventricular rate during atrial flutter or fibrillation.

Cholinergic (vagal) innervation of the His-Purkinje system and ventricular myocardium is sparse (Kent et al., 1974; Levy and Schwartz, 1994) and the effects of ACh are smaller than those observed in the atria and nodal tissues. In the ventricles, ACh, whether released by vagal stimulation or applied directly, has a small negative inotropic effect; this inhibition is most apparent when there is concomitant adrenergic stimulation or underlying sympathetic tone (Brodde and Michel, 1999; Levy and Schwartz, 1994; Lewis et al., 2001). Automaticity of Purkinje fibers is suppressed, and the threshold for ventricular fibrillation is increased (Kent and Epstein, 1976).

**Respiratory Tract.** The parasympathetic nervous system plays a major role in regulating bronchomotor tone. A diverse set of stimuli cause reflex increases in parasympathetic activity that contributes to bronchoconstriction. The effects of ACh on the respiratory system include not only bronchoconstriction but also increased tracheobronchial secretion and stimulation of the chemoreceptors of the carotid and aortic bodies. These effects are mediated primarily by M₃ muscarinic receptors (Fisher et al., 2004).

**Urinary Tract.** Parasympathetic sacral innervation causes detrusor muscle contraction, increased voiding pressure, and ureteral peristalsis. These responses are
difficult to observe with administered ACh because poor perfusion of visceral organs and rapid hydrolysis by plasma butyrylcholinesterase limit access of systemically administered ACh to visceral muscarinic receptors. Control of bladder contraction apparently is mediated by multiple muscarinic receptor subtypes. Receptors of the M₂ subtype appear most prevalent in the bladder, yet studies with selective antagonists and M₁ knockout mice suggest that the M₂ receptor mediates detrusor muscle contraction (Matsui et al., 2000). The M₂ receptor may act to inhibit β adrenergic receptor-mediated relaxation of the bladder and may be involved primarily in the filling stages to diminish urge incontinence (Chapple, 2000; Hegde and Eglen, 1999).

**GI Tract.** Although stimulation of vagal input to the GI tract increases tone, amplitude of contractions, and secretory activity of the stomach and intestine, such responses are inconsistently seen with administered ACh for the same reasons that urinary tract responses are difficult to observe. As in the urinary tract, muscarinic receptors of the M₂ subtype are most prevalent, but M₃ muscarinic receptors appear to be primarily responsible for mediating the cholinergic control of GI motility (Matsui et al., 2002).

**Miscellaneous Peripheral Effects.** In addition to its above-mentioned stimulatory effects on the tracheobronchial and GI secretions, ACh stimulates secretion from other glands that receive parasympathetic or sympathetic cholinergic innervation, including the lacrimal, nasopharyngeal, salivary, and sweat glands. All of these effects are mediated primarily by M₃ muscarinic receptors (Caulfield and Birdsall, 1998); M₃ receptors also contribute significantly to the cholinergic stimulation of salivary secretion (Gautam et al., 2004). When instilled into the eye, ACh produces miosis by contracting the pupillary sphincter muscle and accommodation for near vision by contracting the ciliary muscle (Chapter 64); both of these effects are mediated primarily by M₃ muscarinic receptors, but other subtypes may contribute to the ocular effects of cholinergic stimulation.

**CNS Effects.** While systemically administered ACh has limited CNS penetration, muscarinic agonists that can cross the blood-brain barrier evoke a characteristic cortical arousal or activation response, similar to that produced by injection of anticholinesterase agents or by electrical stimulation of the brainstem reticular formation. All five muscarinic receptor subtypes are found in the brain (Volpicelli and Levey, 2004), and recent studies suggest that muscarinic receptor-regulated pathways may have an important role in cognitive function, motor control, appetite regulation, nociception, and other processes (Wess et al., 2007).

**MUSCARINIC RECEPTOR AGONISTS**

Muscarinic cholinergic receptor agonists can be divided into two groups: 1) choline esters, including ACh and several synthetic esters; and 2) the naturally occurring cholinomimetic alkaloids (particularly pilocarpine, muscarine, and arecoline) and their synthetic congeners.

Of several hundred synthetic choline derivatives investigated, only methacholine, carbachol, and bethanechol (Figure 9–1) have had clinical applications. Methacholine (acetyl-β-methylcholine), the β-methyl analog of ACh, is a synthetic choline ester that differs from ACh chiefly in its greater duration and selectivity of action. Its action is more prolonged because the added methyl group increases its resistance to hydrolysis by cholinesterases. Its selectivity is reflected in a predominance of muscarinic with only minor nicotinic actions, the former manifest most clearly in the cardiovascular system (Table 9–1).

Carbachol, and its β-methyl analog, bethanechol, are unsubstituted carbamoyl esters that are almost completely resistant to hydrolysis by cholinesterases; their t₁/₂ are thus sufficiently long that they become distributed to areas of low blood flow. Carbachol retains substantial nicotinic activity, particularly on autonomic ganglia. Bethanechol has mainly muscarinic actions, with prominent effects on motility of the GI tract and urinary bladder.

![Figure 9–1. Structural formulas of acetylcholine, choline esters, and natural alkaloids that stimulate muscarinic receptors.](image-url)
The major natural alkaloid muscarinic agonists—muscarine, pilocarpine, and arecoline—have the same principal sites of action as the choline esters. Muscarine acts almost exclusively at muscarinic receptor sites, and the classification of these receptors derives from the actions of this alkaloid. Pilocarpine has a dominant muscarinic action but is a partial rather than a full agonist; the sweat glands are particularly sensitive to pilocarpine. Arecoline also acts at nicotinic receptors. Although these naturally occurring alkaloids are of great value as pharmacological tools and muscarine has toxicological significance (discussed later), present clinical use is restricted largely to the employment of pilocarpine as a sialagogue and miotic agent (Chapter 64).

History and Sources. The alkaloid muscarine was isolated from the mushroom *Amanita muscaria* by Schmiedeberg in 1869; its toxicology is discussed later. Pilocarpine is the chief alkaloid obtained from the leaflets of South American shrubs of the genus *Pilocarpus*. Although it was long known by the natives that the chewing of leaves of *Pilocarpus* plants caused salivation, the first experiments were apparently performed in 1874 by the Brazilian physician Coutinhou. The alkaloid was isolated in 1875, and shortly thereafter the actions of pilocarpine on the pupil and on the sweat and salivary glands were described by Weber. Arecoline is the chief alkaloid of areca or betel nuts, the seeds of *Areca catechu*. The red-staining betel nut is consumed as a euphoric by the natives of the Indian subcontinent and East Indies in a masticatory mixture known as betel and composed of the nut, shell lime, and leaves of *Piper betle*, a climbing species of pepper. Methacholine was synthesized and studied by Hunt and Taveau as early as 1911. Carbachol and bethanechol were synthesized and investigated in the 1930s. Methacholine was synthesized and studied by Hunt and Taveau as early as 1911. Carbachol and bethanechol were synthesized and investigated in the 1930s.

### Absorption, Distribution, and Elimination

The absorption and distribution of these compounds may be predicted from their structures: muscarine and the choline esters are quaternary amines; pilocarpine and arecoline are tertiary amines (Figure 9–1).

Because they are quaternary amines, the choline esters are poorly absorbed following oral administration and have a limited ability to cross the blood-brain barrier. Even though these drugs resist hydrolysis, the choline esters are short-acting agents due to rapid elimination by the kidneys.

Pilocarpine and arecoline, being tertiary amines, are readily absorbed and can cross the blood-brain barrier. In contrast, muscarine, a quaternary amine, is poorly absorbed. Muscarine can still, however, be toxic when ingested and can even have CNS effects. Although the specific metabolic pathways have not been elucidated, pilocarpine clearance is decreased in patients with hepatic impairment, in whom doses may need to be reduced. The natural alkaloids are primarily eliminated by the kidneys; excretion of the tertiary amines can be accelerated by acidification of the urine.

### Therapeutic Uses of Muscarinic Receptor Agonists

Muscarinic agonists are currently used in the treatment of urinary bladder disorders and xerostomia and in the diagnosis of bronchial hyperreactivity. They are also used in ophthalmology as miotic agents and for the treatment of glaucoma.

There is growing interest in the role of muscarinic receptors in cognition. The potential utility of *M₂* agonists in treating the cognitive impairment associated with Alzheimer’s disease has long been considered. Other receptor subtypes including *M₃* also appear to be involved in the regulation of cognitive function, at least in animal models (Wess et al., 2007).

<sup>a</sup>Not used therapeutically
The difficulty in developing subtype selective muscarinic receptor agonists, coupled with the lack of efficacy and the significant peripheral side effects of available muscarinic agonists, have prompted a search for other strategies for selectively activating specific muscarinic receptor subtypes, such as allosteric agonists and positive allosteric modulators (PAMs) (Conn et al., 2009b). Selective muscarinic subtype activators may be useful in the treatment of additional CNS disorders, including schizophrenia and drug addiction, and as analgesic agents (Conn et al., 2009b). For example, xanomeline, a muscarinic agonist with some selectivity for the M₁ and M₃ subtypes that was in clinical development for Alzheimer's disease, has an antipsychotic profile in animal models and therapeutic efficacy in patients with schizophrenia (Mirza et al., 2003; Shekhar et al., 2008).

**Acetylcholine.** Although rarely given systemically, ACh (MIOCHOL-E) is used topically for the induction of miosis during ophthalmologic surgery; it is instilled into the eye as a 1% solution (Chapter 64).

**Methacholine.** Methacholine (PROVOCHOLINE) is administered by inhalation for the diagnosis of bronchial airway hyperreactivity in patients who do not have clinically apparent asthma (Crapo et al., 2000). While muscarinic agonists can cause bronchoconstriction and increased tracheobronchial secretions in all individuals, asthmatic patients respond with intense bronchoconstriction and a reduction in vital capacity. Accordingly, contraindications to methacholine testing include severe airflow limitation, recent myocardial infarction or stroke, uncontrolled hypertension, or pregnancy. The response to methacholine also may be exaggerated or prolonged in patients taking β adrenergic receptor antagonists. Emergency resuscitation equipment, oxygen, and medications to treat severe bronchospasm (e.g., β₂ adrenergic receptor agonists for inhalation) should be available during testing. Methacholine is available as a powder that is diluted with 0.9% sodium chloride and administered via a nebulizer.

**Bethanechol.** Bethanechol (URECHOLINE, others) primarily affects the urinary and GI tracts. In the urinary tract, bethanechol has utility in treating urinary retention and inadequate emptying of the bladder when organic obstruction is absent, as in postoperative urinary retention, diabetic autonomic neuropathy, and certain cases of chronic hypotonic, myogenic, or neurogenic bladder (Wein, 1991); catheterization can thus be avoided. When used chronically, 10-50 mg of the drug is given orally three to four times daily; the drug should be administered on an empty stomach (i.e., 1 hour before or 2 hours after a meal) to minimize nausea and vomiting.

In the GI tract, bethanechol stimulates peristalsis, increases motility, and increases resting lower esophageal sphincter pressure. Bethanechol formerly was used to treat postoperative abdominal distention, gastric atony, gastroparesis, adynamic ileus, and gastroesophageal reflux; more efficacious therapies for these disorders are now available (Chapters 45 and 46).

**Carbachol.** Carbachol (MIOSTAT, ISOPTO CARBACHOL, others) is used topically in ophthalmology for the treatment of glaucoma and the induction of miosis during surgery; it is instilled into the eye as a 0.01-3% solution (Chapter 64).

**Pilocarpine.** Pilocarpine hydrochloride (SALAGEN, others) is used for the treatment of xerostomia that follows head and neck radiation treatments or that is associated with Sjögren’s syndrome (Porter et al., 2004; Wiseman and Faulds, 1995), an autoimmune disorder occurring primarily in women in whom secretions, particularly salivary and lacrimal, are compromised (Anaya and Talal, 1999). Provided salivary parenchyma maintains residual function, enhanced salivary secretion, ease of swallowing, and subjective improvement in hydration of the oral cavity are achieved. Side effects typify cholinergic stimulation, with sweating being the most common complaint. The usual dose is 5-10 mg three times daily; the dose should be lowered in patients with hepatic impairment.

Most contraindications, precautions, and adverse effects are predictable consequences of muscarinic receptor stimulation. Thus, important contraindications to the use of muscarinic agonists include asthma, chronic obstructive pulmonary disease, urinary or GI tract obstruction, acid-peptic disease, cardiovascular disease accompanied by bradycardia, hypotension, and hyperthyroidism (muscarinic agonists may precipitate atrial fibrillation in hyperthyroid patients). Common adverse effects include diaphoresis; diarrhea; abdominal cramps, nausea/vomiting, and other GI side effects; a sensation of tightness in the urinary bladder; difficulty in visual accommodation;
and hypotension, which can severely reduce coronary blood flow, especially if it is already compromised. These contraindications and adverse effects are generally of limited concern with topical administration for ophthalmic use.

**Toxicology**

Poisoning from the ingestion of plants containing pilocarpine, muscarine, or arecoline is characterized chiefly by exaggeration of their various parasympathomimetic effects and resembles that produced by consumption of mushrooms of the genus *Inocybe* (described in the previous section). Treatment consists of the parenteral administration of atropine in doses sufficient to cross the blood-brain barrier and measures to support the respiratory and cardiovascular systems and to counteract pulmonary edema.

**Mushroom Poisoning (Mycetism).** Mushroom poisoning has been known for centuries. The Greek poet Euripides (fifth century B.C.E.) is said to have lost his wife and three children from this cause. In recent years, the number of cases of mushroom poisoning has been increasing as the result of the current popularity of the consumption of wild mushrooms. Various species of mushrooms contain many toxins, and species within the same genus may contain distinct toxins.

Although *Amanita muscaria* is the source from which muscarine was isolated, its content of the alkaloid is so low (~0.003%) that muscarine cannot be responsible for the major toxic effects. Much higher concentrations of muscarine are present in various species of *Inocybe* and *Clitocybe*. The symptoms of intoxication attributable to muscarine develop within 30-60 minutes of ingestion; they include salivation, lacrimation, nausea, vomiting, headache, visual disturbances, abdominal colic, diarrhea, bronchospasm, bradycardia, hypotension, and shock. Treatment with atropine (1-2 mg intramuscularly every 30 minutes) effectively blocks these effects (Goldfrank, 2006; Köppel, 1993).

Intoxication produced by *A. muscaria* and related *Amanita* species arises from the neurologic and hallucinogenic properties of muscimol, ibotenic acid, and other isoxazole derivatives. These agents stimulate excitatory and inhibitory amino acid receptors. Symptoms range from irritability, restlessness, ataxia, hallucinations, and delirium to drowsiness and sedation. Treatment is mainly supportive; benzodiazepines are indicated when excitation predominates; atropine often exacerbates the delirium.

Mushrooms from *Psilocybe* and *Panaeolus* species contain psilocybin and related derivatives of tryptamine. They also cause short-lasting hallucinations. *Gyromitra* species (false morels) produce GI disorders and a delayed hepatotoxicity. The toxic substance, acetaldehyde methylformylhydrazone, is converted in the body to reactive hydrazines. Although fatalities from liver and kidney failure have been reported, they are far less frequent than with amatoxin-containing mushrooms.

The most serious form of mycetism is produced by *Amanita phalloides*, other *Amanita* species, *Leptota*, and *Galerina* species (Goldfrank, 2006). These species account for >90% of all fatal cases. Ingestion of as little as 50 g of *A. phalloides* (deadly nightcap) can be fatal. The principal toxins are the amatoxins (α- and β-amanitin), a group of cyclic octapeptides that inhibit RNA polymerase II and thereby block mRNA synthesis. This causes cell death, manifested particularly in the GI mucosa, liver, and kidneys. Initial symptoms, which often are unnoticed or when present are due to other toxins, include diarrhea and abdominal cramps. A symptom-free period lasting up to 24 hours is followed by hepatic and renal malfunction. Death occurs in 4-7 days from renal and hepatic failure (Goldfrank, 2006). Treatment is largely supportive; penicillin, thiocic acid, and silibinin may be effective antidotes, but the evidence is based largely on anecdotal studies (Köppel, 1993).

Because the severity of toxicity and treatment strategies for mushroom poisoning depend on the species ingested, their identification should be sought. Often symptomatic delay is delayed, limiting the value of gastric lavage and administration of activated charcoal. Regional poison control centers in the U.S. maintain up-to-date information on the incidence of poisoning in the region and treatment procedures.

**MUSCARINIC RECEPTOR ANTAGONISTS**

The muscarinic receptor antagonists include: 1) the naturally occurring alkaloids, atropine and scopolamine; 2) semisynthetic derivatives of these alkaloids, which primarily differ from the parent compounds in their disposition in the body or their duration of action; and 3) synthetic derivatives, some of which show selectivity for subtypes of muscarinic receptors. Noteworthy agents among the latter two categories are homatropine and tropicamide, which have a shorter duration of action than atropine, and methscopolamine, ipratropium, and tiotropium, which are quaternized and do not cross the blood-brain barrier or readily cross membranes. The synthetic derivatives possessing some degree of receptor selectivity include pirenzepine, which shows selectivity for M1 receptors; and darifenacin and solifenacin, which show selectivity for M3 receptors.

Muscarinic antagonists prevent the effects of ACh by blocking its binding to muscarinic receptors on effector cells at parasympathetic (and sympathetic cholinergic) neuroeffector junctions, in peripheral ganglia, and in the CNS. In general, muscarinic antagonists cause little blockade of nicotinic receptors. However, the quaternary ammonium antagonists generally exhibit a greater degree of nicotinic blocking activity and therefore are more likely to interfere with ganglionic or neuromuscular transmission.

While many effects of muscarinic antagonists can be predicted from an understanding of the physiological responses mediated by muscarinic receptors at parasympathetic (and sympathetic cholinergic) neuroeffector junctions, paradoxical responses are sometimes seen. For example, presynaptic muscarinic receptors of variable subtype are present on postganglionic parasympathetic nerve terminals. Since blockade of presynaptic receptors generally augments
neurotransmitter release, the presynaptic effects of muscarinic antagonists may counteract their postsynaptic receptor blockade. Blockade of the modulatory muscarinic receptors in peripheral ganglia represents an additional mechanism for paradoxical responses.

An important consideration in the therapeutic use of muscarinic antagonists is the fact that physiological functions in different organs vary in their sensitivity to muscarinic receptor blockade (Table 9–2). Small doses of atropine depress salivary and bronchial secretion and sweating. With larger doses, the pupil dilates, accommodation of the lens to near vision is inhibited, and vagal effects on the heart are blocked so that the heart rate increases. Larger doses antagonize parasympathetic control of the urinary bladder and GI tract, thereby inhibiting micturition and decreasing intestinal tone and motility. Still larger doses are required to inhibit gastric motility and particularly secretion. Thus, doses of atropine and most related muscarinic antagonists that depress gastric secretion also almost invariably affect salivary secretion, ocular accommodation, micturition, and GI motility. This hierarchy of relative sensitivities is not a consequence of differences in the affinity of atropine for the muscarinic receptors at these sites because atropine lacks selectivity toward different muscarinic receptor subtypes. More likely determinants include the degree to which the functions of various end organs are regulated by parasympathetic tone, the “spareness” of receptors and signaling mechanisms, the involvement of intramural neurons and reflexes, and the presence of other regulatory mechanisms.

Most clinically available muscarinic antagonists are nonselective and their actions differ little from those of atropine, the prototype of the group. No subtype-selective antagonist, including pirenzepine, is completely selective (i.e., can be used to define a single receptor subtype relative to all other receptor subtypes). In fact, the clinical efficacy of some agents may arise from a balance of antagonistic actions on two or more receptor subtypes.

### History

The naturally occurring muscarinic receptor antagonists atropine and scopolamine are alkaloids of the belladonna (Solanaceae) plants. Preparations of belladonna were known to the ancient Hindus and have long been used by physicians. During the time of the Roman Empire and in the Middle Ages, the deadly nightshade shrub was frequently used to produce an obscure and often prolonged poisoning, prompting Linnaeus to name the shrub *Atropa belladonna*, after Atropos, the oldest of the three Fates, who cuts the thread of life. The name *belladonna* derives from the alleged use of this preparation by Italian women to dilate their pupils; modern-day fashion models are known to use this same device for visual appeal. Atropine (d,l-hyoscyamine) also is found in *Datura stramonium* (Jamestown or jimson weed). Scopolamine (l-hyoscine) is found chiefly in *Hyoscyamus niger* (henbane). In India, the root and leaves of jimson weed were burned and the smoke inhaled to treat asthma. British colonists observed this ritual and introduced the belladonna alkaloids into western medicine in the early 1800s.

Accurate study of the actions of belladonna dates from the isolation of atropine in pure form by Mein in 1831. Bezold and Bloebaum (1867) showed that atropine blocked the cardiac effects of vagal stimulation, and Heidenhain (1872) found that it prevented salivary secretion produced by stimulation of the chorda tympani. Many semisynthetic congeners of the belladonna alkaloids and a large number of synthetic muscarinic receptor antagonists have been prepared, primarily with the objective of altering GI or bladder activity without causing dry mouth or pupillary dilation.

### Chemistry

Atropine and scopolamine are esters formed by combination of an aromatic acid, tropic acid, and complex organic bases, either tropine (tropanol) or scopine. Scopine differs from tropine only in having an oxygen bridge between the carbon atoms designated as 6 and 7 (Figure 9–2). Homatropine is a semisynthetic compound produced by combining the base tropine with mandelic acid. The corresponding quaternary ammonium derivatives, modified by the addition of a second methyl group to the nitrogen, are methylytropine nitrate, methscopolamine bromide, and homatropine methylbromide. Ipratropium and tiotropium also are quaternary tropine...
analogs esterified with synthetic aromatic acids. A similar agent, oxitropium bromide, an N-ethyl-substituted, quaternary derivative of scopolamine, is available in Europe.

Structure-Activity Relationships. An intact ester of tropine and tropic acid is essential for antimuscarinic action, since neither the free acid nor the basic alcohol exhibits significant antimuscarinic activity. The presence of a free OH group in the acyl portion of the ester also is important for activity. When given parenterally, quaternary ammonium derivatives of atropine and scopolamine are generally more potent than their parent compounds in both muscarinic and ganglionic (nicotinic) blocking activities. The quaternary derivatives, when given orally, are poorly and unreliably absorbed.

Both tropic and mandelic acids have an enantiomeric center (boldface red C in the formulas in Figure 9–2). Scopolamine is $l$-hyoscine and is much more active than $d$-hyoscine. Atropine is racemized during extraction and consists of $d,l$-hyoscyamine, but antimuscarinic activity is almost wholly due to the naturally occurring $l$ isomer. Synthetic derivatives show a wide range of structures that spatially replicate the aromatic acid and the bridged nitrogen of the tropine.

Mechanism of Action. Atropine and related compounds compete with ACh and other muscarinic agonists for a common binding site on the muscarinic receptor. Since antagonism by atropine is competitive, it can be overcome if the concentration of ACh at muscarinic receptors of the effector organ is increased sufficiently. Muscarinic receptor antagonists inhibit responses to postganglionic cholinergic nerve stimulation less effectively than they inhibit responses to injected choline esters. The difference may be explained by the fact that release of ACh by cholinergic nerve terminals occurs in close proximity to the receptors, resulting in very high concentrations of the transmitter at the receptors.

Pharmacological Effects of Muscarinic Antagonists

The pharmacological effects of atropine, the prototypical muscarinic antagonist, provide a good background for understanding the therapeutic uses of the various muscarinic antagonists. The effects of other muscarinic antagonists will be mentioned only when they differ significantly from those of atropine. The major pharmacological effects of increasing doses of atropine, summarized in Table 9–2, offer a general guide to the problems associated with administration of this class of agents.

Cardiovascular System

Heart. The main effect of atropine on the heart is to alter the rate. Although the dominant response is tachycardia, the heart rate often decreases transiently with average clinical doses (0.4–0.6 mg; Table 9–2). The slowing is modest (4–8 beats per minute) and is usually absent after rapid intravenous injection. There are no accompanying changes in blood pressure or cardiac output. This unexpected effect has been attributed to the block of presynaptic $M_1$ muscarinic receptors on
parasympathetic postganglionic nerve terminals in the SA node, which normally inhibit ACh release (Wellstein and Pitschner, 1988).

Larger doses of atropine cause progressive tachycardia by blocking M1 receptors on the SA nodal pacemaker cells, thereby antagonizing parasympathetic (vagal) tone to the heart. The resting heart rate is increased by ~35-40 beats per minute in young men given 2 mg of atropine intramuscularly. The maximal heart rate (e.g., in response to exercise) is not altered by atropine. The influence of atropine is most noticeable in healthy young adults, in whom vagal tone is considerable. In infancy and old age, even large doses of atropine may fail to accelerate the heart. Atropine often produces cardiac arrhythmias, but without significant cardiovascular symptoms.

Atropine can abolish many types of reflex vagal cardiac slowing or asystole, such as from inhalation of irritant vapors, stimulation of the carotid sinus, pressure on the eyeballs, peritoneal stimulation, or injection of contrast dye during cardiac catheterization. Atropine also prevents or abruptly abolishes bradycardia or asystole caused by choline esters, acetylcholinesterase inhibitors, or other parasympathomimetic drugs, as well as cardiac arrest from electrical stimulation of the vagus.

The removal of vagal tone to the heart by atropine also may facilitate AV conduction. Atropine shortens the functional refractory period of the AV node and can increase ventricular rate in patients who have atrial fibrillation or flutter. In certain cases of second-degree AV block (e.g., Wenckebach AV block), in which vagal activity is an etiological factor (as with digitalis toxicity), atropine may lessen the degree of block. In some patients with complete AV block, the idioventricular rate may be accelerated by atropine; in others it is stabilized. Atropine may improve the clinical condition of patients with inferior or posterior wall myocardial infarction by relieving severe sinus or nodal bradycardia or AV block.

**Circulation.** Atropine, in clinical doses, completely counteracts the peripheral vasodilation and sharp fall in blood pressure caused by choline esters. In contrast, when given alone, its effect on blood vessels and blood pressure is neither striking nor constant. This result is expected because most vascular beds lack significant cholinergic innervation. In toxic and occasionally in therapeutic doses, atropine can dilate cutaneous blood vessels, especially those in the blush area (atropine flush). This may be a compensatory reaction permitting the radiation of heat to offset the atropine-induced rise in temperature that can accompany inhibition of sweating.

**Respiratory System.** Although atropine can cause some bronchodilation and decrease in tracheobronchial secretion in normal individuals by blocking parasympathetic (vagal) tone to the lungs, its effects on the respiratory system are most significant in patients with respiratory disease. Atropine can inhibit the bronchoconstriction caused by histamine, bradykinin, and the eicosanoids, which presumably reflects the participation of reflex parasympathetic (vagal) activity in the bronchoconstriction elicited by these agents. The ability to block the indirect bronchoconstrictive effects of these mediators forms the basis for the use of muscarinic receptor antagonists, along with β adrenergic receptor agonists, in the treatment of asthma (Chapter 36). Muscarinic antagonists also have an important role in the treatment of chronic obstructive pulmonary disease (Chapter 36).

Atropine inhibits the secretions of the nose, mouth, pharynx, and bronchi, and thus dries the mucous membranes of the respiratory tract. This action is especially marked if secretion is excessive and formed the basis for the use of atropine and other muscarinic antagonists to prevent irritating inhalational anesthetics such as diethyl ether from increasing bronchial secretion. While the newer inhalational anesthetics are less irritating, muscarinic antagonists are similarly used to decrease the rhinorrhea associated with the common cold or with allergic and nonallergic rhinitis. Reduction of mucous secretion and mucociliary clearance can, however, result in mucus plugs, a potentially undesirable side effect of muscarinic antagonists in patients with airway disease.

**Eye.** Muscarinic receptor antagonists block the cholinergic responses of the pupillary sphincter muscle of the iris and the ciliary muscle controlling lens curvature (Chapter 64). Thus, they dilate the pupil (mydriasis) and paralyze accommodation (cycloplegia). The wide pupillary dilation results in photophobia; the lens is fixed for far vision, near objects are blurred, and objects may appear smaller than they are. The normal pupillary reflex constriction to light or upon convergence of the eyes is abolished. These effects can occur after either local or systemic administration of the alkaloids.

However, conventional systemic doses of atropine (0.6 mg) have little ocular effect, in contrast to equal doses of scopolamine, which cause evident mydriasis and loss of accommodation. Locally applied atropine produces ocular effects of considerable duration; accommodation and pupillary reflexes may not fully recover for 7-12 days. Other muscarinic receptor antagonists with shorter durations of action are therefore preferred as mydriatics in ophthalmologic practice (Chapter 64). Pilocarpine and choline esters (e.g., carbachol) in sufficient concentrations can reverse the ocular effects of atropine.

Muscarinic receptor antagonists administered systemically have little effect on intraocular pressure except in patients predisposed to angle-closure glaucoma, in whom the pressure may occasionally rise dangerously. The rise in pressure occurs when the anterior chamber is narrow and the iris obstructs outflow of aqueous...
GI Tract. Knowledge of the actions of muscarinic receptor agonists on the stomach and intestine led to the use of muscarinic receptor antagonists as antispasmodic agents for GI disorders and in the treatment of peptic ulcer disease. Although atropine can completely abolish the effects of ACh (and other parasympathomimetic drugs) on GI motility and secretion, it inhibits only incompletely the gastrointestinal responses to vagal stimulation. This difference, which is particularly striking in the effects of atropine on gut motility, can be attributed to the fact that preganglionic vagal fibers innervating the GI tract synapse not only with postganglionic cholinergic fibers, but also with a network of noncholinergic intramural neurons. These neurons, which form the plexuses of the enteric nervous system, utilize numerous neurotransmitters or neuromodulators including serotonin (5-HT), dopamine, and peptides, the effects of which are not blocked by atropine. Another reason that atropine only incompletely inhibits the GI responses to vagal activity is that vagal stimulation of gastrin secretion is mediated by gastrin-releasing peptide (GRP), not ACh. The parietal cell secretes acid in response to at least three agonists: gastrin, histamine, and acetylcholine; furthermore, stimulation of muscarinic receptors on enterochromaffin-like cells will cause histamine release. Atropine will inhibit the component of acid secretion that results from muscarinic stimulation of enterochromaffin cells (histamine secretors) and parietal cells (acid secretors).

Secretions. Salivary secretion is particularly sensitive to inhibition by muscarinic receptor antagonists, which can completely abolish the copious, watery secretion induced by parasympathetic stimulation. The mouth becomes dry, and swallowing and talking may become difficult. Gastric secretion during the cephalic and fasting phases is also reduced markedly by muscarinic receptor antagonists. In contrast, the intestinal phase of gastric secretion is only partially inhibited. The concentration of acid is not necessarily lowered because secretion of \( HCO_3^- \) as well as that of \( H^+ \) is blocked. The gastric cells that secrete mucin and proteolytic enzymes are more directly under vagal influence than are the acid-secreting cells, and atropine decreases their secretory function. Although muscarinic antagonists can reduce gastric secretion, the doses required also affect salivary secretion, ocular accommodation, micturition, and GI motility (Table 9–2). Thus, histamine \( H_2 \) receptor antagonists and, more recently, proton pump inhibitors have replaced muscarinic antagonists as inhibitors of acid secretion (Chapter 45).

In contrast to most muscarinic receptor antagonists, pirenzepine, which shows some selectivity for \( M_1 \) receptors, inhibits gastric acid secretion at doses that have little effect on salivation or heart rate. Since the muscarinic receptors on the parietal cells are primarily \( M_2 \) receptors and do not appear to have a high affinity for pirenzepine, the \( M_2 \) receptor responsible for alterations in gastric acid secretion is postulated to be localized in intramural ganglia (Eglen et al., 1996). Blockade of ganglionic muscarinic receptors (rather than those at the neuroeffector junction) may underlie the ability of pirenzepine to inhibit the relaxation of the lower esophageal sphincter. The physiology and pharmacology here are complex: Pirenzepine reportedly inhibits carbachol-stimulated acid secretion in KO mice lacking \( M_1 \) receptors (Aihara et al., 2005).

Motility. The parasympathetic nerves enhance both tone and motility and relax sphincters, thereby favoring the passage of gastrointestinal contents. Both in normal subjects and in patients with gastrointestinal disease, muscarinic antagonists produce prolonged inhibitory effects on the motor activity of the stomach, duodenum, jejunum, ileum, and colon, characterized by a reduction in tone and in amplitude and frequency of peristaltic contractions. Relatively large doses are needed to produce such inhibition. This probably can be explained by the ability of the enteric nervous system to regulate motility independently of parasympathetic control; parasympathetic nerves serve only to modulate the effects of the enteric nervous system (Chapter 8).

Other Smooth Muscle

Urinary Tract. Muscarinic antagonists decrease the normal tone and amplitude of contractions of the ureter and bladder, and often eliminate drug-induced enhancement of ureteral tone. However, this inhibition cannot be achieved in the absence of inhibition of salivation and lacrimation and blurring of vision (Table 9–2).

Biliary Tract. Atropine exerts a mild antispasmodic action on the gallbladder and bile ducts in humans. However, this effect usually is not sufficient to overcome or prevent the marked spasm and increase in biliary duct pressure induced by opioids. The nitrates (Chapter 27) are more effective than atropine in this respect.

Sweat Glands and Temperature. Small doses of atropine inhibit the activity of sweat glands innervated by...
sympathetic cholinergic fibers, and the skin becomes hot and dry. Sweating may be depressed enough to raise the body temperature, but only notably so after large doses or at high environmental temperatures.

**Central Nervous System.** Atropine has minimal effects on the CNS at therapeutic doses, although mild stimulation of the parasympathetic medullary centers may occur. With toxic doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, hallucinations, or delirium (see the discussion of atropine poisoning later in the chapter). With still larger doses, stimulation is followed by depression, leading to circulatory collapse and respiratory failure after a period of paralysis and coma.

In contrast to atropine, scopolamine has prominent central effects at low therapeutic doses; atropine therefore is preferred over scopolamine for many purposes. The basis for this difference is probably the greater permeation of scopolamine across the blood-brain barrier. Specifically, scopolamine in therapeutic doses normally causes CNS depression manifest as drowsiness, amnesia, fatigue, and dreamless sleep, with a reduction in rapid eye movement (REM) sleep. It also causes euphoria and can therefore be subject to abuse. The depressant and amnesic effects formerly were sought when scopolamine was used as an adjunct to anesthetic agents or for preanesthetic medication. However, in the presence of severe pain, the same doses of scopolamine can occasionally cause excitement, restlessness, hallucinations, or delirium. These excitatory effects resemble those of toxic doses of atropine. Scopolamine also is effective in preventing motion sickness, probably by blocking neural pathways from the vestibular apparatus in the inner ear to the emetic center in the brainstem.

Muscarinic receptor antagonists have long been used in the treatment of Parkinson disease. These agents can be effective adjuncts to treatment with levodopa (Chapter 22). Muscarinic receptor antagonists also are used to treat the extrapyramidal symptoms that commonly occur as side effects of conventional antipsychotic drug therapy (Chapter 16). Certain antipsychotic drugs are relatively potent muscarinic receptor antagonists (Richelson, 1999; Roth et al., 2004) and, perhaps for this reason, cause fewer extrapyramidal side effects.

**Ipratropium and Tiotropium**

The quaternary ammonium compounds ipratropium and tiotropium are used exclusively for their effects on the respiratory tract. When inhaled, their action is confined almost completely to the mouth and airways. Dry mouth is the only frequently reported side effect, as the absorption of these drugs from the lungs or the GI tract is very inefficient. The degree of bronchodilation achieved by these agents is thought to reflect the level of basal parasympathetic tone, supplemented by reflex activation of cholinergic pathways brought about by various stimuli. In normal individuals, inhalation of the drugs can provide virtually complete protection against the bronchoconstriction produced by the subsequent inhalation of such irritants as sulfur dioxide, ozone, or cigarette smoke. However, patients with atopic asthma or patients with demonstrable bronchial hyperresponsiveness are less well protected. Although these drugs cause a marked reduction in sensitivity to methacholine in asthmatic subjects, more modest inhibition of responses to challenge with histamine, bradykinin, or PGF$_{2\alpha}$ is achieved, and little protection is afforded against the bronchoconstriction induced by 5-HT or leukotrienes. A therapeutically important property of ipratropium and tiotropium is their minimal inhibitory effect on mucociliary clearance relative to atropine. Hence, the choice of these agents for use in patients with airway disease minimizes the increased accumulation of lower airway secretions encountered with atropine.

Ipratropium appears to block all subtypes of muscarinic receptors and accordingly also antagonizes the inhibition of ACh release by presynaptic M$_2$ receptors on parasympathetic postganglionic nerve terminals in the lung; the resulting increase in ACh release may counteract its blockade of M$_1$ receptor-mediated bronchoconstriction. In contrast, tiotropium shows some selectivity for M$_1$ and M$_3$ receptors; its lower affinity for M$_2$ receptors minimizes its presynaptic effect to enhance ACh release (Barnes, 2004; Disse et al., 1999)

**Absorption, Distribution, and Elimination.** The belladonna alkaloids and the tertiary synthetic and semisynthetic derivatives are absorbed rapidly from the GI tract. They also enter the circulation when applied locally to the mucosal surfaces of the body. Absorption from intact skin is limited, although efficient absorption does occur in the postauricular region for some agents (e.g., scopolamine, allowing delivery by transdermal patch). Systemic absorption of inhaled or orally ingested quaternary muscarinic receptor antagonists is limited. The quaternary ammonium derivatives of the belladonna alkaloids also penetrate the conjunctiva of the eye less readily, and central effects are lacking because the quaternary agents do not cross the blood-brain barrier. Atropine has a $t_{1/2}$ of ~4 hours; hepatic metabolism accounts for the elimination of about half of a dose; the remainder is excreted unchanged in the urine.

Ipratropium is administered as an aerosol or solution for inhalation whereas tiotropium is administered as a dry powder. As with most drugs administered by inhalation, ~90% of the dose is swallowed. Most of the swallowed drug appears in the feces. After inhalation, maximal responses usually develop over 30-90 minutes,
with tiotropium having the slower onset. The effects of ipratropium last for 4-6 hours, while tiotropium’s effects persist for 24 hours so that the drug is amenable to once-daily dosing (Barnes and Hansel, 2004).

**Therapeutic Uses of Muscarinic Receptor Antagonists**

Muscarinic receptor antagonists have been used in the treatment of a wide variety of clinical conditions, predominantly to inhibit effects of parasympathetic activity in the respiratory tract, urinary tract, GI tract, eye, and heart. Their CNS effects have resulted in their use in the treatment of Parkinson disease, the management of extrapyramidal side effects of antipsychotic drugs, and the prevention of motion sickness. The major limitation in the use of the nonselective drugs is often failure to obtain desired therapeutic responses without concomitant side effects. While the latter usually are not serious, they can be sufficiently disturbing to decrease patient compliance, particularly during long-term administration. To date, selectivity has mainly been achieved by local administration, e.g., by pulmonary inhalation or instillation in the eye, since few available muscarinic antagonists show absolute selectivity. The development of allosteric modulators that recognize sites unique to particular receptor subtypes is currently considered an important approach to the development of selective drugs for the treatment of specific clinical conditions (Conn et al., 2009b).

**Respiratory Tract.** Ipratropium (ATROVENT, others) and tiotropium (SPIRIVA) are important agents in the treatment of chronic obstructive pulmonary disease; they are less effective in most asthmatic patients (Barnes, 2004; Barnes and Hansel, 2004; Gross, 2004). These agents often are used with inhaled long-acting $\beta_2$ adrenergic receptor agonists, although there is little evidence of true synergism. Ipratropium is administered four times daily via a metered-dose inhaler or nebulizer; tiotropium is administered once daily via a dry powder inhaler. The therapeutic uses of ipratropium and tiotropium are discussed further in Chapter 36.

Ipratropium also is FDA-approved for use in nasal inhalers for the treatment of the rhinorrhea associated with the common cold or with allergic or nonallergic perennial rhinitis. Although the ability of muscarinic antagonists to reduce nasopharyngeal secretions may provide some symptomatic relief, such therapy does not affect the natural course of the condition. It is probable that the contribution of first-generation antihistamines employed in nonprescription cold medications is due primarily to their antimuscarinic properties, except in conditions with an allergic basis (Chapter 32). The uncomplicated common cold will generally last 2 weeks if treated and 14 days if untreated; cold medications may, however, ameliorate some of the symptoms.

**Genitourinary Tract.** Overactive urinary bladder can be successfully treated with muscarinic receptor antagonists. These agents can lower intravesicular pressure, increase capacity, and reduce the frequency of contractions by antagonizing parasympathetic control of the bladder; they also may alter bladder sensation during filling (Chapple et al., 2005). Muscarinic antagonists can be used to treat enuresis in children, particularly when a progressive increase in bladder capacity is the objective, and to reduce urinary frequency and increase bladder capacity in spastic paraplegia (Chapple, 2000; Goessl et al., 2000).

The muscarinic receptor antagonists indicated for overactive bladder are oxybutynin (DITROPAN, others), tolterodine (DETROL), trospium chloride (SANCTORAL), darifenacin (ENABLEX), solifenacin (VESICARE), and fesoterodine (TOVIAZ); available preparations and dosages are summarized in Table 9–3. Although some comparison trials have demonstrated small but statistically significant differences in efficacy between agents (Chapple et al., 2005), whether these efficacy differences are clinically significant is uncertain. The most important adverse reactions are consequences of muscarinic receptor blockade and include xerostomia, blurred vision, and GI side effects such as constipation and dyspepsia. CNS-related antimuscarinic effects, including drowsiness, dizziness, and confusion, can occur and are particularly problematic in elderly patients. CNS effects appear to be less likely with trospium, a quaternary amine, and with darifenacin and solifenacin; the latter agents are relatively selective for $M_3$ receptors and therefore have minimal effects on $M_1$ receptors in the CNS, which appear to play an important role in memory and cognition (Kay et al., 2006). Adverse effects can limit the tolerability of these drugs with continued use, and patient acceptance declines. Xerostomia is the most common reason for discontinuation.

Oxybutynin, the oldest of the antimuscarinics currently used to treat overactive bladder disorders, is associated with a high incidence of antimuscarinic side effects, particularly xerostomia. In an attempt to increase patient acceptance, oxybutynin is marketed as a transdermal system (OXYTROL) that is associated with a lower incidence of side effects than the oral immediate- or extended-release formulations; a topical gel formulation of oxybutynin (GELNIQUE) also appears to offer a more favorable side effect profile. Because of the extensive metabolism of oral oxybutynin by enteric and hepatic CYP3A4, higher doses are used in oral than transdermal administration; the dose may need to be reduced in patients taking drugs that inhibit CYP3A4.

Tolterodine shows selectivity for the urinary bladder in animal models and in clinical studies, resulting in greater patient acceptance; however, studies on isolated receptors do not reveal a unique subtype selectivity (Abrams et al., 1998, 1999; Chapple, 2000).
Inhibition of a particular complement of receptors in the bladder may give rise to synergism and clinical efficacy. Tolterodine is metabolized by CYP2D6 to 5-hydroxymethyltolterodine. Since this metabolite possesses similar activity to the parent drug, variations in CYP2D6 levels do not affect the net antimuscarinic activity or duration of action of the drug. However, in patients who poorly metabolize tolterodine via CYP2D6, the CYP3A4 pathway becomes important in tolterodine elimination. Because it is often difficult to assess which patients will be poor metabolizers, tolterodine doses may need to be reduced in patients taking drugs that inhibit CYP3A4 (dosage adjustments generally are not necessary in patients taking drugs that inhibit CYP2D6). Patients with significant renal or hepatic impairment also should receive lower doses of the drug.

Fesoterodine, a new agent, is a prodrug that is rapidly hydrolyzed to the active metabolite of tolterodine.

Trospium, a quaternary amine, is as effective as oxybutynin with better tolerability. Trospium is the only antimuscarinic used for overactive bladder that is eliminated primarily by the kidneys; 60% of the absorbed trospium dose is excreted unchanged in the urine, and dosage adjustment is necessary for patients with impaired renal function.

Like solifenacin, darifenacin is relatively selective for M3 receptors. It is metabolized by CYP2D6 and CYP3A4; as with tolterodine, the latter pathway becomes more important in patients who poorly metabolize the drug by CYP2D6. Darifenacin doses may need to be reduced in patients taking drugs that inhibit either of these CYPs.

Flavoxate hydrochloride, a drug with direct spasmyloitic actions on smooth muscle, especially of the urinary tract, is used for the relief of dysuria, urgency, nocturia, and other urinary symptoms associated with genitourinary disorders (e.g., cystitis, prostatitis, urethritis). Flavoxate also has weak antihistaminic, local anesthetic, analgesic, and, at high doses, antimuscarinic effects.

GI Tract. Muscarinic receptor antagonists were once widely used for the management of peptic ulcer. Although they can reduce gastric motility and the secretion of gastric acid, antisecretory doses produce pronounced side effects, such as xerostomia, loss of visual accommodation, photophobia, and difficulty in urination (Table 9–2). As a consequence, patient compliance in the long-term management of symptoms of acid-peptic disease with these drugs is poor.

Pirenzepine, a tricyclic drug similar in structure to imipramine, has selectivity for M1 over M2 and M3 receptors (Caulfield, 1993; Caulfield and Birdsall, 1998). However, pirenzepine’s affinities for M1 and M3 receptors are comparable, so it does not possess total M1 selectivity. Telenzepine, an analog of pirenzepine, has higher potency and similar selectivity for M1 muscarinic receptors. Both drugs are used in the treatment of acid-peptic disease in Europe, Japan, and Canada, but not currently in the U.S. At therapeutic doses of pirenzepine, the incidence of xerostomia,
blurred vision, and central muscarinic disturbances is relatively low. Central effects are not seen because of the drug’s limited penetration into the CNS.

Most studies indicate that pirenzepine (100-150 mg per day) produces about the same rate of healing of duodenal and gastric ulcers as the $H_2$ receptor antagonists cimetidine or ranitidine; it also may be effective in preventing the recurrence of ulcers (Carmine and Brogden, 1985; Tryba and Cook, 1997). Side effects necessitate drug withdrawal in <1% of patients. Studies in human subjects have shown pirenzepine to be more potent in inhibiting gastric acid secretion produced by neural stimuli than by muscarinic agonists, supporting the postulated localization of $M_3$ receptors at ganglionic sites. Nevertheless, $H_2$ receptor antagonists and proton pump inhibitors generally are considered to be the current drugs of choice to reduce gastric acid secretion (Chapter 45).

Myriads of conditions known or supposed to involve increased tone (spasticity) or motility of the GI tract are treated with belladonna alkaloids (e.g., atropine, hyoscymine sulfate [ANASP, others], and scopolamine) alone or in combination with sedatives (e.g., phenobarbital [DONNATAL, others]) or anti-anxiety agents (e.g., chlordiazepoxide [LIBRAX]). The belladonna alkaloids and their synthetic substitutes can reduce tone and motility when administered in maximally tolerated doses, and they might be expected to be efficacious in conditions simply involving excessive smooth muscle contraction, a point that is often in doubt. $M_3$-selective antagonists might achieve more selectivity but are unlikely to be better tolerated, as $M_1$ receptors also have an important role in the control of salivation, bronchial secretion and contraction, and bladder motility. Glycopyrrolate (ROBINAL, others), a muscarinic antagonist that is structurally unrelated to the belladonna alkaloids, also is used to reduce GI tone and motility; being a quaternary amine, it is less likely to cause adverse CNS effects than atropine, scopolamine, and other tertiary amines. Alternative agents for treatment of increased GI motility and its associated symptoms are discussed in Chapter 46.

Diarrhea associated with irritation of the lower bowel, such as mild dysenteries and diverticulitis, may respond to atropine-like drugs, an effect that likely involves actions on ion transport as well as motility. However, more severe conditions such as Salmonella dysentery, ulcerative colitis, and Crohn’s disease respond little if at all to muscarinic antagonists. The belladonna alkaloids and synthetic substitutes are very effective in reducing excessive salivation, such as drug-induced salivation and that associated with heavy-metal poisoning and Parkinson disease.

Dicyclomine hydrochloride (BENTYL, others) is a weak muscarinic receptor antagonist that also has nonspecific direct spasmolytic effects on smooth muscle of the GI tract. It is occasionally used in the treatment of diarrhea-predominant irritable bowel syndrome.

**Eye.** Effects limited to the eye are obtained by topical administration of muscarinic receptor antagonists to produce mydriasis and cycloplegia. Cycloplegia is not attainable without mydriasis and requires higher concentrations or more prolonged application of a given agent. Mydriasis often is necessary for thorough examination of the retina and optic disc and in the therapy of iridocyclitis and keratitis. The belladonna mydriatics may be alternated with miotics for breaking or preventing the development of adhesions between the iris and the lens. Complete cycloplegia may be necessary in the treatment of iridocyclitis and choroiditis and for accurate measurement of refractive errors.

Homatropine hydrobromide (ISOPTO HOMATROPINE, others), a semisynthetic derivative of atropine (Figure 9–2), cyclopentolate hydrochloride (CYCLOGYL, others), and tropicamide (MYDRIACYL, others) are agents used in ophthalmological practice. These agents are preferred to topical atropine or scopolamine because of their shorter duration of action. Additional information on the ophthalmological properties and preparations of these and other drugs is provided in Chapter 64.

**Cardiovascular System.** The cardiovascular effects of muscarinic receptor antagonists are of limited clinical utility. Generally, these agents are used only in coronary care units for short-term interventions or in surgical settings.

Atropine may be considered in the initial treatment of patients with acute myocardial infarction in whom excessive vagal tone causes sinus bradycardia or AV nodal block. Sinus bradycardia is the most common arrhythmia seen during acute myocardial infarction of the inferior or posterior wall. Atropine may prevent further clinical deterioration in cases of high vagal tone or AV block by restoring heart rate to a level sufficient to maintain adequate hemodynamic status and to eliminate AV nodal block. Dosing must be judicious; doses that are too low can cause a paradoxical bradycardia (described earlier), while excessive doses will cause tachycardia that may extend the infarct by increasing the demand for oxygen.

Atropine occasionally is useful in reducing the severe bradycardia and syncope associated with a hyperactive carotid sinus reflex. It has little effect on most ventricular rhythms. In some patients, atropine may eliminate premature ventricular contractions associated with a very slow atrial rate. It also may reduce the degree of AV block when increased vagal tone is a major factor in the conduction defect, such as the second-degree AV block that can be produced by digitalis. Selective $M_2$ receptor antagonists would be of potential utility in blocking ACh-mediated bradycardia or AV block; however, none is currently available for clinical use.

**Central Nervous System.** The belladonna alkaloids were among the first drugs to be used in the prevention of motion sickness. Scopolamine is the most effective prophylactic agent for short (4-6 hour) exposures to severe motion, and probably for exposures of up to several days. All agents used to combat motion sickness should be given prophylactically; they are much less effective after severe nausea or vomiting has developed. A transdermal preparation of scopolamine (TRANSDERM SCOP) has been shown to be highly effective when used prophylactically for the prevention of motion sickness. The drug, incorporated into a multilayered adhesive unit, is applied to the postauricular mastoid region, an area where transdermal absorption of the drug is especially
efficient, resulting in the delivery of ~ 0.5 mg of scopolamine over 72 hours.

Xerostomia is common, drowsiness is not infrequent, and blurred vision occurs in some individuals. Mydriasis and cycloplegia can occur by inadvertent transfer of the drug to the eye from the fingers after handling the patch. Rare but severe psychotic episodes have been reported. As noted earlier, the preoperative use of scopolamine to produce tranquilization and amnesia is no longer recommended. Given alone in the presence of pain or severe anxiety, scopolamine may induce outbursts of uncontrolled behavior.

For many years, the belladonna alkaloids and subsequently synthetic substitutes were the only agents helpful in the treatment of Parkinson disease. Levodopa combined with carbidopa (Sinemet) and dopamine receptor agonists are currently the most important treatments for Parkinson disease, but alternative or concurrent therapy with muscarinic receptor antagonists may be required in some patients (Chapter 22). Centrally acting muscarinic antagonists are efficacious in preventing extrapyramidal side effects such as dystonias or parkinsonian symptoms in patients treated with antipsychotic drugs (Chapter 16). The muscarinic antagonists used for Parkinson disease and drug-induced extrapyramidal symptoms include benztropine mesylate (Cogentin, others), trihexyphenidyl hydrochloride (Artane, others), and biperiden; all are tertiary amines that readily gain access to the CNS.

Current evidence based on studies using muscarinic receptor knockout mice, subtype-selective drugs, and early-stage clinical trials suggest that selective blockade of specific muscarinic receptor subtypes in the CNS may have important therapeutic applications. For example, selective M 1 and M 3 muscarinic antagonists may be efficacious for the treatment of Parkinson disease with fewer side effects than nonselective muscarinic antagonists, while selective M 4 antagonists may be useful in the treatment of obesity and associated metabolic abnormalities (Wess et al., 2007).

Uses in Anesthesia. The use of anesthetics that are relatively nonirritating to the bronchi has virtually eliminated the need for prophylactic use of muscarinic receptor antagonists. Atropine commonly is given to block responses to vagal reflexes induced by surgical manipulation of visceral organs. Atropine or glycopyrrolate is used with neostigmine to block its parasympathomimetic effects when the latter agent is used to reverse skeletal muscle relaxation after surgery (Chapter 11). Serious cardiac arrhythmias have occasionally occurred, perhaps because of the initial bradycardia produced by atropine combined with the cholinomimetic effects of neostigmine.

Anticholinesterase Poisoning. The use of atropine in large doses for the treatment of poisoning by anticholinesterase organophosphorus insecticides is discussed in Chapter 10. Atropine also may be used to antagonize the parasympathomimetic effects of pyridostigmine or other anticholinesterases administered in the treatment of myasthenia gravis. It does not interfere with the salutary effects at the skeletal neuromuscular junction. It is most useful early in therapy, before tolerance to muscarinic side effects of anticholinesterases have developed.

Other Therapeutic Uses of Muscarinic Antagonists. Methscopolamine bromide (Pamirex) is a quaternary ammonium derivative of scopolamine and therefore lacks the central actions of scopolamine. Although formerly used to treat peptic ulcer disease, at present it is primarily used in certain combination products for the temporary relief of symptoms of allergic rhinitis, sinusitis, and the common cold.

Homatropine methylbromide, the methyl derivative of homatropine, is less potent than atropine in antimuscarinic activity but four times more potent as a ganglionic blocking agent. Formerly used for the treatment of irritable bowel syndrome and peptic ulcer disease, at present it is primarily used with hydrocodone as an antitussive combination (Hycozan, others).

Contraindications and Adverse Effects

Most contraindications, precautions, and adverse effects are predictable consequences of muscarinic receptor blockade: xerostomia, constipation, blurred vision, dyspepsia, and cognitive impairment. Important contraindications to the use of muscarinic antagonists include urinary tract obstruction, GI obstruction, and uncontrolled (or susceptibility to attacks of) angle-closure glaucoma. Muscarinic receptor antagonists also are contraindicated (or should be used with extreme caution) in patients with benign prostatic hyperplasia. These adverse effects and contraindications generally are of more limited concern with muscarinic antagonists that are administered by inhalation or used topically in ophthalmology.

Toxicology of Drugs with Antimuscarinic Properties

The deliberate or accidental ingestion of natural belladonna alkaloids is a major cause of poisonings. Many histamine H 1 receptor antagonists, phenothiazines, and tricyclic antidepressants also block muscarinic receptors, and in sufficient dosage, produce syndromes that include features of atropine intoxication.

Among the tricyclic antidepressants, protriptyline and amitriptyline are the most potent muscarinic receptor antagonists, with an affinity for the receptor that is ~ one-tenth of that reported for atropine. Since these drugs are administered in therapeutic doses considerably higher than the effective dose of atropine, antimuscarinic effects are often observed clinically (Chapter 15). In addition, overdose with suicidal intent is a danger in the population using antidepressants. Fortunately, most of the newer antidepressants and selective serotonin reuptake inhibitors have more limited anticholinergic properties (Cusack et al., 1994).

Like the tricyclic antidepressants, many of the older antipsychotic drugs have antimuscarinic effects. These effects are most likely to be observed with the less potent drugs, e.g., chlorpromazine and thioridazine, which must be given in higher doses. The newer antipsychotic drugs, classified as “atypical” and characterized by their low propensity for inducing extrapyramidal side effects, also include agents that are potent muscarinic receptor antagonists. In particular, clozapine binds to human brain muscarinic receptors with high affinity (10 nM, compared to 1-2 nM for atropine); olanzapine
also is a potent muscarinic receptor antagonist (Richelson, 1999; Roth et al., 2004). Accordingly, xerostomia is a prominent side effect of these drugs. A paradoxical side effect of clozapine is increased salivation and drooling, possibly the result of partial agonist properties of this drug (Richelson, 1999).

Infants and young children are especially susceptible to the toxic effects of muscarinic antagonists. Indeed, cases of intoxication in children have resulted from conjunctival instillation for ophthalmic refraction and other ocular effects. Systemic absorption occurs either from the nasal mucosa after the drug has traversed the nasolacrimal duct or from the GI tract if the drug is swallowed. Poisoning with diphenoxylate-atropine (LOMOTIL, others), used to treat diarrhea, has been extensively reported in the pediatric literature. Transdermal preparations of scopolamine used for motion sickness have been noted to cause toxic psychoses, especially in children and in the elderly. Serious intoxication may occur in children who ingest berries or seeds containing belladonna alkaloids. Poisoning from ingestion and smoking of jimson weed is seen with some frequency today.

Table 9–2 shows the oral doses of atropine causing undesirable responses or symptoms of overdose. These symptoms are predictable results of blockade of parasympathetic innervation. In cases of full-blown atropine poisoning, the syndrome may last 48 hours or longer. Intravenous injection of the anticholinesterase agent physostigmine may be used for confirmation. If physostigmine does not elicit the expected salivation, sweating, bradycardia, and intestinal hyperactivity, intoxication with atropine or a related agent is almost certain. Depression and circulatory collapse are evident only in cases of severe intoxication; the blood pressure declines, convulsions may ensue, respiration becomes inadequate, and death due to respiratory failure may follow after a period of paralysis and coma.

Measures to limit intestinal absorption should be initiated without delay if the poison has been taken orally. For symptomatic treatment, slow intravenous injection of physostigmine rapidly abolishes the delirium and coma caused by large doses of atropine, but carries some risk of overdose in mild atropine intoxication. Since physostigmine is metabolized rapidly, the patient may again lapse into coma within 1-2 hours, and repeated doses may be needed (Chapter 10). If marked excitement is present and more specific treatment is not available, a benzodiazepine is the most suitable agent for sedation and for control of convulsions. Phenothiazines or agents with antimuscarinic activity should not be used, because their antimuscarinic action is likely to intensify toxicity. Support of respiration and control of hyperthermia may be necessary. Ice bags and alcohol sponges help to reduce fever, especially in children.

**CLINICAL SUMMARY**

Drugs that target muscarinic receptors have a wide variety of therapeutic uses. For example, muscarinic agonists are used in the treatment of urinary retention and xerostomia; muscarinic antagonists are used in the treatment of overactive bladder, chronic obstructive pulmonary disease, and increased GI motility; and both groups of agents have important uses in ophthalmology. The cloning of five distinct muscarinic receptor subtypes and their subsequent genetic deletion in mice has raised the expectation that one might greatly improve the therapeutic utility of drugs that interact with muscarinic receptors by the development of subtype-selective agonists and antagonists. By targeting unique subsets of receptors that control muscarinic responses within a particular organ, unwanted side effects that typify the use of these drugs could be avoided. Subtype-selective muscarinic receptor agonists and antagonists show particular promise in the treatment of CNS disorders such as Alzheimer’s disease and Parkinson disease. Although complete selectivity has been difficult to achieve, the development of allosteric modulators may allow enhanced selectivity and new therapeutic uses in the future.

**BIBLIOGRAPHY**

The function of acetylcholinesterase (AChE) in terminating the action of acetylcholine (ACh) at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites is considered in Chapter 8. Drugs that inhibit AChE are called anticholinesterase (anti-ChE) agents. They cause ACh to accumulate in the vicinity of cholinergic nerve terminals and thus are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems. In view of the widespread distribution of cholinergic neurons across animal species, it is not surprising that the anti-ChE agents have received extensive application as toxic agents, in the form of agricultural insecticides, pesticides, and potential chemical warfare “nerve gases.” Nevertheless, several compounds of this class are widely used therapeutically; others that cross the blood-brain barrier have been approved or are in clinical trials for the treatment of Alzheimer’s disease.

Prior to World War II, only the “reversible” anti-ChE agents were generally known, of which physostigmine is the prototype. Shortly before and during World War II, a new class of highly toxic chemicals, the organophosphates, was developed first as agricultural insecticides and later as potential chemical warfare “nerve gases.” Nevertheless, several compounds of this class are widely used therapeutically; others that cross the blood-brain barrier have been approved or are in clinical trials for the treatment of Alzheimer’s disease.

History. Physostigmine, also called eserine, is an alkaloid obtained from the Calabar or ordeal bean, the dried, ripe seed of Physostigma venenosum, a perennial plant found in tropical West Africa. The Calabar bean once was used by native tribes of West Africa as an “ordeal poison” in trials for witchcraft, in which guilt was judged by death from the poison, innocence by survival after ingestion of a bean. A pure alkaloid was isolated by Jobst and Hesse in 1864 and named physostigmine. The first therapeutic use of the drug was in 1877 by Laqueur, in the treatment of glaucoma, one of its clinical uses today. Accounts of the history of physostigmine have been presented by Karczmar (1970) and Holmstedt (2000).

After basic research elucidated the chemical basis of the activity of physostigmine, scientists began systematic investigations of a series of substituted aromatic esters of alkyl carbamic acids. Neostigmine was introduced into therapeutics in 1931 for its stimulant action on the GI tract and subsequently was reported to be effective in the symptomatic treatment of myasthenia gravis.

Remarkably, the first account of the synthesis of a highly potent organophosphorus anti-ChE, tetraethyl pyrophosphate (TEPP), was published by Clermont in 1854. It is even more remarkable that the investigator survived to report on the compound’s taste; a few drops should have been lethal. Modern investigations of the organophosphorus compounds date from the 1932 publication of Lange and Krueger on the synthesis of dimethyl and diethyl phosphorofluoridates.

Upon synthesizing ~2000 compounds, Schrader defined the structural requirements for insecticidal activity [(and, as learned subsequently, for anti-ChE) (discussed later) (Gallo and Lawryk, 1991)]. One compound in this early series, parathion (a phosphorothioate), later became the most widely used insecticide of this class. Malathion, which currently is used extensively, also contains the thionophosphorus bond found in parathion. Prior to and during World War II, the efforts of Schrader’s group were directed toward the development of chemical warfare agents. The synthesis of several compounds of much greater toxicity than parathion, such as sarin, soman, and tabun, was kept secret by the German government. Investigators in the Allied countries also followed Lange and Krueger’s lead in the search for potentially toxic compounds; diisopropyl phosphorofluoridate (diisopropyl fluorophosphate; DFP), synthesized by McCombie and Saunders, was studied most extensively by British and American scientists.
In the 1950s, a series of aromatic carbamates was synthesized and found to have substantial selective toxicity against insects and to be potent anti-ChE agents (Ecobichon, 2000).

**Structure of Acetylcholinesterase.** AChE exists in two general classes of molecular forms: simple homomeric oligomers of catalytic subunits (monomers, dimers, and tetramers) and heteromeric associations of catalytic subunits with structural subunits (Massoulié, 2000; Taylor et al., 2000). The homomeric forms are found as soluble species in the cell, presumably destined for export or for association with the outer membrane of the cell, typically through an attached glycosphospholipid. One heteromeric form, largely found in neuronal synapses, is a tetramer of catalytic subunits disulfide-linked to a 20,000-Da lipid-linked subunit and localized to the outer surface of the cell membrane. The other heteromeric form consists of tetramers of catalytic subunits, disulfide linked to each of three strands of a collagen-like structural subunit. This molecular species, whose molecular mass approaches 10^6 Da, is associated with the basal lamina of junctional areas of skeletal muscle.

Molecular cloning revealed that a single gene encodes vertebrate AChEs (Schumacher et al., 1986; Taylor et al., 2000). However, multiple gene products arise from alternative processing of the mRNA that differ only in their carboxyl-termini; the portion of the gene encoding the catalytic core of the enzyme is invariant. Hence, the individual AChE species can be expected to show identical substrate and inhibitor specificities.

A separate, structurally related gene encodes butyrylcholinesterase, which is synthesized in the liver and is primarily found in plasma (Lockridge et al., 1987). The cholinesterases define a superfamily of proteins whose structural motif is the α, β hydrolase-fold (Cygler et al., 1993). The family includes several esterases, other hydrolases not found in the nervous system, and surprisingly, proteins without hydrolase activity such as thyroglobulin and members of the spectrin and neuroligin families of proteins (Taylor et al., 2000).

The three-dimensional structures of AChEs show the active center to be nearly centrosymmetric to each subunit, residing at the base of a narrow gorge ~20 Å in depth (Bourne et al., 1995; Sussman et al., 1991). At the base of the gorge lie the residues of the catalytic triad: Ser203, His447, and Glu334 in mammals (Figure 10–1). The catalytic mechanism resembles that of other hydrolases; the serine hydroxyl group is rendered highly nucleophilic through a charge-relay system involving the carboxylate anion from glutamate, the imidazole of histidine, and the hydroxyl of serine (Figure 10–2A).

During enzymatic attack of ACh, an ester with trigonal geometry, a tetrahedral intermediate between enzyme and substrate is formed (Figure 10–2A) that collapses to an acetyl enzyme conjugate with the concomitant release of choline. The acetyl enzyme is

---

**Figure 10–1. The active center gorge of mammalian acetylcholinesterase.** Bound acetylcholine is shown by the dotted structure depicting its van der Waals radii. The crystal structure of mouse cholinesterase active center, which is virtually identical to human AChE, is shown (Bourne et al., 1995). Included are the side chains of (a) the catalytic triad, Glu334, His447, Ser203 (hydrogen bonds are denoted by the dotted lines); (b) acyl pocket, Phe295 and Phe297; (c) choline subsite, Trp86, Glu202, and Tyr337; and (d) the peripheral site: Trp286, Tyr72, Tyr124, and Asp74. Tyrosines 337 and 449 are further removed from the active center but likely contribute to stabilization of certain ligands. The catalytic triad, choline subsite, and acyl pocket are located at the base of the gorge, while the peripheral site is at the lip of the gorge. The gorge is 18-20 Å deep, with its base centrosymmetric to the subunit.
very labile to hydrolysis, which results in the formation of acetate and active enzyme (Froede and Wilson, 1971; Rosenberry, 1975). AChE is one of the most efficient enzymes known: one molecule of AChE can hydrolyze $6 \times 10^5$ ACh molecules per minute; this yields a turnover time of 100 microseconds.

**Mechanism of Action of AChE Inhibitors.** The mechanisms of the action of compounds that typify the three classes of anti-ChE agents are also shown in Figure 10–2.

Three distinct domains on AChE constitute binding sites for inhibitory ligands and form the basis for specificity differences between AChE and butyrylcholinesterase: the acyl pocket of the active center, the choline subsite of the active center, and the peripheral anionic site (Reiner and Radics, 2000; Taylor and Radics, 1994). Reversible inhibitors, such as edrophonium and tacrine, bind to the choline subsite in the vicinity of Trp86 and Glu202 (Silman and Sussman, 2000) (Figure 10–2B). Edrophonium has a brief duration of action because its quaternary structure facilitates renal elimination and it binds reversibly to the AChE active center. Additional reversible inhibitors, such as donepezil, bind with higher affinity to the active center.

Other reversible inhibitors, such as propidium and the snake peptidic toxin fasciculin, bind to the peripheral anionic site on AChE. Drugs that have a carbamoyl ester linkage, such as physostigmine and neostigmine, are hydrolyzed by AChE, but much more slowly than is ACh. The quaternary amine neostigmine and the
tertiary amine physostigmine exist as cations at physiological pH. By serving as alternate substrates to ACh (Figure 10–2C), attack by the active center serine generates the carbamoylated enzyme. The carbamoyl moiety resides in the acyl pocket outlined by Phe295 and Phe297. In contrast to the acetyl enzyme, methylcarbamoyl AChE and dimethylcarbamoyl AChE are far more stable (the t1/2 for hydrolysis of the dimethylcarbamoyl enzyme is 15–30 minutes). Sequestration of the enzyme in its carbamoylated form thus precludes the enzyme-catalyzed hydrolysis of ACh for extended periods of time. When administered systemically, the duration of inhibition by the carbamoylating agents is 3–4 hours.

The organophosphate inhibitors, such as diisopropyl fluorophosphate (DFP), serve as true hemisubstrates, since the resultant conjugate with the active center serine phosphorylated or phosphorylated is extremely stable (Figure 10–2D). The organophosphorus inhibitors are tetrahedral in configuration, a configuration that resembles the transition state formed in carboxyl ester hydrolysis. Similar to the carboxyl esters, the phosphoryl oxygen binds within the oxyanion hole of the active center. If the alkyl groups in the phosphorylated enzyme are ethyl or methyl, spontaneous regeneration of active enzyme requires several hours. Secondary (as in DFP) or tertiary alkyl groups further enhance the stability of the phosphorylated enzyme, and significant regeneration of active enzyme usually is not observed. The stability of the phosphorylated enzyme is enhanced through “aging,” which results from the loss of one of the alkyl groups. Hence, the return of AChE activity depends on synthesis of a new enzyme.

Thus, the terms reversible and irreversible as applied to the carbamoyl ester and organophosphate anti-ChE agents, respectively, reflect only quantitative differences in rates of decarbamoylation or dephosphorylation of the conjugated enzyme. Both chemical classes react covalently with the active center serine in essentially the same manner as does ACh.

**Action at Effector Organs.** The characteristic pharmacological effects of the anti-ChE agents are due primarily to the prevention of hydrolysis of ACh by AChE at sites of cholinergic transmission. Transmitter thus accumulates, enhancing the response to ACh that is liberated by cholinergic impulses or that is spontaneously released from the nerve ending. Virtually all acute effects of moderate doses of organophosphates are attributable to this action. For example, characteristic miosis that follows local application of DFP to the eye is not observed after chronic postganglionic denervation of the eye because there is no source from which to release endogenous ACh. The consequences of enhanced concentrations of ACh at motor end-plates are unique to these sites and are discussed later.

The tertiary amine and particularly the quaternary ammonium anti-ChE compounds may have additional direct actions at certain cholinergic receptor sites. For example, the effects of neostigmine on the spinal cord and neuromuscular junction are based on a combination of its anti-ChE activity and direct cholinergic stimulation.

---

**CHEMISTRY AND STRUCTURE-ACTIVITY RELATIONSHIPS**

The structure-activity relationships of anti-ChE agents are reviewed in previous editions of this book. Only agents of general therapeutic or toxicological interest are considered here.

**Noncovalent Inhibitors.** While these agents interact by reversible and noncovalent association with the active site in AChE, they differ in their disposition in the body and their affinity for the enzyme. Edrophonium, a quaternary drug whose activity is limited to peripheral nervous system synapses, has a moderate affinity for AChE. Its volume of distribution is limited and renal elimination is rapid, accounting for its short duration of action. By contrast, tacrine and donepezil (Figure 10–3) have higher affinities for AChE, are more hydrophobic, and readily cross the blood-brain barrier to inhibit AChE in the CNS. Their partitioning into lipid and their higher affinities for AChE account for their longer durations of action.

“Reversible” Carbamate Inhibitors. Drugs of this class that are of therapeutic interest are shown in Figure 10–3. Early studies showed that the essential moiety of the physostigmine molecule was the methylcarbamate of an amine-substituted phenol. The quaternary ammonium derivative neostigmine is a compound of equal or greater potency. Pyridostigmine is a close congener that also is used to treat myasthenia gravis.

An increase in anti-ChE potency and duration of action can result from the linking of two quaternary ammonium moieties. One such example is the miotic agent demecarium, which consists of two neostigmine molecules connected by a series of ten methylene groups. The second quaternary group confers additional stability to the interaction by associating with a negatively charged amino side chain, Asn74, near the rim of the gorge. Carbamoylating inhibitors with high lipid solubilities (e.g., rivastigmine), which readily cross the blood-brain barrier and have longer durations of action, are approved or in clinical trial for the treatment of Alzheimer’s disease (Cummings, 2004; Giacobini, 2000) (Chapter 22).

The carbamate insecticides carbaryl (SEVIN), propoxur (Baygon), and aldicarb (Temik), which are used extensively as garden insecticides, inhibit ChE in a fashion identical with other carbamoylating inhibitors. The symptoms of poisoning closely resemble those of the organophosphates (Baron, 1991; Ecobichon, 2000). Carbaryl has a particularly low toxicity from dermal absorption. It is used topically for control of head lice in some countries. Not all carbamates in garden formulations are ChE inhibitors; the dithiocarbamates are fungicidal.

**Organophosphorus Compounds.** The general formula for this class of ChE inhibitors is presented in Table 10–1. A great variety of substituents is possible: R1 and R2 may be alkyl, alkoxy, aryloxy, amido, mercaptan, or other groups; and X, the leaving group, typically a conjugate base of a weak acid, is a halide, cyanide, thiocyanate, phenoxy, thiophenoxy, phosphate, thiocholine, or carboxylate group.

For a compilation of the organophosphorus compounds and their toxicity, see Gallo and Lawryk (1991).

DFP produces virtually irreversible inactivation of AChE and other esterases by alkylphosphorylation. Its high lipid solubility, low molecular weight, and volatility facilitate inhalation, transdermal...
absorption, and penetration into the CNS. After desulfuration, the insecticides in current use form the dimethoxy or diethoxyphosphoryl enzyme.

The “nerve gases”—tabun, sarin, and soman—are among the most potent synthetic toxins known; they are lethal to laboratory animals in nanogram doses. Insidious employment of these agents has occurred in warfare and terrorism attacks (Nozaki and Aikawa, 1995).

Because of their low volatility and stability in aqueous solution, parathion and methylparathion were widely used as insecticides. Acute and chronic toxicity has limited their use, and potentially less hazardous compounds have replaced them for home and garden use, now largely throughout the world. These compounds are inactive in inhibiting AChE in vitro; paraoxon is the active metabolite. The phosphoryl oxygen for sulfur substitution is carried out predominantly by hepatic CYPs. This reaction also occurs in the insect, typically with more efficiency. Other insecticides possessing the phosphorothioate structure have been widely employed for home, garden, and agricultural use. These include diazinon (SPECTRACIDE, others) and chlorpyrifos (DURBAN, LORSBAN). Both of these agents have been placed under restricted use because of evidence of chronic toxicity in the newborn animal. They have been banned from indoor and outdoor residential use since 2005.

Malathion (CHEMATHION, MALA-SPRAY) also requires replacement of a sulfur atom with oxygen in vivo, conferring resistance to mammalian species. Also, this insecticide can be detoxified by hydrolysis of the carboxyl ester linkage by plasma carboxylesterases, and plasma carboxylesterase activity dictates species resistance to malathion. The detoxification reaction is much more rapid in mammals and birds than in insects (Costa et al., 2003). In recent years, malathion has been employed in aerial spraying of relatively populous areas for control of citrus orchard-destructive Mediterranean fruit flies and mosquitoes that harbor and transmit viruses harmful to human beings, such as the West Nile encephalitis virus.

Evidence of acute toxicity from malathion arises only with suicide attempts or deliberate poisoning. The lethal dose in mammals is ~1 g/kg. Exposure to the skin results in a small fraction (<10%) of systemic absorption. Malathion is used topically in the treatment of pediculosis (lice) infestations.

(Continued)
Among the quaternary ammonium organophosphorus compounds (group D in Table 10–1), only echothiophate is useful clinically and is limited to ophthalmic administration. Being positively charged, it is not volatile and does not readily penetrate the skin.

Metrifonate is a low-molecular-weight organophosphate that is spontaneously converted to the active phosphoryl ester, dimethyl 2,2-dichlorovinyl phosphate (DDVP, dichlorvos). Both metrifonate and DDVP readily cross the blood-brain barrier to inhibit AChE in the CNS. Metrifonate originally was developed for the treatment of schistosomiasis (Chapter 51). Its capacity to inhibit AChE in the CNS and its reported low toxicity led to its clinical trial in treatment of Alzheimer’s disease (Cummings, 2004); a low incidence of skeletal muscle paralysis has limited its acceptance.

### PHARMACOLOGICAL PROPERTIES

Generally, the pharmacological properties of anti-ChE agents can be predicted by knowing those loci where ACh is released physiologically by nerve impulses, the degree of nerve impulse activity, and the responses of the corresponding effector organs to ACh (see Chapter 8). The anti-ChE agents potentially can produce all the following effects:

- stimulation of muscarinic receptor responses at autonomic effector organs
- stimulation, followed by depression or paralysis, of all autonomic ganglia and skeletal muscle (nicotinic actions)
- stimulation, with occasional subsequent depression, of cholinergic receptor sites in the CNS.

Following toxic or lethal doses of anti-ChE agents, most of these effects are evident (discussed later). However, with smaller doses, particularly those used therapeutically, several modifying factors are significant. In general, compounds containing a quaternary ammonium group do not penetrate cell membranes readily; hence, anti-ChE agents in this category are absorbed poorly from the GI tract or across the skin and are excluded from the CNS by the blood-brain barrier after moderate doses. On the other hand, such compounds act preferentially at the neuromuscular junctions of skeletal muscle, exerting their action both as anti-ChE agents and as direct agonists. They have comparatively less effect at autonomic effector sites and ganglia. In contrast, the more lipid-soluble agents are well absorbed after oral administration, have ubiquitous effects at both peripheral and central cholinergic sites, and may be sequestered in lipids for long periods of time. Lipid-soluble organophosphorus agents also are well absorbed through the skin, and the volatile agents are transferred readily across the alveolar membrane (Storm et al., 2000).

The actions of anti-ChE agents on autonomic effector cells and on cortical and subcortical sites in the CNS, where the receptors are largely of the muscarinic type, are blocked by atropine. Likewise, atropine blocks some of the excitatory actions of anti-ChE agents on autonomic ganglia, since both nicotinic and muscarinic receptors are involved in ganglionic neurotransmission (Chapter 11).
The sites of action of anti-ChE agents of therapeutic importance are the CNS, eye, intestine, and the neuromuscular junction of skeletal muscle; other actions are of toxicological consequence.

**Eye.** When applied locally to the conjunctiva, anti-ChE agents cause conjunctival hyperemia and constriction of the pupillary sphincter muscle around the pupillary margin of the iris (miosis) and the ciliary muscle (block of accommodation reflex with resultant focusing to near vision). Miosis is apparent in a few minutes and can last several hours to days. Although the pupil may be “pinpoint” in size, it generally contracts further when exposed to light. The block of accommodation is more transient and generally disappears before termination of miosis. Intraocular pressure, when elevated, usually falls as the result of facilitation of outflow of the aqueous humor (Chapter 64).

**GI Tract.** In humans, neostigmine enhances gastric contractions and increases the secretion of gastric acid. After bilateral vagotomy, the effects of neostigmine on gastric motility are greatly reduced. The lower portion of the esophagus is stimulated by neostigmine; in patients with marked achalasia and dilation of the esophagus, the drug can cause a salutary increase in tone and peristalsis.

Neostigmine also augments motor activity of the small and large bowel; the colon is particularly stimulated. Atony produced by muscarinic receptor antagonists or prior surgical intervention may be overcome, propulsive waves are increased in amplitude and frequency, and movement of intestinal contents is thus promoted. The total effect of anti-ChE agents on intestinal motility probably represents a combination of actions at the ganglion cells of Auerbach’s plexus and at the smooth muscle fibers, as a result of the preservation of ACh released by the cholinergic preganglionic and postganglionic fibers, respectively (Chapter 46).

**Neuromuscular Junction.** Most of the effects of potent anti-ChE drugs on skeletal muscle can be explained adequately on the basis of their inhibition of AChE at neuromuscular junctions. However, there is good evidence for an accessory direct action of neostigmine and other quaternary ammonium anti-ChE agents on skeletal muscle. For example, the intra-arterial injection of neostigmine into chronically denervated muscle, or muscle in which AChE has been inactivated by prior administration of DFP, evokes an immediate contraction, whereas physostigmine does not.

Normally, a single nerve impulse in a terminal motor-axon branch liberates enough ACh to produce a localized depolarization (end-plate potential) of sufficient magnitude to initiate a propagated muscle action potential. The ACh released is rapidly hydrolyzed by AChE, such that the lifetime of free ACh within the nerve-muscle synapse (~200 μsec) is shorter than the decay of the end-plate potential or the refractory period of the muscle. Therefore, each nerve impulse gives rise to a single wave of depolarization. After inhibition of AChE, the residence time of ACh in the synapse increases, allowing for lateral diffusion and rebinding of the transmitter to multiple receptors. Successive stimulation of neighboring receptors to the release site in the end plate results in a prolongation of the decay time of the end-plate potential. Quanta released by individual nerve impulses are no longer isolated. This action destroys the synchrony between end-plate depolarizations and the development of the action potentials. Consequently, asynchronous excitation and fasciculations of muscle fibers occur. With sufficient inhibition of AChE, depolarization of the end plate predominates, and blockade owing to depolarization ensues (Chapter 11). When ACh persists in the synapse, it also may depolarize the axon terminal, resulting in antidromic firing of the motoneuron; this effect contributes to fasciculations that involve the entire motor unit.

The anti-ChE agents will reverse the antagonism caused by competitive neuromuscular blocking agents. Neostigmine is not effective against the skeletal muscle paralysis caused by succinylcholine; this agent also produces neuromuscular blockade by depolarization, and depolarization will be enhanced by neostigmine.

**Actions at Other Sites.** Secretory glands that are innervated by postganglionic cholinergic fibers include the bronchial, lacrimal, sweat, salivary, gastric (antral G cells and parietal cells), intestinal, and pancreatic acinar glands. Low doses of anti-ChE agents augment secretory responses to nerve stimulation, and higher doses actually produce an increase in the resting rate of secretion.

Anti-ChE agents increase contraction of smooth muscle fibers of the bronchioles and ureters, and the ureters may show increased peristaltic activity.

The cardiovascular actions of anti-ChE agents are complex, since they reflect both ganglionic and postganglionic effects of accumulated ACh on the heart and blood vessels and actions in the CNS. The predominant effect on the heart from the peripheral action of accumulated ACh is bradycardia, resulting in a fall in cardiac output. Higher doses usually cause a fall in blood pressure, often as a consequence of effects of anti-ChE agents on the medullary vasomotor centers of the CNS.

Anti-ChE agents augment vagal influences on the heart. This shortens the effective refractory period of atrial muscle fibers and increases the refractory period and conduction time at the SA and AV nodes. At the ganglionic level, accumulating ACh initially is excitatory on nicotinic receptors, but at higher concentrations, ganglionic blockade ensues as a result of persistent depolarization of the cell membrane. The excitatory action on the parasympathetic ganglion cells would tend to reinforce the diminished cardiac output, whereas the opposite sequence would result from the action of ACh on sympathetic ganglion cells. Excitation followed by inhibition also is elicited by ACh at the central medullary vasomotor and cardiac centers. All of these effects are complicated further by the hypoxemia resulting from the bronchoconstrictor and secretory actions of
increased ACh on the respiratory system; hypoxemia, in turn, can reinforce both sympathetic tone and ACh-induced discharge of epinephrine from the adrenal medulla. Hence, it is not surprising that an increase in heart rate is seen with severe ChE inhibitor poisoning. Hypoxemia probably is a major factor in the CNS depression that appears after large doses of anti- ChE agents. The CNS-stimulant effects are antagonized by larger doses of atropine, although not as completely as are the muscarinic effects at peripheral autonomic effector sites.

**Absorption, Fate, and Excretion.** Physostigmine is absorbed readily from the GI tract, subcutaneous tissues, and mucous membranes. The conjunctival instillation of solutions of the drug may result in systemic effects if measures (e.g., pressure on the inner canthus) are not taken to prevent absorption from the nasal mucosa. Parenterally administered physostigmine is largely destroyed within 2-3 hours, mainly by hydrolytic cleavage by plasma esterases; renal excretion plays only a minor role in its elimination.

Neostigmine and pyridostigmine are absorbed poorly after oral administration, such that much larger doses are needed than by the parenteral route. Whereas the effective parenteral dose of neostigmine is 0.5-2 mg, the equivalent oral dose may be 15-30 mg or more. Neostigmine and pyridostigmine are destroyed by plasma esterases, and the quaternary aromatic alcohols and parent compounds are excreted in the urine; the half-lives of these drugs are only 1-2 hours (Cohan et al., 1976).

Organophosphate anti-ChE agents with the highest risk of toxicity are highly lipid-soluble liquids; many have high vapor pressures. The less volatile agents that are commonly used as agricultural insecticides (e.g., diazinon, malathion) generally are dispersed as aerosols or as dusts adsorbed to an inert, finely particulate material. Consequently, the compounds are absorbed rapidly through the skin and mucous membranes following contact with moisture, by the lungs after inhalation, and by the GI tract after ingestion (Storm et al., 2000).

Following their absorption, most organophosphates are excreted almost entirely as hydrolysis products in the urine. Plasma and liver esterases are responsible for hydrolysis to the corresponding phosphoric and phosphonic acids. However, the CYPs are responsible for converting the inactive phosphorothioates containing a phosphorus-sulfur (thiono) bond to phosphorates with a phosphorus-oxygen bond, resulting in their activation. These enzymes also play a role in the inactivation of certain organophosphorus agents, and allelic differences are known to affect rates of metabolism (Furlong, 2007).

The organophosphate anti-ChE agents are hydrolyzed by two families of enzymes: the carboxylesterases and the paraoxonases (A-esterases). These enzymes are found in the plasma and liver and scavenge or hydrolyze a large number of organophosphates by cleaving the phosphoester, anhydride, PF, or PCN bonds. The paraoxonases are low-molecular-weight enzymes, requiring Ca^{2+} for catalysis, whose natural substrate may be lactones. Some of the isozymes are associated with high density lipoproteins, and in addition to their capacity to hydrolyze organophosphates, they may control low density lipoprotein oxidation, thereby exerting a protective effect in atherosclerosis (Harel et al., 2004; Mackness et al., 2004). Genetic polymorphisms that govern organophosphate substrate specificity and possible susceptibility to atherosclerosis have been found (Costa et al., 2003; Mackness et al., 2004). Wide variations in paraoxonase activity exist among animal species. Young animals are deficient in carboxylesterases and paraoxonases, which may account for age-related toxicities seen in newborn animals and suspected to be a basis for toxicity in human beings (Padilla et al., 2004).

Plasma and hepatic carboxylesterases (aliesterases) and plasma butyrylcholinesterase are inhibited irreversibly by organophosphates (Lockridge and Masson, 2000); their scavenging capacity for organophosphates can afford partial protection against inhibition of AChE in the nervous system. The carboxylesterases also catalyze hydrolysis of malathion and other organophosphates that contain carboxyl-ester linkages, rendering them less active or inactive. Since carboxylesterases are inhibited by organophosphates, toxicity from simultaneous exposure to two organophosphorus insecticides can be synergistic.

**TOXICOLOGY**

The toxicological aspects of the anti-ChE agents are of practical importance to clinicians. In addition to cases of accidental intoxication from the use and manufacture of organophosphorus compounds as agricultural insecticides, these agents have been used frequently for homicidal and suicidal purposes. Organophosphates account for as many as 80% of pesticide-related hospital admissions. The World Health Organization documents pesticide toxicity as a widespread global problem associated with over 200,000 deaths a year; most poisonings occur in Southeast Asia (Eddleston et al., 2008). Occupational exposure occurs most commonly by the dermal and pulmonary routes, while oral ingestion is most common in cases of non-occupational poisoning.

In the U.S., the Environmental Protection Agency (EPA), by virtue of revised risk assessments and the Food Quality Protection Act of 1996, has placed several organophosphate insecticides, including diazinon and chlorpyrifos, on restricted use and phase-out status in consumer products for home and garden use. A primary concern relates to children, since the developing nervous system may be particularly susceptible to certain of these agents (Eaton et al., 2008). The Office of Pesticide Programs of the EPA provides continuous reviews of the status of organophosphate pesticides, their
Acute Intoxication. The effects of acute intoxication by anti-ChE agents are manifested by muscarinic and nicotinic signs and symptoms, and, except for compounds of extremely low lipid solubility, by signs referable to the CNS (Costa, 2006). Systemic effects appear within minutes after inhalation of vapors or aerosols. The onset of symptoms is delayed after GI and percutaneous absorption. The duration of toxic symptoms is determined largely by the properties of the compound: its lipid solubility, whether it must be activated to form the oxon, the stability of the organophosphate-AChE bond, and whether “aging” of the phosphorylated enzyme has occurred.

After local exposure to vapors or aerosols or after their inhalation, ocular and respiratory effects generally appear first. Ocular manifestations include marked miosis, ocular pain, conjunctival congestion, diminished vision, ciliary spasm, and brow ache. With acute systemic absorption, miosis may not be evident due to sympathetic discharge in response to hypotension. In addition to rhinorrhea and hyperemia of the upper respiratory tract, respiratory responses consist of tightness in the chest and wheezing respiration, caused by the combination of bronchoconstriction and increased bronchial secretion. GI symptoms occur earliest after ingestion and include anorexia, nausea and vomiting, abdominal cramps, and diarrhea. With percutaneous absorption of liquid, localized sweating and muscle fasciculations in the immediate vicinity are generally the earliest symptoms. Severe intoxication is manifested by extreme salivation, involuntary defecation and urination, sweating, lacrimation, penile erection, bradycardia, and hypotension.

Nicotinic actions at the neuromuscular junctions of skeletal muscle usually consist of fatigability and generalized weakness, involuntary twitchings, scattered fasciculations, and eventually severe weakness and paralysis. The most serious consequence is paralysis of the respiratory muscles. Knockout mice lacking the gene encoding AChE can survive under highly supportive conditions and with a special diet, but they exhibit continuous tremors and are stunted in growth (Xie et al., 2000). Mice that selectively lack AChE expression in skeletal muscle but have normal or near normal expression in brain and organs innervated by the autonomic nervous system can reproduce, but have continuous tremors and severe compromise of skeletal muscle strength. By contrast, mice with selective reductions of CNS AChE by elimination of the exons encoding alternative splices or expression of the structural subunits influencing expression in brain yield no obvious phenotype. This arises from large compensatory reductions of acetylcholine synthesis and storage and receptor responses (Camp et al., 2008; Dobbertin et al., 2009). These studies show that cholinergic systems in the CNS adapt in development to chronically diminished hydrolytic capacity for AChE.

The broad spectrum of effects of acute AChE inhibition on the CNS includes confusion, ataxia, slurred speech, loss of reflexes, Cheyne-Stokes respiration, generalized convulsions, coma, and central respiratory paralysis. Actions on the vasomotor and other cardiovascular centers in the medulla oblongata lead to hypotension.

The time of death after a single acute exposure may range from < 5 minutes to nearly 24 hours, depending on the dose, route, agent, and other factors. The cause of death primarily is respiratory failure, usually accompanied by a secondary cardiovascular component. Peripheral muscarinic and nicotinic as well as central actions all contribute to respiratory compromise; effects include laryngospasm, bronchoconstriction, increased tracheobronchial and salivary secretions, compromised voluntary control of the diaphragm and intercostal muscles, and central respiratory depression. Blood pressure may fall to alarmingly low levels and cardiac arrhythmias intervene. These effects usually result from hypoxemia and often are reversed by assisted pulmonary ventilation.

Delayed symptoms appearing after 1-4 days and marked by persistent low blood ChE and severe muscle weakness are termed the intermediate syndrome (Lotti, 2002). Delayed neurotoxicity also may be evident after severe intoxication (discussed later).

Diagnosis and Treatment. The diagnosis of severe, acute anti-ChE intoxication is made readily from the history of exposure and the characteristic signs and symptoms. In suspected cases of milder acute or chronic intoxication, determination of the ChE activities in erythrocytes and plasma generally will establish the diagnosis (Storm et al., 2000). Although these values vary considerably in the normal population, they usually are depressed well below the normal range before symptoms are evident.

Atropine in sufficient dosage (described later in the chapter) effectively antagonizes the actions at muscarinic receptor sites, including increased tracheobronchial and salivary secretion, bronchoconstriction, bradycardia, and to a moderate extent, peripheral ganglionic and central actions. Larger doses are required to get appreciable concentrations of atropine into the CNS. Atropine is virtually without effect against the peripheral neuromuscular compromise, which can be reversed by pralidoxime (2-PAM), a cholinesterase reactivator.

In moderate or severe intoxication with an organophosphorus anti-ChE agent, the recommended adult dose of pralidoxime is 1-2 g, infused intravenously over not < 5 minutes. If weakness is not relieved or if it recurs after 20-60 minutes, the dose should be repeated. Early treatment is very important to assure that the oxime reaches the phosphorylated AChE while the latter still can be reactivated. Many of the alkylphosphates are extremely lipid soluble, and if extensive partitioning into body fat has occurred and desulfuration is required for inhibition of AChE, toxicity will persist and symptoms may recur after initial treatment. With severe toxicities from the lipid-soluble agents, it is necessary to continue treatment with atropine and pralidoxime for a week or longer.

General supportive measures also are important, including:

- termination of exposure, by removal of the patient or application of a gas mask if the atmosphere remains
contaminated, removal and destruction of contaminated clothing, copious washing of contaminated skin or mucous membranes with water, or gastric lavage • maintenance of a patent airway, including endobronchial aspiration • artificial respiration, if required, administration of oxygen • alleviation of persistent convulsions with diazepam (5-10 mg, intravenously) • treatment of shock

Atropine should be given in doses sufficient to cross the blood-brain barrier. Following an initial injection of 2-4 mg, given intravenously if possible, otherwise intramuscularly, 2 mg should be given every 5-10 minutes until muscarinic symptoms disappear, if they reappear, or until signs of atropine toxicity appear. More than 200 mg may be required on the first day. A mild degree of atropine block then should be maintained for as long as symptoms are evident. The AChE reactivators can be of great benefit in the therapy of anti-ChE intoxication (described below), but their use is supplemental to the administration of atropine.

Cholinesterase Reactivators. Although the phosphorylated esteratic site of AChE undergoes hydrolytic regeneration at a slow or negligible rate, nucleophilic agents, such as hydroxylamine (NH₂OH), hydroxamic acids (RCNOH—OH), and oximes (RCH=NOH), reactivate the enzyme more rapidly than does spontaneous hydrolysis. Researchers reasoned that selective reactivation could be achieved by a site-directed nucleophile, wherein interaction of a quaternary nitrogen with the negative subsite of the active center would place the nucleophile in close apposition to the phosphorus. This goal was achieved to a remarkable degree with pyridine-2-aldoxide methyl chloride (pralidoxime); reactivation with this compound occurs at a million times the rate of that with hydroxylamine. The oxime is oriented proximally to exert a nucleophilic attack on the phosphorus; a phosphoryloxime is formed, leaving the regenerated enzyme (Figure 10–2E).

Several bis-quaternary oximes are even more potent as reactivators for insecticide and nerve gas poisoning (described later); an example is HI-6, which is used in Europe as an antidote.

![Pralidoxime (2-PAM) and HI-6](image)

The velocity of reactivation of phosphorylated AChE by oximes depends on their accessibility to the impacted active center serine (Wong et al., 2000). Furthermore, certain phosphorylated AChEs can undergo a fairly rapid process of "aging," so that within the course of minutes or hours they become completely resistant to the reactivators. "Aging" is due to the loss of one alkoxy group, leaving a much more stable monoalkyl- or monoalkoxy-phosphoryl-AChE (Figure 10–2D and E). Organophosphorus compounds containing tertiary alkoxy groups are more prone to "aging" than are congeners containing the secondary or primary alkoxy groups. The oximes are not effective in antagonizing the toxicity of the more rapidly hydrolyzing carbamoyl ester inhibitors; since pralidoxime itself has weak anti-ChE activity, it is not recommended for the treatment of overdosage with neostigmine or physostigmine or poisoning with carbamoylating insecticides such as carbaryl.

Pharmacology, Toxicology, and Disposition. The reactivating action of oximes in vivo is most marked at the skeletal neuromuscular junction. Following a dose of an organophosphorus compound that produces total blockade of transmission, the intravenous injection of an oxime can restore the response to stimulation of the motor nerve within a few minutes. Antidotal effects are less striking at autonomic effector sites, and the quaternary ammonium group restricts entry into the CNS (Eddleston et al., 2009).

Although high doses or accumulation of oximes can inhibit AChE and cause neuromuscular blockade, they should be given until one can be assured of clearance of the offending organophosphate. Many organophosphates partition into lipid and are released slowly as the active entity. Current antidotal therapy for organophosphate exposure resulting from warfare or terrorism includes parenteral atropine, an oxime (2-PAM or HI-6), and a benzodiazepine as an anticonvulsant. The oximes and their metabolites are readily eliminated by the kidney.

Parenterally administered human butyrylcholinesterase is under development as an antidote, to scavenge the AChE inhibitor in the plasma before it reaches peripheral and central tissue sites (Cerasoli et al., 2005). Because this effect of butyrylcholinesterase is stoichiometric rather than catalytic, large quantities are required.

Delayed Neurotoxicity of Organophosphorus Compounds. Certain fluorine-containing organophosphorus anti-ChE agents (e.g., DFP, mipafox) have the property of inducing delayed neurotoxicity, a property they share with the triarylphtosphates, of which triorthocresyl phosphate (TOCP) is the classical example. This syndrome first received wide-spread attention following the demonstration that TOCP, an adulterant of Jamaica ginger, was responsible for an outbreak of thousands of cases of paralysis that occurred in the U.S. during Prohibition.

The clinical picture is that of a severe polyneuropathy manifested initially by mild sensory disturbances, ataxia, weakness, muscle fatigue and twitching, reduced tendon reflexes, and tenderness to palpation. In severe cases, the weakness may progress to flaccid paralysis and muscle wasting. Recovery may require several years and may be incomplete.

Toxicity from this organophosphate-induced delayed polyneuropathy is not dependent upon inhibition of cholinesterases; instead a distinct esterase, termed neurotoxic esterase, is linked to the lesions (Johnson, 1993). This enzyme has a specificity for hydrophobic esters, but its natural substrate and function remain unknown (Glynn, 2000). Myopathies that result in generalized necrotic lesions and changes in end-plate cytostructure also are found in experimental
animals after long-term exposure to organophosphates (De Bleecker et al., 1992).

**THERAPEUTIC USES**

Current use of anti-AChE agents is limited to four conditions in the periphery:

- atony of the smooth muscle of the intestinal tract and urinary bladder
- glaucoma
- myasthenia gravis
- reversal of the paralysis of competitive neuromuscular blocking drugs (Chapter 11)

Long-acting and hydrophobic ChE inhibitors are the only inhibitors with well-documented efficacy, albeit limited, in the treatment of dementia symptoms of Alzheimer’s disease. Physostigmine, with its shorter duration of action, is useful in the treatment of intoxication by atropine and several drugs with anticholinergic side effects (discussed later); it also is indicated for the treatment of Friedreich’s or other inherited ataxias. Edrophonium has been used for terminating attacks of paroxysmal supraventricular tachycardia.

**Available Therapeutic Agents.** The compounds described here are those commonly used as anti-ChE drugs and ChE reactivators in the U.S. Preparations used solely for ophthalmic purposes are described in Chapter 64. Conventional dosages and routes of administration are given in the later discussion of therapeutic applications.

Physostigmine salicylate (ANTILIRIUM) is available for injection. Physostigmine sulfate ophthalmic ointment and physostigmine salicylate ophthalmic solution also are available. Pyridostigmine bromide is available for oral (MESTINON) or parenteral (REGONOL, MESTINON) use. Neostigmine bromide (PROSTIGMIN) is available for oral use. Neostigmine methylsulfate (PROSTIGMIN) is marketed for parenteral injection. Ambenonium chloride (MYTELASE) is available for oral use. Tacrine (COGNEX), donepezil (ARICEPT), rivastigmine (EXELON), and galantamine (REMINYL) have been approved for the treatment of Alzheimer’s disease.

Pralidoxime chloride (PROTAPAM CHLORIDE) is the only AChE reactivator currently available in the U.S. and can be obtained in a parenteral formulation. HI-6 is available in several European and Near Eastern countries.

**Paralytic Ileus and Atony of the Urinary Bladder.** In the treatment of both these conditions, neostigmine generally is preferred among the anti-ChE agents. Directly acting muscarinic agonists (Chapter 9) are employed for the same purposes.

Neostigmine is used for the relief of abdominal distension and acute colonic pseudo-obstruction from a variety of medical and surgical causes (Ponec et al., 1999). The usual subcutaneous dose of neostigmine methylsulfate for postoperative paralytic ileus is 0.5 mg, given as needed. Peristaltic activity commences 10-30 minutes after parenteral administration, whereas 2-4 hours are required after oral administration of neostigmine bromide (15-30 mg). It may be necessary to assist evacuation with a small low enema or gas with a rectal tube.

When neostigmine is used for the treatment of atony of the detrusor muscle of the urinary bladder, postoperative dysuria is relieved, and the time interval between operation and spontaneous urination is shortened. The drug is used in a similar dose and manner as in the management of paralytic ileus. Neostigmine should not be used when the intestine or urinary bladder is obstructed, when peritonitis is present, when the viability of the bowel is doubtful, or when bowel dysfunction results from inflammatory bowel disease.

**Glaucmoma and Other Ophthalmologic Indications.** Glaucoma is a complex disease characterized by an increase in intraocular pressure that, if sufficiently high and persistent, leads to damage to the optic disc at the juncture of the optic nerve and the retina; irreversible blindness can result. Of the three types of glaucoma—primary, secondary, and congenital—anti-AChE agents are of value in the management of the primary as well as of certain categories of the secondary type (e.g., aphakic glaucoma, following cataract extraction); congenital glaucoma rarely responds to any therapy other than surgery. Primary glaucoma is subdivided into narrow-angle (acute congestive) and wide-angle (chronic simple) types, based on the configuration of the angle of the anterior chamber where the aqueous humor is reabsorbed.

Narrow-angle glaucoma is nearly always a medical emergency in which drugs are essential in controlling the acute attack, but the long-range management is often surgical (e.g., peripheral or complete iridectomy). Wide-angle glaucoma, on the other hand, has a gradual, insidious onset and is not generally amenable to surgical improvement; in this type, control of intraocular pressure usually is dependent upon continuous drug therapy.

Since the cholinergic agonists and ChE inhibitors also block accommodation and induce myopia, these agents produce transient blurring of far vision, limited visual acuity in low light, and loss of vision at the margin when instilled in the eye. With long-term administration of the cholinergic agonists and anti-ChE agents, the compromise of vision diminishes. Nevertheless, other agents without these side effects, such as β adrenergic receptor antagonists, prostaglandin analogs, or carbonic anhydrase inhibitors, have become the primary topical therapies for open-angle glaucoma (Alward, 1998), with AChE inhibitors held in reserve for the chronic conditions when patients become refractory to the above agents. Topical treatment with long-acting ChE inhibitors such as echothiophate gives rise to symptoms characteristic of systemic ChE inhibition. Echothiophate treatment in advanced glaucoma may be associated with the production of cataracts (Alward, 1998).
Anti-ChE agents have been employed locally in the treatment of a variety of other less common ophthalmologic conditions, including accommodative esotropia and myasthenia gravis confined to the extraocular and eyelid muscles. Adie (or tonic pupil) syndrome results from dysfunction of the ciliary body, perhaps because of local nerve degeneration. Low concentrations of physostigmine are reported to decrease the blurred vision and pain associated with this condition. In alternation with a mydriatic drug such as atropine, short-acting anti-ChE agents have proven useful for breaking adhesions between the iris and the lens or cornea. (For a complete account of the use of anti-ChE agents in ocular therapy, see Chapter 64).

Myasthenia Gravis. Myasthenia gravis is a neuromuscular disease characterized by weakness and marked fatigability of skeletal muscle (Drachman, 1994); exacerbations and partial remissions occur frequently. The similarity between the symptoms of myasthenia gravis and curare poisoning in animals suggested to Jolly that physostigmine, an agent known to antagonize curare, might be of therapeutic value. Forty years elapsed before his suggestion was given systematic trial.

The defect in myasthenia gravis is in synaptic transmission at the neuromuscular junction. When a motor nerve of a normal subject is stimulated at 25 Hz, electrical and mechanical responses are well sustained. A suitable margin of safety exists for maintenance of neuromuscular transmission. Initial responses in the myasthenic patient may be normal, but they diminish rapidly, consistent with the rapid muscle fatigue seen in patients.

The relative importance of prejunctional and postjunctional defects in myasthenia gravis was a matter of considerable debate until Patrick and Lindstrom found that rabbits immunized with the nicotinic receptor purified from electric eels slowly developed muscular weakness and respiratory difficulties that resembled the symptoms of myasthenia gravis. The rabbits also exhibited decremental responses following repetitive nerve stimulation, enhanced sensitivity to curare, and following the administration of anti-ChE agents, symptomatic and electrophysiological improvement of neuromuscular transmission. This animal model prompted intense investigation into whether the natural disease represented an autoimmune response directed toward the ACh receptor. Anti-receptor antibodies are detectable in sera of 90% of patients with the disease, although the clinical status of the patient does not correlate precisely with antibody titer (Drachman, 1994; Lindstrom, 2000). Sequences and the structural location in the α1 subunit constituting the main immunogenic region are well defined (Lindstrom 2008).

The picture that emerges is that myasthenia gravis is caused by an autoimmune response primarily to the ACh receptor at the post-junctional end plate. These antibodies reduce the number of receptors detectable either by snake α-neurotoxin-binding assays (Fambrough et al., 1973) or by electrophysiological measurements of ACh sensitivity (Drachman, 1994). Immune complexes along with marked ultrastructural abnormalities appear in the synaptic cleft and enhance receptor degradation through complement-mediated lysis in the end plate. A related disease that also compromises neuromuscular transmission is Lambert-Eaton syndrome. Here, antibodies are directed against Ca2+ channels that are necessary for presynaptic release of ACh (Lang et al., 1998).

In a subset of ~10% of patients presenting with a myasthenic syndrome, muscle weakness has a congenital rather than an autoimmune basis. Characterization of biochemical and genetic bases of the congenital condition has shown mutations to occur in the acetylcholine receptor which affect ligand-binding and channel-opening kinetics and durations (Engel et al., 2008; Sine and Engel, 2006). Other mutations occur as a deficiency in the form of AChE that contains the collagen-like tail unit. As expected, following administration of anti-ChE agents (see following discussion), subjective improvement is not seen in most congenital myasthenic patients, although some of the above channel syndromes can be ameliorated pharmacologically.

Diagnosis. Although the diagnosis of autoimmune myasthenia gravis usually can be made from the history, signs, and symptoms, its differentiation from certain neuasthenic, infectious, endocrine, congenital, neoplastic, and degenerative neuromuscular diseases can be challenging. However, myasthenia gravis is the only condition in which the aforementioned deficiencies can be improved dramatically by anti-ChE medication. The edrophonium test for evaluation of possible myasthenia gravis is performed by rapid intravenous injection of 2 mg of edrophonium chloride, followed 45 seconds later by an additional 8 mg if the first dose is without effect; a positive response consists of brief improvement in strength, unaccompanied by lingual fasciculation (which generally occurs in non-myasthenic patients).

An excessive dose of an anti-ChE drug results in a cholinergic crisis. The condition is characterized by weakness resulting from generalized depolarization of the motor end plate; other features result from overstimulation of muscarinic receptors. The weakness resulting from depolarization blockade may resemble myasthenic weakness, which is manifest when anti-ChE medication is insufficient. The distinction is of obvious practical importance, since the former is treated by withholding, and the latter by administering, the anti-ChE agent. When the edrophonium test is performed cautiously, limiting the dose to 2 mg and with facilities for respiratory resuscitation available, a further decrease in strength indicates cholinergic crisis, while improvement signifies myasthenic weakness. Atropine sulfate, 0.4-0.6 mg or more intravenously, should be given immediately if a severe muscarinic reaction ensues (for complete details, see Drachman, 1994; Osserman et al., 1972). Detection of anti-receptor antibodies in muscle biopsies or plasma is now widely employed to establish the diagnosis.

Treatment. Pyridostigmine, neostigmine, and ambenonium are the standard anti-ChE drugs used in the symptomatic treatment of myasthenia gravis. All can increase the response of myasthenic muscle to repetitive nerve impulses, primarily by the preservation of endogenous ACh. Following AChE inhibition, receptors over a greater cross-sectional area of the end plate presumably are exposed to concentrations of ACh that are sufficient for channel opening and production of a postsynaptic end-plate potential.
When the diagnosis of myasthenia gravis has been established, the optimal single oral dose of an anti-ChE agent can be determined empirically. Baseline recordings are made for grip strength, vital capacity, and a number of signs and symptoms that reflect the strength of various muscle groups. The patient then is given an oral dose of pyridostigmine (30-60 mg), neostigmine (7.5-15 mg), or ambenonium (2.5-5 mg). The improvement in muscle strength and changes in other signs and symptoms are noted at frequent intervals until there is a return to the basal state. After an hour or longer in the basal state, the drug is given again, with the dose increased to one and one-half times the initial amount, and the same observations are repeated. This sequence is continued, with increasing increments of one-half the initial dose, until an optimal response is obtained.

The duration of action of these drugs is such that the interval between oral doses required to maintain muscle strength usually is 2-4 hours for neostigmine, 3-6 hours for pyridostigmine, or 3-8 hours for ambenonium. However, the dose required may vary from day to day; physical or emotional stress, intercurrent infections, and medication usually necessitate an increase in the frequency or size of the dose. Unpredictable exacerbations and remissions of the myasthenic state may require adjustment of dosage. Pyridostigmine is available in sustained-release tablets containing a total of 180 mg, of which 60 mg is released immediately and 120 mg over several hours; this preparation is of value in maintaining patients for 6–8-hour periods, but should be limited to use at bedtime. Muscarinic cardiovascular and GI side effects of anti-ChE agents generally can be controlled by atropine or other anticholinergic drugs (Chapter 9). However, these anticholinergic drugs mask many side effects of an excessive dose of an anti-ChE agent. In most patients, tolerance develops eventually to the muscarinic effects. Several drugs, including curariform agents and certain antibiotics and general anesthetics, interfere with neuromuscular transmission (Chapter 11); their administration to patients with myasthenia gravis requires proper adjustment of anti-ChE dosage and other precautions.

Other therapeutic measures are essential elements in the management of this disease. Glucocorticoids promote clinical improvement in a high percentage of patients. However, when treatment with steroids is continued over prolonged periods, a high incidence of side effects may result (Chapter 42). Gradual lowering of maintenance doses and alternate-day regimens of short-acting steroids are used to minimize side effects. Initiation of steroid treatment augments muscle weakness; however, as the patient improves with continued administration of steroids, doses of anti-ChE drugs can be reduced (Drachman, 1994). Other immunosuppressive agents such as azathioprine and cyclosporine also have been beneficial in more advanced cases (Chapter 35).

Thymectomy should be considered in myasthenia associated with a thymoma or when the disease is not controlled adequately by anti-ChE agents and steroids. The relative risks and benefits of the surgical procedure versus anti-ChE and glucocorticoid treatment require careful assessment. Since the thymus contains myoid cells with nicotinic receptors (Schlupe et al., 1987), and a predominance of patients have thymic abnormalities, the thymus may be responsible for the initial pathogenesis. It also is the source of autoreactive T-helper cells.

In keeping with the presumed autoimmune etiology of myasthenia gravis, plasmapheresis and immune therapy have proven beneficial in patients who have remained disabled in the face of other treatments (Drachman, 1994, 1996). Improvement in muscle strength correlates with the reduction of the titer of antibody directed against the nicotinic ACh receptor.

Prophylaxis in Cholinesterase Inhibitor Poisoning. Studies in experimental animals have shown that pretreatment with pyridostigmine reduces the incapacitation and mortality associated with nerve agent poisoning, particularly for agents such as soman that show rapid aging. The first large-scale administration of pyridostigmine to humans occurred in 1990 in anticipation of nerve-agent attack in the first Persian Gulf War. At an oral dose of 30 mg every 8 hours, the incidence of side effects was around 1%, but fewer than 0.1% of the subjects had responses sufficient to warrant discontinuing the drug in the setting of military action (Keeler et al., 1991). Long-term follow-up indicates that veterans of the Persian Gulf War who received pyridostigmine showed a low incidence of a neurologic syndrome, now termed the Persian Gulf War syndrome. It is characterized by impaired cognition, ataxia, confusion, myoneuropathy, adrenopathy, weakness, and incontinence (Haley et al., 1997; Institute of Medicine, 2003). While pyridostigmine has been implicated by some as the causative agent, the absence of similar neuropathies in pyridostigmine-treated myasthenic patients makes it far more likely that a combination of agents, including combusted organophosphates and insect repellents in addition to pyridostigmine, contributed to this persisting syndrome. It also is difficult to distinguish residual chemical toxicity from post-traumatic stress experienced after combat action. Pyridostigmine is FDA-approved for prophylaxis against soman, an organophosphate that rapidly “ages” following inhibition of cholinesterases.

Intoxication by Anticholinergic Drugs. In addition to atropine and other muscarinic agents, many other drugs, such as the phenothiazines, antihistamines, and tricyclic antidepressants, have central and peripheral anticholinergic activity. Physostigmine is potentially useful in reversing the central anticholinergic syndrome produced by overdosage or an unusual reaction to these drugs (Nilsson, 1982). The effectiveness of physostigmine in reversing the anticholinergic effects of these agents has been clearly documented. However, other toxic effects of the tricyclic antidepressants and phenothiazines (Chapters 15 and 16), such as intraventricular conduction deficits and ventricular arrhythmias, are not reversed by physostigmine. In addition, physostigmine may precipitate seizures; hence, its usually small potential benefit must be weighed against this risk. The initial intravenous or intramuscular dose of physostigmine is 2 mg, with additional doses given as necessary. Physostigmine, a tertiary amine, crosses the blood-brain barrier, in contrast to the quaternary anti-ChE drugs. The use of anti-ChE agents to reverse the effects of competitive neuromuscular blocking agents is discussed in Chapter 11.

Alzheimer’s Disease. A deficiency of intact cholinergic neurons, particularly those extending from subcortical areas such as the nucleus basalis of Meynert, has been observed in patients with progressive dementia of the Alzheimer type (Chapter 22). Using a rationale similar to that in other CNS degenerative diseases, therapy for enhancing concentrations of cholinergic neurotransmitters in the CNS was investigated.

In 1993, the FDA approved tacrine (tetrahydroaminoacridine) for use in mild to moderate Alzheimer’s disease, but a high incidence of enhanced
alanine aminotransferase and hepatotoxicity limited the utility of this drug. Other side effects were typical of AChE inhibitors. Subsequently, donepezil was approved for clinical use. Improved cognition and global clinical function were seen in the 21–81-week intervals studied (Dooley and Lamb, 2000). In long-term studies, the drug delayed symptomatic progression of the disease for periods up to 55 weeks. Side effects are largely attributable to excessive cholinergic stimulation, with nausea, diarrhea, and vomiting being most frequently reported. The drug is well tolerated in single daily doses. Usually, 5-mg doses are administered at night; if this dose is well tolerated, the dose can be increased to 10 mg daily.

Rivastigmine, a long-acting carbamoylating inhibitor, is approved for use in the U.S. and Europe. Although fewer studies have been conducted, its efficacy, tolerability, and side effects are similar to those of donepezil (Corey-Bloom et al., 1998; Giacobini, 2000). Galantamine is another AChE inhibitor recently approved by the FDA. It has a side-effect profile similar to those of donepezil and rivastigmine.

These three cholinesterase inhibitors, which have the requisite affinity and hydrophobicity to cross the blood-brain barrier and exhibit a prolonged duration of action, along with an excitatory amino acid transmitter mimic, memantine, constitute current modes of therapy. These agents are not disease modifying and have no well-documented actions on the pathology of Alzheimer’s disease. However, the bulk of the evidence indicates that they slow the decline in cognitive function and behavioral manifestation for limited intervals of time (Chapter 22). Associated symptoms, such as depression, may be preferentially delayed (Lu et al., 2009). Current clinical research efforts are directed to synergistic actions of arresting inflammatory processes or neurodegeneration and combining cholinesterase inhibition with selective cholinergic receptor modulation.

BIBLIOGRAPHY

The nicotinic acetylcholine (ACh) receptor mediates neurotransmission postsynaptically at the neuromuscular junction and peripheral autonomic ganglia; in the CNS, it largely controls release of neurotransmitters from presynaptic sites. The receptor is called the nicotine acetylcholine receptor because both the alkaloid nicotine and the neurotransmitter ACh can stimulate the receptor. Distinct subtypes of nicotinic receptors exist at the neuromuscular junction and the ganglia, and several pharmacological agents discriminate between the receptor subtypes.

**THE NICOTINIC ACETYLCHOLINE RECEPTOR**

The binding of ACh to the nicotinic ACh receptor initiates the end-plate potential (EPP) in muscle or an excitatory postsynaptic potential (EPSP) in peripheral ganglia, as was introduced in Chapter 8. Classical studies of the actions of curare and nicotine defined the concept of the nicotinic ACh receptor over a century ago and made this the prototypical pharmacological receptor. By taking advantage of specialized structures that have evolved to mediate cholinergic neurotransmission and of natural toxins that block motor activity, peripheral and then central nicotinic receptors were isolated and characterized. These accomplishments represent landmarks in the development of molecular pharmacology.

**History.** The electrical organs from the aquatic species of *Electrophorus* and *Torpedo* provide rich sources of nicotinic receptor. The electrical organ is derived embryologically from myoid tissue; however, in contrast to vertebrate skeletal muscle, in which motor end plates occupy 0.1% or less of the cell surface, up to 40% of the surface of the electric organ’s membrane is excitable and contains cholinergic receptors. The discovery of seemingly irreversible antagonism of neuromuscular transmission by $\alpha$-toxins from venoms of the krait, *Bungarus multicinctus*, or varieties of the cobra, *Naja naja*, offered suitable markers for identification of the receptor. The $\alpha$-toxins are peptides of ~7 kDa. Radioisotope-labeled toxins were used in 1970 to assay the isolated cholinergic receptor *in vitro* (Changeux and Edelstein, 1998). The $\alpha$-toxins have extremely high affinities and slow rates of dissociation from the receptor, yet the interaction is noncovalent. *In situ and in vitro*, their behavior resembles that expected for a high-affinity antagonist. Since cholinergic neurotransmission mediates motor activity in marine vertebrates and mammals, a large number of peptide, terpinoid, and alkaloid toxins that block the nicotinic receptors have evolved to enhance predation or protect plant and animal species from predation (Taylor *et al.*, 2007).

Purification of the receptor from *Torpedo* ultimately led to isolation of complementary DNAs for each of the subunits. These cDNAs, in turn, permitted the cloning of genes encoding the multiple receptor subunits from mammalian neurons and muscle (Numa *et al.*, 1983). By simultaneously expressing various permutations of the genes that encode the individual subunits in cellular systems and then measuring binding and the electrophysiological events that result from activation by agonists, researchers have been able to correlate functional properties with details of primary structures of the receptor subtypes (Changeux and Edelstein, 2005; Karlin, 2002; Sine *et al.*, 2008).

**Nicotinic Receptor Structure.** The nicotinic receptor of the electrical organ and vertebrate skeletal muscle is a pentamer composed of four distinct subunits ($\alpha$, $\beta$, $\gamma$, and $\delta$) in the stoichiometric ratio of 2:1:1:1, respectively. In mature, innervated muscle end plates, the $\gamma$ subunit is replaced by $\epsilon$, a closely related subunit. The individual subunits arose from a common primordial gene and are ~40% identical in their amino acid sequences.

The nicotinic receptor became the prototype for other pentameric ligand-gated ion channels, which include the receptors for...
the inhibitory amino acids (γ-aminobutyric acid and glycine; Chapter 14) and certain serotonin (5-HT₃) receptors (Chapter 13). Each of the subunits in the pentameric receptor has a molecular mass of 40-60 kDa. In each subunit, the amino-terminal ~210 residues constitute a large extracellular domain. This is followed by four transmembrane-spanning (TM) domains; the region between TM3 and TM4 forms most of the cytoplasmic component (Figure 11–1).

The five subunits are arranged around a pseudo-axis of symmetry to circumscribe a channel (Changeux and Edelstein, 1998; Karlin, 2002; Unwin, 2005). The resulting receptor is an asymmetrical molecule (16 × 8 nm) of 290 kDa, with the bulk of the nonmembrane-spanning domain on the extracellular surface. The receptor is present at high densities (10,000/μm²) in junctional areas (i.e., the motor end plate in skeletal muscle and the ventral surface of the electrical organ). The regular packing of receptors in these membranes has facilitated electron microscopic image reconstruction of the molecular structure (Figure 11–2). Agonist-binding sites are found at the subunit interfaces; in muscle, only two of the five subunit interfaces, αγ and αδ, have evolved to bind ligands (Figure 11-2D). Both of the subunits forming the subunit interface contribute to ligand specificity. The binding of agonists and reversible competitive antagonists involves overlapping surfaces on the receptor and is mutually exclusive.

Measurements of membrane conductance demonstrate that rates of ion translocation are sufficiently rapid (5 × 10⁷ ions per second) to require ion translocation through an open channel rather than by a rotating carrier. Moreover, agonist-mediated changes in ion permeability (typically an inward movement of Na⁺, and secondarily, of Ca²⁺) occur through a cation channel intrinsic to the receptor structure. The TM2 regions of the five subunits form the internal perimeter of the channel. The agonist-binding site is intimately coupled with an ion channel; in the muscle receptor, simultaneous binding of two agonist molecules results in a rapid conformational change that opens the channel. Both the binding and gating response show positive cooperativity. Details on the kinetics of channel opening have emerged from electrophysiological patch-clamp techniques that distinguish the individual opening and closing events of a single receptor (Sakmann, 1992).

An ACh-binding protein homologous to only the extracellular domain of the nicotinic receptor has been identified in fresh- and saltwater snails and characterized structurally and pharmacologically (Brejc et al., 2001). This protein assembles as a homomeric pentamer and binds nicotinic receptor ligands with selectivity similar to neuronal nicotinic ACh receptors; its crystal structure reveals an atomic organization expected of the nicotinic receptor. Moreover, fusion of the ACh-binding protein and the transmembrane spans of the receptor yields a functional protein that exhibits the channel gating and changes in state expected of the receptor (Bouzat et al., 2004). This binding protein serves as both a structural and functional surrogate of the receptor and has provided a detailed understanding of the determinants governing ligand specificity of the nicotinic receptor.

Neuronal Nicotinic Receptor Composition. Cloning by sequence homology identified the genes encoding the vertebrate nicotinic receptor. Neuronal nicotinic receptors found in ganglia and the CNS also exist as pentamers of one, two, or more types of subunits. A single subunit of the α-type sequence (denoted as α₁) is found in

---

**Figure 11–1. Subunit organization of pentameric ligand-gated ion channels and the ACh binding protein.** For each receptor, the amino terminal region of ~ 210 amino acids is found at the extracellular surface. It is then followed by four hydrophobic regions that span the membrane (TM1-TM4), leaving the small carboxyl terminus on the extracellular surface. The TM2 region is α-helical, and TM2 regions from each subunit of the pentameric receptor line the internal pore of the receptor. Two disulfide loops at positions 128–142 and 192–193 are found in the α-subunit of the nicotinic receptor. The 128–142 motif is conserved in the family of receptors, whereas the vicinal cysteines at 192 and 193 distinguish α- subunits and the acetylcholine binding protein from β, γ, δ, and ε in the nicotinic receptor.
Figure 11–2. *Subunit arrangement and molecular structure of the nicotinic acetylcholine receptor.* **A.** Longitudinal view of receptor schematic with the γ subunit removed. The remaining subunits, two copies of α, one of β, and one of δ, are shown to surround an internal channel with an outer vestibule and its constriction located deep in the membrane bilayer region. Spans of α-helices with slightly bowed structures form the perimeter of the channel and come from the TM2 region of the linear sequence (Figure 11–1). Acetylcholine (ACh) binding sites, indicated by arrows, are found at the αγ and αδ (not visible) interfaces. **B.** Longitudinal view of the receptor from *Torpedo* showing secondary structure and membrane topology from 4 Å electron micrograph data (Unwin, 2005). The ACh binding protein (panel C) is homologous to the extracellular domain of the nicotinic receptor (Figure 11–1). The protein is a homopentamer that binds nicotinic receptor ligands with the expected selectivity and, when fused to the TM portions of the receptor, yields a functional ligand-gated channel. The subunit structure of the ACh binding protein is clear from the top view (panel C, *upper orientation*) and side view (panel C, *lower orientation*). The agonist nicotine is shown bound to the ACh binding protein with its atoms modeled as spheres in C. Nicotinic receptor subunit arrangement is shown in D, with examples of subunit assembly and location of agonist binding sites (small red circles) at α subunit-containing interfaces in nicotinic receptors. A total of 17 functional receptor isoforms have been observed in vivo, with different ligand specificity, relative Ca2+/Na+ permeability, and physiological function as determined by their subunit composition. The only isoform found at the neuromuscular junction (and in the electric organ of *Torpedo*) is that shown here. The 16 neuronal receptor isoforms, found at autonomic ganglia and in the central nervous system, form homo- and heteropentameric nicotinic receptors composed of α2-α10 and β2-β4 subunits.
abundance in muscle, along with β, δ, and γ or ε. At least eight subtypes of α (α2 through α9) and three of the non-α type (designated as β2 through β4) are found in neuronal tissues (Figure 11–2). Studies of neuronal receptor subunit abundance and associations in brain and the periphery have enabled investigators to identify subunit combinations that confer function. Although not all permutations of α and β subunits lead to functional receptors, the diversity in subunit composition is large and exceeds the capacity of ligands to distinguish subtypes on the basis of their selectivity. For example, the α3/β4 and α3/β2 subtypes are prevalent in peripheral ganglia, whereas the α4/β2 subtype is most prevalent in brain. The subtypes α2 through α6 and β2 through β4 associate as heteromeric pentamers composed of two or three distinct subtypes, whereas α7 through α9 often are seen as homomeric associations. Distinctive selectivities of the receptor subtypes for Na⁺ and Ca²⁺ suggest that certain subtypes may possess functions other than rapid trans-synaptic signaling.

**NEUROMUSCULAR BLOCKING AGENTS**

The classical neuromuscular blocker, curare, was the tool that Claude Bernard used in the mid-19th century to demonstrate a locus of drug action at or near the neuromuscular junction. Modern-day neuromuscular blocking agents fall generally into two classes, depolarizing and competitive/non-depolarizing. At present, only a single depolarizing agent, succinylcholine (ANECTINE, QUELICIN), is in general clinical use, whereas multiple competitive or non-depolarizing agents are available (Figure 11–3).

**History, Sources, and Chemistry.** Curare is a generic term for various South American arrow poisons. The drug has been used for centuries by Indians along the Amazon and Orinoco Rivers for immobilizing and paralyzing wild animals used for food; death results from paralysis of skeletal muscles. The preparation of curare was long shrouded in mystery and was entrusted only to tribal witch doctors. Soon after the discovery of the American continent, European explorers and botanists became interested in curare, and late in the 16th century, samples of the native preparations were brought to Europe. Following the pioneering work of the scientist/explorer von Humboldt in 1805, the botanical sources of curare became the object of much field research. The curares from eastern Amazonia come from *Strychnos* species; these and other South American species of *Strychnos* contain chiefly quaternary neuromuscular-blocking alkaloids. The Asiatic, African, and Australian species nearly all contain tertiary strychnine-like alkaloids.

The modern clinical use of curare apparently dates from 1932, when West employed highly purified fractions in patients with tetanus and spastic disorders. Research on curare was accelerated greatly by the work of Gill, who, after prolonged and intimate study of the native methods of preparing curare, brought to the U.S. a sufficient amount of the authentic drug to permit chemical and pharmacological investigations. Griffith and Johnson reported the first trial of curare for promoting muscular relaxation in general anesthesia in 1942. Details of the fascinating history of curare and the chemical identification of the curare alkaloids are presented in previous editions of this book.

King established the essential structure of tubocurarine in 1935 (Figure 11–3). A synthetic derivative, metocurine (formerly called dimethyl tubocurarine), contains three additional methyl groups and possesses two to three times the potency of tubocurarine in human beings. The most potent curare alkaloids are the toxiferines, obtained from *Strychnos toxifera*. A semisynthetic derivative, alcuronium chloride (*N,N*-diallylnortoxiferinichloride), was widely used clinically in Europe and elsewhere. The seeds of the trees and shrubs of the genus *Erythrina*, widely distributed in tropical and subtropical areas, contain erythroidines that possess curare-like activity. Gallamine is one of a series of synthetic substitutes for curare described by Bovet and co-workers in 1949.

Early structure-activity studies led to the development of the polymethylene bis-trimethyl-ammonium series (referred to as the methonium compounds). The most potent of these agents at the neuromuscular junction was the compound with 10 carbon atoms between the quaternary nitrogens: decamethonium (C10) (Figure 11–3). The compound with 6 carbon atoms in the chain, hexamethonium (C6), was found to be essentially devoid of neuromuscular blocking activity but particularly effective as a ganglionic blocking agent (see following discussion).

**Structure-Activity Relationships.** Several structural features distinguish competitive and depolarizing neuromuscular blocking agents. The competitive agents (e.g., tubocurarine, the benzylisoquinolines, the ammonio steroids, and the asymmetric mixed-onium chlorofumarates) are relatively bulky, rigid molecules, whereas the depolarizing agents (e.g., decamethonium [no longer marketed in the U.S. and succinylcholine]) generally have more flexible structures that enable free bond rotations (Figure 11–3). While the distance between quaternary groups in the flexible depolarizing agents can vary up to the limit of the maximal bond distance (1.45 nm for decamethonium), the distance for the rigid competitive blockers is typically 1.0 ± 0.1 nm. L-Tubocurarine is considerably less potent than D-tubocurarine, perhaps because the D-isomer has all the hydrophilic groups localized uniquely to one surface.

**Pharmacological Properties**

**Actions on Organ Systems**

**Skeletal Muscle.** Claude Bernard first described a localized paralytic action of curare in the 1850s. The site of action of D-tubocurarine and other competitive blocking agents was identified as the motor end plate (a thickened region of postjunctional membrane) by fluorescence and electron microscopy, micro-iontophoretic application of drugs, patch-clamp analysis of single channels, and intracellular recording. Competitive antagonists combine with the nicotinic ACh receptor at the end plate and thereby competitively block the binding of ACh. When the drug is applied directly to the end plate of a single isolated muscle fiber, the muscle cell becomes insensitive to motor-nerve impulses and to directly applied ACh; however, the end-plate region

and the remainder of the muscle fiber membrane retain their normal sensitivities to K⁺ depolarization and direct electrical stimulation.

The steps involved in ACh release by the nerve action potential, the development of miniature end-plate potentials (MEPPs), their summation to form a postjunctional end-plate potential (EPP), the triggering of the muscle action potential, and contraction are described in Chapter 8. Biophysical studies with patch electrodes reveal that the fundamental event elicited by ACh or other agonists is an “all or none” opening of the individual receptor channels, which gives rise to a square wave pulse with an average open-channel conductance of 20-30 picosiemens (pS) and a duration that is exponentially distributed around a time of ~1 ms. The duration of channel opening is far more dependent on the nature of the agonist than is the magnitude of the open-channel conductance (Sakmann, 1992).

Increasing concentrations of the competitive antagonist tubocurarine progressively diminish the amplitude of the excitatory postjunctional EPP. The amplitude of this potential may fall to below 70% of its initial value before it is insufficient to initiate the propagated muscle action potential; this provides a safety factor in neuromuscular transmission. Analysis of the antagonism of tubocurarine on single-channel events shows that, as expected for a competitive antagonist, tubocurarine reduces the frequency of channel-opening events but does not affect the conductance or duration of opening for a single channel (Katz and Miledi, 1978). At higher concentrations, curare and other competitive antagonists block the channel directly in a fashion that is noncompetitive with agonists and dependent on membrane potential (Colquhoun et al., 1979).

The decay time of the MEPP is similar to the average lifetime of channel opening (1-2 ms). MEPPs are a consequence of the spontaneous release of one or more quanta of ACh (~10⁵ molecules); individual molecules of ACh in the synapse have only a transient opportunity to activate the receptor and do not rebind successively to receptors to activate multiple channels before being hydrolyzed by acetylcholinesterase (AChE). The concentration of unbound ACh in the synapse from nerve-released ACh diminishes more rapidly than does the decay of the EPP (or current). In the presence of anticholinesterase drugs, the EPP is prolonged up to 25-30 ms, which is indicative of the re-binding of transmitter to neighboring receptors before hydrolysis by AChE or diffusion from the synapse.

Simultaneous binding by two agonist molecules at the respective αγ and αδ subunit interfaces of the receptor is required for activation. Activation shows positive cooperativity and thus occurs over a narrow range of concentrations (Changeux and Edelstein, 1998; Sine and Claudio, 1991). Although two molecules of competitive antagonist or snake α-toxin can bind to each receptor molecule at the agonist sites, the binding of one molecule of antagonist to each receptor is sufficient to render it nonfunctional (Taylor et al., 1983).

The depolarizing agents, such as succinylcholine, act by a different mechanism. Their initial action is to depolarize the membrane by opening channels in the same manner as ACh. However, they persist for longer durations at the neuromuscular junction primarily because of their resistance to AChE. The depolarization is thus longer-lasting, resulting in a brief period of repetitive excitation that may elicit transient and repetitive muscle excitation (fasciculations). This initial depolarization is followed by block of neuromuscular transmission and flaccid paralysis (called phase I block). The block arises because, after an initial opening, perijunctional sodium channels close and will not reopen until the end plate is repolarized. At this point, neural release of ACh results in the binding of ACh to receptors on an already depolarized end plate. These closed perijunctional channels keep the depolarization signal from affecting downstream channels and effectively shield the rest of the muscle from activity at the motor end plate. In humans, depolarizing agents elicit a sequence of repetitive excitation followed by block of transmission and neuromuscular paralysis; however, this sequence is influenced by such factors as the anesthetic agent used concurrently, the type of muscle, and the rate of drug administration. The characteristics of depolarization and competitive blockade are contrasted in Table 11–3.

In other animal species and occasionally in humans, depolarizing agents produce a blockade that has unique features, some of which combine those of the depolarizing and the competitive agents; this type of action is termed a dual mechanism. In such cases, the depolarizing agent initially produces characteristic fasciculations and potentiation of the maximal twitch, followed by the rapid onset of neuromuscular block. This phase I block is potentiated by anticholinesterase agents (e.g., ambenonium, edrophonium, neostigmine, pyridostigmine, donepezil, galantamine, rivastigmine, and tacrine): Inhibition of ACh degradation results in additional depolarizing agent, in this case endogenous ACh, at the neuromuscular junction. Following the onset of blockade, there is a poorly sustained response to tetanic stimulation of the motor nerve, intensification of the block by tubocurarine, and lack of potentiation by anti-cholinesterase agents. The dual action of the depolarizing blocking agents is also seen in intracellular recordings of membrane potential; when agonist is applied continuously, the initial depolarization is followed by a gradual repolarization, which in many respects resembles receptor desensitization.

Under clinical conditions, with increasing concentrations of succinylcholine and over time, the block may convert slowly from a depolarizing phase I block to a non-depolarizing, phase II block (Durant and Katz, 1982). The pattern of neuromuscular blockade produced by depolarizing drugs in anesthetized patients appears to depend, in part, on the anesthetic; fluorinated hydrocarbons may be more apt to predispose the motor end plate to non-depolarization blockade after prolonged use of succinylcholine (Fogdall and Miller, 1975). While the response to peripheral stimulation during phase II block resembles that of the competitive agents, reversal of phase II block by administration of anti-cholinesterase agents (e.g., with neostigmine) is difficult to predict and should be undertaken with much caution. The characteristics of phase I and phase II blocks are shown in Table 11–1.

Although the observed fasciculations also may be a consequence of stimulation of the prejunctional nerve terminal by the
A depolarizing agent, giving rise to stimulation of the motor unit in an antidromic fashion, the primary site of action of both competitive and depolarizing blocking agents is the post-junctional membrane. Presynaptic actions of the competitive agents may become significant on repetitive high-frequency stimulation because pre-junctional nicotinic receptors may be involved in the mobilization of ACh for release from the nerve terminal (Bowman et al., 1990; Van der Kloot and Molgo, 1994).

Many drugs and toxins block neuromuscular transmission by other mechanisms, such as interference with the synthesis or release of ACh (Chapter 8), but most of these agents are not employed clinically for this purpose. One exception is botulinum toxin, which has been administered locally into muscles of the orbit in the management of ocular blepharospasm and strabismus and has been used to control other muscle spasms and to facilitate facial muscle relaxation (Chapters 8 and 64). This toxin also has been injected into the lower esophageal sphincter to treat achalasia (Chapter 47). The sites of action and interrelationship of several agents that serve as pharmacological tools are shown in Figure 11–4.

**Sequence and Characteristics of Paralysis.** When an appropriate dose of a competitive blocking agent is injected intravenously in human beings, motor weakness progresses to a total flaccid paralysis. Small, rapidly moving muscles such as those of the eyes, jaw, and larynx relax before those of the limbs and trunk. Ultimately, the intercostal muscles and finally the diaphragm are paralyzed, and respiration then ceases. Recovery of muscles usually occurs in the reverse order to that of their paralysis, and thus the diaphragm ordinarily is the first muscle to regain function (Feldman and Fauvel, 1994; Viby-Mogensen, 2005).

After a single intravenous dose of 10-30 mg of succinylcholine, muscle fasciculations, particularly over the chest and abdomen, occur briefly; then relaxation occurs within 1 minute, becomes maximal within 2 minutes, and generally disappears within 5 minutes. Transient apnea usually occurs at the time of maximal effect. Muscle relaxation of longer duration is achieved by continuous intravenous infusion. After infusion is discontinued, the effects of the drug usually disappear rapidly because of its efficient hydrolysis by plasma and hepatic butyrylcholinesterase. Muscle soreness may follow the administration of succinylcholine. Small prior doses of competitive blocking agents have been employed to minimize fasciculations and muscle pain caused by succinylcholine, but this procedure is controversial because it increases the requirement for the depolarizing drug.

During prolonged depolarization, muscle cells may lose significant quantities of K⁺ and gain Na⁺, Cl⁻, and Ca²⁺. In patients with extensive injury to soft tissues, the efflux of K⁺ following continued administration of succinylcholine can be life-threatening. The life-threatening complications of succinylcholine-induced hyperkalemia are discussed later, but it is important to stress that there are many conditions for which succinylcholine administration is contraindicated or should be undertaken with great caution. The change in the nature of the blockade produced by succinylcholine (from phase I to phase II) presents an additional complication with long-term infusions.

**Central Nervous System.** Tubocurarine and other quaternary neuromuscular blocking agents are virtually devoid of central effects following ordinary clinical doses because of their inability to penetrate the blood-brain barrier. The most decisive experiment performed to resolve whether curare significantly affects central functions in the dose range used clinically was that of Smith and associates (1947). Smith (an anesthesiologist) daringly permitted himself to receive, intravenously, two and one-half times the amount of tubocurarine necessary for paralysis of all skeletal muscles. Adequate respiratory exchange was maintained by artificial respiration. At no time was there any evidence of lapse of consciousness, clouding of sensorium, analgesia, or disturbance of special senses. Despite adequate artificially controlled respiration, Smith experienced “shortness of breath” and the sensation of choking due to the accumulation of unswallowed saliva in the pharynx. The experience was decidedly unpleasant,
but the results were clear: Tubocurarine given intravenously, even in large doses, has no significant central stimulant, depressant, or analgesic effects.

**Autonomic Ganglia and Muscarinic Sites.** Neuromuscular blocking agents show variable potencies in producing ganglionic blockade. Just as at the motor end plate, ganglionic blockade by tubocurarine and other stabilizing drugs is reversed or antagonized by anti-ChE agents.

At the doses of tubocurarine once used clinically, partial blockade probably is produced both at autonomic ganglia and at the adrenal medulla, which results in a fall in blood pressure and tachycardia. Pancuronium shows less ganglionic blockade at common clinical doses. Atracurium, vecuronium, doxacurium, pipecuronium, mivacurium, and rocuronium are even more selective (Naguib and Lien, 2005; Pollard, 1994)). The maintenance of cardiovascular reflex responses usually is desired during anesthesia. Pancuronium has a vagolytic action, presumably from blockade of muscarinic receptors, which leads to tachycardia.

Of the depolarizing agents, succinylcholine at doses producing neuromuscular relaxation rarely causes effects attributable to ganglionic blockade. However, cardiovascular effects are sometimes observed, probably owing to the successive stimulation of vagal ganglia (manifested by bradycardia) and sympathetic ganglia (resulting in hypertension and tachycardia).

**Mast Cells and Histamine Release.** Tubocurarine produces typical histamine-like wheals when injected intracutaneously or intra-arterially in humans, and some
clinical responses to neuromuscular blocking agents (e.g., bronchospasm, hypotension, excessive bronchial and salivary secretion) appear to be caused by the release of histamine. Succinylcholine, mivacurium, and atracurium also cause histamine release, but to a lesser extent unless administered rapidly. The ammonio steroids, pancuronium, vecuronium, pipecuronium, and rocuronium, have even less tendency to release histamine after intradural or systemic injection (Basta, 1992; Watkins, 1994). Histamine release typically is a direct action of the muscle relaxant on the mast cell rather than IgE-mediated anaphylaxis (Watkins, 1994).

Release of Cellular K+. Depolarizing agents can release K+ rapidly from intracellular sites; this may be a factor in several of the clinical toxicities of these drugs (see “Toxicology” later in the chapter).

Absorption, Distribution, and Elimination

Quaternary ammonium neuromuscular blocking agents are very poorly absorbed from the GI tract, a fact well known to the South American Indians, who ate with impunity the flesh of game killed with curare-poisoned arrows. Absorption is quite adequate from intramuscular sites. Rapid onset is achieved with intravenous administration. The more potent agents, of course, must be given in lower concentrations, and diffusional requirements slow their rate of onset.

When long-acting competitive blocking agents such as D-tubocurarine and pancuronium are administered, blockade may diminish after 30 minutes owing to redistribution of the drug, yet residual blockade and plasma levels of the drug persist. Subsequent doses show diminished redistribution. Long-acting agents may accumulate with multiple doses.

The ammonio steroids contain ester groups that are hydrolyzed in the liver. Typically, the metabolites have about one-half the activity of the parent compound and contribute to the total relaxation profile. Ammonio steroids of intermediate duration of action, such as vecuronium and rocuronium (Table 11–2), are cleared more rapidly by the liver than is pancuronium. The more rapid decay of neuromuscular blockade with compounds of intermediate duration argues for sequential dosing of these agents rather than administering a single dose of a long-duration neuromuscular blocking agent. There is a modified γ-cyclodextrin available as an investigational chelating agent specific for rocuronium and vecuronium (see “Reversal of Effects by Chelation Therapy” later in the chapter).

Atracurium is converted to less active metabolites by plasma esterases and spontaneous Hofmann elimination (Figure 11–3). Cisatracurium is also subject to this spontaneous degradation. Because of these alternative routes of metabolism, atracurium and cisatracurium do not exhibit an increased $t_{1/2}$ in patients with impaired renal function and therefore are good choices in this setting (Hunter, 1994; Naguib and Lien, 2005).

The extremely brief duration of action of succinylcholine is due largely to its rapid hydrolysis by the butyrylcholinesterase synthesized by the liver and found in the plasma. Among the occasional patients who exhibit prolonged apnea following the administration of succinylcholine or mivacurium, most have an atypical plasma cholinesterase or a deficiency of the enzyme owing to allelic variations (Pantuck, 1993; Primo-Parmo et al., 1996), hepatic or renal disease, or a nutritional disturbance; however, in some, the enzymatic activity in plasma is normal (Whittaker, 1986).

Gantacurium is degraded by two chemical mechanisms, a rapid cysteine adduction and a slower hydrolysis of the ester bond adjacent to the chlorine. Both processes are purely chemical and hence not dependent on enzymatic activities. The adduction process has a $t_{1/2}$ of 1-2 minutes and is likely the basis for the ultrashort duration of action of gantacurium. Administration of exogenous cysteine, which may have excitotoxic side effects, can accelerate the antagonism of gantacurium-induced neuromuscular blockade (Naguib and Brull, 2009).

Clinical Pharmacology

Choice of Agent

Therapeutic selection of a neuromuscular blocking agent should be based on achieving a pharmacokinetic profile consistent with the duration of the interventional procedure and minimizing cardiovascular compromise or other side effects, with attention to drug-specific modes of elimination in patients with renal or hepatic failure (Table 11–2).

Two characteristics are useful in distinguishing side effects and pharmacokinetic behavior of neuromuscular blocking agents. The first relates to the duration of drug action: These agents are categorized as long-, intermediate-, or short-acting. The persistent blockade and difficulty in complete reversal after surgery with D-tubocurarine, metocurine, doxacurium, and pancuronium led to the development of vecuronium (Norcuron, others) and atracurium (Tracrium, others), agents of intermediate duration; cisatracurium (Nimbex) is one of ten isomers of atracurium with three times its potency. This was followed by the development of a short-acting agent, mivacurium (not available in the U.S.). Often, the long-acting agents are the more potent, requiring the use of low concentrations (Table 11–3). The necessity of administering potent agents in low concentrations delays their onset. Rocuronium (Zemuron, others) is an agent of intermediate duration but of rapid onset and lower potency. Its rapid onset allows its use as an alternative to succinylcholine in rapid-induction anesthesia and in relaxing the laryngeal and jaw muscles to facilitate tracheal intubation (Bevan, 1994; Naguib and Lien, 2005). Gantacurium, a mixed-onium chlorofumarate, recently completed phase 2 clinical trials and is the first in a new class of ultra-short acting, competitive neuromuscular blocking agents designed to replace succinylcholine in rapid-induction anesthesia (Naguib and Brull, 2009; Savarese, 2006).

The second useful classification is derived from the chemical nature of the agents and includes the natural alkaloids or their congeners, the ammonio steroids, the benzylisoquinolines, and the asymmetric mixed-onium chlorofumarates (Table 11–2, Figure 11–3). The natural alkaloid D-tubocurarine and the semisynthetic alkaloid alcuronium are not approved for use in the U.S. Apart from a shorter duration of action, newer agents exhibit greatly diminished frequency of side effects, chief of which are ganglionic blockade, block
of vagal responses, and histamine release. The prototypical ammonio steroid, pancuronium, induces virtually no histamine release; however, it blocks muscarinic receptors, and this antagonism is manifested primarily in vagal blockade and tachycardia. Tachycardia is eliminated in the newer ammonio steroids, vecuronium and rocuronium.

The benzylisoquinolines appear to be devoid of vagolytic and ganglionic blocking actions but show a slight propensity to cause histamine release. The unusual metabolism of the prototype compound atracurium and its congener mivacurium confers special indications for use of these compounds. For example, atracurium’s disappearance from the body depends on hydrolysis of the ester

<sup>c</sup>Gantacurium is in investigational status.
moiety by plasma esterases and by a spontaneous or Hofmann degra-
dation (cleavage of the N-alkyl portion in the benzylisoquinoline).
Hence two routes for degradation are available, both of which remain functional in renal failure. Mivacurium is extremely sensitive to catalysis by cholinesterase or other plasma hydrolases, accounting for its short duration of action.

Side effects are not yet fully characterized for gantacurium, but transient adverse cardiovascular effects suggestive of histamine release have been observed at doses over three times the ED$_{95}$.

Clinical Uses

Muscle Relaxation. The main clinical use of the neuromuscular blocking agents is as an adjuvant in surgical anesthesia to obtain relaxation of skeletal muscle, particularly of the abdominal wall, to facilitate operative manipulations. With muscle relaxation no longer dependent on the depth of general anesthesia, a much lighter level of anesthesia suffices. Thus, the risk of respiratory and cardiovascular depression is minimized, and post-anesthetic recovery is shortened. These considerations notwithstanding, neuromuscular blocking agents cannot be used to substitute for inadequate depth of anesthesia. Otherwise, a risk of reflex responses to painful stimuli and conscious recall may occur.

Muscle relaxation is also of value in various orthopedic procedures, such as the correction of dislocations and the alignment of fractures. Neuromuscular blocking agents of short duration often are used to facilitate endotracheal intubation and have been used to facilitate laryngoscopy, bronchoscopy, and esophagoscopy in combination with a general anesthetic agent.

Neuromuscular blocking agents are administered parenterally, nearly always intravenously. As potentially hazardous drugs, they should be administered to patients only by anesthesiologists and other clinicians who have had extensive training in their use and in a setting where facilities for respiratory and cardiovascular resuscitation are immediately at hand. Detailed information on dosage and monitoring the extent of muscle relaxation can be found in anesthesiology textbooks (Naguib and Lien, 2005; Pollard, 1994).

Measurement of Neuromuscular Blockade in Humans. Assessment of neuromuscular block usually is performed by stimulation of the ulnar nerve. Responses are monitored from compound action potentials or muscle tension developed in the adductor pollicis (thumb) muscle. Responses to repetitive or tetanic stimuli are most useful for evaluation of blockade of transmission because individual measurements of twitch tension must be related to control values obtained prior to the administration of drugs. Thus, stimulus schedules such as the “train of four” and the “double burst” or responses to tetanic stimulation are preferred procedures (Drenck et al., 1989; Waud and Waud, 1972). Rates of onset of blockade and recovery are more rapid in the airway musculature (jaw, larynx, and diaphragm) than in the thumb. Hence, tracheal intubation can be performed before onset of complete block at the adductor pollicis, whereas partial recovery of function of this muscle allows sufficient recovery of respiration for extubation (Naguib and Lien, 2005). Differences in rates of onset of blockade, recovery from blockade, and intrinsic sensitivity between the stimulated muscle and those of the larynx, abdomen, and diaphragm should be considered.

*Not commercially available in the U.S.*
Preventing Trauma During Electroshock Therapy. Electroconvulsive therapy (ECT) of psychiatric disorders occasionally is complicated by trauma to the patient; the seizures induced may cause dislocations or fractures. Inasmuch as the muscular component of the convulsion is not essential for benefit from the procedure, neuromuscular blocking agents, usually succinylcholine, and a short-acting barbiturate, usually methohexital or thiopental, are employed. The combination of the blocking drug, the anesthetic agent, and postictal depression usually results in respiratory depression or temporary apnea. An endotracheal tube and oxygen always should be available. An oropharyngeal airway should be inserted as soon as the jaw muscles relax (after the seizure) and provision made to prevent aspiration of mucus and saliva. A cuff may be applied to one extremity to prevent the effects of the drug in that limb; evidence of an effective electroshock is provided by contraction of the group of protected muscles. After the procedure, ventilation with oxygen by mask should be continued until adequate breathing resumes (Stensrud, 2005). These agents are also used in capital punishment by electrocution. Although a convulsive response is blocked, ethical concerns have been raised because all motor function is blocked.

Control of Muscle Spasms and Rigidity. Botulinum toxins and dantrolene act peripherally to reduce muscle contraction; a variety of other agents act centrally to reduce skeletal muscle tone and spasm.

The anaerobic bacterium Clostridium botulinum produces a family of toxins targeted to presynaptic proteins that block the release of ACh (Chapter 8). Onabotulinum toxin A (BOTOX), abobotulinum toxin A (DYSPORT), and rimabotulinum toxin B (MYOBLOC), by blocking ACh release, produce flaccid paralysis of skeletal muscle and diminished activity of parasympathetic and sympathetic cholinergic synapses. Inhibition lasts from several weeks to 3 to 4 months, and restoration of function requires nerve sprouting. Immunoresistance is uncommon but may develop with continued use (Davis and Barnes, 2000). Originally approved for the treatment of the ocular conditions of strabismus and blepharospasm and for hemifacial spasms, botulinum toxin has been used to treat spasms and dystonias such as adductor spasmodic dysphonia, oromandibular dystonia, cervical dystonia, and spasms associated with the lower esophageal sphincter and anal fissures. Its dermatological uses include treatment of hyperhidrosis of the palms and axillae that is resistant to topical and iontophoretic remedies and removal of facial lines associated with excessive nerve stimulation and muscle activity. Treatment involves local intramuscular or intradermal injections (Boni et al., 2000; Flynn, 2006). Botox treatments also have become a popular cosmetic procedure for those seeking a wrinkle-free face. Like the bloom of youth, the effect of Botox can be renewed by re-administration. The FDA has issued a safety alert, warning of respiratory paralysis from unexpected spread of the toxin from the site of injection (Chapter 65).

Dantrolene (DANTRUM, others) inhibits Ca²⁺ release from the sarcoplasmic reticulum of skeletal muscle by limiting the capacity of Ca²⁺ and calmodulin to activate RYR-1 (Fruen et al., 1997). RYR-1 and the L-type Ca²⁺ channel are juxtaposed to associate at a triadic junction formed between the T-tubule and the sarcoplasmic reticulum. The L-type channel with its T-tubular location serves as the voltage sensor receiving the depolarizing activation signal. The intimate coupling of the two proteins at the triad, along with a host of modulatory proteins in the two organelles and the surrounding cytoplasm, regulates the release of and response to Ca²⁺ (Lehmann-Horn and Jurkat-Rott, 1999). Because of its efficacy in managing an acute attack of malignant hyperthermia (described under “Toxicology”), dantrolene has been used experimentally in the treatment of muscle rigidity and hyperthermia in neuroleptic malignant syndrome (NMS). NMS is a life-threatening complication of treatment with both typical and atypical antipsychotic drugs (Chapter 16) characterized by fever, severe muscle rigidity, mental status change, and dysautonomia. Administration of 1-2.5 mg/kg dantrolene in severe NMS cases, concurrent with immediate discontinuation of antipsychotic therapy, usually results in rapid reversal of hyperthermia and rigidity (Strawn et al., 2007). Dantrolene is also used in treatment of spasticity and hyperreflexia. With its peripheral action, it causes a generalized weakness. Thus, its use should be reserved to non-ambulatory patients with severe spasticity. Hepatotoxicity has been reported with continued use, requiring liver function tests (Kita and Goodkin, 2000).

Several agents, many of limited efficacy, have been used to treat spasticity involving the α-motor neuron with the objective of increasing functional capacity and relieving discomfort. Agents that act in the CNS at either higher centers or the spinal cord to block spasms are considered in Chapter 22. These include baclofen (Lioresal, others), the benzodiazepines, tizanidine (Zanaflex, others), and cyclobenzaprine (Flexaril, others). A number of other agents used as muscle relaxants seem to rely on sedative properties and blockade of nociceptive pathways; this group includes carisoprodol (which is metabolized to meprobamate; Soma, others); metaxalone (Skelaxin); methocarbamol (Robaxin, others); and orphenadrine (Norflex, others). Tetrabenazine (Xenazine) is available for treatment of the chorea associated with Huntington’s disease; the drug is a VMAT2 inhibitor that depletes vesicular stores of dopamine in the CNS (Chapters 8 and 22).

Synergisms and Antagonisms. Interactions between competitive and depolarizing neuromuscular blocking agents already have been considered (Table 11–4). From a clinical viewpoint, important pharmacological interactions of these drugs are with certain general anesthetics, certain antibiotics, Ca²⁺ channel blockers, and anti-cholinesterase (anti-ChE) compounds.

Since the anti-ChE agents neostigmine, pyridostigmine, and edrophonium preserve endogenous ACh and also act directly on the neuromuscular junction, they have been used in the treatment of overdose with competitive blocking agents. Similarly, on completion of the surgical procedure, many anesthesiologists employ neostigmine or edrophonium to reverse and decrease the duration of competitive neuromuscular blockade. A muscarinic antagonist (atropine or glycopyrrolate) is used concomitantly to prevent stimulation of muscarinic receptors and thereby to avoid slowing of the heart rate. Since
anti-cholinesterase agents will not reverse depolarizing neuromuscular blockade and, in fact, can enhance it, the distinction between competitive and depolarizing types of neuromuscular blocking agent must be clearly communicated in healthcare settings to avoid potential adverse clinical outcomes.

Many inhalational anesthetics exert a stabilizing effect on the postjunctional membrane and therefore potentiate the activity of competitive blocking agents. Consequently, when such blocking drugs are used for muscle relaxation as adjuncts to these anesthetics, their doses should be reduced. The rank of order of potentiation is desflurane > sevoflurane > isoflurane > halothane > nitrous oxide-barbiturate-opioid or propofol anesthesia (Naguib and Lien, 2005).

Aminoglycoside antibiotics produce neuromuscular blockade by inhibiting ACh release from the preganglionic terminal (through competition with Ca$^{2+}$) and to a lesser extent by noncompetitively blocking the receptor. The blockade is antagonized by Ca$^{2+}$ salts but only inconsistently by anti-ChE agents (Chapter 54). The tetracyclines also can produce neuromuscular blockade, possibly by chelation of Ca$^{2+}$. Additional antibiotics that have neuromuscular blocking action, through both presynaptic and postsynaptic actions, include polymyxin B, colistin, clindamycin, and lincomycin (Pollard, 1994). Ca$^{2+}$ channel blockers enhance neuromuscular blockade produced by both competitive and depolarizing antagonists. It is not clear whether this is a result of a diminution of Ca$^{2+}$-dependent release of transmitter from the nerve ending or is a postsynaptic action. When neuromuscular blocking agents are administered to patients receiving these agents, dose adjustments should be considered; if recovery of spontaneous respiration is delayed, Ca$^{2+}$ salts may facilitate recovery.

Miscellaneous drugs that may have significant interactions with either competitive or depolarizing neuromuscular blocking agents include trimethaphan (no longer marketed in the U.S.), lithium, opioid analgesics, procaine, lidocaine, quinidine, phentolamine, carbamazepine, phenytoin, propranolol, dantrolene, azathioprine, tamoxifen, magnesium salts, corticosteroids, digitalis glycosides, chloroquine, catecholamines, and diuretics (Naguib and Lien, 2005; Pollard, 1994).

### Toxicology

The important untoward responses of the neuromuscular blocking agents include prolonged apnea, cardiovascular collapse, those resulting from histamine release, and rarely, anaphylaxis. Failure of respiration to become adequate in the postoperative period may not always be due directly to excessive muscle paralysis from the drug. An obstruction of the airway, decreased arterial PCO$_2$ secondary to hyperventilation during the operative procedure, or the neuromuscular depressant effect of excessive amounts of neostigmine used to reverse the action of the competitive blocking drugs, may also be implicated. Directly related factors may include alterations in body temperature; electrolyte imbalance, particularly of K$^+$ (see the next paragraph); low plasma butyrylcholinesterase levels, resulting in a reduction in the rate of destruction of succinylcholine; the presence of latent myasthenia gravis or of malignant disease such as small cell carcinoma of the lung with Eaton-Lambert myasthenic syndrome; reduced blood flow to skeletal muscles, causing delayed removal of the blocking drugs; and decreased elimination of the muscle relaxants secondary to hepatic dysfunction (cisatricurium, rocuronium, vecuronium) or

reduced renal function (pancuronium). Great care should be taken when administering neuromuscular blockers to dehydrated or severely ill patients.

The depolarizing agents can release K⁺ rapidly from intracellular sites; this may be a factor in production of the prolonged apnea in patients who receive these drugs while in electrolyte imbalance. Succinylcholine-induced hyperkalemia is a life-threatening complication of that drug (Yentis, 1990). For example, such alterations in the distribution of K⁺ are of particular concern in patients with congestive heart failure who are receiving digoxin or diuretics. For the same reason, caution should be used or depolarizing blocking agents should be avoided in patients with extensive soft-tissue trauma or burns. A higher dose of a competitive blocking agent often is indicated in these patients. In addition, succinylcholine administration is contraindicated or should be given with great caution in patients with nontraumatic rhabdomyolysis, ocular lacerations, spinal cord injuries with paraplegia or quadriplegia, or muscular dystrophies. Succinylcholine no longer is indicated for children ≤8 years of age unless emergency intubation or securing an airway is necessary. Hyperkalemia, rhabdomyolysis, and cardiac arrest have been reported. A subclinical dystrophy is frequently associated with these adverse responses. Neonates may also have an enhanced sensitivity to competitive neuromuscular blocking agents.

Malignant Hyperthermia. Malignant hyperthermia is a potentially life-threatening event triggered by the administration of certain anesthetics and neuromuscular blocking agents. The clinical features include contracture, rigidity, and heat production from skeletal muscle resulting in severe hyperthermia (increases of up to 1°C/5 min), accelerated muscle metabolism, metabolic acidosis, and tachycardia. Uncontrolled release of Ca²⁺ from the sarcoplasmic reticulum of skeletal muscle is the initiating event. Although the halogenated hydrocarbon anesthetics (e.g., halothane, isoflurane, and sevoflurane) and succinylcholine alone have been reported to precipitate the response, most of the incidents arise from the combination of depolarizing blocking agent and anesthetic. Susceptibility to malignant hyperthermia, an autosomal dominant trait, is associated with certain congenital myopathies such as central core disease. In the majority of cases, however, no clinical signs are visible in the absence of anesthetic intervention.

Determination of susceptibility is made with an in vitro contracture test on a fresh biopsy of skeletal muscle, where contractures are measured by the contracture test and a mutation in the gene encoding the sarcoplasmic reticulum of skeletal muscle (see “Control of Muscle Spasms and Rigidity” earlier in the chapter). Rapid cooling, inhalation of 100% oxygen, and control of acidosis should be considered adjunct therapy in malignant hyperthermia. Declining fatality rates for malignant hyperthermia relate to anesthesiologists’ awareness of the condition and the efficacy of dantrolene.

Patients with central core disease, so named because of the presence of myofibrillar cores seen on biopsy of slow-twitch muscle fibers, show muscle weakness in infancy and delayed motor development. These individuals are highly susceptible to malignant hyperthermia with the combination of an anesthetic and a depolarizing neuromuscular blocker. Central core disease has five allelic variants of RYR-1 in common with malignant hyperthermia. Patients with other muscle syndromes or dystonias also have an increased frequency of contracture and hyperthermia in the anesthesia setting. Succinylcholine in susceptible individuals also induces trismus-masseter spasm, an increase in jaw muscle tone, which may complicate endotracheal tube insertion and airway management (van der Spek et al., 1990). This condition has been correlated with a mutation in the gene encoding the α subunit of the voltage-sensitive Na⁺ channel (Vita et al., 1995). This increase in jaw muscle tone can be an early sign of the onset of malignant hyperthermia, and when observed along with rigidity in other muscles, is a signal that anesthesia should be halted and treatment of malignant hyperthermia begun (Gronert et al., 2005).

Respiratory Paralysis. Treatment of respiratory paralysis arising from an adverse reaction or overdose of a neuromuscular blocking agent should be by positive-pressure artificial respiration with oxygen and maintenance of a patent airway until recovery of normal respiration is ensured. With the competitive blocking agents, this may be hastened by the administration of neostigmine methylsulfate (0.5-2 mg IV) or edrophonium (10 mg IV, repeated as required up to a total of 40 mg) (Watkins, 1994).

Interventional Strategies for Other Toxic Effects. Neostigmine effectively antagonizes only the skeletal muscular blocking action of the competitive blocking agents and may aggravate such side effects as hypotension or induce bronchospasm. In such circumstances, sympathomimetic amines may be given to support the blood pressure. Atropine or glycopyrrolate is administered to counteract muscarinic stimulation. Antihistamines are definitely beneficial to counteract the responses that follow the release of histamine, particularly when administered before the neuromuscular blocking agent.

Reversal of Effects by Chelation Therapy. There is now an investigational chelating agent specific for rocuronium and vecuronium, sugammadex (BRIDION), a modified γ-cyclodextrin. Administration of sugammadex at doses >2 mg/kg is able to reverse neuromuscular blockade from rocuronium within 3 minutes. The majority of sugammadex and its complex with rocuronium is eliminated in the urine. In patients with impaired renal function, sugammadex clearance is markedly reduced and this agent should be avoided. Theoretically, neuromuscular blockade can reoccur if rocuronium or vecuronium become displaced from the sugammadex complex, necessitating careful monitoring and repeat dosing if necessary. Sugammadex is approved for clinical use in Europe but not yet in the U.S. (Naguib and Brull, 2009). Side effects include dysgeusia and rare self-limiting hypersensitivity.
GANGLIONIC NEUROTRANSMISSION

Neurotransmission in autonomic ganglia is a complex process involving multiple neurotransmitter-receptor systems. The primary event involves release of ACh and the rapid depolarization of postsynaptic membranes via the activation of neuronal nicotinic (Nn) receptors by ACh. Intracellular recordings from postganglionic neurons indicate that at least four different changes in postsynaptic membrane potential can be elicited by stimulation of the preganglionic nerve (Figure 11–5):

1. An initial excitatory postsynaptic potential (EPSP, via nicotinic receptors) that may result in an action potential
2. An inhibitory postsynaptic potential (IPSP) mediated by M2 muscarinic receptors
3. A secondary slow EPSP mediated by M1 muscarinic receptors
4. A late, slow EPSP mediated by myriad peptides

There are multiple nicotinic receptor subunits (e.g., α3, α5, α7, β2, and β4) in ganglia, with α3 and β2 being most abundant. The ganglionic nicotinic ACh receptors are sensitive to classical blocking agents such as hexamethonium and trimethaphan.

An action potential is generated in the postganglionic neuron when the initial EPSP attains a critical amplitude. In mammalian sympathetic ganglia in vivo, it is common for multiple synapses to be activated before transmission is effective. Unlike the neuromuscular junction, discrete end plates with focal localization of receptors do not exist in ganglia; rather, the dendrites and nerve cell bodies contain the receptors. Iontophoretic application of ACh to the ganglion results in a depolarization with a latency < 1 ms; this decays over a period of 10-50 ms (Ascher et al., 1979). Measurements of single-channel conductances indicate that the characteristics of nicotinic-receptor channels of the ganglia and the neuromuscular junction are quite similar.

The secondary events that follow the initial depolarization (IPSP; slow EPSP; late, slow EPSP) are insensitive to hexamethonium or other Nn antagonists. The IPSP is unaffected by the classical nicotinic-receptor blocking agents. Electrophysiological and neurochemical evidence suggests that catecholamines participate in the generation of the IPSP. Dopamine and norepinephrine cause hyperpolarization of ganglia; however, in some ganglia IPSPs are mediated by M1 muscarinic receptors (Chapter 9). Since the IPSP is sensitive in most systems to blockade by both atropine and α-adrenergic receptor antagonists, ACh that is released at the preganglionic terminal may act on catecholamine-containing interneurons to stimulate the release of dopamine or norepinephrine; the catecholamine in turn produces hyperpolarization (an IPSP) of ganglion cells. Histochemical studies indicate that dopamine- or norepinephrine-containing small, intensely fluorescent (SIF) cells and adrenergic nerve terminals are present in ganglia. Details of the functional linkage between the SIF cells and the electrogenic mechanism of the IPSP remain to be resolved (Prud’homme et al., 1999; Slavikova et al., 2003).

The slow EPSP is generated by ACh activation of M1 (Gq-coupled) muscarinic receptors and is blocked by atropine or antagonists

Figure 11–5. Postsynaptic potentials recorded from an autonomic postganglionic nerve cell body after stimulation of the preganglionic nerve fiber. The preganglionic nerve releases ACh onto postganglionic cells. The initial EPSP results from the inward Na+ current (and perhaps Ca2+ current) through the nicotinic receptor channel. If the EPSP is of sufficient magnitude, it triggers an action potential spike, which is followed by a slow IPSP, a slow EPSP, and a late, slow EPSP. The slow IPSP and slow EPSP are not seen in all ganglia. The electrical events subsequent to the initial EPSP are thought to modulate the probability that a subsequent EPSP will reach the threshold for triggering a spike. Other interneurons, such as catecholamine-containing, small, intensely fluorescent (SIF) cells, and axon terminals from sensory, afferent neurons also release transmitters and that may influence the slow potentials of the postganglionic neuron. A number of cholinergic, peptidergic, adrenergic, and amino acid receptors are found on the dendrites and soma of the postganglionic neuron and the interneurons. The preganglionic fiber releases ACh and peptides; the interneurons store and release catecholamines, amino acids, and peptides; the sensory afferent nerve terminals release peptides. The initial EPSP is mediated through nicotinic (Nn) receptors, the slow IPSP and EPSP through M2 and M1 muscarinic receptors, and the late, slow EPSP through several types of peptidergic receptors.
that are selective for M₁ muscarinic receptors (Chapter 9). The slow EPSP has a longer latency and greater duration (10-30 seconds) than the initial EPSP. Slow EPSPs result from decreased K⁺ conductance, the M current that regulates the sensitivity of the cell to repetitive fast-depolarizing events (Adams et al., 1982). In contrast, the late slow EPSP lasts for several minutes and is mediated by peptides released from presynaptic nerve endings or interneurons in specific ganglia, as discussed in the next section. The peptides and ACh may be co-released at the presynaptic nerve terminals; the relative stability of the peptides in the ganglion extends its sphere of influence to postsynaptic sites beyond those in the immediate proximity of the nerve ending.

The secondary synaptic events modulate the initial EPSP. The importance of the secondary pathways and the nature of the modulating transmitters appear to differ among individual ganglia and between parasympathetic and sympathetic ganglia. A variety of peptides, including gonadotropin-releasing hormone, substance P, angiotensin, calcitonin gene–related peptide, vasoactive intestinal polypeptide, neuropeptide Y, and enkephalins, have been identified in ganglia by immunofluorescence. They appear localized to particular cell bodies, nerve fibers, or SIF cells, are released on nerve stimulation, and are presumed to mediate the late slow EPSP (Elfvin et al., 1993). Other neurotransmitter substances, such as 5-hydroxytryptamine and γ-aminobutyric acid, are known to modify ganglionic transmission. Precise details of their modulatory actions are not understood, but they appear to be most closely associated with the late slow EPSP and inhibition of the M current in various ganglia. Conventional ganglionic blocking agents can inhibit ganglionic transmission completely; the same cannot be said for muscarinic antagonists or α adrenergic receptor agonists (Volle, 1980).

GANGLIONIC STIMULATING DRUGS

Drugs that stimulate cholinergic receptor sites on autonomic ganglia have been essential for analyzing the mechanism of ganglionic function; however, these ganglionic agonists have very limited therapeutic use. They can be grouped into two categories. The first group consists of drugs with nicotinic specificity, including nicotine, itself, which millions of tobacco users ingest on a daily basis. Nicotine’s excitatory effects on ganglia are rapid in onset, are blocked by ganglionic nicotinic-receptor antagonists, and mimic the initial EPSP. The second group consists of muscarinic receptor agonists such as muscarine, McN-A-343, and methacholine (Chapter 9); their excitatory effects on ganglia are delayed in onset, blocked by atropine-like drugs, and mimic the slow EPSP.

History. Two natural alkaloids, nicotine and lobeline, exhibit peripheral actions by stimulating autonomic ganglia. Nicotine (Figure 11–6) was first isolated from leaves of tobacco, *Nicotiana tabacum*, by Posselt and Reiman in 1828; Orfila initiated the first pharmacological studies of the alkaloid in 1843. Langley and Dickinson painted the superior cervical ganglion of rabbits with nicotine and demonstrated that its site of action was the ganglion rather than the preganglionic or postganglionic nerve fiber. Lobeline, from *Lobelia inflata*, has many of the same actions as nicotine but is less potent.

Other ganglionic stimulants include tetramethylammonium (TMA) and 1,1-dimethyl-4-phenylpiperazinium iodide (DMPP) (Figure 11–6). Stimulation of ganglia by TMA or DMPP differs from that produced by nicotine in that the initial stimulation is not followed by a dominant blocking action. DMPP is about three times more potent and slightly more ganglion-selective than nicotine. Although parasympathomimetic drugs stimulate ganglia, their effects usually are obscured by stimulation of other neuroeffector sites. McN-A-343 represents an exception: in certain tissues its primary action appears to occur at muscarinic M₁ receptors in ganglia.

Nicotine

Nicotine is of considerable medical significance because of its toxicity, presence in tobacco, and propensity for conferring a dependence on its users. The chronic effects of nicotine and the untoward effects of the chronic use of tobacco are considered in Chapter 24. Nicotine is one of the few natural liquid alkaloids. It is a colorless, volatile base (pKₐ = 8.5) that turns brown and acquires the odor of tobacco on exposure to air.

Pharmacological Actions. The complex and often unpredictable changes that occur in the body after administration of nicotine are due not only to its actions on a variety of neuroeffector and chemosensitive sites but also to the fact that the alkaloid can both stimulate
and desensitize receptors. The ultimate response of any one system represents the summation of stimulatory and inhibitory effects of nicotine. For example, the drug can increase heart rate by excitation of sympathetic ganglia or by paralysis of parasympathetic cardiac ganglia, and it can slow heart rate by paralysis of sympathetic or stimulation of parasympathetic cardiac ganglia. In addition, the effects of the drug on the chemoreceptors of the carotid and aortic bodies and on regions of the CNS can influence heart rate, as can the compensatory baroreceptor reflexes resulting from changes in blood pressure caused by nicotine. Finally, nicotine elicits a discharge of epinephrine from the adrenal medulla, which accelerates heart rate and raises blood pressure.

**Peripheral Nervous System.** The major action of nicotine consists initially of transient stimulation and subsequently of a more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and may facilitate impulse transmission. Following larger doses, the initial stimulation is followed very quickly by a blockade of transmission. Whereas stimulation of the ganglion cells coincides with their depolarization, depression of transmission by adequate doses of nicotine occurs both during the depolarization and after it has subsided. Nicotine also possesses a biphasic action on the adrenal medulla: small doses evoke the discharge of catecholamines; larger doses prevent their release in response to splanchnic nerve stimulation.

The effects of high doses of nicotine on the neuromuscular junction are similar to those on ganglia. However, with the exception of avian and denervated mammalian muscle, the stimulant phase is obscured largely by the rapidly developing paralysis. In the latter stage, nicotine also produces neuromuscular blockade by receptor desensitization. At lower concentrations, such as those typically achieved by recreational tobacco use (~200 nM), nicotine’s effects reflect its higher affinity for a neuronal nicotinic receptor (α4β2) than for the neuromuscular junction receptor (α1β1γδ), as explained in molecular detail by Xi and associates (2009). This high affinity, coupled with the ability of nicotine to cross the blood-brain barrier, allows nicotine to selectively activate neuronal receptors without causing intolerable contractions or paralysis of skeletal muscle.

Nicotine, like ACh, stimulates a number of sensory receptors. These include mechanoreceptors that respond to stretch or pressure of the skin, mesentery, tongue, lung, and stomach; chemoreceptors of the carotid body; thermal receptors of the skin and tongue; and pain receptors. Prior administration of hexamethonium prevents stimulation of the sensory receptors by nicotine but has little, if any, effect on the activation of sensory receptors by physiological stimuli.

**Central Nervous System.** Nicotine markedly stimulates the CNS. Low doses produce weak analgesia; with higher doses, tremors leading to convulsions at toxic doses are evident. The excitation of respiration is a prominent action of nicotine; although large doses act directly on the medulla oblongata, smaller doses augment respiration reflexly by excitation of the chemoreceptors of the carotid and aortic bodies. Stimulation of the CNS with large doses is followed by depression, and death results from failure of respiration owing to both central paralysis and peripheral blockade of the diaphragm and intercostal muscles that facilitate respiration.

Nicotine induces vomiting by both central and peripheral actions. The central component of the vomiting response is due to stimulation of the emetic chemoreceptor trigger zone in the area postrema of the medulla oblongata. In addition, nicotine activates vagal and spinal afferent nerves that form the sensory input of the reflex pathways involved in the act of vomiting. Studies in isolated higher centers of the brain and spinal cord reveal that the primary sites of action of nicotine in the CNS are prejunctional, causing the release of other transmitters. Accordingly, the stimulatory and pleasure-reward actions of nicotine appear to result from release of excitatory amino acids, dopamine, and other biogenic amines from various CNS centers (MacDermott et al., 1999). Release of excitatory amino acids may account for much of nicotine’s stimulatory action.

Chronic exposure to nicotine in several systems causes a marked increase in the density or number of nicotinic receptors, possibly contributing to tolerance and dependence. Nicotine acts as an intracellular molecular chaperone to promote the assembly of receptor subunits by inducing an active conformation in the nascent subunits that assemble more efficiently. Chronic low dose exposure to nicotine also significantly increases the t1/2 of receptors on the cell surface (Kuryatov et al., 2005; Lester et al., 2009).

**Cardiovascular System.** When administered intravenously to dogs, nicotine characteristically produces an increase in heart rate and blood pressure. The latter is usually more sustained. In general, the cardiovascular responses to nicotine are due to stimulation of sympathetic ganglia and the adrenal medulla, together with the discharge of catecholamines from sympathetic nerve endings. Contributing to the sympathomimetic response to nicotine is the activation of chemoreceptors of the aortic and carotid bodies, which reflexly results in vasoconstriction, tachycardia, and elevated blood pressure.

**GI Tract.** The combined activation of parasympathetic ganglia and cholinergic nerve endings by nicotine results in increased tone and motor activity of the bowel. Nausea, vomiting, and occasionally diarrhea are observed following systemic absorption of nicotine in an individual who has not been exposed to nicotine previously.

**Exocrine Glands.** Nicotine causes an initial stimulation of salivary and bronchial secretions that is followed by inhibition.

**Absorption, Distribution, and Elimination.** Nicotine is readily absorbed from the respiratory tract, buccal membranes, and skin. Severe poisoning has resulted from percutaneous absorption. As a relatively strong base, nicotine has limited absorption from the stomach. Intestinal absorption is far more efficient. Nicotine in chewing tobacco, because it is absorbed more slowly than inhaled nicotine, has a longer duration of effect. The average cigarette contains 6-11 mg nicotine and delivers ~1-3 mg nicotine systemically to the smoker; bioavailability can increase as much as 3-fold with the intensity of puffing and technique of the smoker (Benowitz, 1998).

Approximately 80-90% of nicotine is altered in the body, mainly in the liver but also in the kidney and lung. Cotinine is the major metabolite, with nicotine-1’-N-oxide and 3-hydroxycotinine and conjugated metabolites found in lesser quantities (Benowitz, 1998). The profile of metabolites and the rate of metabolism appear to be similar in smokers and nonsmokers. The t1/2 of nicotine following inhalation or parenteral administration is ~2 hours. Nicotine
and its metabolites are eliminated rapidly by the kidney. The rate of urinary excretion of nicotine diminishes when the urine is alkaline. Nicotine also is excreted in the milk of lactating women who smoke; the milk of heavy smokers may contain 0.5 mg/L.

**Acute Nicotine Poisoning.** Poisoning from nicotine may occur from accidental ingestion of nicotine-containing insecticide sprays or in children from ingestion of tobacco products. The acutely fatal dose of nicotine for an adult is probably ~ 60 mg. Smoking tobacco usually contains 1–2% nicotine. Apparently, the gastric absorption of nicotine from tobacco taken by mouth is delayed because of slowed gastric emptying, so vomiting caused by the central effect of the initially absorbed fraction may remove much of the tobacco remaining in the GI tract.

The onset of symptoms of acute, severe nicotine poisoning is rapid; they include nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, disturbed hearing and vision, mental confusion, and marked weakness. Faintness and prostration ensue; the blood pressure falls; breathing is difficult; the pulse is weak, rapid, and irregular; and collapse may be followed by terminal convulsions. Death may result within a few minutes from respiratory failure.

**Therapy.** Vomiting may be induced, or gastric lavage should be performed. Alkaline solutions should be avoided. A slurry of activated charcoal is then passed through the tube and left in the stomach. Respiratory assistance and treatment of shock may be necessary.

**Smoking Cessation.** Two goals of the pharmacotherapy of smoking cessation are the reduction of the craving for nicotine and inhibition of the reinforcing effects of nicotine. Myriad approaches and drug regimens are used, including nicotine replacement, bupropion (Chapter 15), and nicotinic ACh receptor agonists (Chapters 15 and 24 and the review by Frishman, 2009). Nicotine dependence is likely mediated, at least in part, by subtypes of the neuronal nicotinic acetylcholine receptor (Nn). The mesolimbic α4β2 subtype of Nn and α7β2-stimulated release of dopamine seem to play major roles in nicotine dependence. Thus, one aim of drug development in this area is discovery of an agent that will stimulate the α7 nicotinic receptor sufficiently to inhibit nicotine reinforcement during smoking (Rollena et al., 2007).

Varenicline (CHANTIX) has been recently introduced as an aid to smoking cessation. The drug interacts with nicotinic ACh receptors. In model systems, varenicline is a partial agonist at α4β2 receptors and a full agonist at the α7 subtype, with weak activity toward α7β2- and α7-containing receptors (Mihalak et al., 2006). The drug is effective clinically; however, it is not benign: Based on postmarketing studies, the FDA has issued a warning about mood and behavioral changes associated with its use (Frishman, 2009).

Nicotine itself is available in several dosage forms to help achieve abstinence from tobacco use. Efficacy results primarily from preventing a withdrawal or abstinence syndrome. Nicotine is marketed for over-the-counter use as a gum or lozenge (NICOTINE POLACRILEX, NICORETTE, COMMIT, THRIVE, others), a nasal spray (NICOTROL), or a vapor inhaler (NICOTROL). The gum and transdermal systems are used most widely, and the objective is to obtain a sustained plasma nicotine concentration lower than venous blood concentrations after smoking. Arterial blood concentrations immediately following inhalation can be as much as 10-fold higher than venous concentrations. The efficacy of these dosage forms in producing abstinence from smoking is enhanced when linked to counseling and motivational therapy (Benowitz, 1999; Fant et al., 1999; Frishman, 2009).

**GANGLIONIC BLOCKING DRUGS**

There are two categories of agents that block ganglionic nicotinic receptors. The prototype of the first group, nicotine, initially stimulates the ganglia by an ACh-like action and then blocks them by causing a persistent depolarization (Volle, 1980). Compounds in the second category (e.g., trimethaphan and hexamethonium) impair transmission either by competing with ACh for ganglionic nicotinic receptor sites or by blocking the channel. Trimethaphan acts by competition with ACh, analogous to the mechanism of action of curare at the neuromuscular junction. Hexamethonium appears to block the channel after it opens; this action shortens the duration of current flow because the open channel either becomes occluded or closes (Gurney and Rang, 1984). Regardless of the mechanism, the initial EPSP is blocked, and ganglionic transmission is inhibited. The chemical diversity of compounds that block autonomic ganglia without causing prior stimulation is shown in Figure 11–7.

Ganglionic blocking agents such as mecamylamine (INVERSINE) and trimethaphan were the first effective therapy for the treatment of hypertension and were used extensively during the 1950s and 1960s, as described in earlier editions of this text. However, due to the role of ganglionic transmission in both sympathetic and parasympathetic neurotransmission, the antihypertensive action of ganglionic blocking agents was accompanied by numerous undesirable side effects.

**History and Structure-Activity Relationship.** Although Marshall first described the “nicotine-paralyzing” action of tetraethylammonium (TEA) on ganglia in 1913, TEA was largely overlooked until the effects of the ion on the cardiovascular system and autonomic ganglia were analyzed. The prototypical ganglionic blocking drug in this series, hexamethonium (C6), has a bridge of six methylene groups between the two quaternary nitrogen atoms (Figure 11–7). It has minimal neuromuscular and muscarinic blocking activities. Triethylsulfoniums (e.g., trimethaphan), like the quaternary and bis-quaternary ammonium ions, possess ganglionic blocking actions (Figure 11–7). Mecamylamine, a secondary amine, is currently licensed as an orphan drug for Tourette’s syndrome.

**Pharmacological Properties.** Nearly all the physiological alterations observed after the administration of ganglionic blocking agents can be anticipated with reasonable accuracy by a careful inspection of Figure 8–1 and Table 8–1, and by knowing which division of the
autonomic nervous system exercises dominant control of various organs (Table 11–5). For example, blockade of sympathetic ganglia interrupts adrenergic control of arterioles and results in vasodilation, improved peripheral blood flow in some vascular beds, and a fall in blood pressure. Generalized ganglionic blockade also may result in atony of the bladder and GI tract, cycloplegia, xerostomia, diminished perspiration, and by abolishing circulatory reflex pathways, postural hypotension. These changes represent the generally undesirable features of ganglionic blockade that severely limit the therapeutic efficacy of ganglionic blocking agents.

**Cardiovascular System.** Existing sympathetic tone is critical in determining the degree to which blood pressure is lowered by ganglionic blockade; thus, blood pressure may be decreased only minimally in recumbent normotensive subjects but may fall markedly in sitting or standing subjects. Postural hypotension was a major limitation in ambulatory patients receiving ganglionic blocking drugs.

Changes in heart rate following ganglionic blockade depend largely on existing vagal tone. In humans, mild tachycardia usually accompanies the hypotension, a sign that indicates fairly complete ganglionic blockade. However, a decrease may occur if the heart rate is high initially.

Cardiac output often is reduced by ganglionic blocking drugs in patients with normal cardiac function, as a consequence of diminished venous return resulting from venous dilation and peripheral pooling of blood. In patients with cardiac failure, ganglionic blockade frequently results in increased cardiac output owing to a reduction in peripheral resistance. In hypertensive subjects, cardiac output, stroke volume, and left ventricular work are diminished.

Although total systemic vascular resistance is decreased in patients who receive ganglionic blocking agents, changes in blood flow and vascular resistance of individual vascular beds are variable. Reduction of cerebral blood flow is small unless mean systemic blood pressure falls below 50-60 mm Hg. Skeletal muscle blood flow is unaltered, but splanchnic and renal blood flow decrease following the administration of a ganglionic blocking agent.

**Absorption, Distribution, and Elimination.** The absorption of quaternary ammonium and sulfonium compounds from the enteric tract is incomplete and unpredictable. This is due both to the limited ability of these ionized substances to penetrate cell membranes and to the depression of propulsive movements of the small intestine and

gastric emptying. Although the absorption of mecamylamine is less erratic, a danger exists of reduced bowel activity leading to frank paralytic ileus.

After absorption, the quaternary ammonium- and sulfonium-blocking agents are confined primarily to the extracellular space and are excreted mostly unchanged by the kidney. Mecamylamine concentrates in the liver and kidney and is excreted slowly in an unchanged form.

**Untoward Responses and Severe Reactions.** Among the milder untoward responses observed are visual disturbances, dry mouth, conjunctival suffusion, urinary hesitancy, decreased potency, subjective chilliness, moderate constipation, occasional diarrhea, abdominal discomfort, anorexia, heartburn, nausea, eructation, and bitter taste and the signs and symptoms of syncope caused by postural hypotension. More severe reactions include marked hypotension, constipation, syncope, paralytic ileus, urinary retention, and cycloplegia.

**Clinical Summary**

Neuromuscular blocking agents paralyze skeletal muscle by blocking neurotransmission through nicotinic ACh receptors at the neuromuscular junction. They have no sedative, amnestic, or analgesic properties, and are mainly used in combination with narcotic or volatile anesthetics to relax skeletal muscle and facilitate surgical procedures. Depolarizing neuromuscular blocking agents cause an initial depolarization of the motor end plate that renders it refractory to further stimulation. Competitive or non-depolarizing blocking agents compete directly with ACh at its receptor in the motor end plate. Neuromuscular blocking agents are preferably administered as a single or as intermittent intravenous injections. Depth of blockade is monitored by peripheral nerve stimulation. Competitive agents can be reversed by administration of anti-cholinesterase agents.

Sucinylcholine, the most common depolarizing neuromuscular blocking agent, is used to facilitate endotracheal intubation during rapid-sequence induction of anesthesia due to its rapid onset and short duration of action. The numerous non-depolarizing neuromuscular blocking agents provide a spectrum of pharmacokinetic and pharmacodynamic profiles; vecuronium and pancuronium are used frequently. Due to differences in metabolism/elimination, certain non-depolarizing agents are appropriate for patients with compromised renal, hepatic, or cardiovascular function. Vecuronium or rocuronium are appropriate for patients with normal hepatic and renal function. Gantacurium, currently in clinical trial, represents a new class of competitive agents with ultrashort duration of action comparable to succinylcholine but reportedly with fewer side effects.

Ganglionic blocking agents have been supplanted by superior agents for the treatment of chronic hypertension (Chapter 28). Alternative agents also are available for management of acute hypertensive crises and for the production of controlled hypotension (e.g., reduction in blood pressure during surgery to minimize hemorrhage in the operative field, to reduce blood loss in various orthopedic procedures, and to facilitate surgery on blood vessels).

**BIBLIOGRAPHY**

Adrenergic Agonists and Antagonists

Thomas C. Westfall and David P. Westfall

Not all sympathomimetic drugs show each of the above types of action to the same degree; however, many of the differences in their effects are only quantitative. The pharmacological properties of these drugs as a class are described in detail for the prototypical agent, epinephrine.

Appreciation of the pharmacological properties of the drugs described in this chapter depends on an understanding of the classification, distribution, and mechanism of action of $\alpha$ and $\beta$ adrenergic receptors (Chapter 8).

**CLASSIFICATION OF SYMPATHOMIMETIC DRUGS**

Catecholamines and sympathomimetic drugs are classified as direct-acting, indirect-acting, or mixed-acting sympathomimetics (Figure 12–1). Direct-acting sympathomimetic drugs act directly on one or more of the adrenergic receptors. These agents may exhibit considerable selectivity for a specific receptor subtype (e.g., phenylephrine for $\alpha_1$, terbutaline for $\beta_2$) or may have no or minimal selectivity and act on several receptor types (e.g., epinephrine for $\alpha_1$, $\alpha_2$, $\beta_1$, $\beta_2$, and $\beta_3$ receptors; norepinephrine for $\alpha_1$, $\alpha_2$, and $\beta_1$ receptors). Indirect-acting drugs increase the availability of norepinephrine (NE) or epinephrine to stimulate adrenergic receptors. This can be accomplished in several ways:

- by releasing or displacing NE from sympathetic nerve varicosities
- by blocking the transport of NE into sympathetic neurons (e.g., cocaine)
- by blocking the metabolizing enzymes, monoamine oxidase (MAO) (e.g., pargyline) or catechol-O-methyltransferase (COMT) (e.g., entacapone)

Catecholamines and Sympathomimetic Drugs

Most of the actions of catecholamines and sympathomimetic agents can be classified into seven broad types:

1. A peripheral excitatory action on certain types of smooth muscle, such as those in blood vessels supplying skin, kidney, and mucous membranes; and on gland cells, such as those in salivary and sweat glands.
2. A peripheral inhibitory action on certain other types of smooth muscle, such as those in the wall of the gut, in the bronchial tree, and in blood vessels supplying skeletal muscle.
3. A cardiac excitatory action that increases heart rate and force of contraction.
4. Metabolic actions, such as an increase in the rate of glycogenolysis in liver and muscle and liberation of free fatty acids from adipose tissue.
5. Endocrine actions, such as modulation (increasing or decreasing) of the secretion of insulin, renin, and pituitary hormones.
6. Actions in the central nervous system (CNS), such as respiratory stimulation, an increase in wakefulness and psychomotor activity, and a reduction in appetite.
7. Prejunctional actions that either inhibit or facilitate the release of neurotransmitters, the inhibitory action being physiologically more important.

Many of these actions and the receptors that mediate them are summarized in Tables 8–1 and 8–8.
Drugs that indirectly release NE and also directly activate receptors are referred to as mixed-acting sympathomimetic drugs (e.g., ephedrine, DA).

Prototypical drugs for these various mechanisms are listed in Figure 12–1. Although this classification is convenient, there probably is a continuum of activity from predominantly direct-acting to predominantly indirect-acting drugs. Thus, this classification is relative rather than absolute.

A feature of direct-acting sympathomimetic drugs is that their responses are not reduced by prior treatment with reserpine or guanethidine, which deplete NE from sympathetic neurons. After transmitter depletion, the actions of direct-acting sympathomimetic drugs actually may increase because the loss of the neurotransmitter induces compensatory changes that up-regulate receptors or enhance the signaling pathway. In contrast, the responses of indirect-acting sympathomimetic drugs (e.g., amphetamine, tyramine) are abolished by prior treatment with reserpine or guanethidine. The cardinal feature of mixed-acting sympathomimetic drugs is that their effects are blunted, but not abolished, by prior treatment with reserpine or guanethidine.

Since the actions of NE are more pronounced on $\alpha$ and $\beta_1$ receptors than on $\beta_2$ receptors, many non-catecholamines that release NE have predominantly $\alpha$ receptor–mediated and cardiac effects. However, certain non-catecholamines with both direct and indirect effects on adrenergic receptors show significant $\beta_2$ activity and are used clinically for these effects. Thus, ephedrine, although dependent on release of NE for some of its effects, relieves bronchospasm by its action on $\beta_2$ receptors in bronchial smooth muscle, an effect not seen with NE. Moreover, some non-catecholamines (e.g., phenylephrine) act primarily and directly on target cells. It therefore is impossible to predict precisely the effects of non-catecholamines solely on their ability to provoke NE release.

Chemistry and Structure-Activity Relationship of Sympathomimetic Amines. $\beta$-Phenylethylamine (Table 12–1) can be viewed as the parent compound of the sympathomimetic amines, consisting of a benzene ring and an ethylamine side chain. The structure permits substitutions to be made on the aromatic ring, the $\alpha$- and $\beta$-carbon atoms, and the terminal amino group to yield a variety of compounds with sympathomimetic activity. NE, epinephrine, DA, isoproterenol, and a few other agents have hydroxyl groups substituted at positions 3 and 4 of the benzene ring. Since $o$-dihydroxybenzene is also known as catechol, sympathomimetic amines with these hydroxyl substitutions in the aromatic ring are termed catecholamines.

**Figure 12–1.** Classification of adrenergic receptor agonists (sympathomimetic amines) or drugs that produce sympathomimetic-like effects. For each category, a prototypical drug is shown. (*Not actually sympathetic drugs but produce sympathomimetic-like effects.*)

*Numbers bearing an asterisk refers to substituents numbered in the bottom rows of the table; substituent 3 replaces the N atom, substituent 5 replaces the phenyl ring and 6,7 and 8 are attached directly to the phenyl ring, replacing the ethylamine side chain.

The α and β in the prototypical formula refer to positions of the C atoms in the ethylamine side chain. Prenalol has –OCH₂⁻⁻between the aromatic ring and the carbon atom designated as β in the prototypical formula.
Many directly acting sympathomimetic drugs influence both $\alpha$ and $\beta$ receptors, but the ratio of activities varies among drugs in a continuous spectrum from predominantly $\alpha$ activity (phenylephrine) to predominantly $\beta$ activity (isoproterenol). Despite the multiplicity of the sites of action of sympathomimetic amines, several generalizations can be made (Table 12–1).

**Separation of Aromatic Ring and Amino Group.** By far the greatest sympathomimetic activity occurs when two carbon atoms separate the ring from the amino group. This rule applies with few exceptions to all types of action.

**Substitution on the Amino Group.** The effects of amino substitution are most readily seen in the actions of catecholamines on $\alpha$ and $\beta$ receptors. Increase in the size of the alkyl substituent increases $\beta$ receptor activity (e.g., isoproterenol). NE has, in general, rather feeble $\beta$ activity; this activity is greatly increased in epinephrine by the addition of a methyl group. A notable exception is phenylephrine, which has an N-methyl substituent but is an $\alpha$-selective agonist. $\beta_2$-Selective compounds require a large amino substituent, but depend on other substitutions to define selectivity for $\beta_2$ rather than for $\beta_1$ receptors. In general, the smaller the substitution on the amino group, the greater the selectivity for $\alpha$ activity, although N-methylation increases the potency of primary amines. Thus, $\alpha$ activity is maximal in epinephrine, less in NE and almost absent in isoproterenol.

**Substitution on the Aromatic Nucleus.** Maximal $\alpha$ and $\beta$ activity depends on the presence of hydroxyl groups on positions 3 and 4. When one or both of these groups are absent, with no other aromatic substitution, the overall potency is reduced. Phenylephrine is thus less potent than epinephrine at both $\alpha$ and $\beta$ receptors, with $\beta_1$ activity almost completely absent. Studies of the $\beta$ adrenergic receptor suggest that the hydroxyl groups on serine residues 204 and 207 probably form hydrogen bonds with the catechol hydroxyl groups at positions 3 and 4, respectively. It also appears that aspartate 113 is a point of electrostatic interaction with the amine group on the ligand. Since the serines are in the fifth membrane-spanning region and the aspartate is in the third (Chapter 8), it is likely that catecholamines bind parallel to the plane of the membrane, forming a bridge between the two membrane spans. However, models involving DA receptors suggest alternative possibilities.

Hydroxyl groups in positions 3 and 5 confer $\beta_2$ receptor selectivity on compounds with large amino substituents. Thus, metaproterenol, terbutaline, and other similar compounds relax the bronchial musculature in patients with asthma, but cause less direct cardiac stimulation than do the non-selective drugs. The response to non-catecholamines is partly determined by their capacity to release NE from storage sites. These agents thus cause effects that are mostly mediated by $\alpha$ and $\beta_1$ receptors, since NE is a weak $\beta_2$ agonist. Phenylethylamines that lack hydroxyl groups on the ring and the $\beta$-hydroxyl group on the side chain act almost exclusively by causing the release of NE from sympathetic nerve terminals.

Since substitution of polar groups on the phenylethylamine structure makes the resultant compounds less lipophilic, unsubstituted or alkyl-substituted compounds cross the blood-brain barrier more readily and have more central activity. Thus, ephedrine, amphetamine, and methamphetamine exhibit considerable CNS activity. In addition, as noted, the absence of polar hydroxyl groups results in a loss of direct sympathomimetic activity.

Catecholamines have only a brief duration of action and are ineffective when administered orally, because they are rapidly inactivated in the intestinal mucosa and in the liver before reaching the systemic circulation (Chapter 8). Compounds without one or both hydroxyl substituents are not acted upon by COMT, and their oral effectiveness and duration of action are enhanced.

Groups other than hydroxyls have been substituted on the aromatic ring. In general, potency at $\alpha$ receptors is reduced and $\beta$ receptor activity is minimal; the compounds may even block $\beta$ receptors. For example, methoxamine, with methoxy substituents at positions 2 and 5, has highly selective $\alpha$-stimulating activity, and in large doses blocks $\beta$ receptors. Albuterol, a $\beta_2$-selective agonist, has a substituent at position 3 and is an important exception to the general rule of low $\beta$ receptor activity.

**Substitution on the $\alpha$-Carbon Atom.** This substitution blocks oxidation by MAO, greatly prolonging the duration of action of non-catecholamines because their degradation depends largely on the action of this enzyme. The duration of action of drugs such as ephedrine or amphetamine is thus measured in hours rather than in minutes. Similarly, compounds with an $\alpha$-methyl substituent persist in the nerve terminals and are more likely to release NE from storage sites. Agents such as metaraminol exhibit a greater degree of indirect sympathomimetic activity.

**Substitution on the $\beta$-Carbon Atom.** Substitution of a hydroxyl group on the $\beta$ carbon generally decreases actions within the CNS, largely because it lowers lipid solubility. However, such substitution greatly enhances agonist activity at both $\alpha$ and $\beta$ adrenergic receptors. Although ephedrine is less potent than methamphetamine as a central stimulant, it is more powerful in dilating bronchioles and increasing blood pressure and heart rate.

**Optical Isomerism.** Substitution on either $\alpha$- or $\beta$-carbon yields optical isomers. Levorotatory substitution on the $\beta$-carbon confers the greater peripheral activity, so that the naturally occurring $l$-epinephrine and $l$-NE are at least 10 times as potent as their unnatural $d$-isomers. Dextrorotatory substitution on the $\alpha$-carbon generally results in a more potent compound. $d$-Amphetamine is more potent than $l$-amphetamine in central but not peripheral activity.

**Physiological Basis of Adrenergic Receptor Function.** An important factor in the response of any cell or organ to sympathomimetic amines is the density and proportion of $\alpha$ and $\beta$ adrenergic receptors. For example, NE has relatively little capacity to increase bronchial airflow, since the receptors in bronchial smooth muscle are largely of the $\beta_2$ subtype. In contrast, isoproterenol and epinephrine are potent bronchodilators. Cutaneous blood vessels physiologically express almost exclusively $\alpha$ receptors; thus, NE and epinephrine cause constriction of such vessels, whereas isoproterenol has little effect. The smooth muscle of blood vessels that supply skeletal muscles has both $\beta_1$ and $\alpha$ receptors; activation of $\beta_2$ receptors causes vasodilation, and stimulation of $\alpha$ receptors constricts these vessels. In such vessels, the threshold concentration for activation of $\beta_2$ receptors by epinephrine is lower than that for $\alpha$ receptors, but
when both types of receptors are activated at high concentrations of epinephrine, the response to \( \alpha \) receptors predominates. Physiological concentrations of epinephrine primarily cause vasodilation.

The ultimate response of a target organ to sympathomimetic amines is dictated not only by the direct effects of the agents but also by the reflex homeostatic adjustments of the organism. One of the most striking effects of many sympathomimetic amines is a rise in arterial blood pressure caused by stimulation of vascular \( \alpha \) adrenergic receptors. This stimulation elicits compensatory reflexes that are mediated by the carotid–aortic baroreceptor system. As a result, sympathetic tone is diminished and vagal tone is enhanced; each of these responses leads to slowing of the heart rate. Conversely, when a drug (e.g., a \( \beta \) agonist) lowers mean blood pressure at the mechanoreceptors of the carotid sinus and aortic arch, the baroreceptor reflex works to restore pressure by reducing parasympathetic (vagal) outflow from the CNS to the heart, and increasing sympathetic outflow to the heart and vessels. The baroreceptor reflex effect is of special importance for drugs that have little capacity to activate \( \beta \) receptors directly. With diseases such as atherosclerosis, which may impair baroreceptor mechanisms, the effects of sympathomimetic drugs may be magnified.

**False-Transmitter Concept.** Indirectly acting amines are taken up into sympathetic nerve terminals and storage vesicles, where they replace NE in the storage complex. Phenylethylamines that lack a \( \beta \)-hydroxyl group are retained there poorly, but \( \beta \)-hydroxylated phenylethylamines and compounds that subsequently become \( \beta \)-hydroxylated in the synaptic vesicle by dopamine \( \beta \)-hydroxylase are retained in the synaptic vesicle for relatively long periods of time. Such substances can produce a persistent diminution in the content of NE at functionally critical sites. When the nerve is stimulated, the contents of a relatively constant number of synaptic vesicles are apparently released by exocytosis. If these vesicles contain phenylethylamines that are much less potent than NE, activation of postsynaptic \( \alpha \) and \( \beta \) receptors will be diminished.

This hypothesis, known as the false-transmitter concept, is a possible explanation for some of the effects of MAO inhibitors. Phenylethylamines normally are synthesized in the GI tract as a result of the action of bacterial tyrosine decarboxylase. The tyramine formed in this fashion usually is oxidatively deaminated in the GI tract and the liver, and the amine does not reach the systemic circulation in significant concentrations. However, when an MAO inhibitor is administered, tyramine may be absorbed systemically and transported into sympathetic nerve terminals, where its catabolism again is prevented because of the inhibition of MAO at this site; the tyramine then is \( \beta \)-hydroxylated to octopamine and stored in the vesicles in this form. As a consequence, NE gradually is displaced, and stimulation of the nerve terminal results in the release of a relatively small amount of NE along with a fraction of octopamine. The latter amine has relatively little ability to activate either \( \alpha \) or \( \beta \) receptors.

Thus, a functional impairment of sympathetic transmission parallels long-term administration of MAO inhibitors.

Despite such functional impairment, patients who have received MAO inhibitors may experience severe hypertensive crises if they ingest cheese, beer, or red wine. These and related foods, which are produced by fermentation, contain a large quantity of tyramine, and to a lesser degree, other phenylethylamines. When GI and hepatic MAO are inhibited, the large quantity of tyramine that is ingested is absorbed rapidly and reaches the systemic circulation in high concentration. A massive and precipitous release of NE can result, with consequent hypertension that can be severe enough to cause myocardial infarction or a stroke. The properties of various MAO inhibitors (reversible or irreversible; selective or non-selective at MAO-A and MAO-B) are discussed in Chapter 15.

---

### ENDOGENOUS CATECHOLAMINES

#### Epinephrine

Epinephrine (adrenaline) is a potent stimulant of both \( \alpha \) and \( \beta \) adrenergic receptors, and its effects on target organs are thus complex. Most of the responses listed in Table 8–1 are seen after injection of epinephrine, although the occurrence of sweating, piloerection, and mydriasis depends on the physiological state of the subject. Particularly prominent are the actions on the heart and on vascular and other smooth muscle.

**Blood Pressure.** Epinephrine is one of the most potent vasopressor drugs known. If a pharmacological dose is given rapidly by an intravenous route, it evokes a characteristic effect on blood pressure, which rises rapidly to a peak that is proportional to the dose. The increase in systolic pressure is greater than the increase in diastolic pressure, so that the pulse pressure increases. As the response wanes, the mean pressure may fall below normal before returning to control levels.

The mechanism of the rise in blood pressure due to epinephrine is 3-fold:

- a direct myocardial stimulation that increases the strength of ventricular contraction (positive inotropic action)
- an increased heart rate (positive chronotropic action)
- vasoconstriction in many vascular beds—especially in the precapillary resistance vessels of skin, mucosa, and kidney—along with marked constriction of the veins

The pulse rate, at first accelerated, may be slowed markedly at the height of the rise of blood pressure by compensatory vagal discharge. Small doses of epinephrine (0.1 \( \mu \)g/kg) may cause the blood pressure to fall.
The depressor effect of small doses and the biphasic response to larger doses are due to greater sensitivity to epinephrine of vasodilator \( \beta_2 \) receptors than of constrictor \( \alpha \) receptors.

The effects are somewhat different when the drug is given by slow intravenous infusion or by subcutaneous injection. Absorption of epinephrine after subcutaneous injection is slow due to local vasoconstrictor action; the effects of doses as large as 0.5-1.5 mg can be duplicated by intravenous infusion at a rate of 10-30 \( \mu g/\text{min} \). There is a moderate increase in systolic pressure due to increased cardiac contractile force and a rise in cardiac output (Figure 12–2). Peripheral resistance decreases, owing to a dominant action on \( \beta_2 \) receptors of vessels in skeletal muscle, where blood flow is enhanced; as a consequence, diastolic pressure usually falls. Since the mean blood pressure is not, as a rule, greatly elevated, compensatory baroreceptor reflexes do not appreciably antagonize the direct cardiac actions. Heart rate, cardiac output, stroke volume, and left ventricular work per beat are increased as a result of direct cardiac stimulation and increased venous return to the heart, which is reflected by an increase in right atrial pressure. At slightly higher rates of infusion, there may be no change or a slight rise in peripheral resistance and diastolic pressure, depending on the dose and the resultant ratio of \( \alpha \) to \( \beta \) responses in the various vascular beds; compensatory reflexes also may come into play. The details of the effects of intravenous infusion of epinephrine, NE, and isoproterenol in humans are compared in Table 12–2 and Figure 12–2.

**Vascular Effects.** The chief vascular action of epinephrine is exerted on the smaller arterioles and precapillary sphincters, although veins and large arteries also respond to the drug. Various vascular beds react differently, which results in a substantial redistribution of blood flow.

Injected epinephrine markedly decreases cutaneous blood flow, constricting precapillary vessels and small venules. Cutaneous vasoconstriction accounts for a marked decrease in blood flow in the hands and feet. The “after congestion” of mucosa following the vasoconstriction from locally applied epinephrine probably is due to changes in vascular reactivity as a result of tissue hypoxia rather than to \( \beta \)-agonist activity of the drug on mucosal vessels.

Blood flow to skeletal muscles is increased by therapeutic doses in humans. This is due in part to a powerful \( \beta_2 \)-mediated vasodilator action that is only partially counterbalanced by a vasoconstrictor action on the \( \alpha \) receptors that also are present in the vascular bed. If an \( \alpha \) receptor antagonist is given, the vasodilation in muscle is more pronounced, the total peripheral resistance is decreased, and the mean blood pressure

falls (epinephrine reversal). After the administration of a non-selective β receptor antagonist, only vasoconstriction occurs, and the administration of epinephrine is associated with a considerable pressor effect.

The effect of epinephrine on cerebral circulation is related to systemic blood pressure. In usual therapeutic doses, the drug has relatively little constrictor action on cerebral arterioles. It is physiologically advantageous that the cerebral circulation does not constrict in response to activation of the sympathetic nervous system by stressful stimuli. Indeed, autoregulatory mechanisms tend to limit the increase in cerebral blood flow caused by increased blood pressure.

Doses of epinephrine that have little effect on mean arterial pressure consistently increase renal vascular resistance and reduce renal blood flow by as much as 40%. All segments of the renal vascular bed contribute to the increased resistance. Since the glomerular filtration rate is only slightly and variably altered, the filtration fraction is consistently increased. Excretion of Na⁺, K⁺, and Cl⁻ is decreased; urine volume may be increased, decreased, or unchanged. Maximal tubular reabsorptive and excretory capacities are unchanged. The secretion of renin is increased as a consequence of a direct action of epinephrine on β₁ receptors in the juxtaglomerular apparatus.

Arterial and venous pulmonary pressures are raised. Although direct pulmonary vasoconstriction occurs, redistribution of blood from the systemic to the pulmonary circulation, due to constriction of the more powerful musculature in the systemic great veins, doubtless plays an important part in the increase in pulmonary pressure. Very high concentrations of epinephrine may cause pulmonary edema precipitated by elevated pulmonary capillary filtration pressure and possibly by “leaky” capillaries.

Coronary blood flow is enhanced by epinephrine or by cardiac sympathetic stimulation under physiological conditions. The increased flow, which occurs even with doses that do not increase the aortic blood pressure, is the result of two factors. The first is the increased relative duration of diastole at higher heart rates (described later); this is partially offset by decreased blood flow during systole because of more forceful contraction of the surrounding myocardium and an increase in mechanical compression of the coronary vessels. The increased flow during diastole is further enhanced if aortic blood pressure is elevated by epinephrine; as a consequence, total coronary flow may be increased. The second factor is a metabolic dilator effect that results from the increased strength of contraction and myocardial O₂ consumption due to the direct effects of epinephrine on cardiac myocytes. This vasodilation is mediated in part by adenosine released from cardiac myocytes, which tends to override a direct vasoconstrictor effect of epinephrine that results from activation of β receptors in coronary vessels.

**Cardiac Effects.** Epinephrine is a powerful cardiac stimulant. It acts directly on the predominant β₁ receptors of the myocardium and of the cells of the pacemaker and conducting tissues; β₂, β₃, and α receptors also are present in the heart, although there are considerable species differences. Substantial recent interest has focused on the role of β₁ and β₂ receptors in the human heart, especially in heart failure. The heart rate increases, and the rhythm often is altered. Cardiac systole is shorter and more powerful, cardiac output is enhanced, and the work of the heart and its oxygen consumption are markedly increased. Cardiac efficiency (work done relative to oxygen consumption) is lessened. Direct responses to epinephrine include increases in contractile force, accelerated rate of rise of isometric tension, enhanced rate of relaxation, decreased time to peak tension, increased excitability, acceleration of the rate of spontaneous beating, and induction of automaticity in specialized regions of the heart.

In accelerating the heart, epinephrine preferentially shortens systole so that the duration of diastole usually is not reduced. Indeed, activation of β receptors increases the rate of relaxation of ventricular muscle. Epinephrine speeds the heart by accelerating the slow depolarization of sinoatrial (SA) nodal cells that takes place during diastole, that is, during phase 4 of the action potential (Chapter 29). Consequently, the transmembrane potential of the pacemaker cells rises more rapidly to the threshold level of action potential initiation. The amplitude of the action potential and the maximal rate of depolarization (phase 0) also are increased. A shift in the location of the pacemaker within the SA node often occurs, owing to activation of latent pacemaker cells. In Purkinje fibers, epinephrine also accelerates diastolic depolarization and may activate latent pacemaker cells. These changes do not occur in atrial and ventricular muscle fibers, where epinephrine has little effect on the stable, phase 4 membrane potential after repolarization. If large doses of epinephrine are given, premature ventricular contractions occur and may herald more serious ventricular arrhythmias. This rarely is seen with conventional doses in humans, but ventricular extrasystoles, tachycardia, or even fibrillation may be precipitated by release of endogenous epinephrine when the heart has been sensitized to this action of epinephrine by certain anesthetics or by myocardial ischemia. The mechanism of induction of these cardiac arrhythmias is not clear.

Some effects of epinephrine on cardiac tissues are largely secondary to the increase in heart rate and are small or inconsistent when the heart rate is kept constant. For example, the effect of epinephrine on repolarization of atrial muscle, Purkinje fibers, or ventricular muscle is small if the heart rate is unchanged. When the heart rate is increased, the duration of the action potential is consistently shortened, and the refractory period is correspondingly decreased.

Conduction through the Purkinje system depends on the level of membrane potential at the time of excitation. Excessive reduction of this potential results in conduction disturbances, ranging from slowed conduction to complete block. Epinephrine often increases the membrane potential and improves conduction in Purkinje fibers that have been excessively depolarized.

Epinephrine normally shortens the refractory period of the human atrioventricular (AV) node by direct effects on the heart, although doses of epinephrine that slow the heart through reflex vagal discharge may indirectly tend to prolong it. Epinephrine also decreases the grade of AV block that occurs as a result of disease, drugs, or vagal stimulation. Supraventricular arrhythmias are apt to occur from the combination of epinephrine and cholinergic stimulation. Depression of sinus rate and AV conduction by vagal discharge
probably plays a part in epinephrine-induced ventricular arrhythmias, since various drugs that block the vagal effect confer some protection. The actions of epinephrine in enhancing cardiac automaticity and in causing arrhythmias are effectively antagonized by \( \beta \) receptor antagonists such as propranolol. However, \( \alpha \) receptors exist in most regions of the heart, and their activation prolongs the refractory period and strengthens myocardial contractions.

Cardiac arrhythmias have been seen in patients after inadvertent intravenous administration of conventional subcutaneous doses of epinephrine. Premature ventricular contractions can appear, which may be followed by multifocal ventricular tachycardia or ventricular fibrillation. Pulmonary edema also may occur.

Epinephrine decreases the amplitude of the T wave of the electrocardiogram (ECG) in normal persons. In animals given relatively larger doses, additional effects are seen on the T wave and the ST segment. After decreasing in amplitude, the T wave may become biphasic, and the ST segment can deviate either above or below the isoelectric line. Such ST-segment changes are similar to those seen in patients with angina pectoris during spontaneous or epinephrine-induced attacks of pain. These electrical changes therefore have been attributed to myocardial ischemia. Also, epinephrine as well as other catecholamines may cause myocardial cell death, particularly after intravenous infusions. Acute toxicity is associated with contraction band necrosis and other pathological changes. Recent interest has focused on the possibility that prolonged sympathetic stimulation of the heart, such as in congestive cardiomyopathy, may promote apoptosis of cardiomyocytes.

**Effects on Smooth Muscles.** The effects of epinephrine on the smooth muscles of different organs and systems depend on the type of adrenergic receptor in the muscle (Table 8–1). The effects on vascular smooth muscle noted above are of major physiological importance, whereas those on smooth muscle of the GI tract are relatively minor. GI smooth muscle is, in general, relaxed by epinephrine. This effect is due to activation of both \( \alpha \) and \( \beta \) receptors. Intestinal tone and the frequency and amplitude of spontaneous contractions are reduced. The stomach usually is relaxed and the pyloric and ileocecal sphincters are contracted, but these effects depend on the pre-existing tone of the muscle. If tone already is high, epinephrine causes relaxation; if low, contraction.

The responses of uterine muscle to epinephrine vary with species, phase of the sexual cycle, state of gestation, and dose given. Epinephrine contracts strips of pregnant or nonpregnant human uterus in vitro by interaction with \( \alpha \) receptors. The effects of epinephrine on the human uterus in situ, however, differ. During the last month of pregnancy and at parturition, epinephrine inhibits uterine tone and contractions. Effects of adrenergic agents and other drugs on the uterus are discussed later in this chapter and in Chapter 66.

Epinephrine relaxes the detrusor muscle of the bladder as a result of activation of \( \beta \) receptors and contracts the trigone and sphincter muscles owing to its \( \alpha \)-agonist activity. This can result in hesitancy in urination and may contribute to retention of urine in the bladder. Activation of smooth muscle contraction in the prostate promotes urinary retention.

**Respiratory Effects.** Epinephrine affects respiration primarily by relaxing bronchial muscle. It has a powerful bronchodilator action, most evident when bronchial muscle is contracted because of disease, as in bronchial asthma, or in response to drugs or various autacoids. In such situations, epinephrine has a striking therapeutic effect as a physiological antagonist to substances that cause bronchoconstriction.

The beneficial effects of epinephrine in asthma also may arise from inhibition of antigen-induced release of inflammatory mediators from mast cells, and to a lesser extent from diminution of bronchial secretions and congestion within the mucosa. Inhibition of mast cell secretion is mediated by \( \beta_2 \) receptors, while the effects on the mucosa are mediated by \( \alpha \) receptors; however, other drugs, such as glucocorticoids and leukotriene receptor antagonists, have much more profound anti-inflammatory effects in asthma (Chapters 33 and 34).

**Effects on the CNS.** Because of the inability of this rather polar compound to enter the CNS, epinephrine in conventional therapeutic doses is not a powerful CNS stimulant. While the drug may cause restlessness, apprehension, headache, and tremor in many persons, these effects in part may be secondary to the effects of epinephrine on the cardiovascular system, skeletal muscles, and intermediary metabolism; that is, they may be the result of somatic manifestations of anxiety. Some other sympathomimetic drugs more readily cross the blood-brain barrier.

**Metabolic Effects.** Epinephrine has a number of important influences on metabolic processes. It elevates the concentrations of glucose and lactate in blood by mechanisms described in Chapter 8. Insulin secretion is inhibited through an interaction with \( \alpha_2 \) receptors and is enhanced by activation of \( \beta_2 \) receptors; the predominant effect seen with epinephrine is inhibition. Glucagon secretion is enhanced by an action on the \( \beta \) receptors of the \( \alpha \) cells of pancreatic islets. Epinephrine also decreases the uptake of glucose by peripheral tissues, at least in part because of its effects on the secretion of insulin, but also possibly due to direct effects on skeletal muscle. Glycosuria rarely occurs. The effect of epinephrine to stimulate glycogenolysis in most tissues and in most species involves \( \beta \) receptors.

Epinephrine raises the concentration of free fatty acids in blood by stimulating \( \beta \) receptors in adipocytes. The result is activation of triglyceride lipase, which accelerates the triglyceride breakdown to free fatty acids and glycerol. The calorigenic action of epinephrine (increase in metabolism) is reflected in humans by an
Increase of 20-30% in oxygen consumption after conventional doses. This effect mainly is due to enhanced breakdown of triglycerides in brown adipose tissue, providing an increase in oxidizable substrate (Chapter 8).

**Miscellaneous Effects.** Epinephrine reduces circulating plasma volume by loss of protein-free fluid to the extracellular space, thereby increasing hematocrit and plasma protein concentration. However, conventional doses of epinephrine do not significantly alter plasma volume or packed red cell volume under normal conditions, although such doses are reported to have variable effects in the presence of shock, hemorrhage, hypotension, or anesthesia. Epinephrine rapidly increases the number of circulating polymorphonuclear leukocytes, likely due to β-receptor–mediated demargination of these cells. Epinephrine accelerates blood coagulation in laboratory animals and humans and promotes fibrinolysis.

The effects of epinephrine on secretory glands are not marked; in most glands secretion usually is inhibited, partly owing to the reduced blood flow caused by vasoconstriction. Epinephrine stimulates lacrimation and a scanty mucus secretion from salivary glands. Sweating and pilomotor activity are minimal after systemic administration of epinephrine, but occur after intradermal injection of very dilute solutions of either epinephrine or NE. Such effects are inhibited by α-receptor antagonists.

Mydriasis is readily seen during physiological sympathetic stimulation but not when epinephrine is instilled into the conjunctival sac of normal eyes. However, epinephrine usually lowers intracocular pressure; the mechanism of this effect is not clear but probably reflects reduced production of aqueous humor due to vasoconstriction and enhanced outflow (Chapter 64).

Although epinephrine does not directly excite skeletal muscle, it facilitates neuromuscular transmission, particularly that following prolonged rapid stimulation of motor nerves. In apparent contrast to the effects of α-receptor activation at presynaptic nerve terminals in the autonomic nervous system (α1 receptors), stimulation of α receptors causes a more rapid increase in transmitter release from the somatic motor neuron, perhaps as a result of enhanced influx of Ca2+. These responses likely are mediated by α2 receptors. These actions may explain in part the ability of epinephrine (given intra-arterially) to briefly increase strength of the injected limb of patients with myasthenia gravis. Epinephrine also acts directly on intra-arterially) to increase peak tension. Of greater physiological and clinical interest is the capacity of epinephrine and selective β2 agonists to increase physiological tremor, at least in part due to β-receptor–mediated enhancement of discharge of muscle spindles.

Epinephrine promotes a fall in plasma K+, largely due to stimulation of K+ uptake into cells, particularly skeletal muscle, due to activation of β2 receptors. This is associated with decreased renal K+ excretion. These receptors have been exploited in the management of hyperkalemic familial periodic paralysis, which is characterized by episodic flaccid paralysis, hyperkalemia, and depolarization of skeletal muscle. The β2-selective agonist albuterol apparently is able to ameliorate the impairment in the ability of the muscle to accumulate and retain K+.

The administration of large or repeated doses of epinephrine or other sympathomimetic amines to experimental animals damages arterial walls and myocardium, even inducing necrosis in the heart.

**Absorption, Fate, and Excretion.** Epinephrine is not effective after oral administration because it is rapidly conjugated and oxidized in the GI mucosa and liver. Absorption from subcutaneous tissues occurs relatively slowly because of local vasoconstriction and the rate may be further decreased by systemic hypotension, for example in a patient with shock. Absorption is more rapid after intramuscular injection. In emergencies, it may be necessary to administer epinephrine intravenously. When relatively concentrated solutions are nebulized and inhaled, the actions of the drug largely are restricted to the respiratory tract; however, systemic reactions such as arrhythmias may occur, particularly if larger amounts are used.

Epinephrine is rapidly inactivated in the body. The liver, which is rich in both of the enzymes responsible for destroying circulating epinephrine (COMT and MAO), is particularly important in this regard (see Figure 8–7 and Table 8–4). Although only small amounts appear in the urine of normal persons, the urine of patients with pheochromocytoma may contain relatively large amounts of epinephrine, NE and their metabolites.

Epinephrine is available in a variety of formulations geared for different clinical indications and routes of administration, including self-administration for anaphylactic reactions (EpiPen). Several practical points are worth noting. First, epinephrine is unstable in alkaline solution; when exposed to air or light, it turns pink from oxidation to adrenochrome and then brown from formation of polymers. Epinephrine injection is available in 1 mg/mL (1:1000), 0.1 mg/mL (1:10,000), and 0.5 mg/mL (1:2,000) solutions. The usual adult dose given subcutaneously ranges from 0.3-0.5 mg. Fatal medication errors have occurred as a consequence of confusing these dilutions. The intravenous route is used cautiously if an immediate and reliable effect is mandatory. If the solution is given by vein, it must be adequately diluted and injected very slowly. The dose is seldom as much as 0.25 mg, except for cardiac arrest, when larger doses may be required.

**Toxicity, Adverse Effects, and Contraindications.** Epinephrine may cause disturbing reactions, such as restlessness, throbbing headache, tremor, and palpitations. The effects rapidly subside with rest, quiet, recumbency, and reassurance. More serious reactions include cerebral hemorrhage and cardiac arrhythmias. The use of large doses or the accidental, rapid intravenous injection of epinephrine may result in cerebral hemorrhage from the sharp rise in blood pressure. Ventricular arrhythmias may follow the administration of epinephrine. Angina may be induced by epinephrine in patients...
with coronary artery disease. The use of epinephrine generally is contraindicated in patients who are receiving non-selective β receptor antagonists, since its unopposed actions on vascular α receptors may lead to severe hypertension and cerebral hemorrhage.

**Therapeutic Uses.** The clinical uses of epinephrine are based on its actions on blood vessels, heart, and bronchial muscle. In the past, the most common use of epinephrine was to relieve respiratory distress due to bronchospasm; however, β₂-selective agonists now are preferred. A major use is to provide rapid, emergency relief of hypersensitivity reactions, including anaphylaxis, to drugs and other allergens. Epinephrine also is used to prolong the action of local anesthetics, presumably by decreasing local blood flow (Chapter 20). Its cardiac effects may be of use in restoring cardiac rhythm in patients with cardiac arrest due to various causes. It also is used as a topical hemostatic agent on bleeding surfaces such as in the mouth or in bleeding peptic ulcers during endoscopy of the stomach and duodenum. Systemic absorption of the drug can occur with dental application. In addition, inhalation of epinephrine may be useful in the treatment of post-intubation and infectious croup. The therapeutic uses of epinephrine, in relation to other sympathomimetic drugs, are discussed later in this chapter.

**Norepinephrine**

Norepinephrine (levarterenol, l-noradrenaline, l-β-[3,4-dihydroxyphenyl]-α-aminoethanol, NE) is a major chemical mediator liberated by mammalian postganglionic sympathetic nerves. It differs from epinephrine only by lacking the methyl substitution in the amino group (Table 12–1). NE constitutes 10-20% of the catecholamine content of human adrenal medulla and as much as 97% in some pheochromocytomas, which may not express the enzyme phenylethanolamine-N-methyltransferase. The history of its discovery and its role as a neurohumoral mediator are discussed in Chapter 8.

**Pharmacological Properties.** The pharmacological actions of NE and epinephrine have been extensively compared in vivo and in vitro (Table 12–2). Both drugs are direct agonists on effector cells, and their actions differ mainly in the ratio of their effectiveness in stimulating α and β₂ receptors. They are approximately equipotent in stimulating β₁ receptors. NE is a potent α agonist and has relatively little action on β₂ receptors; however, it is somewhat less potent than epinephrine on the α receptors of most organs.

**Cardiovascular Effects.** The cardiovascular effects of an intravenous infusion of 10 μg/min of NE in humans are shown in Figure 12–2. Systolic and diastolic pressures, and usually pulse pressure, are increased. Cardiac output is unchanged or decreased, and total peripheral resistance is raised. Compensatory vagal reflex activity slows the heart, overcoming a direct cardioaccelerator action, and stroke volume is increased. The peripheral vascular resistance increases in most vascular beds, and renal blood flow is reduced. NE constricts mesenteric vessels and reduces splanchic and hepatic blood flow. Coronary flow usually is increased, probably owing both to indirectly induced coronary dilation, as with epinephrine, and to elevated blood pressure. Although generally a poor β₂ receptor agonist, NE may increase coronary blood flow directly by stimulating β₂ receptors on coronary vessels. The physiological significance of this is not yet established. Patients with Prinzmetal’s variant angina may be supersensitive to the α adrenergic vasoconstrictor effects of NE.

Unlike epinephrine, small doses of NE do not cause vasodilation or lower blood pressure, since the blood vessels of skeletal muscle constrict rather than dilate; α adrenergic receptor antagonists therefore abolish the pressor effects but do not cause significant reversal (i.e., hypotension).

**Other Effects.** Other responses to NE are not prominent in humans. The drug causes hyperglycemia and other metabolic effects similar to those produced by epinephrine, but these are observed only when large doses are given because NE is not as effective a “hormone” as epinephrine. Intradermal injection of suitable doses causes sweating that is not blocked by atropine.

**Absorption, Fate, and Excretion.** NE, like epinephrine, is ineffective when given orally and is absorbed poorly from sites of subcutaneous injection. It is rapidly inactivated in the body by the same enzymes that methylate and oxidatively deaminate epinephrine (discussed earlier). Small amounts normally are found in the urine. The excretion rate may be greatly increased in patients with pheochromocytoma.

**Toxicity, Adverse Effects, and Precautions.** The untoward effects of NE are similar to those of epinephrine, although there typically is greater elevation of blood pressure with NE. Excessive doses can cause severe hypertension, so careful blood pressure monitoring generally is indicated during systemic administration of this agent.

Care must be taken that necrosis and sloughing do not occur at the site of intravenous injection owing to extravasation of the drug. The infusion should be made high in the limb, preferably through a long plastic cannula extending centrally. Impaired circulation at injection sites, with or without extravasation of NE, may be relieved by infiltrating the area with phenolamine, an α receptor antagonist.

Blood pressure must be determined frequently during the infusion and particularly during adjustment of the rate of the infusion. Reduced blood flow to organs such as kidney and intestines is a constant danger with the use of NE.
Therapeutic Uses and Status. NE (LEVOPHED, others) is used as a vasoconstrictor to raise or support blood pressure under certain intensive care conditions. The use of it and other sympathomimetic amines in shock is discussed later in this chapter. In the treatment of low blood pressure, the dose is titrated to the desired pressor response.

Dopamine

Dopamine (3,4-dihydroxyphenylethylamine, DA) (Table 12–1) is the immediate metabolic precursor of NE and epinephrine; it is a central neurotransmitter particularly important in the regulation of movement (Chapters 14, 16, and 22) and possesses important intrinsic pharmacological properties. In the periphery, it is synthesized in epithelial cells of the proximal tubule and is thought to exert local diuretic and natriuretic effects. DA is a substrate for both MAO and COMT and thus is ineffective when administered orally. Classification of DA receptors is described in Chapter 13.

Pharmacological Properties.

Cardiovascular Effects. The cardiovascular effects of DA are mediated by several distinct types of receptors that vary in their affinity for DA (Chapter 13). At low concentrations, the primary interaction of DA is with vascular D₁ receptors, especially in the renal, mesenteric, and coronary beds. By activating adenyl cyclase and raising intra-cellular concentrations of cyclic AMP, D₁ receptor stimulation leads to vasodilation. Infusion of low doses of DA causes an increase in glomerular filtration rate, renal blood flow, and Na⁺ excretion. Activation of D₁ receptors on renal tubular cells decreases Na⁺ transport by cAMP-dependent and cAMP-independent mechanisms. Increasing cAMP production in the proximal tubular cells and the medullary part of the thick ascending limb of the loop of Henle inhibits the Na⁺-H⁺ exchanger and the Na⁺,K⁺-ATPase pump. The renal tubular actions of DA that cause natriuresis may be augmented by the increase in renal blood flow and the small increase in the glomerular filtration rate that follow its administration. The resulting increase in hydrostatic pressure in the peritubular capillaries and reduction in oncotic pressure may contribute to diminished reabsorption of Na⁺ by the proximal tubular cells. As a consequence, DA has pharmacologically appropriate effects in the management of states of low cardiac output associated with compromised renal function, such as severe congestive heart failure.

At somewhat higher concentrations, DA exerts a positive inotropic effect on the myocardium, acting on β₁ adrenergic receptors. DA also causes the release of NE from nerve terminals, which contributes to its effects on the heart. Tachycardia is less prominent during infusion of DA than of isoproterenol (discussed later). DA usually increases systolic blood pressure and pulse pressure and either has no effect on diastolic blood pressure or increases it slightly. Total peripheral resistance usually is unchanged when low or intermediate doses of DA are given, probably because of the ability of DA to reduce regional arterial resistance in some vascular beds, such as mesenteric and renal, while causing only minor increases in others. At high concentrations, DA activates vascular α₁ receptors, leading to more general vasoconstriction.

Other Effects. Although there are specific DA receptors in the CNS, injected DA usually has no central effects because it does not readily cross the blood-brain barrier.

Precautions, Adverse Reactions, and Contraindications. Before DA is administered to patients in shock, hypovolemia should be corrected by transfusion of whole blood, plasma, or other appropriate fluid. Untoward effects due to over dosage generally are attributable to excessive sympathomimetic activity (although this also may be the response to worsening shock). Nausea, vomiting, tachycardia, anginal pain, arrhythmias, headache, hypertension, and peripheral vasoconstriction may be encountered during dopamine infusion. Extravasation of large amounts of DA during infusion may cause ischemic necrosis and sloughing. Rarely, gangrene of the fingers or toes has followed prolonged infusion of the drug.

DA should be avoided or used at a much reduced dosage (one-tenth or less) if the patient has received a MAO inhibitor. Careful adjustment of dosage also is necessary in patients who are taking tricyclic antidepressants.

Therapeutic Uses. DA is used in the treatment of severe congestive heart failure, particularly in patients with oliguria and low or normal peripheral vascular resistance. The drug also may improve physiological parameters in the treatment of cardiogenic and septic shock. While DA may acutely improve cardiac and renal function in severely ill patients with chronic heart disease or renal failure, there is relatively little evidence supporting long-term benefit in clinical outcome (Marik and Iglesias, 1999). The management of shock is discussed later.

Dopamine hydrochloride is used only intravenously, preferably into a large vein to prevent perivascular infiltration; extravasation may cause necrosis and sloughing of the surrounding tissue. The use of a calibrated infusion pump or other device capable of controlling the rate of flow is necessary. The drug initially is administered at a rate of 2-5 μg/kg per minute; this rate may be increased gradually up to 20-50 μg/kg per minute or more as the clinical situation dictates. During the infusion, patients require clinical assessment of myocardial function, perfusion of vital organs such as the brain, and the production of urine. Most patients should receive intensive care, with
monitoring of arterial and venous pressures and the ECG. Reduction in urine flow, tachycardia, or the development of arrhythmias may be indications to slow or terminate the infusion. The duration of action of DA is brief, and hence the rate of administration can be used to control the intensity of effect.

Related drugs include fenoldopam and dopexamine. Fenoldopam (CORLOPAM, others), a benzazepine derivative, is a rapidly acting vasodilator used for control of severe hypertension (e.g., malignant hypertension with end-organ damage) in hospitalized patients for not more than 48 hours. Fenoldopam is an agonist for peripheral D1 receptors and binds with moderate affinity to α1 adrenergic receptors; it has no significant affinity for D2 receptors or α2 or β-adrenergic receptors. Fenoldopam is a racemic mixture; the R-isomer is the active component. It dilates a variety of blood vessels, including coronary arteries, afferent and efferent arterioles in the kidney, and mesenteric arteries (Murphy et al., 2001). Fenoldopam must be administered using a calibrated infusion pump; the usual dose rate ranges from 0.01-1.6 μg/kg per minute.

Less than 6% of an orally administered dose is absorbed because of extensive first-pass formation of sulfate, methyl, and glucuronide conjugates. The elimination t1/2 of intravenously infused fenoldopam, estimated from the decline in plasma concentration in hypertensive patients after the cessation of a 2-hour infusion, is 10 minutes. Adverse effects are related to the vasodilatation and include headache, flushing, dizziness, and tachycardia or bradycardia.

Dopexamine (DOPACARD) is a synthetic analog related to DA with intrinsic activity at dopamine D1 and D2 receptors as well as at β2 receptors; it may have other effects such as inhibition of catecholamine uptake (Fitton and Benfield, 1990). It appears to have favorable hemodynamic actions in patients with severe congestive heart failure, sepsis, and shock. In patients with low cardiac output, dopexamine infusion significantly increases stroke volume with a decrease in systemic vascular resistance. Tachycardia and hypotension can occur, but usually only at high infusion rates. Dopexamine is not currently available in the U.S.

### β ADRENERGIC RECEPTOR AGONISTS

β adrenergic receptor agonists have been utilized in many clinical settings but now play a major role only in the treatment of bronchoconstriction in patients with asthma (reversible airway obstruction) or chronic obstructive pulmonary disease (COPD). Minor uses include management of preterm labor, treatment of complete heart block in shock, and short-term treatment of cardiac decompensation after surgery or in patients with congestive heart failure or myocardial infarction.

Epinephrine first was used as a bronchodilator at the beginning of the past century, and ephedrine was introduced into western medicine in 1924, although it had been used in China for thousands of years. The next major advance was the development in the 1940s of isoproterenol, a β-receptor–selective agonist; this provided a drug for asthma that lacked α receptor activity. The recent development of β2-selective agonists has resulted in drugs with even more valuable characteristics, including adequate oral bioavailability, lack of α adrenergic activity, and diminished likelihood of some adverse cardiovascular effects.

β Receptor agonists may be used to stimulate the rate and force of cardiac contraction. The chronotropic effect is useful in the emergency treatment of arrhythmias such as torsades de pointes, bradycardia, or heart block (Chapter 29), whereas the inotropic effect is useful when it is desirable to augment myocardial contractility. The therapeutic uses of β agonists are discussed later in the chapter.

### Isoproterenol

Isoproterenol (isopropyltererol, isopropyl norepinephrine, isoprenaline, isopropyl noradrenaline, d,l-β-[3,4-dihydroxyphenyl]-α-isopropylaminoethanol) (Table 12–1) is a potent, non-selective β receptor agonist with very low affinity for α receptors. Consequently, isoproterenol has powerful effects on all β receptors and almost no action at α receptors.

**Pharmacological Actions.** The major cardiovascular effects of isoproterenol (compared with epinephrine and NE) are illustrated in Figure 12–2. Intravenous infusion of isoproterenol lowers peripheral vascular resistance, primarily in skeletal muscle but also in renal and mesenteric vascular beds. Diastolic pressure falls. Systolic blood pressure may remain unchanged or rise, although mean arterial pressure typically falls. Cardiac output is increased because of the positive inotropic and chronotropic effects of the drug in the face of diminished peripheral vascular resistance. The cardiac effects of isoproterenol may lead to palpitations, sinus tachycardia, and more serious arrhythmias; large doses of isoproterenol may cause myocardial necrosis in animals.

Isoproterenol relaxes almost all varieties of smooth muscle when the tone is high, but this action is most pronounced on bronchial and GI smooth muscle. It prevents or relieves bronchoconstriction. Its effect in asthma may be due in part to an additional action to inhibit antigen-induced release of histamine and other mediators of inflammation; this action is shared by β2-selective stimulants.

**Absorption, Fate, and Excretion.** Isoproterenol is readily absorbed when given parenterally or as an aerosol. It is metabolized primarily in the liver and other tissues by COMT. Isoproterenol is a relatively poor substrate for MAO and is not taken up by sympathetic neurons to the same extent as are epinephrine and NE. The duration of action of isoproterenol therefore may be longer than that of epinephrine, but it still is brief.

**Toxicity and Adverse Effects.** Palpitations, tachycardia, headache, and flushing are common. Cardiac ischemia and arrhythmias...
may occur, particularly in patients with underlying coronary artery disease.

**Therapeutic Uses.** Isoproterenol (ISUPREL, others) may be used in emergencies to stimulate heart rate in patients with bradycardia or heart block, particularly in anticipation of inserting an artificial cardiac pacemaker or in patients with the ventricular arrhythmia torsades de pointes. In disorders such as asthma and shock, isoproterenol largely has been replaced by other sympathomimetic drugs (discussed later in this chapter and in Chapter 36).

**Dobutamine**

Dobutamine resembles DA structurally but possesses a bulky aromatic substituent on the amino group (Table 12–1). The pharmacological effects of dobutamine are due to direct interactions with $\alpha$ and $\beta$ receptors; its actions do not appear to result from release of NE from sympathetic nerve endings, nor are they exerted by dopaminergic receptors.

Although dobutamine originally was thought to be a relatively selective $\beta_1$ receptor agonist, it now is clear that its pharmacological effects are complex. Dobutamine possesses a center of asymmetry; both enantiomeric forms are present in the racemic mixture used clinically. The (−) isomer of dobutamine is a potent agonist at $\alpha_1$ receptors and is capable of causing marked pressor responses. In contrast, (+)-dobutamine is a potent $\alpha_1$ receptor antagonist, which can block the effects of (−)-dobutamine. The effects of these two isomers are mediated by $\beta$ receptors. The (+) isomer is a more potent $\beta$ receptor agonist than the (−) isomer (−10-fold). Both isomers appear to be full agonists.

**Cardiovascular Effects.** The cardiovascular effects of racemic dobutamine represent a composite of the distinct pharmacological properties of the (−) and (+) stereoisomers. Dobutamine has relatively more prominent inotropic than chronotropic effects on the heart compared to isoproterenol. Although not completely understood, this useful selectivity may arise because peripheral resistance is relatively unchanged. Alternatively, cardiac $\alpha_1$ receptors may contribute to the inotropic effect. At equivalent inotropic doses, dobutamine enhances automaticity of the sinus node to a lesser extent than does isoproterenol; however, enhancement of atrioventricular and intraventricular conduction is similar for both drugs.

In animals, administration of dobutamine at a rate of 2.5-15 μg/kg per minute increases cardiac contractility and cardiac output. Total peripheral resistance is not greatly affected. The relatively constant peripheral resistance presumably reflects counterbalancing of $\alpha_1$ receptor–mediated vasoconstriction and $\beta_1$ receptor–mediated vasodilation (Ruffolo, 1987). Heart rate increases only modestly when the rate of administration of dobutamine is maintained at < 20 μg/kg per minute. After administration of $\beta$ receptor antagonists, infusion of dobutamine fails to increase cardiac output, but total peripheral resistance increases, confirming that dobutamine has modest direct effects on $\alpha$ adrenergic receptors in the vasculature.

**Adverse Effects.** In some patients, blood pressure and heart rate increase significantly during dobutamine administration; this may require reduction of the rate of infusion. Patients with a history of hypertension may exhibit such an exaggerated pressor response more frequently. Since dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of marked increases in ventricular response rates; digoxin or other measures may be required to prevent this from occurring. Some patients may develop ventricular ectopic activity. As with any inotropic agent, dobutamine potentially may increase the size of a myocardial infarct by increasing myocardial O$_2$ demand. This risk must be balanced against the patient’s overall clinical status. The efficacy of dobutamine over a period of more than a few days is uncertain; there is evidence for the development of tolerance.

**Therapeutic Uses.** Dobutamine (DOBUTREX) is indicated for the short-term treatment of cardiac decompensation that may occur after cardiac surgery or in patients with congestive heart failure or acute myocardial infarction. Dobutamine increases cardiac output and stroke volume in such patients, usually without a marked increase in heart rate. Alterations in blood pressure or peripheral resistance usually are minor, although some patients may have marked increases in blood pressure or heart rate. Clinical evidence of longer-term efficacy remains uncertain. An infusion of dobutamine in combination with echocardiography is useful in the noninvasive assessment of patients with coronary artery disease. Stressing of the heart with dobutamine may reveal cardiac abnormalities in carefully selected patients.

Dobutamine has a $t_{1/2}$ $\approx$2 minutes; the major metabolites are conjugates of dobutamine and 3-O-methyldobutamine. The onset of effect is rapid. Consequently, a loading dose is not required, and steady-state concentrations generally are achieved within 10 minutes of initiation of the infusion by calibrated infusion pump. The rate of infusion required to increase cardiac output typically is between 2.5 and 10 μg/kg per minute, although higher infusion rates occasionally are required. The rate and duration of the infusion are determined by the clinical and hemodynamic responses of the patient.

**$\beta_2$-Selective Adrenergic Receptor Agonists**

Some of the major adverse effects of $\beta$ receptor agonists in the treatment of asthma or chronic obstructive pulmonary disease (COPD) are caused by stimulation of $\beta_1$ receptors in the heart. Accordingly, drugs with preferential affinity for $\beta_2$ receptors compared with $\beta_1$ receptors have been developed. However, this selectivity is relative, not absolute, and is lost at high concentrations of these drugs. Moreover up to 40% of the $\beta$ receptors in the human heart are $\beta_2$ receptors, activation of which can cause cardiac stimulation (Brodde and Michel, 1999).

A second strategy that has increased the usefulness of several $\beta_2$-selective agonists in the treatment of
asthma and COPD has been structural modification that results in lower rates of metabolism and enhanced oral bioavailability (compared with catecholamines).

Modifications have included placing the hydroxyl groups at positions 3 and 5 of the phenyl ring or substituting another moiety for the hydroxyl group at position 3. This has yielded drugs such as metaproterenol, terbutaline, and albuterol, which are not substrates for COMT. Bulky substituents on the amino group of catecholamines contribute to potency at β receptors with decreased activity at α receptors and decreased metabolism by MAO. A final strategy to enhance preferential activation of pulmonary β, receptors is the administration by inhalation of small doses of the drug in aerosol form. This approach typically leads to effective activation of β, receptors in the bronchi but very low systemic drug concentrations. Consequently, there is less potential to activate cardiac β, or β, receptors or to stimulate β, receptors in skeletal muscle, which can cause tremor and thereby limit oral therapy.

Administration of β receptor agonists by aerosol (Chapter 36) typically leads to a very rapid therapeutic response, generally within minutes, although some agonists such as salmeterol have a delayed onset of action (discussed later). While subcutaneous injection also causes prompt bronchodilation, the peak effect of a drug given orally may be delayed for several hours. Aerosol therapy depends on the delivery of drug to the distal airways. This, in turn, depends on the size of the particles in the aerosol and respiratory parameters such as inspiratory flow rate, tidal volume, breath-holding time, and airway diameter. Only ~10% of an inhaled dose actually enters the lungs; much of the remainder is swallowed and ultimately may be absorbed. Successful aerosol therapy requires that each patient master the technique of drug administration. Many patients, particularly children and the elderly, do not use optimal techniques, often because of inadequate instructions or incoordination. In these patients, spacer devices may enhance the efficacy of inhalation therapy.

In the treatment of asthma and COPD, β receptor agonists are used to activate pulmonary receptors that relax bronchial smooth muscle and decrease airway resistance. Although this action appears to be a major therapeutic effect of these drugs in patients with asthma, evidence suggests that β receptor agonists also may suppress the release of leukotrienes and histamine from mast cells in lung tissue, enhance mucociliary function, decrease microvascular permeability, and possibly inhibit phospholipase A, (Seale, 1988). These additional actions seem to contribute to the beneficial effects of β agonists in the treatment of human asthma. It is becoming increasingly clear that airway inflammation is also directly involved in airway hyper-responsiveness; consequently, the use of anti-inflammatory drugs such as inhaled steroids has primary importance. Most authorities recommend that long-acting β agonists should not be used without concomitant anti-inflammatory therapy in the treatment of asthma (Drazen and O’Byrne, 2009; Fanta, 2009). The use of β agonists for the treatment of asthma and COPD is discussed in Chapter 36.

**Short Acting β, Adrenergic Agonists**

**Metaproterenol.** Metaproterenol (called orciprenaline in Europe), along with terbutaline and fenoterol, belongs to the structural class of resorcinol bronchodilators that have hydroxyl groups at positions 3 and 5 of the phenyl ring (rather than at positions 3 and 4 as in catechols) (Table 12–1). Consequently, metaproterenol is resistant to methylation by COMT, and a substantial fraction (40%) is absorbed in active form after oral administration. It is excreted primarily as glucuronic acid conjugates. Metaproterenol is considered to be β,-selective, although it probably is less selective than albuterol or terbutaline and hence is more prone to cause cardiac stimulation; as noted earlier, up to 40% of the β receptors in the human heart are of the β, subtype, thus even β,-selective agents have the potential to cause cardiac stimulation.

Effects occur within minutes of inhalation and persist for several hours. After oral administration, onset of action is slower, but effects last 3–4 hours. Metaproterenol is used for the long-term treatment of obstructive airway diseases, asthma, and for treatment of acute bronchospasm (Chapter 36). Side effects are similar to the short- and intermediate-acting sympathomimetic bronchodilators.

**Albuterol.** Albuterol (VENTOLIN-HFA, PROVENTIL-HFA, others; Table 12–1) is a selective β, receptor agonist with pharmacological properties and therapeutic indications similar to those of terbutaline. It is administered either by inhalation or orally for the symptomatic relief of bronchospasm.

When administered by inhalation, it produces significant bronchodilation within 15 minutes, and effects persist for 3–4 hours. The cardiovascular effects of albuterol are considerably weaker than those of isoproterenol when doses that produce comparable bronchodilation are administered by inhalation. Oral albuterol has the potential to delay preterm labor. Although rare, CNS and respiratory side effects are sometimes observed.

Albuterol has been made available in a metered dose inhaler free of chlorofluorocarbons (CFC); CFC-containing albuterol inhalers have been taken off the market. Like CFCs, the alternate propellant, hydrofluoroalkane (HFA) is inert in the human airway, but unlike CFCs, it does not contribute to depletion of the stratospheric ozone layer.

**Levalbuterol.** Levalbuterol (XOPENEX) is the R-enantiomer of albuterol which is a racemic drug used to treat asthma and COPD. Although originally available only as a solution for nebulizer, it is now available as a CFC-free metered dose inhaler. Levalbuterol is β, selective and acts like other β, adrenergic agonists. In general, levalbuterol has similar pharmacokinetic and pharmacodynamics properties to albuterol. Although it has been claimed to have fewer side effects than albuterol, these claims have not been supported by clinical trials.

**Pirbuterol.** Pirbuterol is a relatively selective β, agonist. Its structure is identical to albuterol except for the substitution of a pyridine ring for the benzene ring. Pirbuterol acetate (MAXAIR) is available for inhalation therapy; dosing is typically every 4–6 hours. Pirbuterol is
Figure 12–3. Structural formulas of some β₂ adrenergic receptor agonists.
the only preparation available in a breath-activated meter-dose inhaler, a device meant to optimize medication delivery by releasing a spray of medication only on the patient’s initiation of inspiration.

**Terbutaline.** Terbutaline is a $\beta_2$-selective bronchodilator. It contains a resorcinol ring and thus is not a substrate for COMT methylation. It is effective when taken orally, subcutaneously, or by inhalation (not marketed for inhalation in the U.S.).

Effects are observed rapidly after inhalation or parenteral administration; after inhalation its action may persist 3-6 hours. With oral administration, the onset of effect may be delayed 1-2 hours. Terbutaline (BRETHINE, others) is used for the long-term treatment of obstructive airway diseases and for treatment of acute bronchospasm, and also is available for parenteral use for the emergency treatment of status asthmaticus (Chapter 36).

**Isoetharine.** Isoetharine was the first $\beta_2$-selective drug widely used for the treatment of airway obstruction. However, its degree of selectivity for $\beta_2$ receptors may not approach that of some of the other agents. Although resistant to metabolism by MAO, it is a catecholamine and thus is a good substrate for COMT (Table 12–1). Consequently, it is used only by inhalation for the treatment of acute episodes of bronchoconstriction. Isoetharine is no longer marketed in the U.S.

**Bitolterol.** Bitolterol (TORNALATE) is a novel $\beta_2$-agonist in which the hydroxyl groups in the catechol moiety are protected by esterification with 4-methylbenzoate. Esterases in the lung and other tissues hydrolyze this prodrug to the active form, colterol, or terbutylnorepinephrine (Table 12–1). Animal studies suggest that these esterases are present in higher concentrations in lung than in tissues such as the heart. The duration of effect of bitolterol after inhalation ranges from 3-6 hours. Bitolterol has been discontinued in the U.S.

**Fenoterol.** Fenoterol (BEROTEC) is a $\beta_2$-selective receptor agonist. After inhalation, it has a prompt onset of action, and its effect typically is sustained for 4-6 hours. The possible association of fenoterol use with increased deaths from asthma, although controversial (Pearce et al., 1995; Suissa and Ernst, 1997), has led to its withdrawal from the market. It is thought that the dysrhythmias and cardiac effects are due to effects on $\beta_1$ adrenergic receptors.

**Procaterol.** Procaterol (MASCACIN, others) is a $\beta_2$-selective receptor agonist. After inhalation, it has a prompt onset of action that is sustained for ~5 hours. Procaterol is not available in the U.S.

### Long-Acting $\beta_2$ Adrenergic Agonists

**Salmeterol.** Salmeterol (SEREVENT) is a $\beta_2$-selective agonist with a prolonged duration of action (>12 hours); it has at least 50-fold greater selectivity for $\beta_2$ receptors than albuterol. It provides symptomatic relief and improves lung function and quality of life in patients with COPD; in this setting, it is as effective as the cholinergic antagonist ipratropium and more effective than oral theophylline. It has additive effects when used in combination with inhaled ipratropium or oral theophylline.

Like formoterol, it is highly lipophilic and has a sustained duration of action; for salmeterol, this long action reflects binding to a specific site within the $\beta_2$ receptor that allows for its prolonged activation. It also may have anti-inflammatory activity. Salmeterol is metabolized by CYP3A4 to $\alpha$-hydroxy-salmeterol, which is eliminated primarily in the feces. Since the onset of action of inhaled salmeterol is relatively slow, it is not suitable monotherapy for acute breakthrough attacks of bronchospasm. Salmeterol or formoterol are the agents of choice for nocturnal asthma in patients who remain symptomatic despite anti-inflammatory agents and other standard management.

Salmeterol generally is well tolerated but has the potential to increase heart rate and plasma glucose concentration, to produce tremors, and to decrease plasma potassium concentration through effects on extrapulmonary $\beta_2$ receptors. Salmeterol should not be used more than twice daily (morning and evening) and should not be used to treat acute asthma symptoms, which should be treated with a short-acting $\beta_2$ agonist (e.g., albuterol) when breakthrough symptoms occur despite twice-daily use of salmeterol (Redington, 2001).

Many patients with moderate or severe persistent asthma have benefited immensely with the use of long-acting $\beta_2$ agonists like salmeterol together with an inhaled corticosteroid. These benefits have to be counterbalanced against the results of the Salmeterol Multicenter Asthma Research Trial (SMART), in which the addition of a long acting $\beta_2$ agonist to “usual therapy” was associated with an increased risk of fatal or near-fatal asthmatic attacks, as compared with “usual therapy” alone. This study is controversial and often criticized because only a minority of subjects in SMART were taking inhaled corticosteroids and there is a lack of reports of increased asthma mortality among patients taking both a long-acting $\beta_2$ agonist and an inhaled corticosteroid (Fanta, 2009). Nevertheless, the FDA has placed a black-box warning in the labeling information for salmeterol, formoterol, and arformoterol. Moreover, national and international expert panels (Fanta, 2009) have recommended the use of long-acting agonists only for patients in whom inhaled corticosteroids alone either have failed to achieve good asthma control or for initial therapy.

**Formoterol.** Formoterol (FORADIL, others) is a long-acting $\beta_2$-selective receptor agonist. Significant bronchodilation occurs within minutes of inhalation of a therapeutic dose, which may persist for up to 12 hours (Faulds et al., 1991). It is highly lipophilic and has high affinity for $\beta_2$ receptors. Its major advantage over many other $\beta_2$-selective agonists is this prolonged duration of action, which may be particularly advantageous in settings such as nocturnal asthma. Formoterol’s sustained action is due to its insertion into the lipid bilayer of the plasma membrane, from which it gradually diffuses to provide prolonged stimulation of $\beta_2$ receptors. It is FDA-approved for treatment of asthma, bronchospasm, prophylaxis of exercise-induced bronchospasm, and chronic obstructive pulmonary disease (COPD). It can be used concomitantly with short-acting $\beta_2$ agonists, glucocorticoids (inhaled or systemic), and theophylline (Goldsmith and Keating, 2004).

**Arformoterol.** Arformoterol (BROVENA), the (R,R) enantiomer of formoterol, is a selective long-acting $\beta_2$
agonist that has twice the potency of racemic formoterol. It is FDA-approved for the long-term treatment of bronchoconstriction in patients with COPD, including chronic bronchitis and emphysema (Matera and Cazzola, 2007). It is the first long-acting β₂ agonist developed as inhalational therapy to use with a nebulizer (Abdelghany, 2007). Like other β₂ agonists, arformoterol activates the cyclic AMP pathway, thereby relaxing bronchial smooth muscle and inhibiting release of mast cell mediators (e.g., histamine and leukotrienes).

A substantial portion of systemic exposure to arformoterol is due to pulmonary absorption with plasma levels reaching peak levels in 0.25-1 hour. Plasma protein binding is 52-65%. It is primarily metabolized by direct conjugation to glucuronide or sulfate conjugates and secondarily by O-demethylation by CYP2D6 and CYP2C19. It does not inhibit any of the common CYPs. The drug is well tolerated and the most common side effects are skeletal muscle tremor and cramps, insomnia, tachycardia, decreases in plasma potassium, and increases in plasma glucose. As mentioned previously, a black-box warning has been instituted in response to findings of the SMART trials (Fanta, 2009; Lipworth, 2007).

Carmoterol. Carmoterol is a pure (R,R)-isomer and a non-catechol with a p-methoxyphenyl group on the carbostyril aromatic ring. It is a potent and selective β₂ adrenergic agonist with a selectivity for β₂ over β₁ receptors of 53. It is claimed to be 5 times more selective for the β₂ adrenergic receptor in tracheal preparations than those in the right atrium. Carmoterol has a rapid onset and long duration of action and shows a bronchodilator effect over 24 hours with once a day dosing. Indications for carmoterol include asthma and COPD (Cazzola and Matera, 2008; Matera and Cazzola, 2007).

Indacaterol. Indacaterol is a once-daily long-acting β₂ adrenergic agonist in development for asthma and COPD. It has a fast onset of action, appears well tolerated, and has been shown to be effective in both asthma and COPD with little tachyphalaxis upon continued use. Indacaterol behaves as a potent β₂ agonist with high intrinsic efficacy, which, in contrast to salmeterol, does not antagonize the bronchodilator effect of short-acting β₂ adrenergic agonists. Evidence indicates that indacaterol has a longer duration of action than salmeterol and formoterol.

Both indacaterol and carmoterol are currently in Phase III clinical trials in the U.S. (Cazzola and Matera, 2008; Matera and Cazzola, 2007).

Ritodrine. Ritodrine is a β₂-selective agonist that was developed specifically for use as a uterine relaxant. Nevertheless, its pharmacological properties closely resemble those of the other agents in this group.

Ritodrine is rapidly but incompletely (30%) absorbed following oral administration, and 90% of the drug is excreted in the urine as inactive conjugates; ~50% of ritodrine is excreted unchanged after intravenous administration. The pharmacokinetic properties of ritodrine are complex and incompletely defined, especially in pregnant women.

Ritodrine may be administered intravenously to selected patients to arrest premature labor. Ritodrine and related drugs can prolong pregnancy. However, β₂-selective agonists may not have clinically significant benefits on perinatal mortality and may actually increase maternal morbidity. Ritodrine is not available in the U.S. See Chapter 66 for the pharmacology of tocolytic agents.

Adverse Effects of β₂-Selective Agonists. The major adverse effects of β receptor agonists occur as a result of excessive activation of β receptors. Patients with underlying cardiovascular disease are particularly at risk for significant reactions. However, the likelihood of adverse effects can be greatly decreased in patients with lung disease by administering the drug by inhalation rather than orally or parenterally.

Tremor is a relatively common adverse effect of the β₂-selective receptor agonists. Tolerance generally develops to this effect; it is not clear whether tolerance reflects desensitization of the β₂ receptors of skeletal muscle or adaptation within the CNS. This adverse effect can be minimized by starting oral therapy with a low dose of drug and progressively increasing the dose as tolerance to the tremor develops. Feelings of restlessness, apprehension, and anxiety may limit therapy with these drugs, particularly oral or parenteral administration.

Tachycardia is a common adverse effect of systemically administered β receptor agonists. Stimulation of heart rate occurs primarily by means of β₁ receptors. It is uncertain to what extent the increase in heart rate also is due to activation of cardiac β₂ receptors or to reflex effects that stem from β₂ receptor-mediated peripheral vasodilation. However, β₂ receptors are also present in the human myocardium and all β₂ adrenergic agonists have the potential to produce cardiac stimulation. During a severe asthma attack, heart rate actually may decrease during therapy with a β agonist, presumably because of improvement in pulmonary function with consequent reduction in endogenous cardiac sympathetic stimulation. In patients without cardiac disease, β agonists rarely cause significant arrhythmias or myocardial ischemia; however, patients with underlying coronary artery disease or preexisting arrhythmias are at greater risk. The risk of adverse cardiovascular effects also is increased in patients who are receiving MAO inhibitors. In general, at least 2 weeks should elapse between the use of MAO inhibitors and administration of β₂ agonists or other sympathomimetics.

Large doses of β receptor agonists cause myocardial necrosis in laboratory animals. When given parenterally, these drugs also may increase the concentrations of glucose, lactate, and free fatty acids in plasma and decrease the concentration of K⁺. The decrease in K⁺ concentration may be especially important in patients with cardiac disease, particularly those taking digoxin and diuretics. In some diabetic patients, hyperglycemia may be worsened by these drugs, and higher doses of insulin may be required. All these adverse effects are far less likely with inhalation therapy than with parenteral or oral therapy.

α₁-SELECTIVE ADRENERGIC RECEPTOR AGONISTS

The major clinical effects of a number of sympathomimetic drugs are due to activation of α adrenergic receptors in vascular smooth muscle. As a result, peripheral
vascular resistance is increased and blood pressure is maintained or elevated. Although the clinical utility of these drugs is limited, they may be useful in the treatment of some patients with hypotension, including orthostatic hypotension, or shock. Phenylephrine and methoxamine (discontinued in the U.S.) are direct-acting vasoconstrictors and are selective activators of $\alpha_1$ receptors. Mephentermine and metaraminol act both directly and indirectly. Midodrine is a prodrug that is converted, after oral administration, to desglymidodrine, a direct-acting $\alpha_1$ agonist.

**Phenylephrine**

Phenylephrine (NEO-SYNEPHRINE, others) is a $\alpha_1$-selective agonist; it activates $\beta$ receptors only at much higher concentrations. Chemically, phenylephrine differs from epinephrine only in lacking a hydroxyl group at position 4 on the benzene ring (Table 12–1). The pharmacological effects of phenylephrine are similar to those of methoxamine. The drug causes marked arterial vasoconstriction during intravenous infusion. Phenylephrine (NEO-SYNEPHRINE, others) also is used as a nasal decongestant and as a mydriatic in various nasal and ophthalmic formulations (see Chapter 64 for ophthalmic uses).

**Mephentermine.** Mephentermine is a sympathomimetic drug that acts both directly and indirectly; it has many similarities to ephedrine (discussed later). After an intramuscular injection, the onset of action is prompt (within 5-15 minutes), and effects may last for several hours. Since the drug releases NE, cardiac contraction is enhanced, and cardiac output and diastolic pressures usually are increased. The change in heart rate is variable, depending on the degree of vagal tone. Adverse effects are related to CNS stimulation, excessive rises in blood pressure, and arrhythmias. Mephentermine is used to prevent hypotension, which frequently accompanies spinal anesthesia. The drug has been discontinued in the U.S.

**Metaraminol.** Metaraminol is a sympathomimetic drug with prominent direct effects on vascular $\alpha$ adrenergic receptors. Metaraminol also is an indirectly acting agent that stimulates the release of NE. The drug has been used in the treatment of hypotensive states or off-label to relieve attacks of paroxysmal atrial tachycardia, particularly those associated with hypotension (see Chapter 29 for preferable treatments of this arrhythmia).

**Midodrine.** Midodrine (PROAMATINE, others) is an orally effective $\alpha_1$ receptor agonist. It is a prodrug; its activity is due to its conversion to an active metabolite, desglymidodrine, which achieves peak concentrations ~1 hour after a dose of midodrine. The $t_{1/2}$ of desglymidodrine is ~3 hours. Consequently, the duration of action is ~4-6 hours. Midodrine-induced rises in blood pressure are associated with both arterial and venous smooth muscle contraction. This is advantageous in the treatment of patients with autonomic insufficiency and postural hypotension (McClellan et al., 1998). A frequent complication in these patients is supine hypertension. This can be minimized by administering the drug during periods when the patient will remain upright, avoiding dosing within 4 hours of bedtime, and elevating the head of the bed. Very cautious use of a short-acting antihypertensive drug at bedtime may be useful in some patients. Typical dosing, achieved by careful titration of blood pressure responses, varies between 2.5 and 10 mg three times daily.

### $\alpha_2$-SELECTIVE ADRENERGIC RECEPTOR AGONISTS

$\alpha_2$-Selective adrenergic agonists are used primarily for the treatment of systemic hypertension. Their efficacy as antihypertensive agents is somewhat surprising, since many blood vessels contain postsynaptic $\alpha_2$ adrenergic receptors that promote vasoconstriction (Chapter 8). Indeed, clonidine, the prototypic $\alpha_2$ agonist, was initially developed as a vasoconstricting nasal decongestant. Its capacity to lower blood pressure results from activation of $\alpha_2$ receptors in the cardiovascular control centers of the CNS; such activation suppresses the outflow of sympathetic nervous system activity from the brain.

In addition, $\alpha_2$ agonists reduce intraocular pressure by decreasing the production of aqueous humor. This action first was reported for clonidine and suggested a potential role for $\alpha_2$ receptor agonists in the management of ocular hypertension and glaucoma. Unfortunately, clonidine lowered systemic blood pressure even if applied topically to the eye (Alward, 1998). Two derivatives of clonidine, apraclonidine and brimonidine, have been developed that retain the ability to decrease intraocular pressure with little or no effect on systemic blood pressure.

**Clonidine**

Clonidine, an imidazoline, was originally tested as a vasoconstrictor acting at peripheral $\alpha_2$ receptors. During clinical trials as a topical nasal decongestant, clonidine was found to cause hypotension, sedation, and bradycardia.

**Pharmacological Effects.** The major pharmacological effects of clonidine involve changes in blood pressure and heart rate, although the drug has a variety of other important actions. Intravenous infusion of clonidine causes an acute rise in blood pressure, apparently because of activation of postsynaptic $\alpha_2$ receptors in vascular smooth muscle. The affinity of clonidine for
these receptors is high, although the drug is a partial agonist with relatively low efficacy at these sites. The hypertensive response that follows parenteral administration of clonidine generally is not seen when the drug is given orally. However, even after intravenous administration, the transient vasoconstriction is followed by a more prolonged hypotensive response that results from decreased sympathetic outflow from the CNS. The exact mechanism by which clonidine lowers blood pressure is not completely understood. The effect appears to result, at least in part, from activation of $\alpha_2$ receptors in the lower brainstem region. This central action has been demonstrated by infusing small amounts of the drug into the vertebral arteries or by injecting it directly into the cisterna magna.

Questions remain about whether the sympatho-inhibitory action of clonidine results solely from its $\alpha_2$ receptor agonism or whether part or all of its actions are mediated by imidazoline receptors. Imidazoline receptors include three subtypes ($I_1$, $I_2$, and $I_3$) and are widely distributed in the body, including the CNS. Clonidine, as an imidazoline, binds to these imidazoline receptors, in addition to its well-described binding to $\alpha_2$ receptors. Two newer antihypertensive imidazolines, rilmenidine and moxonidine, have profiles of action similar to clonidine’s, suggesting a role for $I_1$ receptors. However, the lack of an antihypertensive effect of clonidine in knockout mice lacking $\alpha_{2A}$ receptors supports a key role for these receptors in blood pressure regulation (Zhu et al., 1999). Others argue that, while the action of clonidine may be mediated by $\alpha_2$ receptors, the $I_1$ receptor mediates the effects of moxonidine and rilmenidine. Finally, $\alpha_2$ and imidazoline receptors may cooperatively regulate vasomotor tone and may jointly mediate the hypotensive actions of centrally acting drugs with affinity for both receptor types.

Clonidine decreases discharges in sympathetic preganglionic fibers in the splanchnic nerve and in postganglionic fibers of cardiac nerves. These effects are blocked by $\alpha_2$-selective antagonists such as yohimbine. Clonidine also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate as a consequence of increased vagal tone and diminished sympathetic drive. In addition, some of the antihypertensive effects of clonidine may be mediated by activation of presynaptic $\alpha_2$ receptors that suppress the release of NE, ATP, and NPY from postganglionic sympathetic nerves. Clonidine decreases the plasma concentration of NE and reduces its excretion in the urine.

**Absorption, Fate, and Excretion.** Clonidine is well absorbed after oral administration, and its bioavailability is nearly 100%. The peak concentration in plasma and the maximal hypotensive effect are observed 1-3 hours after an oral dose. The elimination $t_{1/2}$ of the drug ranges from 6-24 hours, with a mean of ~12 hours. About half of an administered dose can be recovered unchanged in the urine, and the $t_{1/2}$ of the drug may increase with renal failure. There is good correlation between plasma concentrations of clonidine and its pharmacological effects. A transdermal delivery patch permits continuous administration of clonidine as an alternative to oral therapy. The drug is released at an approximately constant rate for a week; 3-4 days are required to reach steady-state concentrations in plasma. When the patch is removed, plasma concentrations remain stable for ~8 hours and then decline gradually over a period of several days; this decrease is associated with a rise in blood pressure.

**Adverse Effects.** The major adverse effects of clonidine are dry mouth and sedation. These responses occur in at least 50% of patients and may require drug discontinuation. However, they may diminish in intensity after several weeks of therapy. Sexual dysfunction also may occur. Marked bradycardia is observed in some patients. These and some of the other adverse effects of clonidine frequently are related to dose, and their incidence may be lower with transdermal administration of clonidine, since antihypertensive efficacy may be achieved while avoiding the relatively high peak concentrations that occur after oral administration of the drug. About 15-20% of patients develop contact dermatitis when using clonidine in the transdermal system. Withdrawal reactions follow abrupt discontinuation of long-term therapy with clonidine in some hypertensive patients (Chapter 27).

**Therapeutic Uses.** The major therapeutic use of clonidine (CATAPRES, others) is in the treatment of hypertension (Chapter 27). Clonidine also has apparent efficacy in the off-label treatment of a range of other disorders. Stimulation of $\alpha_2$ receptors in the GI tract may increase absorption of sodium chloride and fluid and inhibit secretion of bicarbonate. This may explain why clonidine has been found to be useful in reducing diarrhea in some diabetic patients with autonomic neuropathy. Clonidine also is useful in treating and preparing addicted subjects for withdrawal from narcotics, alcohol, and tobacco (Chapter 24). Clonidine may help ameliorate some of the adverse sympathetic nervous activity associated with withdrawal from these agents, as well as decrease craving for the drug. The long-term benefits of clonidine in these settings and in neuropsychiatric disorders remain to be determined. Clonidine may be useful in selected patients receiving anesthesia because it may decrease the requirement for anesthetic and increase hemodynamic stability (Hayashi and Maze, 1993; Chapter 19). Other potential benefits of clonidine and related drugs such as dexmedetomidine (PRECEDEX; a relatively selective $\alpha_2$ receptor agonist with sedative properties) in anesthesia include preoperative sedation and anxiolysis, drying of secretions, and analgesia. Transdermal administration of clonidine (CATAPRES) may be useful in reducing the incidence of menopausal hot flashes.

Acute administration of clonidine has been used in the differential diagnosis of patients with hypertension and suspected pheochromocytoma. In patients with primary hypertension, plasma concentrations of NE are markedly suppressed after a single dose of clonidine; this response is not observed in many patients with pheochromocytoma. The capacity of clonidine to activate postsynaptic $\alpha_2$ receptors in vascular smooth muscle has been exploited in a limited number of patients whose autonomic failure is so severe that reflex sympathetic responses on standing are absent; postural hypotension is thus marked. Since the central effect of clonidine on blood pressure is unimportant in these patients, the drug can elevate blood pressure and improve the symptoms of postural hypotension.

Among the other off-label uses of clonidine are atrial fibrillation, attention-deficit/hyperactivity disorder, constitutional growth delay in children, cyclosporine-associated nephotoxicity, Tourette’s syndrome, hyperhidrosis, mania, posthepatic neuralgia, psychosis,
restless leg syndrome, ulcerative colitis, and allergy-induced inflammatory reactions in patients with extrinsic asthma.

**Apraclonidine.** Apraclonidine (IOPIDINE) is a relatively selective $\alpha_2$ receptor agonist that is used topically to reduce intraocular pressure. It can reduce elevated as well as normal intraocular pressure whether accompanied by glaucoma or not. The reduction in intraocular pressure occurs with minimal or no effects on systemic cardiovascular parameters; thus apraclonidine is more useful than clonidine for ophthalmic therapy. Apparently apraclonidine does not cross the blood-brain barrier. The mechanism of action of apraclonidine is related to $\alpha_2$ receptor−mediated reduction in the formation of aqueous humor.

The clinical utility of apraclonidine is most apparent as short-term adjunctive therapy in glaucoma patients whose intraocular pressure is not well controlled by other pharmacological agents such as $\beta$ receptor antagonists, parasympathomimetics, or carbonic anhydrase inhibitors. The drug also is used to control or prevent elevations in intraocular pressure that occur in patients after laser trabeculoplasty or iridotomy (Chapter 64).

**Brimonidine.** Brimonidine (ALPHAGAN, others), is another clonidine derivative that is administered orally to lower intraocular pressure in patients with ocular hypertension or open-angle glaucoma. Brimonidine is a $\alpha_2$-selective agonist that reduces intraocular pressure both by decreasing aqueous humor production and by increasing outflow (Chapter 64). The efficacy of brimonidine in reducing intraocular pressure is similar to that of the $\beta$ receptor antagonist timolol. Unlike apraclonidine, brimonidine can cross the blood-brain barrier and can produce hypotension and sedation, although these CNS effects are slight compared to those of clonidine. As with all $\alpha_2$ agonists, this drug should be used with caution in patients with cardiovascular disease.

**Guanfacine.** Guanfacine (TENEX, others) is an $\alpha_2$ receptor agonist that is more selective for $\alpha_2$ receptors than is clonidine. Like clonidine, guanfacine lowers blood pressure by activation of brainstem receptors with resultant suppression of sympathetic activity. A sustained-release form (INTUNIV) has recently been FDA-approved for treatment of ADHD in children aged 6–17 years.

The drug is well absorbed after oral administration and has a large volume of distribution (4–6 L/kg). About 50% of guanfacine appears unchanged in the urine; the rest is metabolized. The $t_{1/2}$ for elimination ranges from 12–24 hours. Guanfacine and clonidine appear to have similar efficacy for the treatment of hypertension. The pattern of adverse effects also is similar for the two drugs, although it has been suggested that some of these effects may be milder and occur less frequently with guanfacine. A withdrawal syndrome may occur after the abrupt discontinuation of guanfacine, but it appears to be less frequent and milder than the syndrome that follows clonidine withdrawal. Part of this difference may relate to the longer $t_{1/2}$ of guanfacine.

**Guanabenz.** Guanabenz (WYTENSIN, others) is a centrally acting $\alpha_2$ agonist that decreases blood pressure by a mechanism similar to those of clonidine and guanfacine. Guanabenz has a $t_{1/2}$ of 4–6 hours and is extensively metabolized by the liver. Dosage adjustment may be necessary in patients with hepatic cirrhosis. The adverse effects caused by guanabenz (e.g., dry mouth and sedation) are similar to those seen with clonidine.

**Methyldopa.** Methyldopa ($\alpha$-methyl-3,4-dihydroyx-phenylalanine) is a centrally acting antihypertensive agent. It is metabolized to $\alpha$-methylnorepinephrine in the brain, and this compound is thought to activate central $\alpha_2$ receptors and lower blood pressure in a manner similar to that of clonidine (Chapter 27).

**Tizanidine.** Tizanidine (ZANAFLEX, others) is a muscle relaxant used for the treatment of spasticity associated with cerebral and spinal disorders. It is also an $\alpha_2$ agonist with some properties similar to those of clonidine (Wagstaff and Bryson, 1997).

**MISCELLANEOUS SYMPATHOMIMETIC AGONISTS**

**Amphetamine**

Amphetamine, racemic $\beta$ phenylisopropylamine (Table 12–1), has powerful CNS stimulant actions in addition to the peripheral $\alpha$ and $\beta$ actions common to indirect-acting sympathomimetic drugs. Unlike epinephrine, it is effective after oral administration and its effects last for several hours.

**Cardiovascular System.** Amphetamine given orally raises both systolic and diastolic blood pressure. Heart rate often is reflexly slowed; with large doses, cardiac arrhythmias may occur. Cardiac output is not enhanced by therapeutic doses, and cerebral blood flow does not change much. The $l$-isomer is slightly more potent than the $d$-isomer in its cardiovascular actions.

**Other Smooth Muscles.** In general, smooth muscles respond to amphetamine as they do to other sympathomimetic amines. The contractile effect on the sphincter of the urinary bladder is particularly marked, and for this reason amphetamine has been used in treating enuresis and incontinence. Pain and difficulty in micturition occasionally occur. The GI effects of amphetamine are unpredictable. If enteric activity is pronounced, amphetamine may cause relaxation and delay the movement of intestinal contents; if the gut already is relaxed, the opposite effect may occur. The response of the human uterus varies, but there usually is an increase in tone.
CNS. Amphetamine is one of the most potent sympathomimetic amines in stimulating the CNS. It stimulates the medullary respiratory center, lessens the degree of central depression caused by various drugs, and produces other signs of CNS stimulation. These effects are thought to be due to cortical stimulation and possibly to stimulation of the reticular activating system. In contrast, the drug can obtund the maximal electroshock seizure discharge and prolong the ensuing period of depression. In eliciting CNS excitatory effects, the d-isomer (dextrorotary amphetamine) is 3-4 times more potent than the l-isomer.

The psychic effects depend on the dose and the mental state and personality of the individual. The main results of an oral dose of 10-30 mg include wakefulness, alertness, and a decreased sense of fatigue; elevation of mood, with increased initiative, self-confidence, and ability to concentrate; often, elation and euphoria; and increase in motor and speech activities. Performance of simple mental tasks is improved, but, although more work may be accomplished, the number of errors may increase. Physical performance—in athletes, e.g.—is improved, and the drug often is abused for this purpose. These effects are not invariable and may be reversed by overdosage or repeated usage. Prolonged use or large doses are nearly always followed by depression and fatigue. Many individuals given amphetamine experience headache, palpitation, dizziness, vasomotor disturbances, agitation, confusion, dysphoria, apprehension, delirium, or fatigue (Chapter 24).

Fatigue and Sleep. Prevention and reversal of fatigue by amphetamine have been studied extensively in the laboratory, in military field studies, and in athletics. In general, the duration of adequate performance is prolonged before fatigue appears, and the effects of fatigue are at least partly reversed. The most striking improvement appears to occur when performance has been reduced by fatigue and lack of sleep. Such improvement may be partly due to alteration of unfavorable attitudes toward the task. However, amphetamine reduces the frequency of attention lapses that impair performance after prolonged sleep deprivation and thus improves execution of tasks requiring sustained attention. The need for sleep may be postponed, but it cannot be avoided indefinitely. When the drug is discontinued after long use, the pattern of sleep may take as long as 2 months to return to normal.

Analgesia. Amphetamine and some other sympathomimetic amines have a small analgesic effect, but it is not sufficiently pronounced to be therapeutically useful. However, amphetamine can enhance the analgesia produced by opiates.

Respiration. Amphetamine stimulates the respiratory center, increasing the rate and depth of respiration. In normal individuals, usual doses of the drug do not appreciably increase respiratory rate or minute volume. Nevertheless, when respiration is depressed by centrally acting drugs, amphetamine may stimulate respiration.

Depression of Appetite. Amphetamine and similar drugs have been used for the treatment of obesity, although the wisdom of this use is at best questionable. Weight loss in obese humans treated with amphetamine is almost entirely due to reduced food intake and only in small measure to increased metabolism. The site of action probably is in the lateral hypothalamic feeding center; injection of amphetamine into this area, but not into the ventromedial region, suppresses food intake. Neurochemical mechanisms of action are unclear but may involve increased release of NE and/or DA. In humans, tolerance to the appetite suppression develops rapidly. Hence, continuous weight reduction usually is not observed in obese individuals without dietary restriction.

Mechanisms of Action in the CNS. Amphetamine appears to exert most or all of its effects in the CNS by releasing biogenic amines from their storage sites in nerve terminals. In addition, the neuronal dopamine transporter (DAT) and the vesicular monoamine transporter 2 (VMAT2) appear to be two of the principal targets of amphetamine’s action (Fleckenstein, 2007). These mechanisms include amphetamine-induced exchange diffusion, reverse transport, channel-like transport phenomena, and effects resulting from the weakly basic properties of amphetamine. Amphetamine analogs affect monamine transporters through phosphorylation, transporter trafficking, and the production of reactive oxygen and nitrogen species. These mechanisms may have potential implications for neurotoxicity as well as dopaminergic neurodegenerative diseases (discussed later) (Fleckenstein, 2007).

The alerting effect of amphetamine, its anorectic effect, and at least a component of its locomotor-stimulating action presumably are mediated by release of NE from central noradrenergic neurons. These effects can be prevented in experimental animals by treatment with metyrosine (α-methyltyrosine), an inhibitor of tyrosine hydroxylase, and therefore of catecholamine synthesis. Some aspects of locomotor activity and the stereotyped behavior induced by amphetamine probably are a consequence of the release of DA from dopaminergic nerve terminals, particularly in the neostriatum. Higher doses are required to produce these behavioral effects, and this correlates with the higher concentrations of amphetamine required to release DA from brain slices or synaptosomes in vitro. With still higher doses of amphetamine, disturbances of perception and overt psychotic behavior occur. These effects may be due to release of 5-hydroxytryptamine (serotonin, 5-HT) from serotonergic neurons and of DA in the mesolimbic system. In addition, amphetamine may exert direct effects on CNS receptors for 5-HT (Chapter 13).

Toxicity and Adverse Effects. The acute toxic effects of amphetamine usually are extensions of its therapeutic actions, and as a rule result from overdosage. CNS effects commonly include restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggressiveness, changes in libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies occur, especially in mentally ill patients. However, these psychotic effects can be elicited in any individual if sufficient quantities of amphetamine are ingested for a prolonged period. Fatigue and depression usually follow central stimulation. Cardiovascular effects are common and include headache, chilliness, pallor or flushing,
palpitation, cardiac arrhythmias, anginal pain, hypertension or hypotension, and circulatory collapse. Excessive sweating occurs. GI symptoms include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Fatal poisoning usually terminates in convulsions and coma, and cerebral hemorrhages are the main pathological findings.

The toxic dose of amphetamine varies widely. Toxic manifestations occasionally occur as an idiosyncratic reaction after as little as 2 mg, but are rare with doses of < 15 mg. Severe reactions have occurred with 30 mg, yet doses of 400-500 mg are not uniformly fatal. Larger doses can be tolerated after chronic use of the drug.

Treatment of acute amphetamine intoxication may include acidification of the urine by administration of ammonium chloride; this enhances the rate of elimination. Sedatives may be required for the CNS symptoms. Severe hypertension may require administration of sodium nitroprusside or an α-adrenergic receptor antagonist.

Chronic intoxication with amphetamine causes symptoms similar to those of acute overdosage, but abnormal mental conditions are more common. Weight loss may be marked. A psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia, is the most common serious effect. Recovery usually is rapid after withdrawal of the drug, but occasionally the condition becomes chronic. In these persons, amphetamine may act as a precipitating factor hastening the onset of incipient schizophrenia.

The abuse of amphetamine as a means of overcoming sleepiness and of increasing energy and alertness should be discouraged. The drug should be used only under medical supervision. The amphetamines are schedule II drugs under federal regulations. The additional contraindications and precautions for the use of amphetamine generally are similar to those described above for epinephrine. Its use is inadvisable in patients with anorexia, insomnia, asthenia, psychopathic personality, or a history of homicidal or suicidal tendencies.

**Dependence and Tolerance.** Psychological dependence often occurs when amphetamine or dextroamphetamine is used chronically, as discussed in Chapter 24. Tolerance almost invariably develops to the anorexigenic effect of amphetamines, and often is seen also in the need for increasing doses to maintain improvement of mood in psychiatric patients. Tolerance is striking in individuals who are dependent on the drug; a daily intake of 1.7 g without apparent ill effects has been reported. Development of tolerance is not invariable, and cases of narcolepsy have been treated for years without requiring an increase in the initially effective dose.

**Therapeutic Uses.** Amphetamine is used chiefly for its CNS effects. Dextroamphetamine (DEXEDRINE, others), with greater CNS action and less peripheral action, was used off-label for obesity (but no longer is approved for this purpose because of the risk of abuse) and is FDA-approved for the treatment of narcolepsy and attention-deficit/hyperactivity disorder (see below, “Therapeutic Uses of Sympathomimetic Drugs”).

**Methamphetamine**

Methamphetamine (DESOXYN) is closely related chemically to amphetamine and ephedrine (Table 12–1). In the brain, methamphetamine releases DA and other biogenic amines, and inhibits neuronal and vesicular monoamine transporters as well as MAO.

Small doses have prominent central stimulant effects without significant peripheral actions; somewhat larger doses produce a sustained rise in systolic and diastolic blood pressures, due mainly to cardiac stimulation. Cardiac output is increased, although the heart rate may be reflexly slowed. Venous constriction causes peripheral venous pressure to increase. These factors tend to increase the venous return, and thus cardiac output. Pulmonary arterial pressure is raised, probably owing to increased cardiac output. Methamphetamine is a schedule II drug under federal regulations and has high potential for abuse (Chapter 24). It is widely used as a cheap, accessible recreational drug and its abuse is a widespread phenomenon. Illegal production of methamphetamine in clandestine laboratories throughout the U.S. is common. It is used principally for its central effects, which are more pronounced than those of amphetamine and are accompanied by less prominent peripheral actions (see below, Therapeutic Uses of Sympathomimetic Drugs).

**Methylphenidate**

Methylphenidate is a piperidine derivative that is structurally related to amphetamine. Methylphenidate (RITALIN, others) is a mild CNS stimulant with more prominent effects on mental than on motor activities. However, large doses produce signs of generalized CNS stimulation that may lead to convulsions.

![METHYLPHENIDATE](image)

Its pharmacological properties are essentially the same as those of the amphetamines. Methylphenidate also shares the abuse potential of the amphetamines and is listed as a schedule II controlled substance in the U.S. Methylphenidate is effective in the treatment of narcolepsy and attention-deficit/hyperactivity disorder, as described in the subsequent paragraphs.

Methylphenidate is readily absorbed after oral administration and reaches peak concentrations in plasma in ~2 hours. The drug is a racemate; its more potent (+) enantiomer has a t₁/₂ of ~6 hours, and the less potent (–) enantiomer has a t₁/₂ of ~4 hours. Concentrations in the brain exceed those in plasma. The main urinary metabolite is a de-esterified product, ritalinic acid, which accounts for 80% of the dose. The use of methylphenidate is contraindicated in patients with glaucoma.

**Dexmethylphenidate**. Dexmethylphenidate (FOCALIN) is the d-threo enantiomer of racemic methylphenidate. It is FDA-approved for the
treatment of attention-deficit/hyperactivity disorder and is listed as a schedule II controlled substance in the U.S.

**Pemoline.** Pemoline (Cylert, others) is structurally dissimilar to methylphenidate but elicits similar changes in CNS function with minimal effects on the cardiovascular system. It is employed in treating attention-deficit/hyperactivity disorder. It can be given once daily because of its long $t_{1/2}$. Clinical improvement may require treatment for 3-4 weeks. Use of pemoline has been associated with severe hepatic failure. The drug was discontinued in the U.S. in 2006.

**Ephedrine**

Ephedrine is an agonist at both $\alpha$ and $\beta$ receptors; in addition, it enhances release of NE from sympathetic neurons and therefore is a mixed-acting sympathomimetic drug. Ephedrine contains two asymmetrical carbon atoms (Table 12–1); only $l$-ephedrine and racemic ephedrine are used clinically.

**Pharmacological Actions.** Ephedrine does not contain a catechol moiety and is effective after oral administration. The drug stimulates heart rate and cardiac output and variably increases peripheral resistance; as a result, ephedrine usually increases blood pressure. Stimulation of the $\alpha$ receptors of smooth muscle cells in the bladder base may increase the resistance to the outflow of urine. Activation of $\beta$ receptors in the lungs promotes bronchodilation. Ephedrine is a potent CNS stimulant. After oral administration, effects of the drug may persist for several hours. Ephedrine is eliminated in the urine largely as unchanged drug, with a $t_{1/2}$ of 3-6 hours.

**Therapeutic Uses and Toxicity.** In the past, ephedrine was used to treat Stokes-Adams attacks with complete heart block and as a CNS stimulant in narcolepsy and depressive states. It has been replaced by alternate treatments in each of these disorders. In addition, its use as a bronchodilator in patients with asthma has become much less extensive with the development of $\beta_2$-selective agonists. Ephedrine has been used to promote urinary continence, although its efficacy is not clear. Indeed, the drug may cause urinary retention, particularly in men with benign prostatic hyperplasia. Ephedrine also has been used to treat the hypotension that may occur with spinal anesthesia.

Untoward effects of ephedrine include hypertension, particularly after parenteral administration or with higher-than-recommended oral dosing. Insomnia is a common CNS adverse effect. Tachyphylaxis may occur with repetitive dosing. Concerns have been raised about the safety of ephedrine. Usual or higher-than-recommended doses may cause important adverse effects in susceptible individuals and are especially of concern in patients with underlying cardiovascular disease that might be unrecognized. Of potentially greater cause for concern, large amounts of herbal preparations containing ephedrine (ma huang, ephedra) are utilized around the world. There can be considerable variability in the content of ephedrine in these preparations, which may lead to inadvertent consumption of higher-than-usual doses of ephedrine and its isomers. Because of this, the FDA has banned the sale of dietary supplements containing ephedra. In addition, the Combat Methamphetamine Epidemic Act of 2005 regulates the sale of ephedrine, phenylpropanolamine, and pseudoephedrine, which can be used as precursors in the illicit manufacture of amphetamine and methamphetamine.

**Other sympathomimetic Agents**

Several sympathomimetic drugs are used primarily as vasoconstrictors for local application to the nasal mucous membrane or the eye. The structures of propylhexedrine (Benzedrex, others), naphazoline (Privine, Naphcon, others), oxymetazoline ( Afrin, Ocuf- clear, others), and xylometazoline (Otrivin, others) are depicted in Table 12–1 and Figure 12–4.

Phenylephrine (described earlier), pseudoephedrine (Sudafed, others) (a stereoisomer of ephedrine), and phenylpropanolamine are the sympathomimetic drugs that have been used most commonly in oral preparations for the relief of nasal congestion. Pseudoephedrine is available without a prescription in a variety of solid and liquid dosage forms. Phenylpropanolamine shares the pharmacological properties of ephedrine and is approximately equal in potency except that it causes less CNS stimulation. Due to concern about the possibility that phenylpropanolamine increases the risk of hemorrhagic stroke, the drug is no longer licensed for marketing in the U.S.

**OTHER SYMPATHOMIMETIC AGENTS**

The variety of vital functions that are regulated by the sympathetic nervous system and the success that has attended efforts to develop therapeutic agents that can
influence adrenergic receptors selectively have resulted in a class of drugs with a large number of important therapeutic uses.

**Shock.** Shock is a clinical syndrome characterized by inadequate perfusion of tissues; it usually is associated with hypotension and ultimately with the failure of organ systems (Hollenberg et al., 1999). Shock is an immediately life-threatening impairment of delivery of oxygen and nutrients to the organs of the body. Causes of shock include hypovolemia (due to dehydration or blood loss), cardiac failure (extensive myocardial infarction, severe arrhythmia, or cardiac mechanical defects such as ventricular septal defect), obstruction to cardiac output (due to pulmonary embolism, pericardial tamponade, or aortic dissection), and peripheral circulatory dysfunction (sepsis or anaphylaxis). Recent research on shock has focused on the accompanying increased permeability of the GI mucosa to pancreatic proteases, and on the role of these degradative enzymes on microvascular inflammation and multi-organ failure (Schmid-Schoenbein and Hugli, 2005). The treatment of shock consists of specific efforts to reverse the underlying pathogenesis as well as nonspecific measures aimed at correcting hemodynamic abnormalities. Regardless of etiology, the accompanying fall in blood pressure generally leads to marked activation of the sympathetic nervous system. This, in turn, causes peripheral vasoconstriction and an increase in the rate and force of cardiac contraction. In the initial stages of shock these mechanisms may maintain blood pressure and cerebral blood flow, although blood flow to the kidneys, skin, and other organs may be decreased, leading to impaired production of urine and metabolic acidosis.

The initial therapy of shock involves basic life-support measures. It is essential to maintain blood volume, which often requires monitoring of hemodynamic parameters. Specific therapy (e.g., antibiotics for patients in septic shock) should be initiated immediately. If these measures do not lead to an adequate therapeutic response, it may be necessary to use vasoactive drugs in an effort to improve abnormalities in blood pressure and flow. This therapy generally is empirically based on response to hemodynamic measurements. Many of these pharmacological approaches, while apparently clinically reasonable, are of uncertain efficacy. Adrenergic receptor agonists may be used in an attempt to increase myocardial contractility or to modify peripheral vascular resistance. In general terms, β receptor agonists increase heart rate and force of contraction, α receptor agonists increase peripheral vascular resistance, and DA promotes dilation of renal and splanchnic vascular beds, in addition to activating β and α receptors (Breslow and Ligier, 1991).

Cardiogenic shock due to myocardial infarction has a poor prognosis; therapy is aimed at improving peripheral blood flow. Definitive therapy, such as emergency cardiac catheterization followed by surgical revascularization or angioplasty, may be very important. Mechanical left ventricular assist devices also may help to maintain cardiac output and coronary perfusion in critically ill patients. In the setting of severely impaired cardiac output, falling blood pressure leads to intense sympathetic outflow and vasoconstriction. This may further decrease cardiac output as the damaged heart pumps against a higher peripheral resistance. Medical intervention is designed to optimize cardiac filling pressure (preload), myocardial contractility, and peripheral resistance (afterload). Preload may be increased by administration of intravenous fluids or reduced with drugs such as diuretics and nitrates. A number of sympathomimetic amines have been used to increase the force of contraction of the heart. Some of these drugs have disadvantages: isoproterenol is a powerful chronotropic agent and can greatly increase myocardial $O_2$ demand; NE intensifies peripheral vasoconstriction; and epinephrine increases heart rate and may predispose the heart to dangerous arrhythmias. DA is an effective inotropic agent that causes less increase in heart rate than does isoproterenol. DA also promotes renal arterial dilation; this may be useful in preserving renal function. When given in high doses (> 10-20 μg/kg per minute), DA activates α receptors, causing peripheral and renal vasoconstriction. Dobutamine has complex pharmacological actions that are mediated by its stereoisomers; the clinical effects of the drug are to increase myocardial contractility with little increase in heart rate or peripheral resistance.

In some patients in shock, hypotension is so severe that vasoconstricting drugs are required to maintain a blood pressure that is adequate for CNS perfusion. Alpha agonists such as NE, phenylephrine, metaraminol, mephentermine, midodrine, ephedrine, epinephrine, DA, and methoxamine all have been used for this purpose. This approach may be advantageous in patients with hypotension due to failure of the sympathetic nervous system (e.g., after spinal anesthesia or injury). However, in patients with other forms of shock, such as cardiogenic shock, reflex vasoconstriction generally is intense, and α receptor agonists may further compromise blood flow to organs such as the kidneys and gut and adversely increase the work of the heart. Indeed, vasodilating drugs such as nitroprusside are more likely to improve blood flow and decrease cardiac work in such patients by decreasing afterload if a minimally adequate blood pressure can be maintained.

The hemodynamic abnormalities in septic shock are complex and poorly understood. Most patients with septic shock initially have low or barely normal peripheral vascular resistance, possibly owing to excessive effects of endogenously produced NO as well as normal or increased cardiac output. If the syndrome progresses, myocardial depression, increased peripheral resistance, and impaired tissue oxygenation occur. The primary treatment of septic shock is antibiotics. Data on the comparative value of various adrenergic agents in the treatment of septic shock are limited. Therapy with drugs such as DA or dobutamine is guided by hemodynamic monitoring, with individualization of therapy depending on the patient’s overall clinical condition.

**Hypotension.** Drugs with predominantly α agonist activity can be used to raise blood pressure in patients with decreased peripheral resistance in conditions such as spinal anesthesia or intoxication with antihypertensive medications. However, hypotension per se is not an indication for treatment with these agents unless there is inadequate perfusion of organs such as the brain, heart, or kidneys. Furthermore, adequate replacement of fluid or blood may be more appropriate than drug therapy for many patients with hypotension. In patients with spinal anesthesia that interrupts sympathetic activation of the heart, injections of ephedrine increase heart rate as well as peripheral vascular resistance; tachyphylaxis may occur with repetitive injections, necessitating the use of a directly acting drug.

Patients with orthostatic hypotension (excessive fall in blood pressure with standing) often represent a pharmacological challenge. There are diverse causes for this disorder, including the Shy-Drager
syndrome and idiopathic autonomic failure. Therapeutic approaches include physical maneuvers and a variety of drugs (fludrocortisone, prostaglandin synthesis inhibitors, somatostatin analogs, caffeine, vasopressin analogs, and DA antagonists). A number of sympathomimetic drugs also have been used in treating this disorder. The ideal agent would enhance venous constriction prominently and produce relatively little arterial constriction so as to avoid supine hypertension. No such agent currently is available. Drugs used in this disorder to activate $\alpha_1$ receptors include both direct- and indirect-acting agents. Midodrine shows promise in treating this challenging disorder.

**Hypertension.** Centrally acting $\alpha_1$ receptor agonists such as clonidine are useful in the treatment of hypertension. Drug therapy of hypertension is discussed in Chapter 27.

**Cardiac Arrhythmias.** Cardiopulmonary resuscitation in patients with cardiac arrest due to ventricular fibrillation, electromechanical dissociation, or asystole may be facilitated by drug treatment. Epinephrine is an important therapeutic agent in patients with cardiac arrest; epinephrine and other $\alpha$ agonists increase diastolic pressure and improve coronary blood flow. Alpha agonists also help to preserve cerebral blood flow during resuscitation. Cerebral blood vessels are relatively insensitive to the vasoconstricting effects of catecholamines, and perfusion pressure is increased. Consequently, during external cardiac massage, epinephrine facilitates distribution of the limited cardiac output to the cerebral and coronary circulations. Although it had been thought that the $\beta$ adrenergic effects of epinephrine on the heart made ventricular fibrillation more susceptible to conversion with electrical countershock, tests in animal models have not confirmed this hypothesis. The optimal dose of epinephrine in patients with cardiac arrest is unclear. Once a cardiac rhythm has been restored, it may be necessary to treat arrhythmias, hypotension, or shock.

In patients with paroxysmal supraventricular tachycardias, particularly those associated with mild hypotension, careful infusion of an $\alpha$ agonist (e.g., phenylephrine) to raise blood pressure to ~160 mm Hg may end the arrhythmia by increasing vagal tone. However, this method of treatment has been replaced largely by Ca$^{2+}$ channel blockers with clinically significant effects on the AV node, $\beta$ antagonists, adenosine, and electrical cardioversion (Chapter 29). Beta agonists such as isoproterenol may be used as adjunctive or temporizing therapy with atropine in patients with marked bradycardia who are compromised hemodynamically; if long-term therapy is required, a cardiac pacemaker usually is the treatment of choice.

**Congestive Heart Failure.** Sympathetic stimulation of $\beta$ receptors in the heart is an important compensatory mechanism for maintenance of cardiac function in patients with congestive heart failure. Responses mediated by $\beta$ receptors are blunted in the failing human heart. While $\beta$ agonists may increase cardiac output in acute emergency settings such as shock, long-term therapy with $\beta$ agonists as inotropic agents is not efficacious. Indeed, interest has grown in the use of $\beta$ receptor antagonists in the treatment of patients with congestive heart failure (Chapter 28).

**Local Vascular Effects of $\alpha$ Adrenergic Receptor Agonists.** Epinephrine is used in many surgical procedures in the nose, throat, and larynx to shrink the mucosa and improve visualization by limiting hemorrhage. Simultaneous injection of epinephrine with local anesthetics retards the absorption of the anesthetic and increases the duration of anesthesia (Chapter 20). Injection of $\alpha$ agonists into the penis may be useful in reversing priapism, a complication of the use of $\alpha$ receptor antagonists or PDE5 inhibitors (e.g., sildenafil) in the treatment of erectile dysfunction. Both phenylephrine and oxymetazoline are efficacious vasoconstrictors when applied locally during sinus surgery.

**Nasal Decongestion.** $\alpha$ Receptor agonists are used extensively as nasal decongestants in patients with allergic or vasomotor rhinitis and in acute rhinitis in patients with upper respiratory infections. These drugs probably decrease resistance to airflow by decreasing the volume of the nasal mucosa; this may occur by activation of $\alpha$ receptors in venous capacitance vessels in nasal tissues that have erectile characteristics. The receptors that mediate this effect appear to be $\alpha_1$ receptors. Interestingly, $\alpha_2$ receptors may mediate contraction of arterioles that supply nutrition to the nasal mucosa. Intense constriction of these vessels may cause structural damage to the mucosa. A major limitation of therapy with nasal decongestants is loss of efficacy, “rebound” hyperemia, and worsening of symptoms with chronic use or when the drug is stopped. Although mechanisms are uncertain, possibilities include receptor desensitization and damage to the mucosa. Agonists that are selective for $\alpha_1$ receptors may be less likely to induce mucosal damage.

For decongestion, $\alpha$ agonists may be administered either orally or topically. Oral ephedrine often causes CNS adverse effects. Pseudoephedrine is a stereoisomer of ephedrine that is less potent than ephedrine in producing tachycardia, increased blood pressure, and CNS stimulation. Sympathomimetic decongestants should be used with great caution in patients with hypertension and in men with prostatic enlargement, and they are contraindicated in patients who are taking MAO inhibitors. A variety of compounds (see under Ephedrine, earlier) are available for topical use in patients with rhinitis. Topical decongestants are particularly useful in acute rhinitis because of their more selective site of action, but they are apt to be used excessively by patients, leading to rebound congestion. Oral decongestants are much less likely to cause rebound congestion but carry a greater risk of inducing adverse systemic effects. Indeed, patients with uncontrolled hypertension or ischemic heart disease generally should carefully avoid the oral consumption of over-the-counter products or herbal preparations containing sympathomimetic drugs.

**Asthma.** Use of $\beta$ adrenergic agonists in the treatment of asthma and chronic obstructive pulmonary disease (COPD) is discussed in Chapter 36.

**Allergic Reactions.** Epinephrine is the drug of choice to reverse the manifestations of serious acute hypersensitivity reactions (e.g., from food, bee sting, or drug allergy). A subcutaneous injection of epinephrine rapidly relieves itching, hives, and swelling of lips, eyelids, and tongue. In some patients, careful intravenous infusion of epinephrine may be required to ensure prompt pharmacological effects. This treatment may be life-saving when edema of the glottis threatens airway patency or when there is hypotension or shock in patients with anaphylaxis. In addition to its cardiovascular effects, epinephrine is thought to activate $\beta$ receptors that suppress the release from mast cells of mediators such as histamine and...
leukotrienes. Although glucocorticoids and antihistamines frequently are administered to patients with severe hypersensitivity reactions, epinephrine remains the mainstay. Epinephrine auto-injectors (EPIPEN, others) are employed widely for the emergency self-treatment of anaphylaxis.

**Chapter 12**

**ADRENERGIC AGONISTS AND ANTAGONISTS**

**Ophthalmic Uses.** Application of various sympathomimetic amines for diagnostic and therapeutic ophthalmic use is discussed in Chapter 64.

**Narcolepsy and Related Syndromes.** Narcolepsy is characterized by hypersomnia, including attacks of sleep that may occur suddenly under conditions that are not normally conducive to sleep. Some patients respond to treatment with tricyclic antidepressants or MAO inhibitors. Alternatively, CNS stimulants such as amphetamine, dextroamphetamine, or methamphetamine may be useful. Modafinil (Provigil), a CNS stimulant, may have benefit in narcolepsy. In the U.S., it is a schedule IV controlled substance. Its mechanism of action in narcolepsy is unclear and may not involve adrenergic receptors. Therapy with amphetamines is complicated by the risk of abuse and the likelihood of the development of tolerance. Depression, irritability, and paranoia also may occur. Amphetamines may disturb nocturnal sleep, which increases the difficulty of avoiding daytime attacks of sleep in these patients. Armodafinil (Nuvigil), the R-enantiomer of modafinil (a mixture of R- and S-enantiomers) is also indicated for narcolepsy, to improve wakefulness in shift workers, and to combat excessive sleepiness in patients with obstructive sleep apnea-hypopnea syndrome.

Narcolepsy in rare individuals is caused by mutations in the related orexin neuropeptides (also called hypocretins), which are expressed in the lateral hypothalamus, or in their G protein–coupled receptors (Mignot, 2004). Although such mutations are not present in most subjects with narcolepsy, the levels of orexins in the CSF are markedly diminished, suggesting that deficient orexin signaling may play a pathogenic role. The association of these neuropeptides and their cognate GPCRs with narcolepsy provides an attractive target for the development of novel pharmacotherapies for this disorder.

**Weight Reduction.** Obesity arises as a consequence of positive caloric balance. Optimally, weight loss is achieved by a gradual increase in energy expenditure from exercise combined with dieting to decrease the caloric intake. However, this obvious approach has a relatively low success rate. Consequently, alternative forms of treatment, including surgery or medications, have been developed in an effort to increase the likelihood of achieving and maintaining weight loss. Amphetamine was found to produce weight loss in early studies of patients with narcolepsy and was subsequently used in the treatment of obesity. The drug promotes weight loss by suppressing appetite rather than by increasing energy expenditure. Other anorectic drugs include methamphetamine, dextroamphetamine (and a pro-drug form, lisdexamfetamine), phentermine, benzphetamine, phenmetrazine, phentramin, diethylpropion, mazindol, phenylpropanolamine, and sibutramine (a mixed adrenergic/serotonergic drug). Phenmetrazine, mazindol, and phenylpropanolamine have been discontinued in the U.S. In short-term (up to 20 weeks), double-blind controlled studies, amphetamine-like drugs have been shown to be more effective than placebo in promoting weight loss; the rate of weight loss typically is increased by ~0.5 pound per week with these drugs. There is little to choose among these drugs in terms of efficacy. However, long-term weight loss has not been demonstrated unless these drugs are taken continuously. In addition, other important issues have not yet been resolved, including the selection of patients who might benefit from these drugs, whether the drugs should be administered continuously or intermittently, and the duration of treatment. Adverse effects of treatment include the potential for drug abuse and habituation, serious worsening of hypertension (although in some patients blood pressure actually may fall, presumably as a consequence of weight loss), sleep disturbances, palpitations, and dry mouth. These agents may be effective adjuncts in the treatment of obesity. However, available evidence does not support the isolated use of these drugs in the absence of a more comprehensive program that stresses exercise and modification of diet. β3 Receptor agonists have remarkable anti-obesity and anti-diabetic effects in rodents. However, pharmaceutical companies have not yet succeeded in developing β3 receptor agonists for the treatment of these conditions in humans, perhaps because of important differences in β3 receptors between humans and rodents. With the cloning of the human β3 receptor, compounds with favorable metabolic effects have been developed. The use of β3 agonists in the treatment of obesity remains a possibility for the future (Fernandez-Lopez et al., 2002; Robidoux et al., 2004).

**Attention-Deficit/Hyperactivity Disorder (ADHD).** This syndrome, usually first evident in childhood, is characterized by excessive motor activity, difficulty in sustaining attention, and impulsiveness. Children with this disorder frequently are troubled by difficulties in school, impaired interpersonal relationships, and excitability. Academic underachievement is an important characteristic. A substantial number of children with this syndrome have characteristics that persist into adulthood, although in modified form. Behavioral therapy may be helpful in some patients. Catecholamines may be involved in the control of attention at the level of the cerebral cortex. A variety of stimulant drugs have been utilized in the treatment of ADHD, and they are particularly indicated in moderate-to-severe cases. Dextroamphetamine has been demonstrated to be more effective than placebo. Methylphenidate is effective in children with ADHD and is the most common intervention (Swanson and Volkow, 2003). Treatment may start with a dose of 5 mg of methylphenidate in the morning and at lunch; the dose is increased gradually over a period of weeks depending on the response as judged by parents, teachers, and the clinician. The total daily dose generally should not exceed 60 mg; because of its short duration of action, most children require two or three doses of methylphenidate each day. The timing of doses is adjusted individually in accordance with rapidity of onset of effect and duration of action. Methylphenidate, dextroamphetamine, and amphetamine probably have similar efficacy in ADHD and are the preferred drugs in this disorder. Sustained-release preparations of dextroamphetamine, methylphenidate (Ritalin SR, Concerta, Meta-Date), dexmethphenidate (Focalin XR), and amphetamine (Adderal XR) may be used once daily in children and adults. Lisdexamfetamine (Vyvanse) can be administered once daily and a transdermal formulation of methylphenidate (Daytrana) is marketed for daytime use. Potential adverse effects of these medications include insomnia, abdominal pain, anorexia, and weight loss that may be associated with suppression of growth in children. Minor symptoms may be
system. For example, selective antagonists of β₁ receptors block most actions of epinephrine and NE on the heart, while having less effect on β₂ receptors in bronchial smooth muscle and no effect on responses mediated by α₁ or α₂ receptors. Detailed knowledge of the autonomic nervous system and the sites of action of drugs that act on adrenergic receptors is essential for understanding the pharmacological properties and therapeutic uses of this important class of drugs. Additional background material is presented in Chapter 8. Agents that block DA receptors are considered in Chapter 13.

**α ADRENERGIC RECEPTOR ANTAGONISTS**

The α adrenergic receptors mediate many of the important actions of endogenous catecholamines. Responses of particular clinical relevance include α₁ receptor–mediated contraction of arterial, venous and visceral smooth muscle. The α₂ receptors are involved in suppressing sympathetic output, increasing vagal tone, facilitating platelet aggregation, inhibiting the release of NE and ACh from nerve endings, and regulating metabolic effects. These effects include suppression of insulin secretion and inhibition of lipolysis. The α₂ receptors also mediate contraction of some arteries and veins.

α receptor antagonists have a wide spectrum of pharmacological specificities and are chemically transient or may respond to adjustment of dosage or administration of the drug with meals. Other drugs that have been utilized include tricyclic antidepressants, antipsychotic agents, and clonidine. A sustained release formulation of guanfacine (INTUNIV), an α₂A receptor agonist, has recently been approved for use in children (ages 6-17 years) in treating ADHD.

**Adrenergic Receptor Antagonists**

Many types of drugs interfere with the function of the sympathetic nervous system and thus have profound effects on the physiology of sympathetically innervated organs. Several of these drugs are important in clinical medicine, particularly for the treatment of cardiovascular diseases.

The remainder of this chapter focuses on the pharmacology of adrenergic receptor antagonists, drugs that inhibit the interaction of NE, epinephrine, and other sympathomimetic drugs with α and β receptors (Figure 12–5). Almost all of these agents are competitive antagonists; an important exception is phenoxybenzamine, an irreversible antagonist that binds covalently to α receptors. There are important structural differences among the various types of adrenergic receptors (Chapter 8). Since compounds have been developed that have different affinities for the various receptors, it is possible to interfere selectively with responses that result from stimulation of the sympathetic nervous system. For example, selective antagonists of β₁ receptors block most actions of epinephrine and NE on the heart, while having less effect on β₂ receptors in bronchial smooth muscle and no effect on responses mediated by α₁ or α₂ receptors. Detailed knowledge of the autonomic nervous system and the sites of action of drugs that act on adrenergic receptors is essential for understanding the pharmacological properties and therapeutic uses of this important class of drugs. Additional background material is presented in Chapter 8. Agents that block DA receptors are considered in Chapter 13.

**Figure 12–5. Classification of adrenergic receptor antagonists.** Drugs marked by an asterisk (*) also block α₁ receptors.
heterogeneous. Some of these drugs have markedly different affinities for \( \alpha_1 \) and \( \alpha_2 \) receptors. For example, prazosin is much more potent in blocking \( \alpha_1 \) than \( \alpha_2 \) receptors (i.e., \( \alpha_1 \) selective), whereas yohimbine is \( \alpha_2 \) selective; phentolamine has similar affinities for both of these receptor subtypes. More recently, agents that discriminate among the various subtypes of a particular receptor have become available; e.g., tamsulosin has higher potency at \( \alpha_{1A} \) than at \( \alpha_{1B} \) receptors. Figure 12–6 shows the structural formulas of many of these agents. Prior editions of this textbook contain information about the chemistry of \( \alpha \) receptor antagonists.

Some of the most important effects of \( \alpha \) receptor antagonists observed clinically are on the cardiovascular system. Actions in both the CNS and the periphery are involved; the outcome depends on the cardiovascular status of the patient at the time of drug administration and the relative selectivity of the agent for \( \alpha_1 \) and \( \alpha_2 \) receptors.

Catecholamines increase the output of glucose from the liver; in humans this effect is mediated predominantly by \( \beta \) receptors, although \( \alpha \) receptors may contribute. \( \alpha \) Receptor antagonists therefore may reduce glucose release. Receptors of the \( \alpha_{2A} \) subtype facilitate platelet aggregation; the effect of blockade of platelet \( \alpha_2 \) receptors in vivo is not clear. Activation of \( \alpha_2 \) receptors in the pancreatic islets suppresses insulin secretion; conversely, blockade of pancreatic \( \alpha_2 \) receptors may facilitate insulin release (Chapter 43).

**\( \alpha_1 \) Receptor Antagonists**

**General Pharmacological Properties.** Blockade of \( \alpha_1 \) adrenergic receptors inhibits vasoconstriction induced by endogenous catecholamines; vasodilation may occur in both arteriolar resistance vessels and veins. The result is a fall in blood pressure due to decreased peripheral resistance. The magnitude of such effects depends on the activity of the sympathetic nervous system at the time the antagonist is administered, and thus is less in supine than in upright subjects and is particularly marked if there is hypovolemia. For most \( \alpha \) receptor antagonists, the fall in blood pressure is opposed by baroreceptor reflexes that cause increases in heart rate and cardiac output, as well as fluid retention. These reflexes are exaggerated if the antagonist also blocks \( \alpha_2 \) receptors on peripheral sympathetic nerve endings, leading to enhanced release of NE and increased stimulation of postsynaptic \( \beta_1 \) receptors in the heart and on juxtaglomerular cells (Chapter 8) (Starke et al., 1989). Although stimulation of \( \alpha_1 \) receptors in the heart may cause an increased force of contraction, the importance of blockade at this site in humans is uncertain.

Blockade of \( \alpha_1 \) receptors also inhibits vasoconstriction and the increase in blood pressure produced by the administration of a sympathomimetic amine. The pattern of effects depends on the adrenergic agonist that is administered: pressor responses to phenylephrine can be completely suppressed; those to NE are only incompletely blocked because of residual stimulation of cardiac \( \beta_1 \) receptors; and pressor responses to epinephrine may be transformed to vasodepressor effects because of residual stimulation of \( \beta_2 \) receptors in the vasculature with resultant vasodilation.

Blockade of \( \alpha_1 \) receptors can alleviate some of the symptoms of benign prostatic hyperplasia (BPH). The symptoms of BPH include a resistance to urine outflow. This results from mechanical pressure on the urethra due to an increase in smooth muscle mass and an \( \alpha \) adrenergic receptor mediated increase in smooth muscle tone in the prostate and neck of the bladder. Antagonism of \( \alpha_1 \) receptors permits relaxation of the smooth muscle and decreases the resistance to the outflow of urine. The prostate and lower urinary tract tissues exhibit a high proportion of \( \alpha_{1A} \) receptors (Michel and Vrydag, 2006).

**Available Agents**

**Prazosin and Related Drugs.** Due in part to its greater \( \alpha_1 \) receptor selectivity, this class of \( \alpha \) receptor antagonists exhibits greater clinical utility and has largely replaced the non-selective haloalkylamine (e.g., phenoxybenzamine) and imidazoline (e.g., phentolamine) \( \alpha \) receptor antagonists.

Prazosin is the prototypical \( \alpha_1 \)-selective antagonist. The affinity of prazosin for \( \alpha_1 \) adrenergic receptors is ~1000-fold greater than that for \( \alpha_2 \) adrenergic receptors. Prazosin has similar potencies at \( \alpha_{1A} \), \( \alpha_{1B} \), and \( \alpha_{1D} \) subtypes. Interestingly, the drug also is a relatively potent inhibitor of cyclic nucleotide phosphodiesterases, and it originally was synthesized for this purpose. The pharmacological properties of prazosin have been characterized extensively. Prazosin and the related \( \alpha \) receptor antagonists, doxazosin and tamsulosin, frequently are used for the treatment of hypertension (Chapter 27).

**Pharmacological Properties.** The major effects of prazosin result from its blockade of \( \alpha_1 \) receptors in arterioles and veins. This leads to a fall in peripheral vascular resistance and in venous return to the heart. Unlike other vasodilating drugs, administration of prazosin usually does not increase heart rate. Since prazosin has little or no \( \alpha_2 \) receptor-blocking effect at concentrations achieved clinically, it probably does
Figure 12–6. Structural formulas of some α adrenergic receptor antagonists.
not promote the release of NE from sympathetic nerve endings in the heart. In addition, prazosin decreases cardiac preload and thus has little tendency to increase cardiac output and rate, in contrast to vasodilators such as hydralazine that have minimal dilatory effects on veins. Although the combination of reduced preload and selective \( \alpha_1 \) receptor blockade might be sufficient to account for the relative absence of reflex tachycardia, prazosin also may act in the CNS to suppress sympathetic outflow. Prazosin appears to depress baroreflex function in hypertensive patients. Prazosin and related drugs in this class tend to have favorable effects on serum lipids in humans, decreasing low-density lipoproteins (LDL) and triglycerides while increasing concentrations of high-density lipoproteins (HDL). Prazosin and related drugs may have effects on cell growth unrelated to antagonism of \( \alpha_1 \) receptors (Hu et al., 1998).

Prazosin (MINIPRESS, others) is well absorbed after oral administration, and bioavailability is \( \sim 50-70\% \). Peak concentrations of prazosin in plasma generally are reached 1-3 hours after an oral dose. The drug is tightly bound to plasma proteins (primarily \( \alpha \)-acid glycoprotein), and only 5% of the drug is free in the circulation; diseases that modify the concentration of this protein (e.g., inflammatory processes) may change the free fraction. Prazosin is extensively metabolized in the liver, and little unchanged drug is excreted by the kidneys. The plasma \( t_{1/2} \) is \( \sim 3 \) hours (may be prolonged to 6-8 hours in congestive heart failure). The duration of action of the drug typically is 7-10 hours in the treatment of hypertension.

The initial dose should be 1 mg, usually given at bedtime so that the patient will remain recumbent for at least several hours to reduce the risk of syncopal reactions that may follow the first dose of prazosin. Therapy is begun with 1 mg given two or three times daily, and the dose is titrated upward depending on the blood pressure. A maximal effect generally is observed with a total daily dose of 20 mg in patients with hypertension. In the off-label treatment of benign prostatic hyperplasia (BPH), doses from 1-5 mg twice daily typically are used.

Terazosin. Terazosin (HYTRIN, others) is a close structural analog of prazosin. It is less potent than prazosin but retains high specificity for \( \alpha_1 \) receptors; terazosin does not discriminate among \( \alpha_{1A}, \alpha_{1B}, \) and \( \alpha_{1D} \) receptors. The major distinction between the two drugs is in their pharmacokinetic properties.

Terazosin is more soluble in water than is prazosin, and its bioavailability is high (>90%). The \( t_{1/2} \) of elimination of terazosin is \( \sim 12 \) hours, and its duration of action usually extends beyond 18 hours. Consequently, the drug may be taken once daily to treat hypertension and BPH in most patients. Terazosin has been found more effective than finasteride in treatment of BPH (Lepor et al., 1996). An interesting aspect of the action of terazosin and doxazosin in the treatment of lower urinary tract problems in men with BPH is the induction of apoptosis in prostate smooth muscle cells. This apoptosis may lessen the symptoms associated with chronic BPH by limiting cell proliferation. The apoptotic effect of terazosin and doxazosin appears to be related to the quinazoline moiety rather than \( \alpha_1 \) receptor antagonism; tamsulosin, a non-quinazoline \( \alpha_1 \) receptor antagonist, does not produce apoptosis (Kyprianou, 2003). Only \( \sim 10\% \) of terazosin is excreted unchanged in the urine. An initial first dose of 1 mg is recommended. Doses are slowly titrated upward depending on the therapeutic response. Doses of 10 mg/day may be required for maximal effect in BPH.

Doxazosin. Doxazosin (CARDURA, others) is another structural analog of prazosin and a highly selective antagonist at \( \alpha_1 \) receptors. It is non-selective among \( \alpha_1 \) receptor subtypes, and differs from prazosin in its pharmacokineti profile.

The \( t_{1/2} \) of doxazosin is \( \sim 20 \) hours, and its duration of action may extend to 36 hours. The bioavailability and extent of metabolism of doxazosin and prazosin are similar. Most doxazosin metabolites are eliminated in the feces. The hemodynamic effects of doxazosin appear to be similar to those of prazosin. As in the cases of prazosin and terazosin, doxazosin should be given initially as a 1-mg dose in the treatment of hypertension or BPH. Doxazosin also may have beneficial actions in the long-term management of BPH related to apoptosis that are independent of \( \alpha_1 \) receptor antagonism. Doxazosin is typically administered once daily. An extended-release formulation marketed for BPH is not recommended for the treatment of hypertension.

Alfuzosin. Alfuzosin (UXOXRATR) is a quinazoline-based \( \alpha_1 \) receptor antagonist with similar affinity at all of the \( \alpha_1 \) receptor subtypes. It has been used extensively in treating BPH; it is not approved for treatment of hypertension. Its bioavailability is \( \sim 64\% \); it has a \( t_{1/2} \) of 3-5 hours. Alfuzosin is a substrate of CYP3A4 and the concomitant administration of CPY3A4 inhibitors (e.g., ketoconazole, clarithromycin, itraconazole, ritonavir) is contraindicated. Alfuzosin should be avoided in patients at risk for prolonged QT syndrome. The recommended dosage is one 10-mg extended-release tablet daily to be taken after the same meal each day.

Tamsulosin. Tamsulosin (FLOMAX), a benzenesulfonamide, is an \( \alpha_1 \) receptor antagonist with some selectivity for \( \alpha_{1A} \) and \( \alpha_{1B} \) subtypes compared to the \( \alpha_{1B} \) subtype (Kenny et al., 1996). This selectivity may favor blockade of \( \alpha_{1A} \) receptors in prostate. Tamsulosin is efficacious in the treatment of BPH with little effect on blood pressure (Beduschi et al., 1998); tamsulosin is not approved for the treatment of hypertension. Tamsulosin is well absorbed and has a \( t_{1/2} \) of 5-10 hours. It is extensively metabolized by CYPs. Tamsulosin may be administered at a 0.4-mg starting dose; a dose of 0.8 mg ultimately will be more efficacious in some patients. Abnormal ejaculation is an adverse effect of tamsulosin, experienced by \( \sim 18\% \) of patients receiving the higher dose.

Silodosin. Silodosin (RAPAFLO) also exhibits selectivity for the \( \alpha_{1A} \) over the \( \alpha_{1B} \) adrenergic receptor. The drug is metabolized by several pathways; the main metabolite is a glucuronide formed by UGT2B7; co-administration with inhibitors of this enzyme (e.g., probenecid, valproic acid, fluconazole) increases systemic exposure to silodosin. The drug is approved for the treatment of BPH and is reported, as is tamsulosin, to have lesser effects on blood pressure than the non-\( \alpha_1 \) subtype selective antagonists. Nevertheless, dizziness and orthostatic hypotension can occur. The chief side effect of silodosin is retrograde ejaculation (in 28% of those treated). Silodosin is available as 4-mg and 8-mg capsules.

Adverse Effects. A major potential adverse effect of prazosin and its congeners is the first-dose effect; marked postural hypotension and syncope sometimes are seen 30-90 minutes after an initial dose of prazosin and 2-6 hours after an initial dose of doxazosin.
Syncopal episodes also have occurred with a rapid increase in dosage or with the addition of a second antihypertensive drug to the regimen of a patient who already is taking a large dose of prazosin. The mechanisms responsible for such exaggerated hypotensive responses or for the development of tolerance to these effects are not clear. An action in the CNS to reduce sympathetic outflow may contribute (described earlier). The risk of the first-dose phenomenon is minimized by limiting the initial dose (e.g., 1 mg at bedtime), by increasing the dosage slowly, and by introducing additional antihypertensive drugs cautiously.

Since orthostatic hypotension may be a problem during long-term treatment with prazosin or its congeners, it is essential to check standing as well as recumbent blood pressure. Nonspecific adverse effects such as headache, dizziness, and asthenia rarely limit treatment with prazosin. The nonspecific complaint of dizziness generally is not due to orthostatic hypotension. Although not extensively documented, the adverse effects of the structural analogs of prazosin appear to be similar to those of the parent compound. For tamsulosin, at a dose of 0.4 mg daily, effects on blood pressure are not expected, although impaired ejaculation may occur.

### Therapeutic Uses

#### Hypertension

Prazosin and its congeners have been used successfully in the treatment of essential hypertension (Chapter 28). Considerable interest has also focused on the tendency of these drugs to improve rather than worsen lipid profiles and glucose-insulin metabolism in patients with hypertension who are at risk for atherosclerotic disease (Grimm, 1991). Catecholamines are also powerful stimulators of vascular smooth muscle hypertrophy, acting by $\alpha_1$ receptors. To what extent these effects of $\alpha_1$ antagonists have clinical significance in diminishing the risk of atherosclerosis is not known.

#### Congestive Heart Failure

$\alpha_1$ receptor antagonists have been used in the treatment of congestive heart failure, as have other vasodilating drugs. The short-term effects of prazosin in these patients are due to dilation of both arteries and veins, resulting in a reduction of preload and afterload, which increases cardiac output and reduces pulmonary congestion. In contrast to results obtained with inhibitors of angiotensin-converting enzyme or a combination of hydralazine and an organic nitrate, prazosin has not been found to prolong life in patients with congestive heart failure.

#### Benign Prostatic Hyperplasia (BPH)

In a significant percentage of older men, BPH produces symptomatic urethral obstruction that leads to weak stream, urinary frequency, and nocturia. These symptoms are due to a combination of mechanical pressure on the urethra due to the increase in smooth muscle mass and the $\alpha_1$ receptor-mediated increase in smooth muscle tone in the prostate and neck of the bladder (Kyprianou, 2003). $\alpha_1$ receptors in the trigone muscle of the bladder and urethra contribute to the resistance to outflow of urine. Prazosin reduces this resistance in some patients with impaired bladder emptying caused by prostatic obstruction or parasympathetic decentralization from spinal injury. The efficacy and importance of $\alpha_1$ receptor antagonists in the medical treatment of benign prostatic hyperplasia have been demonstrated in multiple controlled clinical trials. Transurethral resection of the prostate is the accepted surgical treatment for symptoms of urinary obstruction in men with BPH; however, there are some serious potential complications (e.g., risk of impotence), and improvement may not be permanent. Other, less invasive procedures also are available.

Medical therapy has utilized $\alpha_1$ receptor antagonists for many years. Finasteride (PROPECIA, PROSCAR, others) and dutasteride (AVODART), two drugs that inhibit conversion of testosterone to dihydrotestosterone (Chapter 41) and can reduce prostate volume in some patients, are approved as monotherapy and in combination with $\alpha_1$ receptor antagonists. $\alpha_1$-Selective antagonists have efficacy in BPH owing to relaxation of smooth muscle in the bladder neck, prostate capsule, and prostatic urethra. These drugs rapidly improve urinary flow, whereas the actions of finasteride are typically delayed for months. Combination therapy with doxazosin and finasteride reduces the risk of overall clinical progression of BPH significantly more than treatment with either drug alone (McConnell et al., 2003). Tamsulosin at the recommended dose of 0.4 mg daily and silodosin at 0.8 mg are less likely to cause orthostatic hypotension than are the other drugs. There is growing evidence that the predominant $\alpha_1$ receptor subtype expressed in the human prostate is the $\alpha_1A$ receptor (Michel and Vrydag, 2006). Developments in this area will provide the basis for the selection of $\alpha_1$ receptor antagonists with specificity for the relevant subtype of $\alpha_1$ receptor. However, the possibility remains that some of the symptoms of BPH are due to $\alpha_1$ receptors in other sites, such as bladder, spinal cord, or brain.

#### Other Disorders

Though anecdotal evidence suggested that prazosin might be useful in the treatment of patients with variant angina (Prinzmetal’s angina) due to coronary vasospasm, several small controlled trials have failed to demonstrate a clear benefit. Some studies have indicated that prazosin can decrease the incidence of digital vasospasm in patients with Raynaud’s disease; however, its relative efficacy as compared with other vasodilators (e.g., Ca$^{2+}$ channel blockers) is not known. Prazosin may have some benefit in patients with other vasospastic disorders. Prazosin decreases ventricular arrhythmias induced by coronary artery ligation or reperfusion in laboratory animals; the therapeutic potential for this use in humans is not known. Prazosin also may be useful for the treatment of patients with mitral or aortic valvular insufficiency, presumably because of reduction of afterload.

### $\alpha_2$ Adrenergic Receptor Antagonists

The $\alpha_2$ receptors have an important role in regulation of the activity of the sympathetic nervous system, both peripherally and centrally. As mentioned earlier, activation of presynaptic $\alpha_2$ receptors inhibits the release of NE and other co-transmitters from peripheral
sympathetic nerve endings. Activation of $\alpha_2$ receptors in the pontomedullary region of the CNS inhibits sympathetic nervous system activity and leads to a fall in blood pressure; these receptors are a site of action for drugs such as clonidine. Blockade of $\alpha_2$ receptors with selective antagonists such as yohimbine thus can increase sympathetic outflow and potentiate the release of NE from nerve endings, leading to activation of $\alpha_1$ and $\beta_1$ receptors in the heart and peripheral vasculature with a consequent rise in blood pressure. Antagonists that also block $\alpha_1$ receptors give rise to similar effects on sympathetic outflow and release of NE, but the net increase in blood pressure is prevented by inhibition of vasoconstriction.

Although certain vascular beds contain $\alpha_1$ receptors that promote contraction of smooth muscle, it is thought that these receptors are preferentially stimulated by circulating catecholamines, whereas $\alpha_1$ receptors are activated by NE released from sympathetic nerve fibers. In other vascular beds, $\alpha_1$ receptors reportedly promote vasodilation by stimulating the release of NO from endothelial cells. The physiological role of vascular $\alpha_2$ receptors in the regulation of blood flow within various vascular beds is uncertain. The $\alpha_2$ receptors contribute to smooth muscle contraction in the human saphenous vein, whereas $\alpha_1$ receptors are more prominent in dorsal hand veins. The effects of $\alpha_2$ receptor antagonists on the cardiovascular system are dominated by actions in the CNS and on sympathetic nerve endings.

**Yohimbine.** Yohimbine (YOHON, APIRODYN) is a competitive antagonist that is selective for $\alpha_2$ receptors. The compound is an indolealkylamine alkaloid and is found in the bark of the tree *Pausinystalia yohimbe* and in *Rauwolfia* root; its structure resembles that of reserpine. Yohimbine readily enters the CNS, where it acts to increase blood pressure and heart rate; it also enhances motor activity and produces tremors. These actions are opposite to those of clonidine, an $\alpha_2$ agonist. Yohimbine also antagonizes effects of 5-HT.

In the past, it was used extensively to treat male sexual dysfunction (Tam et al., 2001). Although efficacy never was clearly demonstrated, there is renewed interest in the use of yohimbine in the treatment of male sexual dysfunction. The drug enhances sexual activity in male rats and may benefit some patients with psychogenic erectile dysfunction. However, the efficacies of PDE5 inhibitors (e.g., sildenafil, vardenafil, and tadalafil) and apomorphine (off-label) have been much more conclusively demonstrated in oral treatment of erectile dysfunction. Several small studies suggest that yohimbine also may be useful for diabetic neuropathy and in the treatment of postural hypotension. In the U.S., yohimbine can be legally sold as a dietary supplement; however, labeling claims that it will arouse or increase sexual desire or improve sexual performance are prohibited. Yohimbine (ANTAGONIL, YOBINE) is approved in veterinary medicine for the reversal of xylazine anesthesia.

**Non-selective $\alpha$ Adrenergic Antagonists: Phenoxybenzamine and Phentolamine.** Phenoxybenzamine and phentolamine are non-selective $\alpha$ receptors antagonists. Phenoxybenzamine, a haloalkylamine compound, produces an irreversible antagonism; while phentolamine, an imidazoline, produces a competitive antagonism. Phenoxybenzamine and phentolamine have played an important role in the establishment of the importance of $\alpha$ receptors in the regulation of the cardiovascular and other systems. They are sometimes referred to as “classical” $\alpha$ blockers to distinguish them from more recently developed compounds such as prazosin.

The actions of phenoxybenzamine and phentolamine on the cardiovascular system are similar. These “classical” $\alpha$ blockers cause a progressive decrease in peripheral resistance, due to antagonism of $\alpha$ receptors in the vasculature, and an increase in cardiac output that is due in part to reflex sympathetic nerve stimulation. The cardiac stimulation is accentuated by enhanced release of NE from cardiac sympathetic nerve due to antagonism of presynaptic $\alpha_2$ receptors by these non-selective $\alpha$ blockers. Postural hypotension is a prominent feature with these drugs and this, accompanied by reflex tachycardia that can precipitate cardiac arrhythmias, severely limits the use of these drugs to treat essential hypertension. The more recently developed $\alpha_1$-selective antagonists, such as prazosin, have replaced the “classical” $\alpha$ blockers in the management of essential hypertension. Phenoxybenzamine and phentolamine are still marketed for several specialized uses.

**Therapeutic Uses.** A use of phenoxybenzamine (DIBENZYLINE) is in the treatment of pheochromocytoma. Pheochromocytomas are tumors of the adrenal medulla and sympathetic neurons that secrete enormous quantities of catecholamines into the circulation. The usual result is hypertension, which may be episodic and severe. The vast majority of pheochromocytomas are treated surgically; however, phenoxybenzamine is often used in preparing the patient for surgery. The drug controls episodes of severe hypertension and minimizes other adverse effects of catecholamines, such as contraction of plasma volume and injury of the myocardium. A conservative approach is to initiate treatment with phenoxybenzamine (at a dosage of 10 mg twice daily) 1-3 weeks before the operation. The dose is increased every other day until the desired effect on blood pressure is achieved. Therapy may be limited by postural hypotension; nasal stuffiness is another frequent adverse effect. The usual daily dose of phenoxybenzamine in patients with pheochromocytoma is 40-120 mg given in two or three divided portions. Prolonged treatment with phenoxybenzamine may be necessary in patients with inoperable or malignant pheochromocytoma. In some patients, particularly those with malignant disease, administration of metyrosine may be a useful adjuvant. Metyrosine (DEMSER) is a competitive inhibitor of tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of catecholamines (Chapter 8). $\beta$ Receptor antagonists also are used to treat pheochromocytoma, but only after the administration of an $\alpha$ receptor antagonist (described later).

Phentolamine can also be used in short-term control of hypertension in patients with pheochromocytoma. Rapid infusions of phentolamine may cause severe hypotension, so the drug should be administered cautiously. Phentolamine also may be useful to relieve pseudo-obstruction of the bowel in patients with pheochromocytoma; this condition may result from the inhibitory effects of catecholamines on intestinal smooth muscle.

Phentolamine has been used locally to prevent dermal necrosis after the inadvertent extravasation of an $\alpha$ receptor agonist. The drug also may be useful for the treatment of hypertensive crises that follow the abrupt withdrawal of clonidine or that may result from the
ingestion of tyramine-containing foods during the use of non-selective MAO inhibitors. Although excessive activation of α receptors is important in the development of severe hypertension in these settings, there is little information about the safety and efficacy of phentolamine compared with those of other antihypertensive agents in the treatment of such patients. Direct intracavernous injection of phentolamine (in combination with papaverine) has been proposed as a treatment for male sexual dysfunction. The long-term efficacy of this treatment is not known. Intracavernous injection of phentolamine may cause orthostatic hypotension and priapism; pharmacological reversal of drug-induced erections can be achieved with an α receptor antagonist such as phentylephrine. Repetitive intrapenile injections may cause fibrotic reactions. Buccally or orally administered phentolamine may have efficacy in some men with sexual dysfunction.

In 2008, the FDA approved the use of phentolamine (GRAVERSE) to reverse or shorten the duration of soft-tissue anesthesia. Symptomimetics are frequently administered with local anesthetics to slow the removal of the anesthetic by causing vasoconstriction. When the need for anesthesia is over, phentolamine can help reverse it by antagonizing the α-receptor induced vasoconstriction.

Phenoxybenzamine has been used off-label to control the manifestations of autonomic hyperreflexia in patients with spinal cord transection.

Toxicity and Adverse Effects. Hypotension is the major adverse effect of phenoxybenzamine and phentolamine. In addition, reflex cardiac stimulation may cause alarming tachycardia, cardiac arrhythmias, and ischemic cardiac events, including myocardial infarction. Reversible inhibition of ejaculation may occur due to impaired smooth muscle contraction in the vas deferens and ejaculatory ducts. Phenoxybenzamine is mutagenic in the Ames test, and repeated administration of this drug to experimental animals causes peritoneal sarcomas and lung tumors. The clinical significance of these findings is not known. Phentolamine stimulates GI smooth muscle, an effect antagonized by atropine, and also enhances gastric acid secretion due in part to histamine release. Thus, phentolamine should be used with caution in patients with a history of peptic ulcer.

Additional α Adrenergic Receptor Antagonists

Ergot Alkaloids. The ergot alkaloids were the first adrenergic receptor antagonists to be discovered, and most aspects of their general pharmacology were disclosed in the classic studies of Dale. Ergot alkaloids exhibit a complex variety of pharmacological properties. To varying degrees, these agents act as partial agonists or antagonists at α receptors, DA receptors, and serotonin receptors. Additional information about the ergot alkaloids can be found in Chapter 13 and in previous editions of this book.

Indoramin. Indoramin is a selective, competitive α1 receptor antagonist that is used outside the U.S. for the treatment of hypertension, BPH, and in the prophylaxis of migraine. Competitive antagonism of histamine H1 and 5-HT receptors also is evident. As an α1-selective antagonist, indoramin lowers blood pressure with minimal tachycardia. The drug also decreases the incidence of attacks of Raynaud’s phenomenon.

The bioavailability of indoramin generally is < 30% (with considerable variability), and it undergoes extensive first-pass metabolism. Little unchanged drug is excreted in the urine, and some of the metabolites may be biologically active. The elimination t1/2 is ~5 hours. Some of the adverse effects of indoramin include sedation, dry mouth, and failure of ejaculation. Although indoramin is an effective antihypertensive agent, it has complex pharmacokinetics and lacks a well-defined place in current therapy.

Ketanserin. Although developed as a 5-HT-receptor antagonist, ketanserin also blocks α1 receptors. Ketanserin (not available in the U.S.) is discussed in Chapter 13.

Urapidil. Urapidil is a novel, selective α1 receptor antagonist that has a chemical structure distinct from those of prazosin and related compounds; the drug is not commercially available in the U.S. Blockade of peripheral α1 receptors appears to be primarily responsible for the hypotension produced by urapidil, although it has actions in the CNS as well. The drug is extensively metabolized and has a t1/2 of 3 hours. The role of urapidil in the treatment of hypertension remains to be determined.

Bunazosin. Bunazosin is an α1-selective antagonist of the quinazoline class that has been shown to lower blood pressure in patients with hypertension. Bunazosin is available in Germany, Japan, Thailand, and Indonesia.

Neuroleptic Agents. Natural and synthetic compounds of several other chemical classes developed primarily because they are antagonists of D2 dopamine receptors also exhibit α receptor blocking activity. Chlorpromazine, haloperidol, and other neuroleptic drugs of the phenothiazine and butyrophenone types produce significant α receptor blockade in both laboratory animals and humans.

β ADRENERGIC RECEPTOR ANTAGONISTS

Competitive antagonists of β adrenergic receptors, or β blockers, have received enormous clinical attention because of their efficacy in the treatment of hypertension, ischemic heart disease, congestive heart failure, and certain arrhythmias.

History. Ahlquist’s hypothesis that the effects of catecholamines were mediated by activation of distinct α and β receptors provided the initial impetus for the synthesis and pharmacological evaluation of β receptor antagonists (Chapter 8). The first such selective agent was dichloroisoproterenol, a partial agonist. Sir James Black and his colleagues initiated a program in the late 1950s to develop additional β blockers, with the resulting synthesis and characterization of propranolol.

Chemistry. The structural formulas of some β receptor antagonists in general use are shown in Figures 12–7 and 12–8. The structural similarities between agonists and antagonists that act on β receptors are closer than those between α receptor agonists and antagonists. Substitution of an isopropyl group or other bulky substituent on the amino nitrogen favors interaction with β receptors. There is a rather wide tolerance for the nature of the aromatic moiety in the non-selective β receptor antagonists; however, the structural tolerance for β1-selective antagonists is far more constrained.

Overview. Propranolol is a competitive β receptor antagonist and remains the prototype to which other β antagonists are compared. β antagonists can be distinguished
by the following properties: relative affinity for $\beta_1$ and $\beta_2$ receptors, intrinsic sympathomimetic activity, blockade of $\alpha$ receptors, differences in lipid solubility, capacity to induce vasodilation, and pharmacokinetic parameters. Some of these distinguishing characteristics have clinical significance and help guide the appropriate choice of a $\beta$ receptor antagonist for an individual patient.

Propranolol has equal affinity for $\beta_1$ and $\beta_2$ adrenergic receptors; thus, it is a non-selective $\beta$ adrenergic receptor antagonist. Agents such as metoprolol, atenolol, acebutolol, bisoprolol, and esmolol have somewhat greater affinity for $\beta_1$ than for $\beta_2$ receptors; these are examples of $\beta_1$-selective antagonists, even though the selectivity is not absolute. Propranolol is a pure antagonist, and it has no capacity to activate $\beta$ receptors.
Several β blockers (e.g., pindolol and acebutolol) activate β receptors partially in the absence of catecholamines; however, the intrinsic activities of these drugs are less than that of a full agonist such as isoproterenol. These partial agonists are said to have intrinsic sympathomimetic activity. Substantial sympathomimetic activity would be counterproductive to the response desired from a β antagonist; however, slight residual activity may, e.g., prevent profound bradycardia or negative inotropy in a resting heart. The potential clinical advantage of this property, however, is unclear and may be disadvantageous in the context of secondary prevention of myocardial infarction (described under Therapeutic Uses). In addition, other β receptor antagonists have been found to have the property of inverse agonism (Chapter 3). These drugs can decrease basal activity of β receptor signaling by shifting the equilibrium of spontaneously active receptors toward the inactive state (Chidiac et al., 1994). Several β receptor antagonists also have local anesthetic or membrane-stabilizing activity, similar to lidocaine, that is independent of β blockade. Such drugs include propranolol, acebutolol, and carvedilol. Pindolol, metoprolol, betaxolol, and labetalol have slight membrane-stabilizing effects. Although most β receptor antagonists do not block α adrenergic receptors, labetalol, carvedilol, and bucindolol are examples of agents that block both α and β adrenergic receptors. In addition to carvedilol, labetalol, and bucindolol, many other β receptor antagonists have vasodilating properties due to various mechanisms discussed below. These include celiprolol, nebivolol, nipradilol, carteolol, betaxolol, bopindolol, and bevantolol (Toda, 2003).

**Pharmacological Properties**

As in the case of α receptor blocking agents, the pharmacological properties of α receptor antagonists can be explained largely from knowledge of the responses elicited by the receptors in the various tissues and the activity of the sympathetic nerves that innervate these tissues (Table 8–1). For example, β receptor blockade has relatively little effect on the normal heart of an individual at rest, but has profound effects when sympathetic control of the heart is dominant, as during exercise or stress.

In this chapter, β adrenergic receptor antagonists are classified as non–subtype-selective (“first generation”), β₁-selective (“second generation”), and non–subtype or subtype-selective with additional cardiovascular actions (“third generation”). These latter
drugs have additional cardiovascular properties (especially vasodilation) that seem unrelated to β blockade. Table 12–3 summarizes important pharmacological and pharmacokinetic properties of β receptor antagonists.

**Cardiovascular System.** The major therapeutic effects of β receptor antagonists are on the cardiovascular system. It is important to distinguish these effects in normal subjects from those in subjects with cardiovascular disease such as hypertension or myocardial ischemia.

Since catecholamines have positive chronotropic and inotropic actions, β receptor antagonists slow the heart rate and decrease myocardial contractility. When tonic stimulation of β receptors is low, this effect is correspondingly modest. However, when the sympathetic nervous system is activated, as during exercise or stress, β receptor antagonists attenuate the expected rise in heart rate. Short-term administration of β receptor antagonists such as propranolol decreases cardiac output; peripheral resistance increases in proportion to maintain blood pressure as a result of blockade of vascular β₂ receptors and compensatory reflexes, such as increased sympathetic nervous system activity, leading to activation of vascular α receptors. However, with long-term use of β antagonists, total peripheral resistance returns to initial values (Mimran and Ducailar, 1988) or decreases in patients with hypertension (Man in’t Veld et al., 1988). With β antagonists that also are α₁ receptor antagonists, such as labetalol, carvedilol, and bucindolol, cardiac output is maintained with a greater fall in peripheral resistance. This also is seen with β receptor antagonists that are direct vasodilators.

β Receptor antagonists have significant effects on cardiac rhythm and automaticity. Although it had been thought that these effects were due exclusively to blockade of β₁ receptors, β₂ receptors likely also regulate heart rate in humans (Altschuld and

*Detectable only at doses much greater than required for β blockade.*
Receptors also have been identified in normal myocardial tissue in several species, including humans (Moniote et al., 2001). Signal transduction for $\beta_1$ receptors is complex and includes $G_\text{q}$ but also $G_\text{q}/G_\text{i}$; stimulation of cardiac $\beta_1$ receptors inhibits cardiac contraction and relaxation. The physiological role of $\beta_1$ receptors in the heart remains to be established (Morimoto et al., 2004). $\beta$ Receptor antagonists reduce sinus rate, decrease the spontaneous rate of depolarization of ectopic pacemakers, slow conduction in the atria and in the AV node, and increase the functional refractory period of the AV node.

Although high concentrations of many $\beta$ blockers produce quinidine-like effects (membrane-stabilizing activity), it is doubtful that this is significant at usual doses of these agents. However, this effect may be important when there is overdosage. Interestingly, $d$-propranolol may suppress ventricular arrhythmias independently of $\beta$ receptor blockade.

The cardiovascular effects of $\beta$ receptor antagonists are most evident during dynamic exercise. In the presence of $\beta$ receptor blockade, exercise-induced increases in heart rate and myocardial contractility are attenuated. However, the exercise-induced increase in cardiac output is less affected because of an increase in stroke volume. The effects of $\beta$ receptor antagonists on exercise are somewhat analogous to the changes that occur with normal aging. In healthy elderly persons, catecholamine-induced increases in heart rate are smaller than in younger individuals; however, the increase in cardiac output in older people may be preserved because of an increase in stroke volume during exercise. $\beta$ Blockers tend to decrease work capacity, as assessed by their effects on intense short-term or more prolonged steady-state exertion. Exercise performance may be impaired to a lesser extent by $\beta_1$ selective agents than by non-selective antagonists. Blockade of $\beta_2$ receptors tends to blunt the increase in blood flow to active skeletal muscle during submaximal exercise. Blockade of $\beta$ receptors also may attenuate catecholamine-induced activation of glucose metabolism and lipolysis.

Coronary artery blood flow increases during exercise or stress to meet the metabolic demands of the heart. By increasing heart rate, contractility, and systolic pressure, catecholamines increase myocardial oxygen demand. However, in patients with coronary artery disease, fixed narrowing of these vessels attenuates the expected increase in flow, leading to myocardial ischemia. $\beta$ Receptor antagonists decrease the effects of catecholamines on the determinants of myocardial $O_2$ consumption. However, these agents may tend to increase the requirement for oxygen by increasing end-diastolic pressure and systolic ejection period. Usually, the net effect is to improve the relationship between cardiac $O_2$ supply and demand; exercise tolerance generally is improved in patients with angina, whose capacity to exercise is limited by the development of chest pain (Chapter 28).

Activity as Antihypertensive Agents. $\beta$ Receptor antagonists generally do not reduce blood pressure in patients with normal blood pressure. However, these drugs lower blood pressure in patients with hypertension. Despite their widespread use, the mechanisms responsible for this important clinical effect are not well understood. The release of renin from the juxtaglomerular apparatus is stimulated by the sympathetic nervous system by means of $\beta_1$ receptors, and this effect is blocked by $\beta$ receptor antagonists (Chapter 25). However, the relationship between this phenomenon and the fall in blood pressure is not clear. Some investigators have found that the antihypertensive effect of propranolol is most marked in patients with elevated concentrations of plasma renin, as compared with patients with low or normal concentrations of renin. However, $\beta$ receptor antagonists are effective even in patients with low plasma renin, and pindolol is an effective antihypertensive agent that has little or no effect on plasma renin activity.

Presynaptic $\beta$ receptors enhance the release of NE from sympathetic neurons, but the importance of diminished release of NE to the antihypertensive effects of $\beta$ antagonists is unclear. Although $\beta$ blockers would not be expected to decrease the contractility of vascular smooth muscle, long-term administration of these drugs to hypertensive patients ultimately leads to a fall in peripheral vascular resistance (Man in’t Veld et al., 1988). The mechanism for this important effect is not known, but this delayed fall in peripheral vascular resistance in the face of a persistent reduction of cardiac output appears to account for much of the antihypertensive effect of these drugs. Although it has been hypothesized that central actions of $\beta$ blockers also may contribute to their antihypertensive effects, there is relatively little evidence to support this possibility, and drugs that poorly penetrate the blood-brain barrier are effective antihypertensive agents.

As indicated, some $\beta$ receptor antagonists have additional effects that may contribute to their capacity to lower blood pressure. These drugs all produce peripheral vasodilation; at least six properties have been proposed to contribute to this effect, including production of nitric oxide, activation of $\beta_1$ receptors, blockade of $\alpha_2$ receptors, blockade of $\text{Ca}^{2+}$ entry, opening of $K^+$ channels, and antioxidant activity. The ability of vasodilating $\beta$ receptor antagonists to act through one or more of these mechanisms is depicted in Table 12–4 and Figure 12–9. These mechanisms appear to contribute to the antihypertensive effects by enhancing hypotension, increasing peripheral blood flow, and decreasing afterload. Two of these agents (e.g., celiprolol and nebivolol) also have been observed to produce vasodilation and thereby reduce preload.

Although further clinical trials are needed, these agents may be associated with a lower incidence of bronchospasm, impaired lipid metabolism, impotence, reduced regional blood flow, increased vascular resistance, and withdrawal symptoms. A lower incidence of these adverse effects would be particularly beneficial in patients who have insulin resistance and diabetes mellitus in addition to hypertension (Toda, 2003). The clinical significance in humans of some of these relatively subtle differences in pharmacological properties still is unclear. Particular interest has focused on patients with congestive heart failure or peripheral arterial occlusive disease.

Propranolol and other non-selective $\beta$ receptor antagonists inhibit the vasodilation caused by isoproterenol and augment the pressor response to epinephrine. This is particularly significant in patients with pheochromocytoma, in whom $\beta$ receptor antagonists should be used only after adequate $\alpha$ receptor blockade has been
established. This avoids uncompensated α receptor–mediated vasoconstriction caused by epinephrine secreted from the tumor.

**Pulmonary System.** Non-selective β receptor antagonists such as propranolol block β₂ receptors in bronchial smooth muscle. This usually has little effect on pulmonary function in normal individuals. However, in patients with COPD, such blockade can lead to life-threatening bronchoconstriction. Although β₁-selective antagonists or antagonists with intrinsic sympathomimetic activity are less likely than propranolol to increase airway resistance in patients with asthma, these drugs should be used only with great caution, if at all, in patients with bronchospastic diseases. Drugs such as celiprolol, with β₁ receptor selectivity and β₂ receptor partial agonism, are of potential promise, although clinical experience is limited.

**Metabolic Effects.** β Receptor antagonists modify the metabolism of carbohydrates and lipids. Catecholamines promote glycogenolysis and mobilize glucose in response to hypoglycemia. Non-selective β blockers may delay recovery from hypoglycemia in type 1 (insulin-dependent) diabetes mellitus, but infrequently in type 2 diabetes mellitus. In addition to blocking glycogenolysis, β receptor antagonists can interfere with the counter-regulatory effects of catecholamines secreted during hypoglycemia by blunting the perception of symptoms such as tremor, tachycardia, and nervousness. Thus, β adrenergic receptor antagonists should be used with great caution in patients with labile diabetes and frequent hypoglycemic reactions. If such a drug is indicated, a β₁-selective antagonist is preferred, since these drugs are less likely to delay recovery from hypoglycemia (DiBari et al., 2003).

**Figure 12–9.** Mechanisms underlying actions of vasodilating β blockers in blood vessels. ROS, reactive oxygen species; sGC, soluble guanylyl cyclase; AC adenyl cyclase; L-type VGCC, L-type voltage gated Ca²⁺ channel.) (Modified with permission from Toda, 2003. Copyright © Elsevier.)
The β receptors mediate activation of hormone-sensitive lipase in fat cells, leading to release of free fatty acids into the circulation (Chapter 8). This increased flux of fatty acids is an important source of energy for exercising muscle. β Receptor antagonists can attenuate the release of free fatty acids from adipose tissue. Non-selective β receptor antagonists consistently reduce HDL cholesterol, increase LDL cholesterol, and increase triglycerides. In contrast, β1-selective antagonists, including celiprolol, carteloled, bevantolol, and carvedilol, and bevantine, reportedy improve the serum lipid profile of dyslipidemic patients. While drugs such as propranolol and atenolol increase triglycerides, plasma triglycerides are reduced with chronic celiprolol, bevantolol, reportedly improve the serum lipid profile of dyslipidemic patients with insulin resistance. Together with their cardioprotective effects, improvement in insulin sensitivity from vasodilating β receptor antagonists may partially counterbalance the hazard from worsened lipid abnormalities associated with diabetes. If β blockers are to be used, β1-selective or vasodilating β receptor antagonists are preferred. In addition, it may be necessary to use β receptor antagonists in conjunction with other drugs, (e.g., HMG-CoA reductase inhibitors) to ameliorate adverse metabolic effects (Dunne et al., 2001).

β Receptor agonists decrease the plasma concentration of K+ by promoting the uptake of the ion, predominantly into skeletal muscle. At rest, an infusion of epinephrine causes a decrease in the plasma concentration of K+. The marked increase in the concentration of epinephrine that occurs with stress (such as myocardial infarction) may cause hypokalemia, which could predispose to cardiac arrhythmias. The hypokalemic effect of epinephrine is blocked by an experimental antagonist, ICI 118551, which has a high affinity for β2 and β3 receptors. Exercise causes an increase in the influx of K+ from skeletal muscle. Catecholamines tend to buffer the rise in K+ by increasing its influx into muscle. β Blockers negate this buffering effect.

Other Effects. β Receptor antagonists block catecholamine-induced tremor. They also block inhibition of mast-cell degranulation by catecholamines.

**ADVERSE EFFECTS AND PRECAUTIONS**

The most common adverse effects of β receptor antagonists arise as pharmacological consequences of blockade of β receptors; serious adverse effects unrelated to β receptor blockade are rare.

**Cardiovascular System.** Because the sympathetic nervous system provides critical support for cardiac performance in many individuals with impaired myocardial function, β receptor antagonists may induce congestive heart failure in susceptible patients. Thus, β receptor blockade may cause or exacerbate heart failure in patients with compensated heart failure, acute myocardial infarction, or cardiomegaly. It is not known whether β receptor antagonists that possess intrinsic sympathomimetic activity or peripheral vasodilating properties are safer in these settings. Nonetheless, there is convincing evidence that chronic administration of β receptor antagonists is efficacious in prolonging life in the therapy of heart failure in selected patients (discussed later in this chapter and in Chapter 28).

Bradycardia is a normal response to β receptor blockade; however, in patients with partial or complete AV conduction defects, β antagonists may cause life-threatening bradyarrhythmias. Particular caution is indicated in patients who are taking other drugs, such as verapamil or various anti-arrhythmic agents, which may impair sinus-node function or AV conduction.

Some patients complain of cold extremities while taking β receptor antagonists. Symptoms of peripheral vascular disease may worsen, although this is uncommon, or Raynaud’s phenomenon may develop. The risk of worsening intermittent claudication probably is very small with this class of drugs, and the clinical benefits of β antagonists in patients with peripheral vascular disease and coexisting coronary artery disease may be very important.

Abrupt discontinuation of β receptor antagonists after long-term treatment can exacerbate angina and may increase the risk of sudden death. The underlying mechanism is unclear, but it is well established that there is enhanced sensitivity to β receptor agonists in patients who have undergone long-term treatment with certain β receptor antagonists after the blocker is withdrawn abruptly. For example, chronotropic responses to isoproterenol are blunted in patients who are receiving β receptor antagonists; however, abrupt discontinuation of propranolol leads to greater-than-normal sensitivity to isoproterenol. This increased sensitivity is evident several days after stopping propranolol and may persist for at least 1 week. Such enhanced sensitivity can be attenuated by tapering the dose of the β blocker for several weeks before discontinuation. Supersensitivity to isoproterenol also has been observed after abrupt discontinuation of metoprolol, but not of pindolol. This enhanced β responsiveness may result from up-regulation of β receptors. The number of β receptors on circulating lymphocytes is increased in subjects who have received propranolol for long periods; pindolol has the opposite effect. Optimal strategies for discontinuation of β blockers are not known, but it is prudent to decrease the dose gradually and to restrict exercise during this period.

**Pulmonary Function.** A major adverse effect of β receptor antagonists is caused by blockade of β2 receptors in bronchial smooth muscle. These receptors are particularly important for promoting bronchodilation in patients with bronchospastic disease, and β blockers may cause a life-threatening increase in airway resistance in such patients. Drugs with selectivity for β2 receptors or those with intrinsic sympathomimetic activity at β1 receptors alone are less likely to induce bronchospasm. Since the selectivity of current β blockers for β2 receptors is modest, these drugs should be avoided if at all possible in patients with asthma. However, in selected patients with chronic obstructive pulmonary disease and cardiovascular...
disease (hypertension, heart failure, coronary artery disease), the advantages of using $\beta_1$ receptor antagonists may outweigh the risk of worsening pulmonary function (Salpeter et al., 2005).

**CNS.** The adverse effects of $\beta$ receptor antagonists that are referable to the CNS may include fatigue, sleep disturbances (including insomnia and nightmares), and depression. The previously ascribed association between these drugs and depression is unclear (Gerstman et al., 1996; Ried et al., 1998). Interest has focused on the relationship between the incidence of the adverse effects of $\beta$ receptor antagonists and their lipophilicity; however, no clear correlation has emerged.

**Metabolism.** As already described, $\beta$ adrenergic blockade may blunt recognition of hypoglycemia by patients; it also may delay recovery from insulin-induced hypoglycemia. $\beta$ Receptor antagonists should be used with great caution in patients with diabetes who are prone to hypoglycemic reactions; $\beta_1$-selective agents may be preferable for these patients. The benefits of $\beta$ receptor antagonists in type 1 diabetes with myocardial infarction may outweigh the risk in selected patients (Gottlieb et al., 1998).

**Miscellaneous.** The incidence of sexual dysfunction in men with hypertension who are treated with $\beta$ receptor antagonists is not clearly defined. Although experience with the use of $\beta$ adrenergic receptor antagonists in pregnancy is increasing, information about the safety of these drugs during pregnancy still is limited.

**Overdosage.** The manifestations of poisoning with $\beta$ receptor antagonists depend on the pharmacological properties of the ingested drug, particularly its $\beta_1$ selectivity, intrinsic sympathomimetic activity, and membrane-stabilizing properties. Hypotension, bradycardia, prolonged AV conduction times, and widened QRS complexes are common manifestations of overdosage. Seizures and depression may occur. Hypoglycemia and bronchospasm can occur. Significant bradycardia should be treated initially with atropine, but a cardiac pacemaker often is required. Large doses of isoproterenol or an $\alpha$ receptor agonist may be necessary to treat hypotension. Glucagon, acting through its own GPCR and independently of the $\beta$ adrenergic receptor, has positive chronotropic and inotropic effects on the heart, and the drug has been useful in some patients suffering from an overdose of a $\beta$ receptor antagonist.

**Drug Interactions.** Both pharmacokinetic and pharmacodynamic interactions have been noted between $\beta$ receptor antagonists and other drugs. Interactions with sympathomimetics, $\alpha$ blockers, and $\beta$ agonists are predictable from the pharmacology. Aluminum salts, cholestyramine, and colestipol may decrease the absorption of $\beta$ blockers. Drugs such as phenytoin, rifampin, and phenobarbital, as well as smoking, induce hepatic biotransformation enzymes and may decrease plasma concentrations of $\beta$ receptor antagonists that are metabolized extensively (e.g., propranolol). Cimetidine and hydralazine may increase the bioavailability of agents such as propranolol and metoprolol by affecting hepatic blood flow. $\beta$ Receptor antagonists can impair the clearance of lidocaine.

Other drug interactions have pharmacodynamic explanations. For example, $\beta$ antagonists and Ca$^{2+}$ channel blockers have additive effects on the cardiac conducting system. Additive effects on blood pressure between $\beta$ blockers and other antihypertensive agents often are employed to clinical advantage. However, the antihypertensive effects of $\beta$ receptor antagonists can be opposed by indomethacin and other nonsteroidal anti-inflammatory drugs (Chapter 34).

### THERAPEUTIC USES

#### Cardiovascular Diseases

$\beta$ Receptor antagonists are used extensively in the treatment of hypertension, angina and acute coronary syndromes, and congestive heart failure (Chapters 27 and 28). These drugs also are used frequently in the treatment of supraventricular and ventricular arrhythmias (Chapter 29).

**Myocardial Infarction.** A great deal of interest has focused on the use of $\beta$ receptor antagonists in the treatment of acute myocardial infarction and in the prevention of recurrences for those who have survived an initial attack. Numerous trials have shown that $\beta$ receptor antagonists administered during the early phases of acute myocardial infarction and continued long-term may decrease mortality by $\sim 25\%$ (Freemantle et al., 1999). The precise mechanism is not known, but the favorable effects of $\beta$ receptor antagonists may stem from decreased myocardial oxygen demand, redistribution of myocardial blood flow, and anti-arrhythmic actions. There is likely much less benefit if $\beta$ adrenergic receptor antagonists are administered for only a short time. In studies of secondary prevention, the most extensive, favorable clinical trial data are available for propranolol, metoprolol, and timolol. In spite of these proven benefits, many patients with myocardial infarction do not receive a $\beta$ adrenergic receptor antagonist.

**Congestive Heart Failure.** It is a common clinical observation that acute administration of $\beta$ receptor antagonists can worsen markedly or even precipitate congestive heart failure in compensated patients with multiple forms of heart disease, such as ischemic or congestive cardiomyopathy. Consequently, the hypothesis that $\beta$ receptor antagonists might be efficacious in the long-term treatment of heart failure originally seemed counterintuitive to many physicians. However, the reflex sympathetic responses to heart failure may stress the failing heart and exacerbate the progression of the disease, and blocking those responses could be beneficial. A number of well-designed randomized clinical trials involving numerous patients have demonstrated that certain $\beta$ receptor antagonists are highly effective...
treatment for patients with all grades of heart failure secondary to left ventricular systolic dysfunction. The drugs have been shown to improve myocardial function, to improve life quality, and to prolong life. From the point of view of the history of therapeutic advances in the treatment of congestive heart failure, it is interesting to note how this drug class has moved from being completely contraindicated to being the standard of care in many settings.

Large trials have been conducted with carvedilol, bisoprolol, metoprolol, xamoterol, bucindolol, betaxol, nebivolol, and talinolol (Cleland, 2003). Carvedilol, metoprolol, and bisoprolol all have been shown to reduce the mortality rate in large cohorts of patients with stable chronic heart failure regardless of severity (Bolger and Al-Nasser, 2003; Cleland, 2003). In the initial use of β blockers for treating heart failure, the beginning effects often are neutral or even adverse. Benefits accumulate gradually over a period of weeks to months, although benefits from the third-generation vasodilator β blocker carvedilol may be seen within days in patients with severe heart failure. There also is a reduction in the hospitalization of patients along with a reduction in mortality with fewer sudden deaths and deaths caused by progressive heart failure. These benefits extend to patients with asthma and with diabetes mellitus (Cruickshank, 2002; Dunne et al., 2001; Salpeter, 2003; Self et al., 2003). Patients in atrial fibrillation and heart failure can also benefit from β blockade (Kühlkamp et al., 2002). On the other hand, patients with heart failure and atrial fibrillation are associated with a higher mortality, and the benefit derived from β blockers may not be comparable to those in sinus rhythm (Fung et al., 2003). Long-term β blockade reduces cardiac volume, myocardial hypertrophy, and filling pressure, and increases ejection fraction (e.g., ventricular remodeling). β Receptor antagonists impact mortality even before beneficial effects on ventricular function are observed, possibly due to prevention of arrhythmias or a reduction in acute vascular events.

Some patients are unable to tolerate β blockers. Hopefully, ongoing trials will identify the common characteristics that define this population so that β blockers can be avoided in these patients (Bolger and Al-Nasser, 2003). Because of the real possibility of acutely worsening cardiac function, β receptor antagonists should be initiated only by clinicians experienced in patients with congestive heart failure. As might be anticipated, starting with very low doses of drug and advancing doses slowly over time, depending on each patient’s response, are critical for the safe use of these drugs in patients with congestive heart failure.

It is unknown whether it is necessary to block only the β1 adrenergic receptor or whether non-selective agents would be more desirable in the management of heart failure. Blockade of β2 adrenergic receptors can enhance peripheral vasoconstriction and bronchoconstriction and therefore have a deleterious effect. On the other hand, blocking β2 receptors might be advantageous due to more effectively protecting cardiac cells from catecholamine excess and hypokalemia. Some propose that non-selective β antagonists that block both β1 and β2 receptors and also have peripheral vasodilatory actions (third-generation β blockers) may offer the best myocardial, metabolic, and hemodynamic benefit (Chapter 28) (Cleland, 2003). Some experts have recommended that β blockers be considered as part of the standard treatment regimen for all patients with mild to moderate heart failure (Goldstein, 2002; Maggioni et al., 2003).

### β Adrenergic Receptor Signaling in Heart Failure and Its Treatment

The underlying cellular or subcellular mechanisms leading to the beneficial effects of β blockers are unclear. Sympathetic nervous system activity is increased in patients with congestive heart failure (Bristow et al., 1985). Infusions of β agonists are toxic to the heart in several animal models. Also, overexpression of β receptors in transgenic mice leads to a dilated cardiomyopathy (Engelhardt et al., 1999). A number of changes in β receptor signaling occur in the myocardium of patients with heart failure and in a variety of animal models (Post et al., 1999). Decreased numbers and functioning of β1 receptors consistently have been found in heart failure, leading to attenuation of β receptor–mediated stimulation of positive inotropic responses in the failing heart. These changes may be due in part to increased expression of β adrenergic receptor kinase-1 (βARK-1, GRK2) (Lefkowitz et al., 2000). See also Chapters 3 and 8.

It is of potential interest that expression of β2 receptors is relatively maintained in these settings of heart failure. While both β1 and β2 receptors activate adenyl cyclase by means of Gs, there is evidence suggesting that β2 receptors also stimulate Gi, which may attenuate contractile responses and lead to activation of other effector pathways downstream of Gi (Lefkowitz et al., 2000). Overexpression of β1 adrenergic receptors in mouse heart is associated with increased cardiac force without the development of cardiomyopathy (Liggett et al., 2000). The stimulation of β1 adrenergic receptors inhibits contraction and relaxation (Gauthier et al., 2000). In contrast to β1 and β3 receptors, β2 receptors are upregulated in heart failure (Moniotte et al., 2001). This has led to the hypothesis that in severe congestive heart failure, as β1 and β3 receptor pathways by Gi become less responsive, the inhibitory effects of the β3 receptor pathway may contribute to the detrimental effects of sympathetic stimulation in congestive heart failure (Morimoto et al., 2004). Thus, the blockade of β3 receptors by β antagonists (e.g., carvedilol) could improve the acute tolerability and benefit of β1 and β3 receptor antagonists (Moniotte et al., 2001; Morimoto et al., 2004).

The mechanisms by which β receptor antagonists decrease mortality in patients with congestive heart failure are still unclear. Perhaps this is not surprising, given that the mechanism by which this class of drugs lowers blood pressure in patients with hypertension remains elusive despite years of investigation (Chapter 27). This is much more than an academic undertaking; a deeper understanding of involved pathways could lead to selection of the most appropriate drugs available as well as the development of novel compounds with especially desirable properties. The potential differences among β1, β2, and β3 receptor function in heart failure is one example of the complexity of adrenergic pharmacology of this syndrome. There is evidence for multiple affinity states of the β1 receptor, for cell-type specific coupling of β receptor subtypes to...
signalling pathways other than G\textsubscript{i} -adenyl cyclase–cyclic AMP, and form altered receptor properties when \( \beta \text{A} \) and \( \beta \text{B} \) receptors for hetero-oligomers (Breit et al., 2004; Rozec et al., 2003). Such findings suggest opportunities for the development of more focused \( \beta \)-antagonist therapy in the future.

A number of mechanisms have been proposed to play a role in the beneficial effects of \( \beta \) receptor antagonists in heart failure. Since excess effects of catecholamines may be toxic to the heart, especially through activation of \( \beta \) receptors, inhibition of the pathway may help preserve myocardial function. Also, antagonism of \( \beta \) receptors in the heart may attenuate cardiac remodeling, which ordinarily might have deleterious effects on cardiac function. Interestingly, activation of \( \beta \) receptors and elevation of cellular cyclic AMP may promote myocardial cell death by apoptosis (Singh et al., 2000; Brunton, 2005; Ding et al., 2005). In addition, properties of certain \( \beta \) receptor antagonists that are due to other, unrelated properties of these drugs may be potentially important. For example, afterload reduction by drugs such as carvedilol may be relevant. The potential importance of the \( \alpha \text{A} \)-antagonistic and antioxidant properties of carvedilol in its beneficial effects in patients with heart failure is not clear (Ma et al., 1996).

**Use of \( \beta \) Antagonists in Other Cardiovascular Diseases.** \( \beta \) Receptor antagonists, particularly propranolol, are used in the treatment of hypertrophic obstructive cardiomyopathy. Propranolol is useful for relieving angina, palpitations, and syncope in patients with this disorder. Efficacy probably is related to partial relief of the pressure gradient along the outflow tract. \( \beta \) Blockers also may attenuate catecholamine-induced cardiomyopathy in pheochromocytoma.

\( \beta \) Blockers are used frequently in the medical management of acute dissecting aortic aneurysm; their usefulness comes from reduction in the force of myocardial contraction and the rate of development of such force. Nitroprusside is an alternative, but when given in the absence of \( \beta \) receptor blockade, it causes an undesirable tachycardia. Patients with Marfan’s syndrome may develop progressive dilation of the aorta, which may lead to aortic dissection and regurgitation, a major cause of death in these patients. Chronic treatment with propranolol may be efficacious in slowing the progression of aortic dilation and its complications in patients with Marfan’s syndrome (Shores et al., 1994).

**Glaucoma.** \( \beta \) Receptor antagonists are very useful in the treatment of chronic open-angle glaucoma. Six drugs are currently available: carteolol (OCUPRESS, others), betaxolol (BETAOPCIT, others), levobunolol (BETAGAN, others), metipranolol (OPTIPRANOLOL, others), timolol (TIMOPTIC, others), and levobetaxolol (BETAXON). Timolol, levobunolol, carteolol, and metipranolol are non-selective, while betaxolol and levobetaxolol are \( \beta \text{A} \) selective. None of the agents has significant membrane-stabilizing or intrinsic sympathomimetic activities. Topically administered \( \beta \) blockers have little or no effect on pupil size or accommodation and are devoid of blurred vision and night blindness often seen with miotics. These agents decrease the production of aqueous humor, which appears to be the mechanism for their clinical effectiveness. Glaucoma and therapies for it are presented in Chapter 64.

\( \beta \) Receptor antagonists generally are administered as eye drops and have an onset in ~30 minutes with a duration of 12-24 hours. While topically administered \( \beta \) blockers usually are well tolerated, systemic absorption can lead to adverse cardiovascular and pulmonary effects in susceptible patients. They therefore should be used with great caution in glaucoma patients at risk for adverse systemic effects of \( \beta \) receptor antagonists (e.g., patients with bronchial asthma, severe COPD, or those with bradycardias). The use of topically administered \( \beta \) blockers for treatment of glaucoma is discussed further in Chapter 64. Three \( \beta \) blockers (betaxolol, metipranolol, and timolol) also have been observed to confer protection to retinal neurons, apparently related to their ability to attenuate neuronal Ca\textsuperscript{2+} and Na\textsuperscript{+} influx (Wood et al., 2003). Betaxolol is the most effective antiglaucoma drug at reducing Na\textsuperscript{+}/Ca\textsuperscript{2+} influx. \( \beta \) Blockers may be able to blunt ganglion cell death in glaucoma and that levobetaxolol may be a more important neuroprotectant than timolol because of its greater capacity to block Na\textsuperscript{+} and Ca\textsuperscript{2+} influx (Osborne et al., 2004).

**Other Uses.** Many of the signs and symptoms of hyperthyroidism are reminiscent of the manifestations of increased sympathetic nervous system activity. Indeed, excess thyroid hormone increases the expression of \( \beta \) receptors in some types of cells. \( \beta \) Receptor antagonists control many of the cardiovascular signs and symptoms of hyperthyroidism and are useful adjuvants to more definitive therapy. In addition, propranolol inhibits the peripheral conversion of thyroxine to triiodothyronine, an effect that may be independent of \( \beta \) receptor blockade. However, caution is advised in treating patients with cardiac enlargement, since the use of \( \beta \) receptor antagonists may precipitate congestive heart failure (see Chapter 39 for further discussion of the treatment of hyperthyroidism).

Propranolol, timolol, and metoprolol are effective for the prophylaxis of migraine (Thelt-Hansen, 1986); the mechanism of this effect is not known, and these drugs are not useful for treatment of acute attacks of migraine.

Propranolol and other \( \beta \) blockers are effective in controlling acute panic symptoms in individuals who are required to perform in public or in other anxiety-provoking situations. Public speakers may be calmed by the prophylactic administration of the drug, and the performance of musicians may be improved. Tachycardia, muscle tremors, and other evidence of increased sympathetic activity are reduced. Propranolol also may be useful in the treatment of essential tremor.

\( \beta \) Blockers may be of some value in the treatment of patients undergoing withdrawal from alcohol or those with akathisia. Propranolol and nadolol are efficacious in the primary prevention of variceal bleeding in patients with portal hypertension caused by cirrhosis of the liver (Bosch, 1998; Villanueva et al., 1996). Isosorbide mononitrate may augment the fall in portal pressure seen in some patients treated with \( \beta \) receptor antagonists. These drugs also may be beneficial in reducing the risk of recurrent variceal bleeding.
for an individual patient should be based on pharmacokinetic and pharmacodynamic differences among the drugs, cost, and whether there are concurrent medical problems. For some diseases (e.g., myocardial infarction, migraine, cirrhosis with varices, and congestive heart failure), it should not be assumed that all members of this class of drugs are interchangeable; the appropriate drug should be selected from those that have documented efficacy for the disease. \( \beta \)-Selective antagonists are preferable in patients with bronchospasm, diabetes, peripheral vascular disease, or Raynaud’s phenomenon. Although no clinical advantage of \( \beta \) receptor antagonists with intrinsic sympathomimetic activity has been clearly established, such drugs may be preferable in patients with bradycardia. In addition, third-generation \( \beta \) antagonists that block \( \alpha \) receptors, stimulate \( \beta_2 \) receptors, enhance NO production, block \( \text{Ca}^{2+} \) entry, open \( \text{K}^+ \) channels, or possess antioxidant properties may offer therapeutic advantages.

## NON-SELECTIVE \( \beta \) ADRENERGIC RECEPTOR ANTAGONISTS

### Propranolol

In view of the extensive experience with propranolol (INDERAL, others), it is a useful prototype (Table 12-5). Propranolol interacts with \( \beta_1 \) and \( \beta_2 \) receptors with equal affinity, lacks intrinsic sympathomimetic activity, and does not block \( \alpha \) receptors.

**Absorption, Fate, and Excretion.** Propranolol is highly lipophilic and is almost completely absorbed after oral administration. However, much of the drug is metabolized by the liver during its first passage through the portal circulation; on average, only \(~25\%\) reaches the systemic circulation. In addition, there is great interindividual variation in the presystemic clearance of propranolol by the liver; this contributes to enormous variability in plasma concentrations \((\sim 20\text{-fold})\) after oral administration of the drug and contributes to the wide dosage range for clinical efficacy. A clinical disadvantage of propranolol is that multiple increases in drug dose may be required over time. The degree of hepatic extraction of propranolol declines as the dose is increased. The bioavailability of propranolol may be increased by the concomitant ingestion of food and during long-term administration of the drug.

Propranolol has a large volume of distribution \((4 \text{ L/kg})\) and readily enters the CNS. Approximately 90% of the drug in the circulation is bound to plasma proteins. It is extensively metabolized, with most metabolites appearing in the urine. One product of hepatic metabolism is 4-hydroxypropranolol, which has some \( \beta \) adrenergic antagonist activity.

Analysis of the distribution of propranolol, its clearance by the liver, and its activity is complicated by the stereospecificity of these processes (Walle et al., 1988). The \((\sim)\)-enantiomers of propranolol and other \( \beta \) blockers are the active forms of the drug. The \((\sim)\)-enantiomer of propranolol appears to be cleared more slowly from the body than is the inactive enantiomer. The clearance of propranolol may vary with hepatic blood flow and liver disease and also may change during the administration of other drugs that affect hepatic metabolism. Monitoring of plasma concentrations of propranolol has found little application, since the clinical end points (reduction of blood pressure and heart rate) are readily determined. The relationships between the plasma concentrations of propranolol and its pharmacodynamic effects are complex; for example, despite its short \( t_{1/2} \) in plasma \((\sim 4\text{ hours})\), its antihypertensive effect is sufficiently long-lived to permit administration twice daily in some patients. Some of the \((\sim)\)-enantiomer of propranolol and other \( \beta \) blockers is taken up into sympathetic nerve endings and is released upon sympathetic nerve stimulation (Walle et al., 1988).

Sustained-release formulations of propranolol (INDERAL LA, others) have been developed to maintain therapeutic concentrations of propranolol in plasma throughout a 24-hour period. Suppression of exercise-induced tachycardia is maintained throughout the dosing interval, and patient compliance may be improved.

**Therapeutic Uses.** For the treatment of hypertension and angina, the initial oral dose of propranolol generally is 40-80 mg per day. The dose may then be titrated upward until the optimal response is obtained. For the treatment of angina, the dose may be increased at intervals of < 1 week, as indicated clinically. In hypertension, the full blood-pressure response may not develop for several weeks. Typically, doses are < 320 mg/day. If propranolol is taken twice daily for hypertension, blood pressure should be measured just prior to a dose to ensure that the duration of effect is sufficiently prolonged. Adequacy of \( \beta \) adrenergic blockade can be assessed by measuring suppression of exercise-induced tachycardia. Propranolol also is used for supraventricular arrhythmias/tachycardias, ventricular arrhythmias/tachycardias, premature ventricular contractions, digitalis-induced tachyarrhythmias, myocardial infarction, pheochromocytoma, essential tremor, and the prophylaxis of migraine. It also has been used for several off-label indications including parkinsonian tremors (sustained-release only), akathisia induced by antipsychotic drugs, variceal bleeding in portal hypertension, and generalized anxiety disorder (Table 12-4).

Propranolol may be administered intravenously for the management of life-threatening arrhythmias or to patients under anesthesia. Under these circumstances, the usual dose is 1-3 mg, administered slowly (< 1 mg/min) with careful and frequent monitoring of blood pressure, ECG, and cardiac function. If an adequate response is not obtained, a second dose may be given after several minutes. If bradycardia is excessive, atropine should be administered to increase heart rate. Change to oral therapy should be initiated as soon as possible. Use of propranolol was associated with a 26% reduction in mortality in the \( \beta \) Blocker Heart Attack Trial (BHAT) (Dobre et al., 2007)

### Nadolol

Nadolol (CORGARD, others) is a long-acting antagonist with equal affinity for \( \beta_1 \) and \( \beta_2 \) receptors. It is devoid of both membrane-stabilizing and intrinsic sympathomimetic activity. A distinguishing characteristic of

Vasodilation seen in 3rd generation drugs; multiple mechanisms (see Figure 12–9)

ADHD, attention-deficit/hyperactivity disorder; AV, atrioventricular; BPH, benign prostatic hypertrophy; CAD, coronary artery disease; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CV, cardiovascular; DA, dopamine; D₁, subtype 1 dopamine receptor; Epi, epinephrine; FFA, free fatty acids; 5-HT, serotonin; GFR, glomerular filtration rate; ISA, intrinsic sympathomimetic activity; MI, myocardial infarction; NE, norepinephrine; NO, nitric oxide; PBZ, phenoxybenzamine; PVR, peripheral vascular resistance.
nadolol is its relatively long t_{1/2}. It can be used to treat hypertension and angina pectoris. Unlabeled uses have included migraine prophylaxis, parkinsonian tremors, and variceal bleeding in portal hypertension.

Absorption, Fate, and Excretion. Nadolol is very soluble in water and is incompletely absorbed from the gut; its bioavailability is ~35%. Interindividual variability is less than with propranolol. The low lipid solubility of nadolol may result in lower concentrations of the drug in the brain as compared with more lipid-soluble β receptor antagonists. Although it frequently has been suggested that the incidence of CNS adverse effects is lower with hydrophilic β receptor antagonists, data from controlled trials to support this contention are limited. Nadolol is not extensively metabolized and is largely excreted intact in the urine. The t_{1/2} of the drug in plasma is ~20 hours; consequently, it generally is administered once daily. Nadolol may accumulate in patients with renal failure, and dosage should be reduced in such individuals.

Timolol

Timolol (BLOCADREN, others) is a potent, non-selective β receptor antagonist. It has no intrinsic sympathomimetic or membrane-stabilizing activity. It is used for hypertension, congestive heart failure, acute MI, and migraine prophylaxis. In ophthalmology, timolol has been used in the treatment of open-angle glaucoma and intraocular hypertension. Its mechanism of action in treating open angle glaucoma is not precisely known; but the drug appears to reduce aqueous humour production through blockade of β receptors on the ciliary epithelium.

Absorption, Fate, and Excretion. Timolol is well absorbed from the GI tract. It is metabolized extensively by CYP2D6 in the liver and undergoes first-pass metabolism. Only a small amount of unchanged drug appears in the urine. The t_{1/2} in plasma is ~4 hours. Interestingly, the ocular formulation of timolol (TIMOPTIC, others), used for the treatment of glaucoma, may be extensively absorbed systemically (Chapter 64); adverse effects can occur in susceptible patients, such as those with asthma or congestive heart failure. The systemic administration of cimetidine with topical ocular timolol increases the degree of β blockade, resulting in a reduction of resting heart rate, intraocular pressure, and exercise tolerance (Ishii et al., 2000). For ophthalmic use timolol is available combined with other medications (e.g., with dorzolamide or travoprost). Timolol also provides benefits to patients with coronary heart disease: in the acute post MI period, timolol produced a 39% reduction in mortality in the Norwegian Multicenter Study.

Pindolol

Pindolol (VISKEN, others) is a non-selective β receptor antagonist with intrinsic sympathomimetic activity. It has low membrane-stabilizing activity and low lipid solubility. It is used to treat angina pectoris and hypertension.

Although only limited data are available, β blockers with slight partial agonist activity may produce smaller reductions in resting heart rate and blood pressure. Hence, such drugs may be preferred as antihypertensive agents in individuals with diminished cardiac reserve or a propensity for bradycardia. Nonetheless, the clinical significance of partial agonism has not been substantially demonstrated in controlled trials but may be of importance in individual patients. Agents such as pindolol block exercise-induced increases in heart rate and cardiac output.

Absorption, Fate, and Excretion. Pindolol is almost completely absorbed after oral administration and has moderately high bioavailability. These properties tend to minimize interindividual variation in the plasma concentrations of the drug that are achieved after its oral administration. Approximately 50% of pindolol ultimately is metabolized in the liver. The principal metabolites are hydroxylated derivatives that subsequently are conjugated with either glucuronide or sulfate before renal excretion. The remainder of the drug is excreted unchanged in the urine. The plasma t_{1/2} of pindolol is ~4 hours; clearance is reduced in patients with renal failure.

β₁ SELECTIVE ADRENERGIC RECEPTOR ANTAGONISTS

Metoprolol

Metoprolol (LOPRESSOR, others) is a β₁-selective receptor antagonist that is devoid of intrinsic sympathomimetic activity and membrane-stabilizing activity.

Absorption, Fate, and Excretion. Metoprolol is almost completely absorbed after oral administration, but bioavailability is relatively low (~40%) because of first-pass metabolism. Plasma concentrations of the drug vary widely (up to 17-fold), perhaps because of genetically determined differences in the rate of metabolism. Metoprolol is extensively metabolized in the liver, with CYP2D6 the major enzyme involved, and only 10% of the administered drug is recovered unchanged in the urine. The t_{1/2} of metoprolol is 3-4 hours, but can increase to 7-8 hours in CYP2D6 poor metabolizers. It recently has been reported that CYP2D6 poor metabolizers have a 5-fold higher risk for developing adverse effects during metoprolol treatment than patients who are not poor metabolizers (Wuttke et al., 2002). An extended-release formulation (TOPROL XL) is available for once-daily administration.

Therapeutic Uses. Metoprolol has been used to treat essential hypertension, angina pectoris, tachycardia, heart failure, vasovagal syncope, and as secondary prevention after myocardial infarction, an adjunct in treatment of hyperthyroidism, and for migraine prophylaxis. For the treatment of hypertension, the usual initial dose is 100 mg/day. The drug sometimes is effective when given once daily, although it frequently is used in two divided doses. Dosage may be increased at weekly intervals until optimal reduction of blood pressure is achieved. If the drug is taken only once daily, it is important to confirm that blood pressure is controlled for the entire 24-hour period. Metoprolol generally is used in two divided doses for the treatment of stable angina. For the initial treatment of patients with acute myocardial infarction, an intravenous formulation of
metoprolol tartrate is available. Oral dosing is initiated as soon as the clinical situation permits. Metoprolol generally is contraindicated for the treatment of acute myocardial infarction in patients with heart rates of < 45 beats per minute, heart block greater than first-degree (PR interval ≥ 0.24 second), systolic blood pressure <100 mm Hg, or moderate to severe heart failure. Metoprolol also has been proven to be effective in chronic heart failure. Its use is associated with a striking reduction in all-cause mortality and hospitalization for worsening heart failure and a modest reduction in all-cause hospitalization (MERIT-HF Study Group, 1999; Prakash and Markham, 2000).

Atenolol

Atenolol (TENORMIN, others) is a β₁-selective antagonist that is devoid of intrinsic sympathomimetic and membrane-stabilizing activity. Atenolol is very hydrophilic and appears to penetrate the CNS only to a limited extent. Its $t_{1/2}$ is somewhat longer than that of metoprolol.

Absorption, Fate, and Excretion. Atenolol is incompletely absorbed (~50%), but most of the absorbed dose reaches the systemic circulation. There is relatively little interindividual variation in the plasma concentrations of atenolol; peak concentrations in different patients vary over only a 4-fold range. The drug is excreted largely unchanged in the urine, and the elimination $t_{1/2}$ is 5-8 hours. The drug accumulates in patients with renal failure, and dosage should be adjusted for patients whose creatinine clearance is < 35 mL/min.

Therapeutic Uses. Atenol can be used to treat hypertension, coronary heart disease, arrhythmias, and angina pectoris, and to treat or reduce the risk of heart complications following myocardial infarction. It is also used to treat Graves disease until anti-thyroid medication can take effect. The initial dose of atenolol for the treatment of hypertension usually is 50 mg/day, given once daily. If an adequate therapeutic response is not evident within several weeks, the daily dose may be increased to 100 mg; higher doses are unlikely to provide any greater antihypertensive effect. Atenolol has been shown to be efficacious, in combination with a diuretic, in elderly patients with isolated systolic hypertension. Atenolol causes fewer CNS side effects (depression, nightmares) than most β blockers and few bronchospastic reactions due to its pharmacological and pharmacokinetic profile (Varon, 2008).

Esmolol

Esmolol (BREVIBLOC, others) is a β₁-selective antagonist with a rapid onset and a very short duration of action. It has little if any intrinsic sympathomimetic activity and lacks membrane-stabilizing actions. Esmolol is administered intravenously and is used when β blockade of short duration is desired or in critically ill patients in whom adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. It is a class II anti-arrhythmic agent (Chapter 29).

Absorption, Fate, and Excretion. Esmolol is given by slow IV injection and has a $t_{1/2}$ of ~8 minutes and an apparent volume of distribution of ~2 L/kg. The drug contains an ester linkage, and it is hydrolyzed rapidly by esterases in erythrocytes. The $t_{1/2}$ of the carboxylic acid metabolite of esmolol is far longer (4 hours), and it accumulates during prolonged infusion of esmolol. However, this metabolite has very low potency as a β receptor antagonist (1/500 of the potency of esmolol); it is excreted in the urine.

Esmolol is commonly used in patients during surgery to prevent or treat tachycardia and in the treatment of supraventricular tachycardia. The onset and cessation of β receptor blockade with esmolol are rapid; peak hemodynamic effects occur within 6-10 minutes of administration of a loading dose, and there is substantial attenuation of β blockade within 20 minutes of stopping an infusion. Esmolol may have striking hypotensive effects in normal subjects, although the mechanism of this effect is unclear.

Because esmolol is used in urgent settings where immediate onset of β blockade is warranted, a partial loading dose typically is administered, followed by a continuous infusion of the drug. If an adequate therapeutic effect is not observed within 5 minutes, the same loading dose is repeated, followed by a maintenance infusion at a higher rate. This process, including progressively greater infusion rates, may need to be repeated until the desired end point (e.g., lowered heart rate or blood pressure) is approached. Esmolol is particularly useful in severe postoperative hypertension and is a suitable agent in situations where cardiac output, heart rate, and blood pressure are increased. The American Heart Association/American College of Cardiology guidelines recommend against using esmolol in patients already on β blocker therapy, bradycardiac patients, and decompensated heart failure patients, as the drug may compromise their myocardial function (Varon, 2008).

Acebutolol

Acebutolol (SECTRAL, others) is a β₁-selective antagonist with some intrinsic sympathomimetic and membrane-stabilizing activity.

Absorption, Fate, and Excretion. Acebutolol is well absorbed, and undergoes significant first-pass metabolism to an active metabolite, diacetolol, which accounts for most of the drug’s activity. Overall bioavailability is 35-50%. The elimination $t_{1/2}$ of acebutol typically is ~3 hours, but the $t_{1/2}$ of diacetol is 8-12 hours; it is excreted largely in the urine. Acebutol has lipophilic properties and crosses the blood-brain barrier. It has no negative impact on serum lipids (cholesterol, triglycerides, or HDL).

Therapeutic Uses. Acebutol has been used to treat hypertension, ventricular and atrial cardiac arrhythmias, acute myocardial infarction in high-risk patients, and Smith-Magenis syndrome. The initial dose of acebutol in hypertension usually is 400 mg/day; it may be given as a single dose, but two divided doses may be required for adequate control of blood pressure. Optimal responses usually occur with doses of 400-800 mg per day (range, 200-1200 mg).

Bisoprolol

Bisoprolol (ZEBETA) is a highly selective β₁ receptor antagonist that does not have intrinsic sympathomimetic
or membrane-stabilizing activity (McGavin and Keating, 2002). It has a higher degree of $\beta_2$-selective activity than atenolol, metoprolol, or betaxolol but less than nebivolol. It is approved for the treatment of hypertension and has been investigated in randomized, double-blind multicenter trials in combination with ACE inhibitors and diuretics in patients with moderate to severe chronic heart failure (Simon et al., 2003). All-case mortality was significantly lower with bisoprolol than placebo.

Bisoprolol generally is well tolerated; side effects include dizziness, bradycardia, hypotension, and fatigue. Bisoprolol is well absorbed following oral administration, with bioavailability of ~90%. It is eliminated by renal excretion (50%) and liver metabolism to pharmacologically inactive metabolites (50%). Bisoprolol has a plasma $t_{1/2}$ of 11-17 hours. Bisoprolol can be considered a standard treatment option when selecting a $\beta$ blocker for use in combination with ACE inhibitors and diuretics in patients with stable, moderate to severe chronic heart failure and in treating hypertension (McGavin and Keating, 2002; Simon et al., 2003). It has also been used to treat arrhythmias and ischemic heart disease. Bisoprolol was associated with a 34% mortality benefit in the Cardiac Insufficiency Bisoprolol Study-II (CIBIS-II).

**Betaxolol**

Betaxolol (BETOPTIC, LOKREN, KERLONE, others) is a selective $\beta_1$ receptor antagonist with no partial agonist activity and slight membrane-stabilizing properties.

**Absorption, Fate, and Excretion.** Betaxolol is well absorbed with high bioavailability and an elimination $t_{1/2}$ of 14-22 hours.

**Therapeutic Uses.** Betaxolol is used to treat hypertension, angina pectoris, and glaucoma. It is usually well tolerated and side effects are mild and transient. In glaucoma it reduces intraocular pressure by reducing the production of aqueous humor in the eye.

### $\beta$ RECEPTOR ANTAGONISTS WITH ADDITIONAL CARDIOVASCULAR EFFECTS (“THIRD GENERATION” $\beta$ BLOCKERS)

In addition to the classical non-selective and $\beta_1$-selective adrenergic-receptor antagonists, there is also a series of drugs that possess vasodilatory actions. These effects are produced through a variety of mechanisms including $\alpha_1$ adrenergic receptor blockade (labetalol, carvedilol, bucindolol, bevantolol, nipradilol), increased production of NO (celiprolol, nebivolol, carteolol, bopindolol, nipradolol), $\beta_2$ agonist properties (celiprolol, carteolol, bopindolol), $\mathrm{Ca}^{2+}$ entry blockade (carvedilol, betaxolol, bevantolol), opening of $\mathrm{K}^+$ channels (tilisolol), or antioxidant action (carvedilol) (Toda, 2003). These actions are summarized in Table 12–4 and Figure 12–9. Many third-generation $\beta$ receptor antagonists are not yet available in the U.S. but have undergone clinical trials and are on the market in other countries.

**Labetalol**

Labetalol (NORMODYNE, TRANDATE, others) is representative of a class of drugs that act as competitive antagonists at both $\alpha_1$ and $\beta$ receptors. Labetalol has two optical centers, and the formulation used clinically contains equal amounts of the four diastereomers. The pharmacological properties of the drug are complex, because each isomer displays different relative activities. The properties of the mixture include selective blockade of $\alpha_1$ receptors (as compared with the $\alpha_2$ subtype), blockade of $\beta_1$ and $\beta_2$ receptors, partial agonist activity at $\beta_2$ receptors, and inhibition of neuronal uptake of NE (cocaine-like effect) (Chapter 8). The potency of the mixture for $\beta$ receptor blockade is 5-10 fold that for $\alpha_1$ receptor blockade.

The pharmacological effects of labetalol have become clearer since the four isomers were separated and tested individually. The $R,R$ isomer is about four times more potent as a $\beta$ receptor antagonist than is racemic labetalol and accounts for much of the $\beta$ blockade produced by the mixture of isomers; it no longer is in development as a separate drug (dilevalol). As an $\alpha_1$ antagonist, this isomer is ~20% as potent as the racemic mixture. The $S,S$ isomer is almost devoid of both $\alpha$ and $\beta$ blocking effects. The $S,R$ isomer has almost no $\beta$ blocking activity, yet is about five times more potent as an $\alpha$ blocker than is racemic labetalol. The $S,S$ isomer is devoid of $\beta$ blocking activity and has a potency similar to that of racemic labetalol as an $\alpha_1$ receptor antagonist. The $R,R$ isomer has some intrinsic sympathomimetic activity at $\beta_1$ adrenergic receptors; this may contribute to vasodilation. Labetalol also may have some direct vasodilating capacity.

The actions of labetalol on both $\alpha_1$ and $\beta$ receptors contribute to the fall in blood pressure observed in patients with hypertension. $\alpha_1$ Receptor blockade leads to relaxation of arterial smooth muscle and vasodilation, particularly in the upright position. The $\beta_1$ blockade also contributes to a fall in blood pressure, in part by blocking reflex sympathetic stimulation of the heart. In addition, the intrinsic sympathomimetic activity of labetalol at $\beta_1$ receptors may contribute to vasodilation.

Labetalol is available in oral form for therapy of chronic hypertension and as an intravenous formulation for use in hypertensive emergencies. Labetalol has been associated with hepatic injury in a limited number of patients. Labetalol is one of the few $\beta$ adrenergic antagonists that has been recommended as treatment for acute severe hypertension (hypertensive emergency). Its hypotensive action begins within 2-5 minutes after IV administration, reaching its peak at 5-15 minutes and lasting ~2-4 hours. Heart rate is either maintained or slightly reduced and cardiac output is maintained. Labetalol reduces systemic vascular resistance without reducing total
peripheral blood flow. Cerebral, renal, and coronary blood flow is maintained. It can be used in the setting of pregnancy-induced hypertensive crisis because little placental transfer occurs due to the poor lipid solubility of labetalol.

**Absorption, Fate, and Excretion.** Although labetalol is completely absorbed from the gut, there is extensive first-pass clearance; bioavailability is only ~20-40%, is highly variable, and may be increased by food intake. The drug is rapidly and extensively metabolized in the liver by oxidative biotransformation and glucuronidation; very little unchanged drug is found in the urine. The rate of metabolism of labetalol is sensitive to changes in hepatic blood flow. The elimination t_{1/2} of the drug is ~8 hours. The t_{1/2} of the R,R isomer of labetalol (dilevalol) is ~15 hours. Labetalol provides an interesting and challenging example of pharmacokinetic-pharmacodynamic modeling applied to a drug that is a racemic mixture of isomers with different kinetics and pharmacological actions (Donnelly and Macphee, 1991).

**Carvedilol**

Carvedilol (COREG) is a third-generation β receptor antagonist that has a unique pharmacological profile. It blocks β₁, β₂, and α₁ receptors similarly to labetalol, but also has antioxidant and anti-inflammatory effects (Dandonza et al., 2007). It has membrane-stabilizing activity but it lacks intrinsic sympathomimetic activity. Carvedilol produces vasodilation. Additional properties (e.g., antioxidant and anti-inflammatory effects) may contribute to the beneficial effects seen in treating congestive heart failure and in its cardioprotective effects. The drug is FDA-approved for use in hypertension, congestive heart failure, and left ventricular dysfunction following MI.

Carvedilol possesses two distinct antioxidant properties: it is a chemical antioxidant that can bind to and scavenge reactive oxygen species (ROS), and it can suppress the biosynthesis of ROS and oxygen radicals. Carvedilol is extremely lipophilic and is able to protect cell membranes from lipid peroxidation. It prevents low density lipoprotein (LDL) oxidation, which in turn induces the uptake of LDL into the coronary vasculature. Carvedilol also inhibits ROS-mediated loss of myocardial contractility, stress-induced hypertrophy, apoptosis, and the accumulation and activation of neutrophils. At high doses, carvedilol exerts Ca²⁺ channel-blocking activity. Carvedilol does not increase β receptor density and is not associated with high levels of inverse agonist activity (Cheng et al., 2001; Dandonza et al., 2007; Keating and Jarvis, 2003).

Carvedilol has been tested in numerous double-blind, randomized studies, including the U.S. Carvedilol Heart Failure Trials Program, Carvedilol or Metoprolol European Trial (COMET) (Poole-Wilson et al., 2003), Carvedilol Prospective Randomised Cumulative Survival (COPERNICUS) trial, and the Carvedilol Post Infarct Survival Control in LV Dysfunction (CAPRICORN) trial (Cleland, 2003). These trials showed that carvedilol improves ventricular function and reduces mortality and morbidity in patients with mild to severe congestive heart failure. Several experts recommend it as the standard treatment option in this setting. In addition, carvedilol combined with conventional therapy reduces mortality and attenuates myocardial infarction. In patients with chronic heart failure, carvedilol reduces cardiac sympathetic drive, but it is not clear if blockade of α₁ receptor–mediated vasodilation is maintained over long periods of time.

**Absorption, Fate, and Excretion.** Carvedilol is rapidly absorbed following oral administration, with peak plasma concentrations occurring in 1-2 hours. It is highly lipophilic and thus is extensively distributed into extravascular tissues. It is > 95% protein bound and is extensively metabolized in the liver, predominantly by CYP2D6 and CYP2C9. The t_{1/2} is 7-10 hours. Stereoselective first-pass metabolism results in more rapid clearance of S(-)-carvedilol than R(+)-carvedilol. No significant changes in the pharmacokinetics of carvedilol were seen in elderly patients with hypertension, and no change in dosage is needed in patients with moderate to severe renal insufficiency (Cleland, 2003; Keating and Jarvis, 2003). Because of carvedilol’s extensive oxidative metabolism by the liver, its pharmacokinetics can be profoundly affected by drugs that induce or inhibit oxidation. These include the inducer, rifampin, and inhibitors such as cimetidine, quinidine, fluoxetine, and paroxetine.

**Bucindolol**

Bucindolol (SANDONORM) is a third-generation non-selective β-adrenergic antagonist with weak α₁ adrenergic blocking properties. The intrinsic sympathomimetic activity of bucindolol may be dependent on β₁ receptors.

Bucindolol increases left ventricular systolic ejection fraction and decreases peripheral resistance, thereby reducing afterload. It increases plasma HDL cholesterol, but does not affect plasma triglycerides. A large comprehensive clinical trial, the β Blocker Evaluation of Survival Trial (BEST), was terminated early because of the inability to demonstrate a survival benefit with bucindolol versus placebo. In subsequent analyses from BEST, however, benefits have been demonstrated in discrete subgroups, including a genetically identified subgroup. An evaluation was made of the therapeutic responses to bucindolol among patients with genetic variations or polymorphisms in two adrenergic receptors: β₁, 389 arg/gly and α₂c 322-325 WT/Del. Researchers identified three distinct genotypes that predict the effect of bucindolol: very favorable (47% of BEST patients), favorable (40%), and unfavorable (13%). In the study, patients with the very favorable genotype experienced significant improvements in clinical end points compared to placebo, including reductions in all-cause mortality, cardiovascular mortality, heart failure hospitalization, and cardiovascular hospitalization. A New Drug Application (NDA) has been filed with the FDA and is currently under review.

Bucindolol is well absorbed after oral administration, reaching maximum plasma levels in 2 hours. It is highly protein bound (87%), extensively metabolized by the liver to 5-hydroxybucindolol, and has a t_{1/2} of ~8 hours.

**Celiprolol**

Celiprolol (SELECTOL) is a third-generation cardioselective β receptor antagonist. It has low lipid solubility and possesses weak vasodilating and bronchodilating effects attributed to partial selective β₂ agonist activity.
and possibly papaverine-like relaxant effects on smooth muscle (including bronchial). It also has been reported to antagonize peripheral $\alpha_2$ adrenergic receptor activity, to promote NO production, and to inhibit oxidative stress. There is evidence for intrinsic sympathomimetic activity at the $\beta_2$ receptor. Celiprolol is devoid of membrane-stabilizing activity. Weak $\alpha_2$ antagonistic properties are present, but are not considered clinically significant at therapeutic doses (Toda, 2003).

Celiprolol reduces heart rate and blood pressure and can increase the functional refractory period of the atrioventricular node. Oral bioavailability ranges from 30-70%, and peak plasma levels are seen at 2-4 hours. It is largely unmetabolized and is excreted unchanged in the urine and feces. Celiprolol does not undergo first-pass metabolism. The predominant mode of excretion is renal. Celiprolol is used for treatment of hypertension and angina (Felix et al., 2001; Witchitz et al., 2000).

Nebivolol

Nebivolol (BYSTOLIC) is a third-generation selective $\beta_3$ receptor antagonist with endothelial NO-mediated vasodilator activity. In addition, nebivolol has antioxidant properties and neutral to favorable effects on both carbohydrate and lipid metabolism. Nebivolol lowers blood pressure by reducing peripheral vascular resistance and significantly increases stroke volume with preservation of cardiac output and maintains systemic flow and blood flow to target organs. Nebivolol generally does not negatively affect serum lipids and may increase insulin sensitivity. These benefits are also observed in the presence of metabolic syndrome, which is often present in hypertensive patients (Gielen et al., 2006; Ignarro, 2008). Nebivolol has been approved for treatment of hypertension.

Nebivolol is administered as the racemate containing equal amounts of the $d$ and $l$-enantiomers. The $d$-isomer is the active $\beta$ blocking component; the $l$-isomer is responsible for enhancing production of NO. Nebivolol is devoid of intrinsic sympathomimetic effects as well as membrane stabilizing activity and $\alpha_1$ receptor blocking properties. It is lipophilic, and concomitant administration of chlorthalidone, hydrochlorothiazide, theophylline, or digoxin with nebivolol may reduce its extent of absorption. The NO-dependent vasodilating action of nebivolol and its high $\beta_1$ adrenergic receptor selectivity likely contribute to the drug’s efficacy and improved tolerability (e.g., less fatigue and sexual dysfunction) as an antihypertensive agent (deBoer et al., 2007; Gupta and Wright, 2008; Moen and Wagstaff, 2006; Rosei and Rizzoni, 2007). Metabolism occurs via CYP2D6, and the influence of polymorphisms in the CYP2D6 gene on the bioavailability and duration of nebivolol’s actions is being evaluated (Lefebvre et al., 2006), as is the influence of plasma concentration of receptor selectivity.

Other $\beta$ Adrenergic Receptor Antagonists. There are numerous $\beta$ adrenergic receptor antagonists on the market as ophthalmologic preparations for the treatment of glaucoma or other causes of high blood pressure inside the eye (Chapter 64). These include carteolol (OCTUPRESS, others), metipranolol (OPTIPRANOL), nifedipil (HYPADIL; not available in the U.S.), levobunolol (BETAGAN, LIQUIFILM, others), betaxolol (BETOPTIC, others), and timolol (TIMOPTIC, others) (Henness et al., 2007). The use of $\beta$ adrenergic receptor antagonists in glaucoma is contraindicated in patients with asthma, COPD, sympathetic sinus bradycardia, and cardiogenic shock.

BIBLIOGRAPHY

Brixius K, Bundkirchen A, Bölck B, et al. Nebivolol, bucindolol, betaxolol (BETOPTIC, others), and timolol (TIMOPTIC, others) (Henness et al., 2007). The use of $\beta$ adrenergic receptor antagonists in glaucoma is contraindicated in patients with asthma, COPD, sympathetic sinus bradycardia, and cardiogenic shock.

5-Hydroxytryptamine (5-HT, serotonin) and dopamine (DA) are neurotransmitters in the central nervous system (CNS) and also have prominent peripheral actions. 5-HT is found in high concentrations in enterochromaffin cells throughout the GI tract, in storage granules in platelets, and broadly throughout the CNS. 5-HT regulates smooth muscle in the cardiovascular system and the GI tract and enhances platelet aggregation. The highest concentrations of DA are found in the brain; dopamine stores are also present peripherally in the adrenal medulla and the transmitter is detectable in the plexuses of the GI tract and in enteric nervous system. DA modulates peripheral vascular tone to modulate renal perfusion, heart rate, and vasoconstriction/dilation. Fourteen 5-HT receptor subtypes and five DA-receptor subtypes have been delineated by pharmacological analyses and cDNA cloning. The availability of cloned receptors has allowed the development of subtype-selective drugs and the elucidation of actions of these neurotransmitters at a molecular level. Increasingly, therapeutic goals are being achieved by drugs that target selectively one or more of the subtypes of 5-HT or DA receptors, or that act on a combination of both 5-HT and DA receptors.

5-HT and DA are widely distributed in the animal and plant kingdoms. Several important laboratory invertebrate models have serotonergic and dopaminergic systems, including the fruit fly and nematode. 5-HT and DA are considered below in separate sections.

5-HYDROXYTRYPTAMINE

History. In the 1930s, Erspamer began to study the distribution of enterochromaffin cells, which stained with a reagent for indoles. The highest concentrations were found in GI mucosa, followed by platelets and the CNS. Soon thereafter, Page and colleagues isolated and chemically characterized a vasoconstrictor substance released from platelets in clotting blood. This substance, named serotonin, was shown to be identical to the indole isolated by Erspamer. Subsequent discovery of biosynthetic and degradative pathways for 5-HT and clinical presentation of patients with carcinoid tumors of intestinal enterochromaffin cells spurred interest in 5-HT. The gross effects of 5-HT, produced in excess in malignant carcinoid, gave some indication of the physiologic and pharmacologic actions of 5-HT, as did the identification of several naturally occurring and semi-synthetic tryptamine-like substances that were hallucinogenic and induced behavioral effects similar to those observed in carcinoid patients. In the mid-1950s, the discovery that the pronounced behavioral effects of reserpine are accompanied by a profound decrease in brain 5-HT led to the proposal that serotonin may function as a neurotransmitter in the mammalian CNS.

Sources and Chemistry. 5-HT [3-((β-aminoethyl)-5-hydroxyindole] is present in vertebrates, tunicates, mollusks, arthropods, coelenterates, fruits, and nuts. It is also a component of venoms, including those of the common stinging nettle and of wasps and scorpions. Numerous synthetic or naturally occurring congeners of 5-HT have pharmacological activity (see Figure 13–1 for chemical structures). Many of the N- and O-methylated indoleamines, such as N,N-dimethyltryptamine, are hallucinogens. Because these compounds are behaviorally active and might be synthesized by known metabolic pathways, they have long been considered candidates for endogenous psychotomimetic substances, potentially responsible for some psychotic behaviors. Another close relative of 5-HT, melatonin (5-methoxy-N-acetyltryptamine), is formed by sequential N-acetylation and O-methylation (Figure 13–2). Melatonin, not to be confused with melasin, is the principal indoleamine in the pineal gland, where it may be said to constitute a pigment of the imagination. Its synthesis is controlled by external factors including environmental light. Melatonin induces pigment lightening in skin cells and suppresses ovarian functions; it also serves a role in regulating biological rhythms and shows promise in the treatment of jet lag and other sleep disturbances (Cajochen et al., 2003).

Synthesis and Metabolism of 5-HT. 5-HT is synthesized by a two-step pathway from the essential amino
acid tryptophan (Figure 13–2). Tryptophan is actively transported into the brain by a carrier protein that also transports other large neutral and branched-chain amino acids. Levels of tryptophan in the brain are influenced not only by its plasma concentration but also by the plasma concentrations of other amino acids that compete for the transporter. Tryptophan hydroxylase, a mixed-function oxidase that requires molecular O₂ and a reduced pteridine cofactor for activity, is the rate-limiting enzyme in the synthetic pathway. A brain-specific isoform of tryptophan hydroxylase (TPH2) is entirely responsible for the synthesis of brain 5-HT (Walther and Bader, 2003). Human genetic studies of TPH2, fueled by discoveries of functional SNPs that alter enzyme activity as well as promoter SNPs that alter expression, have focused on mood disorders, but are so far inconclusive. Unlike tyrosine hydroxylase, tryptophan hydroxylase is not regulated by end-product inhibition, although regulation by phosphorylation is common to both enzymes. Brain tryptophan hydroxylase is not generally saturated with substrate; consequently, the concentration of tryptophan in the brain influences the synthesis of 5-HT.

The enzyme that converts L-5-hydroxytryptophan to 5-HT, aromatic L-amino acid decarboxylase (AADC), is widely distributed and has a broad substrate specificity. A long-standing debate about whether L-5-hydroxytryptophan decarboxylase and L-dopa decarboxylase are identical enzymes was clarified when cDNA cloning confirmed that a single gene product decarboxylates both

Figure 13–1. Structures of representative indolealkylamines.

transporter. The 5-HT transporter (SERT [SLC6A4]) is localized in the membrane of serotonergic axon terminals (where it terminates the action of 5-HT in the synapse) and in the membrane of platelets (where it takes up 5-HT from the blood). This uptake system is the means by which platelets acquire 5-HT, since they lack the enzymes required for 5-HT synthesis. The 5-HT transporter and other monoamine transporters have been cloned (Chapters 5, 8, and 12). The amine transporters are distinct from VMAT2, which concentrates amines in intracellular storage vesicles and is a nonspecific amine carrier, whereas the 5-HT transporter is specific. The 5-HT transporter is regulated by phosphorylation and subsequent internalization (for a review, see Steiner et al., 2008), providing a mechanism for dynamic regulation of serotonergic transmission.

The principal route of metabolism of 5-HT involves oxidative deamination by monoamine oxidase (MAO); the aldehyde intermediate thus formed is converted to 5-hydroxyindole acetic acid (5-HIAA) by aldehyde dehydrogenase (Figure 13–2). An alternative route, reduction of the acetaldehyde to an alcohol, 5-hydroxytryptophol, is normally insignificant. 5-HIAA is actively transported out of the brain by a process that is sensitive to the nonspecific transport inhibitor, probenecid.

Since 5-HIAA formation accounts for nearly 100% of the metabolism of 5-HT in brain, the turnover rate of brain 5-HT is estimated by measuring the ratio of 5-HIAA/5-HT. 5-HIAA from brain and peripheral sites of 5-HT storage and metabolism is excreted in the urine along with small amounts of 5-hydroxytryptophol sulfate or glucuronide conjugates. The usual range of urinary excretion of 5-HIAA by a normal adult is 2-10 mg daily. Larger amounts are excreted by patients with malignant carcinoid, providing a reliable diagnostic test for the disease. Ingestion of ethanol results in elevated amounts of NADH (Chapter 23), which diverts 5-HIAA from the oxidative route to the reductive pathway (Figure 13–2) and tends to increase the excretion of 5-hydroxytryptophol and correspondingly reduce the excretion of 5-HIAA.

Of the two isoforms of MAO (A and B) (see Chapter 8 and Bortolato et al., 2008 for a review), MAO-A preferentially metabolizes 5-HT and norepinephrine; clorgyline is a specific inhibitor of MAO; localized primarily in the outer membrane of mitochondria. MAO-B preferentially metabolizes tyramine and benzylamine as substrates; low-dose selegiline is a relatively selective inhibitor of MAO-B. Dopamine and tryptamine are metabolized equally well by both isoforms. Neurons contain both isoforms of MAO, localized primarily in the outer membrane of mitochondria. MAO-B is the principal isofrom in platelets, which contain large amounts of 5-HT.

Other minor pathways of metabolism of 5-HT, such as sulfation and O- or N-methylation, have been suggested. The latter reaction could lead to formation of an endogenous psychotropic substance, 5-hydroxy-N,N-dimethyltryptamine (bufotenine; Figure 13–1). However, other methylated indoleamines such as N,N-dimethyltryptamine and 5-methoxy-N,N-dimethyltryptamine are far more active hallucinogens and are more likely candidates to be endogenous psychotomimetics.

**PHYSIOLOGICAL FUNCTIONS OF SEROTONIN**

### Multiple 5-HT Receptors

Based on data from studies of 5-HT’s actions in peripheral tissues, researchers hypothesized that the multiple actions of 5-HT involved interaction with distinct 5-HT receptor subtypes. Extensive pharmacological characterization and the cloning of receptor cDNAs have confirmed this hypothesis (Barnes and Sharp, 1999; Bockaert et al., 2006). The multiple 5-HT receptor subtypes cloned comprise the largest known neurotransmitter-receptor family. The 5-HT receptor subtypes are expressed in distinct but often overlapping patterns (Palacios et al., 1990) and are coupled to different transmembrane-signaling mechanisms (Table 13–1). Most 5-HT receptors, especially the 5-HT2C receptor, can activate G-proteins independently of agonists, a property known as constitutive activity (Berg et al., 2008). Four of seven currently recognized 5-HT receptor families have defined functions (described later). The 5-HT1, 5-HT2, and 5-HT4–7 receptor families are members of the superfamily of GPCRs (Chapter 3). The 5-HT3 receptor is a ligand-gated ion channel that gates Na+ and K+ and has a predicted membrane topology akin to that of the nicotinic cholinergic receptor (Chapter 11).

**History of 5-HT Receptor Subtypes.** In 1957, Gaddum and Picarelli proposed the existence of two 5-HT receptor subtypes, M and D receptors. M receptors were believed to be located on parasympathetic nerve endings, controlling the release of acetylcholine, whereas D receptors were thought to be located on smooth muscle. Subsequent studies in both the periphery and brain were consistent with the notion of multiple subtypes of 5-HT receptors (for a review, see Sanders-Bush and Airey, 2008), now known to be members of the superfamilies of GPCRs and ligand-gated ion channel receptors. The current classification scheme (Hoyer et al., 1994) is based on pharmacological properties, second-messenger function, and deduced amino acid sequence, and includes seven subfamilies of 5-HT receptors (Table 13–1).

The radioligand-binding studies of Peroutka and Snyder (1979) provided the first definitive evidence for two distinct recognition sites for 5-HT. 5-HT1 receptors had a high affinity for [3H]5-HT, while 5-HT2 receptors had a low affinity for [3H]5-HT and a high affinity for [3H]spiperone. Subsequently, high affinity for 5-HT was used as a primary criterion for classifying a receptor subtype as a member of the 5-HT1 receptor family. This classification strategy proved to be invalid; for example, a receptor expressed in the choroid plexus was named the 5-HT1C receptor because it was the third receptor shown to have a high affinity for 5-HT. However, based on its pharmacological properties, second-messenger function, and deduced amino acid sequence, the 5-HT1C receptor clearly belonged to the 5-HT2 receptor family and was subsequently renamed the 5-HT2C receptor. Evidence suggests that the 5-HT1D receptor is the human

homolog of the 5-HT_{1B} receptor originally characterized and subsequently cloned from rodent brain. Although the rat 5-HT_{1B} receptor and the human 5-HT_{1D} receptor show > 95% amino-acid sequence homology, they have distinct pharmacological properties. The rat 5-HT_{1B} receptor has an affinity for β-adrenergic antagonists (e.g., pindolol and propranolol) that is two to three orders of magnitude higher than that of the human 5-HT_{1D} receptor. This difference appears to be due to a single amino acid difference (D→R) in the seventh transmembrane span. Many 5-HT receptor knockout mice have been created that shed light on the role of specific receptors (Table 13–2); however, most of these models cannot distinguish between developmental events versus changes related to the absence of the receptor in the adult mouse.

5-HT_{1} Receptors. The 5-HT_{1}-receptor subfamily consists of five members, all of which preferentially couple to G_{i/o} and inhibit adenylyl cyclase. The 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{1D} receptor subtypes also activate a receptor-operated K⁺ channel and inhibit a voltage-gated Ca²⁺ channel, a common property of receptors coupled to the pertussis toxin-sensitive G_{i/o} family. The 5-HT_{1A} receptor is found in the raphe nuclei of the brainstem, where it functions as an inhibitory, somatodendritic autoreceptor on cell bodies of serotonergic neurons (Figure 13–3). Another 5-HT_{1}-receptor subtype, the 5-HT_{1D/1B} receptor, functions as an autoreceptor on axon terminals, inhibiting 5-HT release, as does its rat homolog, 5-HT_{1B}. 5-HT_{1D} receptors, abundantly expressed in the substantia nigra and basal ganglia, regulate the firing rate of DA-containing cells and the release of DA at axonal terminals.

5-HT_{2} Receptors. The three subtypes of 5-HT_{2} receptors couple to pertussis toxin–insensitive G_{q/11} proteins and activate phospholipase C, thereby generating two second messengers, diacylglycerol (a cofactor in the activation of PKC) and inositol trisphosphate (which mobilizes intracellular stores of Ca²⁺). 5-HT_{2A} and 5-HT_{2C} receptors also activate phospholipase A₂, promoting the release of arachidonic acid. 5-HT_{2A} receptors are broadly distributed in the CNS, primarily in serotonergic terminal areas. High densities are found in several brain structures, including prefrontal, parietal, and somatosensory cortex, as well as in blood platelets and smooth muscle cells. 5-HT_{2A} receptors in the GI tract are thought to correspond to the D subtype of 5-HT receptor originally described by Gaddum and Picarelli (1957). 5-HT_{2B} receptors originally were found in stomach fundus, where they are abundant. The expression of 5-HT_{2B} receptors is highly restricted in the CNS. 5-HT_{2C} receptors have a very high density in the choroid plexus, an epithelial tissue that is the primary site of cerebrospinal fluid production. The 5-HT_{2C} receptor has been implicated in the control of cerebrospinal fluid production and in feeding behavior and mood. The 5-HT_{2C} receptor is the only GPCR that is regulated by RNA editing (Burns et al., 1997). Multiple 5-HT_{2C} receptor isoforms are generated by RNA editing, with alterations of three amino acids within the second intracellular loop; extensively edited isoforms have modified G protein–coupling efficiencies (Sanders-Bush et al., 2003). Splice variants of 5-HT_{2A} and 5-HT_{2C} receptors exist but do not code for functional proteins.

- Parks et al., 1998; Saudou et al., 1994; Weisstaub et al., 2007; Nebigil et al., 2000; Tecott et al., 1995; Zeitz et al., 2002; Compan et al., 2004; Grailhe et al., 1999; Bonasera et al., 2006; Hedlund et al., 2003.
Activation of 5-HT3 receptors elicits a rapidly desensitizing depolarization, mediated by the gating of cations. These receptors are located on parasympathetic terminals in the GI tract, including vagal and splanchnic afferents. In the CNS, a high density of 5-HT3 receptors is found in the solitary tract nucleus and in the area postrema. 5-HT3 receptors in both the GI tract and the CNS participate in the emetic response, providing a basis for the anti-emetic property of 5-HT3 receptor antagonists. The 5-HT3 receptor, a pentameric ligand-gated channel, belongs to the Cys-loop receptor superfamily, which includes the nicotinic cholinergic receptor and the GABA_A receptor. The original, cloned 5-HT3 receptor subunit forms functional pentameric complexes that gate cations when expressed in Xenopus oocytes or in cultured cells (Maricq et al., 1991). Five genes (HTR3A-E) for 5-HT3 receptor subunits have now been cloned. Heteropentamers of the multiple gene products exhibit distinct properties and anatomical distributions (see Barnes et al., 2009).

5-HT4 Receptors. 5-HT4 receptors couple to Gs to activate adenylyl cyclase, leading to an increase in intracellular cyclic AMP. 5-HT4 receptors are widely distributed throughout the body. In the CNS, the receptors are found on neurons of the superior and inferior colliculi and in the hippocampus. In the GI tract, 5-HT4 receptors are located on neurons of the myenteric plexus and on smooth muscle and secretory cells. In the GI tract, stimulation of the 5-HT4 receptor is thought to evoke secretion and to facilitate the peristaltic reflex. The latter effect may explain the utility of prokinetic benzamides in GI disorders (Chapter 46). Effects of pharmacological manipulation of 5-HT4 receptors on memory and feeding in animal models suggest possible clinical applications in the future (Bockaert et al. 2008).

Additional Cloned 5-HT Receptors. Two other cloned receptors, 5-HT6 and 5-HT7, are linked to activation of adenylyl cyclase. Multiple splice variants of the 5-HT7 receptor have been found, although functional distinctions are not clear. The absence of selective agonists and antagonists has foiled definitive studies of the role of the 5-HT6 and 5-HT7 receptors. Circumstantial evidence suggests that 5-HT, receptors play a role in the relaxation of smooth muscle in the GI tract and the vasculature. The atypical antipsychotic drug clozapine has a high affinity for 5-HT6 and 5-HT7 receptors; whether this property is related to the broader effectiveness of clozapine compared to conventional antipsychotic drugs is not known (Chapter 16). Two subtypes of the 5-HT6 receptor have been cloned; although the 5-HT6A receptor has been shown to inhibit adenylyl cyclase, functional coupling of the cloned 5-HT6B receptor has not yet been described.

Actions of 5-HT in Physiological Systems

Platelets. Platelets differ from other formed elements of blood in expressing mechanisms for uptake, storage, and endocytotic release of 5-HT. 5-HT is not synthesized in platelets, but is taken up from the circulation and stored in secretory granules by active transport, similar to the uptake and storage of serotonin by serotonergic nerve terminals. Thus, Na+-dependent transport across the surface membrane of platelets, via the 5-HT transporter, is followed by VMAT2-mediated uptake into dense core granules creating a gradient of 5-HT as high as 1000:1 with an internal concentration of 0.6 M in the dense core storage vesicles. Measuring the rate of Na+-dependent 5-HT uptake by platelets provides a sensitive assay for 5-HT uptake inhibitors.

Main functions of platelets include adhesion, aggregation, and thrombus formation to plug holes in the endothelium; conversely, the functional integrity of the endothelium is critical for platelet action. A complex local interplay of multiple factors, including 5-HT, regulates thrombosis and hemostasis (Chapters 30 and 33). When platelets make contact with injured endothelium, they release substances that promote platelet aggregation, and secondarily, they release 5-HT (Figure 13-4). 5-HT binds to platelet 5-HT_A receptors and elicits a weak aggregation response that is markedly augmented by the presence of collagen. If the damaged blood vessel is injured to a depth where vascular smooth muscle is exposed, 5-HT exerts a direct vasoconstrictor effect, thereby contributing to hemostasis, which is enhanced by locally released autacoids (thromboxane A2, kinins, and vasoactive peptides). Conversely, 5-HT may interact with endothelial cells to stimulate production of NO and antagonize its own vasoconstrictor action, as well as the vasoconstriction produced by other locally released agents.

Cardiovascular System. The classical response of blood vessels to 5-HT is contraction, particularly in the splanchnic, renal, pulmonary,
341

and cerebral vasculatures. 5-HT also induces a variety of responses by the heart that are the result of activation of multiple 5-HT receptor subtypes, stimulation or inhibition of autonomic nerve activity, or dominance of reflex responses to 5-HT (Kaumann and Levy, 2006). Thus, 5-HT has positive inotropic and chronotropic actions on the heart that may be blunted by simultaneous stimulation of afferent nerves from baroreceptors and chemoreceptors. Activation of 5-HT$_3$ receptors on vagus nerve endings elicits the Bezold-Jarisch reflex, causing extreme bradycardia and hypotension. The local response of arterial blood vessels to 5-HT also may be inhibitory, the result of stimulation of endothelial NO production and prostaglandin synthesis and blockade of norepinephrine release from sympathetic nerves. On the other hand, 5-HT amplifies the local constrictor actions of norepinephrine, angiotensin II, and histamine, which reinforce the hemostatic response to 5-HT. Presumably, these constrictor effects result, at least in part, from direct action of 5-HT on vascular smooth muscle. In response to IV injection of 5-HT, these disparate effects on blood pressure may be temporally distinct.

GI Tract. Enterochromaffin cells in the gastric mucosa are the site of the synthesis and most of the storage of 5-HT in the body and are the source of circulating 5-HT. These cells synthesize 5-HT from tryptophan, by means of TPH1, and store 5-HT and other autacoids, such as the vasodilator peptide substance P and other kinins. Basal release of enteric 5-HT is augmented by mechanical stretching, such as that caused by food, and by efferent vagal stimulation. Released 5-HT enters the portal vein and is subsequently metabolized by MAO-A in the liver. 5-HT that survives hepatic oxidation may be captured by platelets or rapidly removed by the endothelium of lung capillaries and inactivated. 5-HT released from enterochromaffin cells also acts locally to regulate GI function (Gershon and Tack, 2007). Motility of gastric and intestinal smooth muscle may be either enhanced or inhibited by at least six subtypes of 5-HT receptors (Table 13–3). The stimulatory response occurs at nerve endings on longitudinal and circular enteric muscle (5-HT$_4$ receptors), at postsynaptic cells of the enteric ganglia (5-HT$_3$ and 5-HT$_{1A}$ receptors), and by direct effects of 5-HT on the smooth-muscle cells (5-HT$_{2A}$ receptors in intestine, 5-HT$_{2B}$ receptors in stomach fundus). In esophagus, 5-HT acting at 5-HT$_4$ receptors causes either relaxation or contraction, depending on the species. Abundant 5-HT$_3$ receptors on vagal and other afferent neurons and on enterochromaffin cells play a pivotal role in emesis (Chapter 46). Serotonergic nerve terminals have been described in the myenteric plexus. Enteric 5-HT triggers peristaltic contraction when released in response to acetylcholine, sympathetic nerve stimulation, increases in intraluminal pressure, and lowered pH.

CNS. A multitude of brain functions are influenced by 5-HT, including sleep, cognition, sensory perception, motor activity, temperature regulation, nociception, mood, appetite, sexual behavior, and hormone secretion. All of the cloned 5-HT receptors are expressed in the brain, often in overlapping domains. Although patterns of 5-HT receptor expression in individual neurons have not been extensively defined, it is likely that multiple 5-HT receptor subtypes with similar or opposing actions are expressed in individual neurons (Bonsi et al., 2007), leading to a tremendous diversity of actions.

The principal cell bodies of 5-HT neurons are located in raphe nuclei of the brainstem and project throughout the brain and spinal cord (Chapter 14). In addition to being released at discrete synapses, release of serotonin also seems to occur at sites of axonal swelling, termed varicosities, which do not form distinct synaptic
contacts. 5-HT released at nonsynaptic varicosities is thought to diffuse to outlying targets, rather than acting on discrete synaptic targets. Such non-synaptic release with ensuing widespread effects is consistent with the idea that 5-HT acts as a neuromodulator as well as a neurotransmitter (Chapter 14).

Serotonergic nerve terminals contain the proteins needed to synthesize 5-HT from L-tryptophan (Figure 13–2). Newly formed 5-HT is rapidly accumulated in synaptic vesicles (through VMAT2), where it is protected from MAO. 5-HT released by nerve-impulse flow is reaccumulated into the pre-synaptic terminal by the 5-HT transporter, SERT (SLC6A4; Chapter 5). Pre-synaptic reuptake is a highly efficient mechanism for terminating the action of 5-HT released by nerve-impulse flow. MAO localized in postsynaptic elements and surrounding cells rapidly inactivates 5-HT that escapes neuronal reuptake and storage.

Electrophysiology. The physiological consequences of 5-HT release vary with the brain area and the neuronal element involved, as well as with the population of 5-HT receptor subtype(s) expressed (Bockaert et al., 2006). 5-HT has direct excitatory and inhibitory actions (Table 13–4), which may occur in the same preparation, but with distinct temporal patterns. For example, in hippocampal neurons, 5-HT elicits hyperpolarization mediated by 5-HT$_{1A}$ receptors followed by a slow depolarization mediated by 5-HT$_{4}$ receptors.

5-HT$_{1A}$ receptor–induced membrane hyperpolarization and reduction in input resistance results from an increase in K$^{+}$ conductance. These ionic effects, which are blocked by pertussis toxin, are independent of cAMP, suggesting that 5-HT$_{1A}$ receptors couple, by means of G$_{i}$ subunits, to receptor-operated K$^{+}$ channels (Andrade et al., 1986). Somatodendritic 5-HT$_{1A}$ receptors on raphe cells also elicit a K$^{+}$-dependent hyperpolarization. The G protein involved is pertussis toxin–sensitive, but the K$^{+}$ current apparently is different from the current elicited at postsynaptic 5-HT$_{1A}$ receptors in the hippocampus. The precise signaling mechanism involved in inhibition of neurotransmitter release by the 5-HT$_{1B/1D}$ autoreceptor at synaptic terminals is not known, although inhibition of voltage-gated Ca$^{2+}$ channels likely contributes.

Slow depolarization induced by 5-HT$_{2A}$ receptor activation in areas such as the prefrontal cortex and nucleus accumbens involves a decrease in K$^{+}$ conductance. A second, distinct mechanism involving Ca$^{2+}$-activated membrane currents enhances neuronal excitability and potentiates the response to excitatory signals such as glutamate. The role of intracellular signaling cascades in these physiological actions of 5-HT$_{2A}$ receptors has not been clearly defined. In areas where 5-HT$_{1}$ and 5-HT$_{2A}$ receptors co-exist, the effect of 5-HT may reflect a combination of the two opposing responses: a prominent 5-HT$_{1}$ receptor–mediated hyperpolarization and an opposing 5-HT$_{2A}$ receptor–mediated depolarization. When 5-HT$_{2A}$ receptors are blocked, hyperpolarization is enhanced. In many cortical areas, 5-HT$_{2A}$ receptors are localized on both GABAergic interneurons and pyramidal cells. Activation of interneurons enhances GABA (β-aminobutyric acid) release, which secondarily slows the firing rate of pyramidal cells. Thus, there is the potential for the 5-HT$_{2A}$ receptor to differentially regulate cortical pyramidal cells, depending on the specific target cells (interneurons versus pyramidal cells). Activation of 5-HT$_{4}$ receptors has been shown to depress a K$^{+}$ current, an effect that may contribute to the excitatory response. The 5-HT$_{4}$ receptor, which is coupled to activation of adenyl cyclase, also elicits a slow neuronal depolarization mediated by a decrease in K$^{+}$ conductance. It is not clear why two distinct

ACh, acetylcholine.
5-HT receptor families linked to different signaling pathways can elicit a common neurophysiological action. Yet another receptor, the 5-HT<sub>1P</sub> receptor, elicits a slow depolarization. This receptor, which couples to activation of adenyl cyclase, is restricted to the enteric nervous system (Gershon and Tack, 2007). The unique pharmacological profile of the 5-HT<sub>1P</sub> receptor is most consistent with the 5-HT<sub>7</sub> receptor.

The fast depolarization elicited by 5-HT<sub>3</sub> receptors reflects direct gating of an ion channel intrinsic to the receptor structure itself. The 5-HT<sub>3</sub> receptor-induced inward current has the characteristics of a cation-selective, ligand-operated channel. Membrane depolarization is mediated by simultaneous increases in Na<sup>+</sup> and K<sup>+</sup> conductance, comparable to the nicotinic cholinergic receptor. 5-HT<sub>3</sub> receptors have been characterized in the CNS and in sympathetic ganglia, primary afferent parasympathetic and sympathetic nerves, and enteric neurons. The pharmacological properties of 5-HT<sub>3</sub> receptors, which are different from those of other 5-HT receptors, suggest that multiple 5-HT<sub>3</sub> receptor subtypes may exist and may correspond to different combinations of subunits (Jensen et al., 2008).

**Behavior.** The behavioral alterations elicited by drugs that interact with 5-HT receptors are extremely diverse. Many animal behavioral models for initial assessment of agonist and antagonist properties of drugs depend on aberrant motor or reflex responses, such as startle reflexes, hind-limb abduction, head twitches, and other stereotypical behaviors. Operant behavioral paradigms, such as drug discrimination, provide models of specific 5-HT receptor activation and are useful for exploring the action of CNS-active drugs, including agents that interact with 5-HT. For example, investigations of the mechanism of action of hallucinogenic drugs have relied heavily on drug discrimination (Winter, 2009). The following discussion focuses on animal models that may relate to pathological conditions in humans and will not attempt to cover the voluminous literature dealing with 5-HT and behavior. See King and associates (2008), Lesch and coworkers (2003), Lucki (1998), and Swerdlow and colleagues (2000) for excellent reviews on this topic.

**Sleep-Wake Cycle.** Control of the sleep-wake cycle is one of the first behaviors in which a role for 5-HT was identified. Following pioneering work in cats (Jouvet, 1999), many studies showed that depletion of 5-HT with p-chlorophenylalanine, a tryptophan hydroxylase inhibitor, elicits insomnia that is reversed by the 5-HT precursor, 5-hydroxytryptophan. Conversely, treatment with L-tryptophan or with nonselective 5-HT agonists accelerates sleep onset and prolongs total sleep time. 5-HT antagonists reportedly can increase and decrease slow-wave sleep, probably reflecting interacting or opposing roles for subtypes of 5-HT receptors. One relatively consistent finding in humans and in laboratory animals is an increase in slow-wave sleep following administration of a selective 5-HT<sub>2A</sub> receptor antagonist such as ritanserin.

**Aggression and Impulsivity.** Studies in laboratory animals and in humans suggest that 5-HT serves a critical role in aggression and impulsivity. Many human studies reveal a correlation between low cerebrospinal fluid 5-HIAA and violent impulsivity and aggression. As with many effects of 5-HT, pharmacological studies of aggressive behavior in laboratory animals are not definitive, but suggest a role for 5-HT. Two genetic studies have reinforced and amplified this notion. Knockout mice lacking the 5-HT<sub>1B</sub> receptor exhibited extreme aggression (Saudou et al., 1994), suggesting either a role for 5-HT<sub>1B</sub> receptors in the development of neuronal pathways important in aggression or a direct role in the mediation of aggressive behavior. A human genetic study identified a point mutation in the gene encoding MAO-A, which was associated with extreme aggressiveness and mental retardation (Brunner et al., 1993), and this has been confirmed in knockout mice lacking MAO-A (Cases et al., 1995).

**Anxiety and Depression.** The effects of 5-HT–active drugs in anxiety and depressive disorders, like the effects of selective serotonin reuptake inhibitors (SSRIs), strongly suggest a role for 5-HT in the neurochemical mediation of these disorders. Mutant mice lacking the 5-HT transporter display anxiety and a “depressive-like” phenotype (Fox et al., 2007). 5-HT-related drugs with clinical effects in anxiety and depression have varied effects in classical animal models of these disorders, depending on the experimental paradigm, species, and strain. For example, the anxiolytic buspirone (Chapter 15), a partial agonist at 5-HT<sub>1A</sub> receptors, does not reduce anxiety in classical approach-avoidance paradigms that were instrumental in development of anxiolytic benzodiazepines. However, buspirone and other 5-HT<sub>1A</sub> receptor agonists are effective in other animal behavioral tests used to predict anxiolytic effects. Furthermore, studies in 5-HT<sub>1A</sub> receptor knockout mice suggest a role for this receptor in anxiety, and possibly depression. Agonists of certain 5-HT receptors, including 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors (e.g., m-chlorophenylpiperazine), have anxiogenic properties in laboratory animals and in human studies. Similarly, these receptors have been implicated in the animal models of depression, such as learned helplessness.

An impressive finding in humans with depression is the abrupt reversal of the antidepressant effects of drugs such as SSRIs by manipulations that rapidly reduce the amount of 5-HT in the brain. These approaches include administration of p-chlorophenylalanine or a tryptophan-free drink containing large quantities of neutral amino acids (Delgado et al., 1990). Curiously, this kind of 5-HT depletion has not been shown to worsen or to induce depression in nondepressed subjects, suggesting that the continued presence of 5-HT is required to maintain the effects of these drugs. This clinical finding adds credence to somewhat less convincing neurochemical findings that suggest a role for 5-HT in the pathogenesis of depression.

**Pharmacological Manipulation of the Amount of 5-HT in Tissues.**

A highly specific mechanism for altering synaptic availability of 5-HT is inhibition of presynaptic reaccumulation of neuronally released 5-HT. Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine (PROZAC, others), potentiate and prolong the action of 5-HT released by neuronal activity. When co-administered with L-5-hydroxytryptophan, SSRIs elicit a profound activation of serotonergic responses. SSRIs (citalopram [CELEXA], escitalopram [LEXAPRO], fluoxetine, fluvoxamine, paroxetine [PAXIL], and sertraline [ZOLOFT]) are the most widely used treatment for endogenous depression (Chapter 15). Sibutramine (MERIDIA), an inhibitor of the reuptake of 5-HT, NE, and DA, is used as an appetite...
suppressant in the management of obesity. The drug is converted to two active metabolites that contribute to its therapeutic effects. The relative importance of effects on single or multiple neurotransmitters in sibutramine’s anti-obesity action is unclear. Sibutramine is classified as a selective serotonin/ norepinephrine reuptake inhibitor (SNRI). Other SNRIs include duloxetine (Cymbalta; approved for depression, anxiety, peripheral neuropathy, and fibromyalgia), venlafaxine (Effexor; approved for the treatment of depression, anxiety, and panic disorders), desvenlafaxine (Pristiq; approved for depression), and milnacipran (Savella; approved for fibromyalgia).

Nonselective treatments that alter 5-HT levels include MAO inhibitors (e.g., phenelzine [Nardil], tranylcypromine [Parnate, others], and isocarboxazid [Marplan]) and reserpine. MAO inhibitors block the principal route of degradation, thereby increasing levels of 5-HT, whereas reserpine, a VMAT2 inhibitor, depletes intraneuronal stores of 5-HT. These treatments profoundly alter levels of 5-HT throughout the body. Because reserpine and MAO inhibitors also cause comparable changes in the levels of catecholamines, the drugs are of limited utility as research tools. Both agents have been used in the treatment of mental diseases: reserpine as an antipsychotic drug (Chapter 16) and MAO inhibitors as antidepressants (Chapter 15).

Experimental strategies for evaluating the role of 5-HT depend on techniques that manipulate tissue levels of 5-HT or block 5-HT receptors. Until recently, manipulation of the levels of endogenous 5-HT was the more commonly used strategy, because the actions of 5-HT receptor antagonists were poorly understood.

Tryptophan hydroxylase is the rate-limiting enzyme in 5-HT synthesis, and manipulation of its catalytic flux provides useful ways to alter 5-HT levels. A diet low in tryptophan reduces the concentration of brain 5-HT; conversely, ingestion of a tryptophan load increases levels of 5-HT in the brain. An acute decrease in brain 5-HT can be achieved by oral administration of an amino acid mixture devoid of tryptophan, a valuable tool for human studies of the role of 5-HT. In addition, administration of a tryptophan hydroxylase inhibitor causes a profound depletion of 5-HT. The most widely used selective tryptophan hydroxylase inhibitor is p-chlorophenylalanine, which acts irreversibly to produce long-lasting depletion of 5-HT levels with no change in levels of catecholamines.

p-Chloroamphetamine and other halogenated amphetamines promote the release of 5-HT from platelets and neurons. A rapid release of 5-HT is followed by a prolonged and selective depletion of 5-HT in brain. The mechanism of 5-HT release involves reversal of 5-HT transporter, analogous to the mechanism of the catecholamine-releasing action of amphetamine. The halogenated amphetamines are valuable experimental tools and two of them, fenfluramine and dexfenfluramine, were used clinically to reduce appetite; the once popular diet drug regimen, “fen-phen,” combined fenfluramine and phentermine. Fenfluramine (Pondimin) and dexfenfluramine (Redux) were withdrawn from the U.S. market in the late 1990s after reports of life-threatening heart valve disease and pulmonary hypertension associated with their use. This toxicity may be secondary to 5-HT₂B receptor activation (Roth, 2007). The mechanism for long-term depletion of brain 5-HT by the halogenated amphetamines remains controversial. A profound reduction in levels of 5-HT in the brain lasts for weeks and is accompanied by an equivalent loss of proteins (5-HT transporter and tryptophan hydroxylase) selectively localized in 5-HT neurons, suggesting that the halogenated amphetamines have a neurotoxic action. Despite these long-lasting biochemical deficits, neuroanatomical signs of neuronal death are not readily apparent. Another class of compounds, ring-substituted tryptamine derivatives such as 5,7-dihydroxytryptamine (Figure 13–1) produces unequivocal degeneration of 5-HT neurons. In adult animals, 5,7-dihydroxytryptamine selectively destroys serotonergic axon terminals; the remaining intact cell bodies allow eventual regeneration of axon terminals. In newborn animals, degeneration is permanent because 5,7-dihydroxytryptamine destroys serotonergic cell bodies as well as axon terminals.

5-HT Receptor Agonists and Antagonists

5-HT Receptor Agonists

Direct-acting 5-HT receptor agonists have widely different chemical structures, as well as diverse pharmacological properties (Table 13–5), as might be predicted from the multiplicity of 5-HT receptor subtypes. 5-HT₁A receptor–selective agonists have helped elucidate the functions of this receptor in the brain and have resulted in a new class of antianxiety drugs including buspirone (Buspar, others) and the investigational agents, gepirone (Chapter 15). 5-HT₁B/1D receptor–selective agonists, such as sumatriptan, have unique properties that result in constriction of intracranial blood vessels that are effective in the treatment of acute migraine attacks. A number of 5-HT₄ receptor–selective agonists have been developed or are being developed for the treatment of disorders of the GI tract (Chapter 46). These classes of selective 5-HT receptor agonists are discussed in more detail in the chapters that deal directly with treatment of the relevant pathological conditions.

5-HT Receptor Agonists and Migraine. Migraine headache afflicts 10-20% of the population. Although migraine is a specific neurological syndrome, the manifestations vary widely. The principal types are migraine without aura (common migraine); migraine with aura (classic migraine, which includes subclasses of migraine with typical aura, migraine with prolonged aura, migraine aura without headache, and migraine with acute-onset aura), and several rarer types. Premonitory aura may begin as long as 24 hours before the onset of pain and often is accompanied by

Photophobia, hyperacusis, polyuria, and diarrhea, and by disturbances of mood and appetite. A migraine attack may last for hours or days and be followed by prolonged pain-free intervals. The frequency of migraine attacks is extremely variable. Therapy of migraine headaches is complicated by the variable responses among and within individual patients and by the lack of a firm understanding of the pathophysiology of the syndrome. The efficacy of anti-migraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and as yet undefined environmental and genetic factors (Silberstein, 2008).

The pathogenesis of migraine headache is complex, involving both neural and vascular elements (Mehrotra et al., 2008). Evidence suggesting that 5-HT is a key mediator in the pathogenesis of migraine includes:

- plasma and platelet concentrations of 5-HT vary with the different phases of the migraine attack
- urinary concentrations of 5-HT and its metabolites are elevated during most migraine attacks
- migraine may be precipitated by agents (e.g., reserpine and fenfluramine) that release 5-HT from intracellular storage sites

Consistent with the 5-HT hypothesis, 5-HT receptor agonists have become a mainstay for acute treatment of migraine headaches. Treatments for the prevention of migraines, such as β adrenergic antagonists and newer anti-epileptic drugs, have mechanisms of action that are, presumably, unrelated to 5-HT (Mehrotra et al., 2008).

5-HT<sub>1</sub> Receptor Agonists

The Triptans. The triptans are effective, acute anti-migraine agents. Their ability to decrease, rather than exacerbate, the nausea and vomiting of migraine is an important advance in the treatment of the condition. The selective pharmacological effects of the triptans at 5-HT<sub>1</sub> receptors has provided insights into the pathophysiology of migraine. Available compounds include almotriptan (AXERT), eletriptan (RELPAK), frovatriptan (FROVA), naratriptan (AMERGE), rizatriptan (MAXALT, others), sumatriptan (IMITREX, others), and zolmitriptan (ZOMIG). Sumatriptan for migraine headaches is also marketed in a fixed-dose combination with naproxen (TREXIMIT).

**History.** Sumatriptan emerged from the first experimentally based approach to identify and develop a novel therapy for migraine. In 1972, Humphrey and colleagues initiated a project aimed at identifying novel therapeutic agents in the treatment of migraine with the goal of developing selective vasoconstrictors of the extracranial circulation, based on the theories of the etiology of migraine prevalent in the early 1970s (Humphrey et al., 1990). Sumatriptan, first synthesized in 1984, became available for clinical use in the United States in 1992; since then, several other triptans have been FDA-approved for clinical use. The second generation triptans have higher oral bioavailability.

**Chemistry.** The triptans are indole derivatives. Representative structures are given in Figure 13–5.

**Pharmacological Properties.** In contrast to ergot alkaloids (described later), the pharmacological effects of the triptans appear to be limited to the 5-HT<sub>1</sub> family of receptors, providing evidence that this receptor subclass plays an important role in the acute relief of a migraine attack. The triptans interact potently with 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors and have a low or no affinity for other subtypes of 5-HT receptors, as well as α<sub>1</sub> and α<sub>2</sub> adrenergic, β adrenergic, dopaminergic, muscarinic cholinergic, and benzodiazepine receptors. Clinically effective doses of the triptans correlate well with their affinities for both 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors, supporting the hypothesis that 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors are the most likely receptors involved in the mechanism of action of acute anti-migraine drugs.

**Mechanism of Action.** There remains a controversy about the relative importance of vascular versus neurological dysfunction in migraine; thus the mechanism of the efficacy of 5-HT<sub>1D</sub> agonists in migraine is not resolved. One hypothesis implicates the capacity of these receptors to cause constriction of intracranial blood vessels including arteriovenous anastomoses. According to a prominent pathophysiological model of migraine, unknown events lead to the abnormal dilation of carotid arteriovenous anastomoses in the head and shunting of carotid arterial blood flow, producing cerebral ischemia and hypoxia. Based on this model, an effective anti-migraine agent would close the shunts and restore blood flow to the brain. Indeed,
ergotamine, dihydroergotamine, and sumatriptan share the capacity to produce this vascular effect with a pharmacological specificity that mirrors the effects of these agents on 5-HT₁ receptors. An alternative hypothesis concerning the significance of one or more 5-HT₁ receptors in migraine pathophysiology relates to the observation that both 5-HT₁A and 5-HT₁D receptors serve as presynaptic autoreceptors, modulating neurotransmitter release from neuronal terminals (Figure 13–5). 5-HT₁ agonists may block the release of pro-inflammatory neuropeptides at the level of the nerve terminal in the perivascular space, which could account for their efficacy in the acute treatment of migraine.

Absorption, Fate, and Excretion. When given subcutaneously, sumatriptan reaches its peak plasma concentration in ~12 minutes. Following oral administration, peak plasma concentrations occur within 1-2 hours. Bioavailability following the subcutaneous route of administration is ~97%; after oral administration or nasal spray, bioavailability is only 14-17%. The elimination t½ is ~1-2 hours. Sumatriptan is metabolized predominantly by MAO-A, and its metabolites are excreted in the urine.

Zolmitriptan reaches its peak plasma concentration 1.5-2 hours after oral administration. Its bioavailability is ~40% following oral ingestion. Zolmitriptan is converted to an active N-desmethyl metabolite, which has severalfold higher affinity for 5-HT₁A and 5-HT₁D receptors than does the parent drug. Both the metabolite and the parent drug have half-lives of 2-3 hours.

Naratriptan, administered orally, reaches its peak plasma concentration in 2-3 hours and has an absolute bioavailability of ~70%. It is the second longest acting of the triptans, having a t½ of ~6 hours. Fifty percent of an administered dose of naratriptan is excreted unchanged in the urine, and ~30% is excreted as products of oxidation by CYPs.

Rizatriptan has an oral bioavailability of ~45% and reaches peak plasma levels within 1-1.5 hours after oral ingestion of tablets of the drug. An orally disintegrating dosage form has a somewhat slower rate of absorption, yielding peak plasma levels of the drug 1.6-2.5 hours after administration. The principal route of metabolism of rizatriptan is by oxidative deamination by MAO-A.

Plasma protein binding of the triptans ranges from ~14% (sumatriptan and rizatriptan) to 85% (eletriptan).

Adverse Effects and Contraindications. Rare but serious cardiac events have been associated with the administration of 5-HT₁ agonists, including coronary artery vasospasm, transient myocardial ischemia, atrial and ventricular arrhythmias, and myocardial infarction, predominantly in patients with risk factors for coronary artery disease. In general, however, only minor side effects are seen with the triptans in the acute treatment of migraine. After subcutaneous injection of sumatriptan, patients often experience irritation at the site of injection (transient mild pain, stinging, or burning sensations). The most common side effect of sumatriptan nasal spray is a bitter taste. Orally administered triptans can cause paresthesias; asthenia and fatigue; flushing; feelings of pressure, tightness, or pain in the chest, neck, and jaw; drowsiness; dizziness; nausea; and sweating.

The triptans are contraindicated in patients who have a history of ischemic or vasospastic coronary artery disease (including history of stroke or transient ischemic attacks), cerebrovascular or peripheral vascular disease, hemiplegic or basilar migraines, other significant cardiovascular diseases, or ischemic bowel diseases. Because triptans may cause an acute, usually small, increase in blood pressure, they also are contraindicated in patients with uncontrolled hypertension. Naratriptan is contraindicated in patients with severe renal or hepatic impairment. Rizatriptan should be used with caution in patients with renal or hepatic disease but is not contraindicated in such patients. Eletriptan is contraindicated in hepatic disease. Almotriptan, rizatriptan, sumatriptan, and zolmitriptan are contraindicated in patients who have taken a monoamine oxidase inhibitor within the preceding 2 weeks, and all triptans are contraindicated in patients with near-term prior exposure to ergot alkaloids or other 5-HT₁ agonists.

Use in Treatment of Migraine. The triptans are effective in the acute treatment of migraine (with or without aura), but are not intended for use in prophylaxis of migraine. Treatment with triptans should begin as soon as possible after onset of a migraine attack. Oral dosage forms of the triptans are the most convenient to use, but they may not be practical in patients experiencing migraine-associated nausea and vomiting. Approximately 70% of individuals report significant headache relief from a 6-mg subcutaneous dose of sumatriptan. This dose may be repeated once within a 24-hour period if the first dose does not relieve the headache. An oral formulation and a nasal spray of sumatriptan also are available. The onset of
action is as early as 15 minutes with the nasal spray. The recommended oral dose of sumatriptan is 25-100 mg, which may be repeated after 2 hours up to a total dose of 200 mg over a 24-hour period. When administered as nasal spray, from 5-20 mg of sumatriptan is recommended, repeatable after 2 hours up to a maximum dose of 40 mg over a 24-hour period. Zolmitriptan is given orally in a dose of 1.25-2.5 mg, which can be repeated after 2 hours, up to a maximum dose of 10 mg over 24 hours if the migraine attack persists. Naratriptan is given orally in a dose of 1-2.5 mg, which should not be repeated until 4 hours after the previous dose. The maximum dose over a 24-hour period should not exceed 5 mg. The recommended oral dose of rizatriptan is 5-10 mg. The dose can be repeated after 2 hours up to a maximum dose of 30 mg over a 24-hour period. The safety of treating more than 3 or 4 headaches over a 30-day period with triptans has not been established. No triptan should be used concurrently with (or within 24 hours of) an ergot derivative (described later) or another triptan.

**Ergot and the Ergot Alkaloids.** The elucidation of the constituents of ergot and their complex actions was an important chapter in the evolution of modern pharmacology, even though the very complexity of their actions limits their therapeutic uses. The pharmacological effects of the ergot alkaloids are varied and complex; in general, the effects result from their actions as partial agonists or antagonists at serotonergic, dopaminergic, and adrenergic receptors. The spectrum of effects depends on the agent, dosage, species, tissue, physiological and endocrinological state, and experimental conditions.

**History.** Ergot is the product of a fungus (*Claviceps purpurea*) that grows on rye and other grains. The contamination of an edible grain by a poisonous, parasitic fungus spread death for centuries. As early as 600 B.C., an Assyrian tablet alluded to a “noxious pustule in the ear of grain.” Written descriptions of ergot poisoning first appeared in the Middle Ages, describing strange epidemics in which the characteristic symptom was gangrene of the feet, legs, hands, and arms. In severe cases, extremities became dry and black, and mummified limbs separated off without loss of blood. Limbs were said to be consumed by the holy fire, blackened like charcoal with agonizing burning sensations, the disease was called holy fire or St. Anthony’s fire in honor of the saint at whose shrine relief was said to be obtained. The relief that followed migration to the shrine of St. Anthony was probably real, for the sufferers received a diet free of contaminated grain during their sojourn at the shrine. The symptoms of ergot poisoning were not restricted to limbs. A frequent complication of it was a dramatic abortive effect of ergot ingested during pregnancy. The active principles of ergot were isolated and chemically identified in the early 20th century.

**Chemistry.** The ergot alkaloids can all be considered to be derivatives of the tetracyclic compound 6-methylergoline (Table 13–6). The naturally occurring alkaloids contain a substituent in the beta configurations at position 8 and a double bond in ring D. The natural alkaloids of therapeutic interest are amide derivatives of d-lysergic acid. The first pure ergot alkaloid, ergotamine, was obtained in 1920, followed by the isolation of ergonovine in 1932. Numerous semi-synthetic derivatives of the ergot alkaloids have been prepared by catalytic hydrogenation of the natural alkaloids (e.g., dihydroergotamine). Another synthetic derivative, bromocriptine (2-bromo-d-ergocryptine), is used to control the secretion of prolactin, a property derived from its DA agonist effect. Other products of this series include lysergic acid diethylamide (LSD), a potent hallucinogen, and methysergide, a serotonin antagonist.

**Absorption, Fate, and Excretion.** The oral administration of ergotamine by itself generally results in low or undetectable systemic drug concentrations, because of extensive first-pass metabolism. The bioavailability after administration of rectal suppositories is greater. Ergotamine is metabolized in the liver by largely undefined pathways, and 90% of the metabolites are excreted in the bile. Despite a plasma t1/2 of ~2 hours, ergotamine produces vasoconstriction that lasts for 24 hours or longer. Dihydroergotamine is eliminated more rapidly than ergotamine, presumably due to its rapid hepatic clearance.

Ergonovine and methylergonovine are rapidly absorbed after oral administration and reach peak concentrations in plasma within 60-90 minutes that are more than 10-fold those achieved with an equivalent dose of ergotamine. Although often given IV, an uterine effect in postpartum women can be observed within 10 minutes after oral administration of 0.2 mg of ergonovine. The t1/2 of methylergonovine in plasma ranges between 0.5 and 2 hours.

**Use in the Treatment of Migraine.** The multiple pharmacological effects of ergot alkaloids have complicated the determination of their precise mechanism of action in the acute treatment of migraine. Based on the mechanism of action of sumatriptan and other 5-HT1B/1D receptor agonists, the actions of ergot alkaloids at 5-HT1B/1D receptors likely mediate their acute anti-migraine effects.

The use of ergot alkaloids for migraine should be restricted to patients having frequent, moderate migraine or infrequent, severe migraine attacks. As with other medications used to abort an attack, ergot preparations should be administered as soon as possible after the onset of a headache. GI absorption of ergot alkaloids is erratic, perhaps contributing to the large variation in patient response to these drugs. Available preparations currently in the United States include sublingual tablets of ergotamine tartrate (ERGOMAR) and a nasal spray and solution for injection of dihydroergotamine mesylate (MIGRANAL, D.H.E. 45, respectively). Ergotamine in fixed-dose combinations with caffeine is also marketed under the brand names of CAFERGOT (oral tablets) and MIGERGOT (rectal suppositories) and as generic formulations (oral tablets). The recommended dose for ergotamine tartrate is 2 mg sublingually, which can be repeated at 30-minute intervals if necessary up to a total dose of 6 mg in a 24-hour period or 10 mg a week. Dihydroergotamine mesylate injections can be given intravenously, subcutaneously, or intramuscularly. The recommended dose is 1 mg, which can be repeated after 1 hour if necessary up to a total dose of 2 mg (intravenously) or 3 mg (subcutaneously or intramuscularly) in a 24-hour period or 6 mg in a week. The dose of dihydroergotamine mesylate administered as a nasal spray is 0.5 mg (one spray) in each nostril, repeated after 15 minutes for a total dose of 2 mg (4 sprays). The safety of > 3 mg over 24 hours or 4 mg over 7 days has not been established.

**Adverse Effects and Contraindications of Ergot Alkaloids.** Nausea and vomiting, due to a direct effect on CNS emetic centers, occur in ~10% of patients after oral administration of ergotamine, and in
about twice that number after parenteral administration. This side effect is problematic, since nausea and sometimes vomiting are part of the symptomatology of a migraine headache. Leg weakness is common, and muscle pains that occasionally are severe may occur in the extremities. Numbness and tingling of fingers and toes are other reminders of the ergotism that this alkaloid may cause. Precordial distress and pain suggestive of angina pectoris, as well as transient tachycardia or bradycardia, also have been noted, presumably as a result of coronary vasospasm induced by ergotamine. Localized edema and itching may occur in an occasional hypersensitive patient, but usually do not necessitate interruption of ergotamine therapy. In the event of acute or chronic poisoning (ergotism), treatment consists of complete withdrawal of the offending drug and symptomatic measures to maintain adequate circulation by agents such as anticoagulants, low-molecular-weight dextran, and potent vasodilator drugs such as intravenous sodium nitroprusside. Dihydroergotamine has lower potency than does ergotamine as an emetic, vasoconstrictor, and oxytocic.

Ergot alkaloids are contraindicated in women who are, or may become, pregnant because the drugs may cause fetal distress and miscarriage. Ergot alkaloids also are contraindicated in patients with peripheral vascular disease, coronary artery disease, hypertension, impaired hepatic or renal function, and sepsis. Ergot alkaloids should not be taken within 24 hours of the use of the triptans, and should not be used concurrently with other drugs that can cause vasoconstriction.

**Use of Ergot Alkaloids in Postpartum Hemorrhage.** All of the natural ergot alkaloids markedly increase the motor activity of the uterus. After small doses, uterine contractions are increased in force or frequency, or both, but are followed by a normal degree of relaxation. As the dose is increased, contractions become more forceful and prolonged, resting tone is dramatically increased, and sustained contracture can result. Although this characteristic precludes their use for induction or facilitation of labor, it is quite compatible with their use postpartum or after abortion to control bleeding and maintain uterine contraction. The gravid uterus is very sensitive, and small doses of ergot alkaloids can be given immediately postpartum to obtain a marked uterine response, usually without significant side effects. In current obstetric practice,
ergot alkaloids are used primarily to prevent postpartum hemorrhage. Although all natural ergot alkaloids have qualitatively the same effect on the uterus, ergonovine is the most active and also is less toxic than ergotamine. For these reasons ergonovine (ERGO-TRATE) and its semisynthetic derivative methylergonovine (METHERGINE, others) have replaced other ergot preparations as uterine-stimulating agents in obstetrics.

**Methysergide.** Methysergide (SANSERT; 1-methyl-\textit{d}-lysergic acid butanolamide) is a congener of methylergonovine (Table 13–6). Reflecting the fickle nature of the ergot compounds, methysergide is neither a selective antagonist nor always an antagonist. It interacts with 5-HT receptors, but its therapeutic effects appear primarily to reflect blockade of 5-HT\textsubscript{1A} receptors; it blocks 5-HT\textsubscript{2A} and 5-HT\textsubscript{2C} receptors, but has partial agonist activity in some preparations. Although methysergide is an ergot derivative, it has only weak vasoconstrictor and oxytocic activity.

Methysergide is without benefit when given during an acute migraine attack but has been used for the prophylactic treatment of migraine and other vascular headaches, including Horton’s syndrome. A potentially serious complication of prolonged treatment is inflammatory fibrosis, giving rise to various syndromes that include retroperitoneal fibrosis, pleuropulmonary fibrosis, and coronary and endocardial fibrosis. Usually the fibrosis regresses after drug withdrawal, although persistent cardiac valvular damage has been reported. Because of this danger, other drugs are preferred for the prophylactic treatment of migraine (see the earlier discussion of migraine therapy). If methysergide is used chronically, treatment should be interrupted for 3 weeks or more every 6 months. Methysergide is not available in the U.S.

**D-Lysergic Acid Diethylamide (LSD).** Of the many drugs that are non-selective 5-HT\textsubscript{1A} agonists, LSD (see structure in Table 13–6) is the most remarkable. This ergot derivative profoundly alters human behavior, eliciting perception disturbances such as sensory distortion (especially visual) and hallucinations at doses as low as 1 \textmu g/kg. The potent, mind-altering effects of LSD explain its abuse by humans (Chapter 24), as well as the fascination of scientists with the mechanism of action of LSD.

LSD was synthesized in 1943 by Albert Hoffman, who discovered its unique properties by accidental ingestion of the drug. The chemical precursor, lysergic acid, occurs naturally in a fungus that grows on wheat and rye but is devoid of hallucinogenic actions. LSD contains an indolealkylamine moiety embedded within its structure, and early investigators postulated that it would interact with 5-HT receptors. Indeed, LSD interacts with brain 5-HT receptors as an agonist/partial agonist. LSD mimics 5-HT at 5-HT\textsubscript{1A} autoreceptors on raphe cell bodies, producing a marked slowing of the firing rate of serotonergic neurons. In the raphe, LSD and 5-HT are equi-effective; however, in areas of serotonergic axonal projections (such as visual relay centers), LSD is far less effective than is 5-HT. In an animal behavioral model thought to reflect the subjective effects of abused drugs, the discriminative stimulus effects of LSD and other hallucinogenic drugs appear to be mediated by activation of 5-HT\textsubscript{2A} receptors (Winter, 2009). Recent studies of 5-HT\textsubscript{2A} receptor knockout mice confirm the critical role for this receptor in LSD hallucinogenic effects (González-Maeso et al., 2007). LSD also interacts potently with many other 5-HT receptors, including cloned receptors whose functions have not yet been determined. On the other hand, the hallucinogenic phenethylamine derivatives such as 1-(4-bromo-2,5-dimethoxyphenyl)-2-amino propane are selective 5-HT\textsubscript{1A/2C} receptor agonists. Current theories of the mechanism of action of LSD and other hallucinogens focus on 5-HT\textsubscript{2A} receptor-mediated dislocation of thalamic gating with sensory overload of the cortex (Geyer and Vollenweider, 2008). Progress in understanding the unusual properties of hallucinogens are arising from clinical investigations. For example, positron emission tomography imaging studies revealed that administration of the hallucinogen psilocybin (the active component of “shrooms”) mimics the pattern of brain activation found in schizophrenic patients experiencing hallucinations. Consistent with animal studies, this action of psilocybin is blocked by pretreatment with a 5-HT\textsubscript{2A/2C} antagonist.

8-Hydroxy-(2-N,N-Dipropylamino)-Tetraline (8-OH-DPAT). This prototypic 5-HT\textsubscript{1A}-selective receptor agonist is a valuable experimental tool.

8-OH-DPAT is considered to be a 5-HT\textsubscript{1A} selective agonist. It does not interact with other members of the 5-HT\textsubscript{1}-receptor subfamily or with 5-HT\textsubscript{2}, 5-HT\textsubscript{3}, or 5-HT\textsubscript{4} receptors, although activation of the 5-HT\textsubscript{1A} receptor has been reported. 8-OHDPAT reduces the firing rate of raphe cells by activating 5-HT\textsubscript{1A} autoreceptors and inhibits neuronal firing in terminal fields (e.g., hippocampus) by direct interaction with postsynaptic 5-HT\textsubscript{1A} receptors.

**Buspirone (BUSPAR, others).** A series of long-chain arylpiperazines, such as buspirone, gepirone, and ipsapirone, are selective partial agonists at 5-HT\textsubscript{1A} receptors. Other closely related arylpiperazines act as 5-HT\textsubscript{1A}-receptor antagonists. Buspirone, the first clinically available drug in this series, has been effective in the treatment of anxiety (Chapter 15). Buspirone mimics the anxiolytic properties of benzodiazepines but does not interact with GABA\textsubscript{A} receptors and or display the sedative and anticonvulsant properties of benzodiazepines. The absence of sedative effects may explain why patients prefer the benzodiazepines to relieve anxiety.

**m-Chlorophenylpiperazine (mCPP).** The actions of mCPP in vivo primarily reflect activation of 5-HT\textsubscript{1B} and/or 5-HT\textsubscript{2A/2C} receptors, although this agent is not subtype selective in radioligand-binding studies in vitro.
mCPP, an active metabolite of the antidepressant drug trazodone, has been employed to probe brain 5-HT function in humans, where it alters a number of neuroendocrine parameters and elicits profound behavioral effects, with anxiety as a prominent symptom. Animal studies suggest a greater involvement of the 5-HT2c receptor in the anxiogenic actions of mCPP. mCPP elevates cortisol and prolactin secretion, probably through a combination of 5-HT1 and 5-HT2A/C receptor activation. It also increases growth hormone secretion, apparently by a 5-HT independent mechanism.

5-HT Receptor Antagonists

The properties of 5-HT receptor antagonists also vary widely. Ergot alkaloids and related compounds tend to be nonspecific 5-HT receptor antagonists; however, a few ergot derivatives, such as metergoline, bind preferentially to members of the 5-HT2 receptor family. A number of selective antagonists for 5-HT2A/C and 5-HT3 receptors are currently available. Members of these drug classes have widely different chemical structures, with no common structural motif predictably conveying high affinity. Ketanserin is the prototypic 5-HT2A receptor antagonist. A large series of 5-HT3 receptor antagonists are being explored for treatment of various GI disturbances (e.g., ondansetron [ZOFRA]), dolasetron [ANZEMET], granisetron [KYTRIL], and palonosetron [ALOXI]). All 5-HT3 receptor antagonists have proven to be highly efficacious in the treatment of chemotherapy-induced nausea, and alosetron (LOTRONEX) is licensed for irritable bowel syndrome (Chapter 46).

Clinical effects of 5-HT related drugs often exhibit a significant delay in onset. This is particularly the case with drugs used to treat affective disorders such as anxiety and depression (see Chapter 15). This delayed onset has generated considerable interest in potential adaptive changes in 5-HT receptor density and sensitivity after chronic drug treatments.

Laboratory studies have documented agonist-promoted receptor subsensitivity and down-regulation of 5-HT receptor subtypes, a compensatory response common to many neurotransmitter systems. However, an unusual adaptive process, antagonist-induced down-regulation of 5-HT1/5-HT2 receptors, takes place in rats and mice after chronic treatment with receptor antagonists (Gray and Roth, 2001). The mechanism of this paradoxical regulation of 5-HT2A/C receptors has generated considerable interest, since many clinically effective drugs, including clozapine, ketanserin (not licensed for use in the U.S.), and amitriptyline, exhibit this unusual property. These drugs, as well as several other 5-HT2A/C-receptor antagonists, possess negative intrinsic activity, reducing constitutive (spontaneous) receptor activity as well as blocking agonist occupancy. This property of negative intrinsic activity or inverse agonism is frequently observed when constitutive (agonist-independent) activity can be measured; in the absence of constitutive activity, inverse agonists behave as competitive antagonists. Another group of 5-HT2A/C receptor antagonists acts in the classical manner, simply blocking receptor occupancy by agonists. Recent evidence for constitutive activity of the 5-HT2c receptor in vivo (Aloyo et al., 2009) justifies refinement of drug development to target pre-existing constitutive neuronal activity as opposed to blockade of excess neurotransmitter action.

Ketanserin. Ketanserin (SUFREXAL, others) opened a new era in 5-HT receptor pharmacology. Ketanserin potently blocks 5-HT2A receptors, less potently blocks 5-HT2C receptors, and has no significant effect on 5-HT1A or 5-HT1D receptors or any members of the 5-HT1-receptor family. Notably, ketanserin also has high affinity for α1 adrenergic receptors and histamine H1 receptors.

Ketanserin lowers blood pressure in patients with hypertension, causing a reduction comparable to that seen with β adrenergic-receptor antagonists or diuretics. The drug appears to reduce the tone of both capacitance and resistance vessels. This effect likely relates to its blockade of α1 adrenergic receptors, not its blockade of 5-HT2A receptors. Ketanserin inhibits 5-HT-induced platelet aggregation, but it does not greatly reduce the capacity of other agents to cause aggregation. Severe side effects after treatment with ketanserin have not been reported. Its oral bioavailability is ~50%, and its plasma t1/2 is 12-25 hours. The primary mechanism of inactivation is hepatic metabolism. Ketanserin is not marketed in the U.S. but is available in Europe.

Chemical relatives of ketanserin such as ritanserin are more selective 5-HT2A receptor antagonists with low affinity for α1 adrenergic receptors. However, ritanserin, as well as most other 5-HT2A receptor antagonists, also potently antagonize 5-HT2C receptors. The physiological significance of 5-HT2C-receptor blockade is unknown. M100,907 is the prototype of a new series of potent 5-HT2A receptor antagonists, with high selectivity for 5-HT2A versus 5-HT2C receptors. Clinical trials of M100,907 in the treatment of schizophrenia have been inconclusive.

Atypical Antipsychotic Drugs. Clozapine (CLOZARIL, others), a 5-HT2A/C receptor antagonist, represents a class of atypical antipsychotic drugs with reduced incidence of extrapyramidal side effects compared to the classical neuroleptics, and possibly a greater efficacy for reducing negative symptoms of schizophrenia (Chapter 16). Clozapine also has a high affinity for subtypes of DA receptors.

A common strategy for the design of additional atypical antipsychotic drugs is to combine 5-HT2A/C and...
dopamine D<sub>2</sub> receptor–blocking actions in the same molecule (Meltzer and Huang, 2008). Risperidone (RISPERDAL, others), for example, is a potent 5-HT<sub>2A</sub> and D<sub>2</sub> receptor antagonist. Low doses of risperidone have been reported to attenuate negative symptoms of schizophrenia with a low incidence of extrapyramidal side effects. Extrapyramidal effects are commonly seen, however, with doses of risperidone in excess of 6 mg/day. Other atypical antipsychotic agents—quetiapine (SEROQUEL) and olanzapine (ZYPREXA)—act on multiple receptors, but their antipsychotic properties are thought to be due to antagonism of DA and 5-HT.

**Cyproheptadine.** The structure of cyproheptadine resembles that of the phenothiazine histamine H<sub>1</sub> receptor antagonists, and indeed, cyproheptadine is an effective H<sub>1</sub> receptor antagonist. Cyproheptadine also has prominent 5-HT blocking activity on smooth muscle by virtue of its binding to 5-HT<sub>2A</sub> receptors. In addition, it has weak anticholinergic activity and possesses mild CNS depressant properties.

Cyproheptadine shares the properties and uses of other H<sub>1</sub> receptor antagonists (Chapter 32). In allergic conditions, the action of cyproheptadine as a 5-HT receptor antagonist is irrelevant, since 5-HT<sub>2A</sub> receptors are not involved in human allergic responses. The 5-HT blocking actions of cyproheptadine explain its value in the off-label uses for postgastrectomy dumping syndrome, intestinal hypermotility of carcinoid, and migraine prophylaxis. Cyproheptadine is not, however, a preferred treatment for these conditions.

**Methysergide.** Methysergide (SANSERT; 1-methyl-d-lysergic acid butanolamide) is a congener of methylergonovine (Figure 13–5). It has both agonist and antagonist activities at multiple 5-HT receptors. For details, see “Ergot and the Ergot Alkaloids”, above.

**Clinical Manipulation of 5-HT Levels: Serotonin Syndrome**

The clinical uses of drugs that alter 5-HT content in the CNS are discussed in Chapter 15. Excessive elevation of 5-HT levels in the body can cause serotonin syndrome, a constellation of symptoms sometimes observed in patients starting new or increased antidepressant therapy or combining an SSRI with a NE reuptake inhibitor or a triptan (for migraine), and others. Symptoms (from mild to major) include restlessness, confusion, shivering, tachycardia, diarrhea, muscle twitches/rigidity, fever, seizures, loss of consciousness, and death. Serotonin syndrome and its treatment are discussed in Chapter 15.

**DOPAMINE**

**History.** Dopamine (DA) was first synthesized in 1910. Later that year, Henry Dale characterized the biological properties of DA in the periphery, and described it as a weak, adrenaline-like substance. In the 1930s, DA was recognized as a transitional compound in the synthesis of NE and epinephrine, but was believed to be little more than a biosynthetic intermediate. Not until the early 1950s were stores of DA were found in tissues, suggesting DA had a signaling function of its own. By decade’s end, Carlsson and Montagu had each identified DA stores in the brain. Soon thereafter, Hornykiewicz discovered the DA deficit in the parkinsonian brain, fueling interest in the role of DA in neurological diseases and disorders (see Hornykiewicz, 2002).

**Sources and Chemistry.** DA consists of a catechol moiety linked to an ethyl amine, leading to its classification as a catecholamine. DA is closely related to melanin, a pigment that is formed by oxidation of DA, tyrosine, or L-DOPA. Melanin exists in the skin and cuticle and gives the substantia nigra its namesake dark color. Both DA and L-DOPA are readily oxidized by non-enzymatic pathways to form cytotoxic reactive oxygen species and quinones. DA- and DOPA-quinones form adducts with α-synuclein, a major constituent of Lewy bodies in Parkinson disease (Chapter 22). DA is a polar molecule that does not readily cross the blood-brain barrier.

**Synthesis and Metabolism of DA.** The synthesis of DA is similar to the 5-HT biosynthetic pathway (Figure 13–6). The amino acids phenylalanine and tyrosine are the precursors of DA. For the most part, mammals convert dietary phenylalanine to tyrosine by phenylalanine hydroxylase (predominantly located in the liver). Diminished levels of this enzyme lead to high levels of phenylalanine, a condition known as phenylketonuria, which must be controlled by dietary restrictions in order to avoid intellectual impairment. Tyrosine crosses readily into the brain through uptake; however, unlike tryptophan, normal brain levels of tyrosine are typically saturating. Conversion of tyrosine to l-DOPA (3,4-dihydroxyphenylalanine) by the enzyme tyrosine hydroxylase is the rate-limiting step in the synthesis of DA. Tyrosine hydroxylase is a mixed-function enzyme that requires iron and a biopterin co-factor; enzyme activity is regulated by phosphorylation and by end-product inhibition.
by AADC, the same enzyme that generates 5-HT from L-5-hydroxytryptophan. In the CNS and periphery, AADC activity is very high, and basal levels of L-DOPA cannot be readily measured. Unlike DA, L-DOPA readily crosses the blood-brain barrier and is converted to DA in the brain, which explains its utility in therapy for Parkinson disease (Chapter 22).

The neurochemical events that underlie DA neurotransmission are summarized in Figure 13–7. In dopaminergic neurons, synthesized DA is packaged into secretory vesicles (or into granules within adrenal chromaffin cells) by the vesicular monoamine transporter, VMAT2. This packaging allows DA to be stored in readily releasable aliquots and protects the transmitter from further anabolism or catabolism. By contrast, in adrenergic or noradrenergic cells, the DA is not packaged; instead, it is converted to NE by DA β-hydroxylase and, in adrenergic cells, further altered to epinephrine in cells expressing phenylethanolamine N-methyltransferase (Chapter 8). Synaptically released DA is subject to both transporter clearance and metabolism. The DA transporter (DAT) is not selective for DA; moreover, DA can also be cleared from the synapse by the NE transporter, NET. Reuptake of DA by the DA transporter is the primary mechanism for termination of DA action, and allows for either vesicular repackaging of transmitter or metabolism. The DA transporter is regulated by phosphorylation, offering the potential for DA to regulate its own uptake.

The DA transporter is predominantly localized perisynaptically so that DA is cleared at a distance from its release site, suggesting that high concentrations of DA are released into the synapse, thus necessitating a spatially distant transporter. In addition to clearing synaptic neurotransmitter, the DA transporter is a site of action for cocaine and methamphetamine, which have distinct mechanisms to increase extracellular DA. The DA transporter is also the molecular target for some neurotoxins, including 6-hydroxydopamine and 1-methyl-4-phenylpyridinium (MPP+), the neurotoxic metabolite of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Following uptake into dopaminergic neurons, MPP+ and 6-hydroxydopamine elicit intra- and extracellular DA release, ultimately resulting in neuronal death. This selective dopaminergic degeneration mimics Parkinson disease, and serves as an animal model for this disorder.

Metabolism of DA occurs primarily by the cellular MAO enzymes localized on both pre- and postsynaptic elements. MAO acts on DA to generate an inactive aldehyde derivative by oxidative deamination (Figures 13–6 and 13–7), which is subsequently metabolized by aldehyde dehydrogenase to form 3,4-dihydroxyphenylacetic acid (DOPAC).

DOPAC can be further metabolized by catechol-O-methyltransferase (COMT) to form homovanillic acid (HVA). Both DOPAC and HVA, as well as DA, are excreted in the urine. Levels of DOPAC and HVA are reliable indicators of DA turnover; ratios of these metabolites to DA in cerebral spinal fluid serve as accurate representations of brain dopaminergic activity. In addition to metabolizing DOPAC, COMT also utilizes DA as a substrate to generate 3-methoxytyramine, which is subsequently converted to HVA by MAO. In humans, HVA is the principal metabolite of DA. COMT in

---

**Figure 13–6. Synthesis and inactivation of dopamine.** Enzymes are identified in blue lettering, and co-factors are shown in black letters.
the periphery also metabolizes L-DOPA to 3-O-methyldopa, which then competes with L-DOPA for uptake into the CNS. Consequently, L-DOPA given in the treatment of Parkinson disease must be co-administered with peripheral COMT inhibitors to preserve L-DOPA and allow sufficient entry into the CNS (Chapter 22).

PHYSIOLOGICAL FUNCTIONS OF DOPAMINE

Multiple DA Receptors

Five distinct GPCRs have been cloned and determined to mediate the actions of DA (Figure 13–8). Though the cloning and classification of these receptors was initially based on mammalian studies, subsequent experimentation has revealed similar DA receptor groups in both vertebrate and invertebrate systems. The DA receptors are distinct from one another in pharmacology, amino acid sequence, distribution, and physiological function. They have been organized into two families—the D1-like and D2-like receptors—based upon their effector-coupling profile (for a recent review of DA receptors, see Rankin et al., 2009).

History of DA Receptor Subtypes. In 1971, Kebabian and Greengard determined that DA caused an increase in neostriatal cyclic AMP production, presumably by activating a DA-sensitive adenyl cyclase enzyme. Subsequently, the DA-induced increase in cyclic AMP was attributed to a D1 receptor while a second category of DA receptors that did not raise cyclic AMP levels was termed the D2 receptor. Differences in pharmacological responsiveness gave rise to the hypothesis that there were multiple subtypes of DA

---

**Figure 13–7. Dopaminergic nerve terminal.** Dopamine (DA) is synthesized from tyrosine in the nerve terminal by the sequential actions of tyrosine hydrolase (TH) and aromatic amino acid decarboxylase (AADC). DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D1 and D2 receptors. Synaptic DA may be taken up into the neuron via the DA and NE transporters (DAT, NET), or removed by postsynaptic uptake via OCT3 transporters. Cytosolic DA is subject to degradation by monoamine oxidase (MAO) and aldehyde dehydrogenase (ALDH) in the neuron, and by catechol-O-methyl transferase (COMT) and MAO/ALDH in non-neuronal cells; the final metabolic product is homovanillic acid (HVA). See structures in Figure 13-6. PH, phenylalanine hydroxylase.
receptors beyond the D1 and D2. This idea proved to be correct. The D1 subfamily consists of the D1 and D5 receptor subtypes (initially classified as D1A and D1B); both are GPCRs that couple to Gs to stimulate cellular cyclic AMP production, but they differ in their pharmacological profiles and primary amino acid sequences. The D2 subfamily contains the D2, D3, and D4 receptors. All reduce intracellular cyclic AMP production by coupling to Gi/o proteins, but they diverge in amino acid sequence and pharmacology. The D1 and D2 families can be further differentiated by their anatomical distribution and by structural differences—the D1-like receptors have a relatively long carboxyl terminus and a short third intracellular loop.

D1 Receptors. The D1 receptor is the most highly conserved and the most highly expressed of the DA receptors. The highest levels of D1 receptor protein are found within the CNS, particularly in the caudate putamen, substantia nigra pars reticulata, nucleus accumbens, hypothalamus, frontal cortex, and olfactory bulb. The D1 receptor is also located in the kidney, retina, and cardiovascular system. Cloning reveals that the D1 receptor lacks introns and encodes a protein that is 446 amino acids long in the human. The D1 receptor couples primarily to Gs, activating the cAMP-PKA pathway. However, the neostriatum expresses the highest levels of D1 receptor, but does not express any detectable Gs protein. In this region of the brain, the D1 receptor appears to couple to Go to increase levels of cAMP and its downstream effectors (for a review of dopaminergic signaling, see Neve et al., 2004). The presence of a functionally distinct heterodimer with a unique dopaminergic pharmacology is a novel concept that could shed new light on the actions of DA and drugs acting on the dopaminergic system. In addition to forming protein complexes with other DA receptors, the D1 receptor has been shown to interact with a variety of other proteins, including A1 adenosine receptors, NMDA receptors, Na+K+-ATPase, calnexin, and caveolin (for a review of DA receptor protein-protein interactions, see Hazelwood et al., 2009). The potential significance of these interactions with respect to DA receptor function and potential pharmacotherapies has not been fully realized.

D2 Receptors. The D2 receptor was the first dopamine receptor to be cloned. It is expressed throughout the brain, including the striatum, nucleus accumbens, olfactory tubercle, prefrontal cortex, amygdala, ventral tegmental area, hippocampus, hypothalamus, and substantia nigra pars compacta. Unlike the D1 receptor, the D2 receptor contains six introns and exists as either a long or short splice variant. The D2 short (D2S) receptor is missing 29 amino acids in the third intracellular loop that are present in the D2 long (D2L) receptor variant. The D2S variant is primarily expressed post-synthetically, where it likely regulates impulse/signal propagation (Usiello et al., 2000). The D2S variant is expressed pre-synthetically and likely acts to limit DA release. The D2S and D2L receptors have similar pharmacological properties and both function as autoreceptors, inhibiting cAMP formation by coupling to Go6.

D1 receptor signaling through Go also regulates a variety of cellular functions, including inwardly rectifying K+ channels, N-type
Chapter 13
5-HYDROXYTRYPTAMINE (SEROTONIN) AND DOPAMINE

**Ca^2+** channels, arachidonic acid levels (via PLAc), extracellular signal-regulated kinase, and IP3-sensitive Ca^2+ stores and L-type Ca^2+ channels. The D2 receptor has the ability to activate Gαq proteins independent of agonist, a property known as constitutive activity (Strange, 1999). As with the D1 receptor, the D2 DA receptor can also form stable complexes with other proteins, including the AMPA receptor, Na^+/K^+ -ATPase, calnexin, and the DA transporter (Hazelwood et al., 2009).

**D3 Receptors.** The D3 receptor contains five introns. It is less abundant than the D2 receptor, and is only expressed in the limbic regions of the brain. The highest levels of the D3 receptor are found in the islands of Calleja, nucleus accumbens, substantia nigra pars compacta, and ventral tegmental area. Splice variants of the human D3 receptor exist, but do not code functional protein products. The D3 receptor signals through pertussis toxin-sensitive Gq/o proteins, though not as effectively as the D2 receptor.

**D4 Receptors.** The D4 receptor contains three introns. It is abundantly expressed in the retina, and is also found in the hypothalamus, prefrontal cortex, amygdala, hippocampus, and pituitary. D4 is the most polymorphic of the DA receptors, containing a variable number of tandem repeats (VNTR) within the third intracellular loop (Van Tol et al., 1992). In humans, the four-repeat variant is the most common. There are several single nucleotide polymorphisms (SNPs) in the D4 receptor, one of which results in dramatic alterations in ligand binding (Liu et al., 1996). There are associations between a seven-repeat D4 VNTR variant and attention deficit hyperactivity disorder (see below).

**D5 Receptors.** The D5 gene, like the D4 gene, is intronless. Pseudogenes of the D5 receptor yield protein products with no known functional role. Like the D4 receptor, the D5 gene is polymorphic; several functional SNPs within the transmembrane domains alter binding properties of numerous ligands, including DA (Cravchik and Gejman, 1999). The D5 receptor couples primarily to Gαi and exhibits ligand-independent constitutive activity. The D5 receptor also activates Gq, but the functional consequences of this interaction remain unclear. The D5 receptor is most highly expressed in the substantia nigra, hypothalamus, striatum, cerebral cortex, nucleus accumbens, and olfactory tubercle.

**Actions of DA on Physiologic Systems**

**Heart and Vasculature.** At low concentrations, circulating DA primarily stimulates vascular D1 receptors, causing vasodilation and reducing cardiac afterload. The net result is a decrease in blood pressure and an increase in cardiac contractility. As circulating DA concentrations rise, DA is able to activate β adrenergic receptors to further increase cardiac contractility. At very high concentrations, circulating DA activates α adrenergic receptors in the vasculature, thereby causing vasoconstriction; thus, high concentrations of DA increase blood pressure. Clinically, DA administration is used to treat severe congestive heart failure, sepsis, or cardiogenic shock. It is only administered intravenously and is not considered a long-term treatment.

**Kidney.** DA is a paracrine/autocrine transmitter in the kidney and binds to both D1-like and D2-like receptors. Renal DA primarily serves to increase natriuresis, though it can also increase renal blood flow and glomerular filtration. Under basal sodium conditions, DA regulates Na^+ excretion by inhibiting the activity of various Na^+ transporters, including the apical Na^+ -H^+ exchanger and the basolateral Na^+ ,K^+ -ATPase. DA can also influence the renin-angiotensin system: activation of D1 receptors increases renin secretion, whereas DA, acting on D2 receptors, reduces renin secretion. Abnormalities in the DA system and its receptors have been implicated in human hypertension (Jose et al., 1998). In some cases, poor regulation of natriuresis occurs due to constitutive desensitization of the D1 receptor and uncoupling of the receptor from the signal transduction machinery. Although multiple polymorphisms exist in the DA receptors, none has been consistently associated with human hypertension.

**Pituitary Gland.** DA is the primary regulator of prolactin secretion from the pituitary gland. DA is released from the hypothalamus into the hypophyseal portal blood supply, directly influencing lactotrophs in the pituitary with high concentrations of DA. DA acts on lactotroph D2s and D2l receptors to decrease prolactin secretion (Chapter 38).

**Catecholamine Release.** Both D1 and D2 receptors modulate the release of NE and epinephrine. The D2 receptor provides tonic inhibition of epinephrine release from chromaffin cells of the adrenal medulla, and of norepinephrine release from sympathetic nerve terminals. In contrast, the D1 receptor responds to high-frequency DA stimulation to promote the release of catecholamines from the adrenal medulla. This D1 receptor stimulation is thought to contribute to the “fight or flight” response.

**CNS.** DA in the brain projects via four main pathways (Figure 13–9)—mesolimbic, mesocortical, nigrostriatal and tuberoinfundibular—to regulate a variety of functions. The physiological processes under dopaminergic control include reward, emotion, cognition, memory, and motor activity. Dysregulation of the dopaminergic system is critical in a number of disease states, including Parkinson disease, Tourette’s syndrome, bipolar depression, schizophrenia, attention-deficit hyperactivity disorder, and addiction/substance abuse.

The mesolimbic pathway is associated with reward and, less so, with learned behaviors. Dysfunction in this pathway is associated with addiction, schizophrenia, and psychoses (including bipolar depression), and learning deficits. The mesocortical pathway is important for “higher-order” cognitive functions including motivation, reward, emotion, and impulse control. It is also implicated in psychoses, including schizophrenia, and in attention-deficit hyperactivity disorder. The mesolimbic and mesocortical pathways are sometimes grouped together as mesolimbocortical. The nigrostriatal pathway is a key regulator of movement (Chapter 22). Impairments in this pathway are evident in Parkinson disease and underlie
Detrimental movement side effects associated with dopaminergic therapy, including tardive dyskinesia. DA released in the tuberoinfundibular pathway is carried by the hypophyseal blood supply to the pituitary, where it regulates prolactin secretion.

**Electrophysiology.** DA receptors regulate multiple distinct voltage-gated ion channels that impact firing of action potentials and neural transmission. D1-like receptor activation modulates Na⁺, as well as N-, P- and L-type Ca²⁺ currents, via a PKA-dependent pathway. D2 receptors regulate K⁺ currents. DA also modulates the activity of ligand-gated ion channels, including NMDA and AMPA receptors. As such, DA is not a classical excitatory or inhibitory neurotransmitter, but rather acts as a modulator of neurotransmission. A lack of subtype-specific ligands, and overlapping expression patterns, makes investigation of individual DA receptors difficult. As a consequence, most studies have investigated D1 and D2 families of receptors (with family-specific ligands) in discrete brain regions, especially the striatum and prefrontal cortex.

Dopaminergic neurons are strongly influenced by excitatory glutamate and inhibitory GABA input. In general, glutamate inputs enable burst-like firing of dopaminergic neurons, resulting in high concentrations of synaptic DA. GABA inhibition of DA neurons causes a tonic, basal level of DA release into the synapse (Goto et al., 2007). Interestingly, DA release also modulates GABA and glutamate neurons, thus providing an additional level of interaction and complexity between DA and other neurotransmitters. Strong phasic or slow tonic release of DA, and the subsequent activation of DA receptors, has differential effects on the induction of long-term potentiation (LTP) and long-term depression (LTD). In the striatum, phasic activation of DA neurons and stimulation of D1 receptors favors LTP induction, while tonic DA release with concomitant activation of both D1- and D2-like receptors favors LTD (Gerdeeman et al., 2003).

**Roles of DA in Behavior: Lesioning and Knockout Studies**

For several decades, pharmacological agents have been used to specifically ablate dopaminergic neurons. This technique allowed functional characterization of discrete dopaminergic brain regions in animal models. More recently, the generation of knockout mice lacking specific DA receptor subtypes has furthered understanding of the dopaminergic system, from brain regions to the functional impact of individual receptors (Holmes et al., 2004; Sibley, 1999). These tools, along with dopaminergic ligands, have enabled exploration of the broad-reaching effects of DA on physiological processes and behaviors.

**Locomotion: Models of Parkinson Disease (PD).** In the early 1980s, several young people in California developed rapid-onset parkinsonism. All of the affected individuals had injected a synthetic analog of meperidine that was contaminated with 1-methyl-4-phenyl-1,2,3, 6-tetrahydropyridine (MPTP). MPTP is metabolized by MAO-B to the neurotoxic MPP⁺, which is selectively taken into dopaminergic neurons by the DA transporter. Once inside the cell, MPP⁺ causes intra- and extracellular DA release, which is oxidized to form quinones and reactive oxygen species that cause neuronal death. Because of the high specificity of MPP⁺ for the DA transporter, neuronal death is largely restricted to the substantia nigra and ventral segmental area, resulting in a phenotype remarkably similar to Parkinson’s disease. 6-Hydroxydopamine (6-OHDA) is similar to MPTP in both mechanism of action and utility as an animal model. In contrast to MPTP, however, 6-OHDA does not cross the blood-brain barrier and it is not specific to dopaminergic neurons (it is also a substrate for NET, the neuronal NE transporter). Thus, in animal models of Parkinson disease, 6-OHDA must be injected intracranially and co-administered with a blocker of NET. Locomotion in animals with MPTP or 6-OHDA results in tremor, grossly diminished locomotor activity, and rigidity. As with Parkinson disease, these motor deficits are alleviated with L-DOPA therapy or dopaminergic agonists. These neurotoxins are valuable tools for studying potential neuroprotective agents and novel treatment strategies, such as neural grafting and stem cell transplantation; their effects underscore the singular importance of the dopaminergic system in locomotor activity and Parkinson disease.

Other pharmacological agents are also known to alter locomotor activity via dopaminergic actions, including cocaine and amphetamine. These drugs of abuse bind to DAT and inhibit reuptake of synaptic DA. Amphetamine is a substrate for the transporter, blocks it competitively, and enters the neuron, where it displaces (releases) DA from vesicular stores, causing an efflux of DA from the neuronal cytosol into the synapse, possibly by reversal of the DA transporter. The accumulation of synaptic DA increases stimulation of DA receptors and results in heightened locomotor activity. Mice lacking DAT are hyperactive, and do not display increased locomotion in response to cocaine or amphetamine treatment.

Targeted disruption of the DA receptor genes has revealed specific information about the receptor subtypes that mediate locomotor activity. Mice lacking the D₁ receptor show generalized alterations in locomotor activity, although there is not good agreement about the specific motor phenotype. Studies with D₂ receptor knock-out mice indicate that the D₁ receptor, but not the D₂ receptor, is primarily responsible for the increase in locomotor activity that occurs following administration of D₁-family agonists. D₂ receptor
D1 knockout mice display marked reductions in locomotor activity, initiation of movement, and rearing behaviors. This reduction in motor activity is also present in mice that are specifically lacking only the D2L receptor, indicating that the D2S isoform plays a lesser role in regulation of movement and is not able to compensate for the lack of D2L receptor. The D1 and D4 receptor knockout animals display unique locomotor alterations in response to novel environments. However, these changes may be related to novelty-seeking behavior rather than actual motor impairments.

**Reward: Implications in Addiction.** In general, drugs of abuse cause increased DA levels in the nucleus accumbens, an area critical for rewarded behaviors. This role for mesolimbic DA in addiction has led to numerous studies on abused drugs in DA receptor knockout mice. Studies of D1 receptor knockout mice show a reduction in the rewarding properties of ethanol, suggesting that the rewarding and reinforcing properties of ethanol are dependent, at least in part, on the D1 receptor. D2 receptor knockout mice also display reduced preference for ethanol consumption. Morphine also lacks rewarding properties in D2 knockout mice when measured by conditioned place-preference or self-administration paradigms. However, mice lacking the D3 receptor exhibit enhanced self-administration of high doses of cocaine. These data implicate a complex and drug-specific role for the D3 receptor in rewarding and reinforcing behaviors. The D3 receptor, highly expressed in the limbic system, has also been implicated in the rewarding properties of several drugs of abuse. However, D3 knockout mice display drug-associated place preference similar to wild-type mice following amphetamine or morphine administration. Recently developed D3-selective ligands implicate a role for the D3 receptor in motivation for drug-seeking and in drug relapse, rather than in the direct reinforcing effects of the drugs (Heidbreder, 2008).

**Cognition, Learning and Memory.** Mice lacking the D1 receptor display deficits in multiple forms of memory. D1 knockout mice have impaired spatial memory using the Morris water maze as a read-out. Deficits in prefrontal cortex-dependent working memory occur in D1 knockout mice, in agreement with pharmacological evidence that cortical working memory can be modulated with D1 agonists and antagonists (Williams and Castner, 2006). Amphetamine administration disrupts prepulse inhibition in wildtype animals but not in D1 knockout animals. Prepulse inhibition is unaltered in mice lacking only the D2L isoform of the receptor, indicating that the long and short isoforms of the receptor may serve different purposes in sensorimotor gating and higher order processing. These findings imply an important role for the D2 receptor in disorders with defects in sensorimotor gating, most notably schizophrenia. Indeed, many of the antipsychotic drugs used in the treatment of schizophrenia are high affinity antagonists for the D2 receptor.

**DA Receptor Agonists and Antagonists**

**DA Receptor Agonists.** DA receptor agonists are currently used in the treatment of PD, restless leg syndrome, and hyperprolactinemia. One of the primary limitations to the therapeutic use of dopaminergic agonists is the lack of receptor subtype selectivity, that is, stimulation of DA receptor subtypes not involved with the disease causes an array of unpleasant side effects. However, recent advances in receptor-ligand structure-function relationships have enabled the development of subtype-specific drugs, many of which have already proven to be useful experimental tools (Table 13–7). Some ligands can preferentially activate one downstream signaling cascade over another, a property known as functional selectivity (Urban et al., 2007). Furthermore, DA receptor activity can be modulated by drugs that bind to allosteric sites on the receptor, thereby enhancing or decreasing endogenous DA signaling in a receptor-specific manner (Schetz, 2005). All of these interactions between ligands and DA receptors can be exploited in future drug development endeavors to evoke a more specific receptor-mediated response.

**DA Receptor Agonists and Parkinson Disease.** Parkinson disease (PD), a neurodegenerative disorder of unknown etiology, is characterized by extensive degeneration of dopaminergic neurons within the substantia nigra, resulting in tremor, rigidity, and bradykinesia. While the principal pharmacotherapy for PD is l-DOPA, limitations to its therapeutic effects (Chapter 22) have generated intense interest in developing alternative therapies for PD, with the intent of either delaying the usage of l-DOPA or alleviating l-DOPA side effects and restoring its efficacy. One treatment strategy is the use of DA receptor agonists, which act directly on the depleted nigrostriatal dopaminergic system and have fewer undesirable side effects. DA agonists can be used in conjunction with lower doses of l-DOPA in a combined therapy approach. Two general classes of dopaminergic agonists are used in the treatment of PD: ergots and non-ergots. The pharmacological properties of these drugs are described below; their use in the management of PD is described in Chapter 22.

**D1/D2 Receptor Agonists: Ergot Alkaloids.** Ergot derivatives are nonselective compounds that act on several different neurotransmitter systems, including DA, 5-HT, and adrenergic receptors. In the U.S., bromocriptine (Parlodol) and pergolide (Permax) are approved for the treatment of PD (see Table 13–6 for structures); however, their use has fallen out of favor because of the associated risk for serious cardiac complications. Bromocriptine is a potent D2...
receptor agonist and a weak D1 antagonist. Pergolide is a partial agonist of D2 receptors and a strong D2-family agonist with high affinity for both D2 and D3 receptor subtypes. Ergot derivatives are commonly reported to cause unpleasant side effects, including nausea, dizziness, and hallucinations. Pergolide was removed from the U.S. market as therapy for PD after it was associated with an increased risk for valvular heart disease.

**Ergot Alkaloids in the Treatment of Hyperprolactinemia.** Despite the contraindications for PD, ergot-based DA agonists are still used in the treatment of hyperprolactinemia. Like bromocriptine, cabergoline (DOSTINEX) is a strong agonist at D2 receptors, and has lower affinity for D3, 5-HT, and α adrenergic receptors. The therapeutic utility of bromocriptine and cabergoline in hyperprolactinemia is derived from their properties as DA receptor agonists: they activate D2 receptors in the pituitary to reduce prolactin secretion. The risk of valvular heart disease in ergot therapy is associated with higher doses of drug (necessary for PD treatment), but not with the lower doses used in treating hyperprolactinemia. The use of bromocriptine and cabergoline in the management of hyperprolactinemia is described in Chapter 38.

**D1/D2 Receptor Agonists (Non-Ergot Alkaloids).** Apomorphine (APOKYN), a derivative of morphine, is approved for the treatment of PD. Apomorphine binds with the order of potency D2 > D3 > D1. Apomorphine also binds with lower affinity to D3, α-adrenergic, 5-HT1A, and 5-HT2 receptors. The therapeutic benefits of apomorphine in PD are likely due to its higher affinity and efficacy at DA receptors, especially D2-family receptors. Apomorphine is most commonly used in combination with L-DOPA to surmount the sudden “off” periods that can occur after long-term L-DOPA treatment.

Rotigotine is offered in a transdermal patch (NEUPRO) for the treatment of PD. Rotigotine preferentially binds to D3 and D4 receptors and has much lower affinity for D2 receptors. In addition, rotigotine is an agonist at 5-HT1A and 5-HT2 receptors, and an antagonist at α1 adrenergic receptors. Due to problems with patch release, rotigotine is currently not sold in the U.S., but is available in Europe.

**D2 Family Receptor Agonists (Non-Ergot Alkaloids).** Based on the role of DA in PD and the initial therapeutic utility of ergot compounds, more selective D2 dopaminergic agonists were developed for PD treatment. Pramipexole (MIRAPEX) and ropinirole (REQUIP) are agonists at all D2 family receptors and, notably, bind with highest affinity to the D3 receptor subtype. Interestingly, pramipexole is reported to have neuroprotective properties when administered before MPTP or 6-OHDA in animal models of PD (Joyce and Millan, 2007); agonist activity at the D3 receptor may be the underlying neuroprotective mechanism.

**Rotigotine in the Treatment of Restless Leg Syndrome (RLS).** In addition to its utility in the treatment of PD, rotigotine has also been FDA-approved as pharmacotherapy for RLS. Mild dopaminergic hypofunction has been noted in patients with RLS. Somnolence and other side effects reported for PD therapy are less pronounced in the treatment of RLS, presumably due to the lower dose required for RLS therapy.

**D4 Receptor Agonists and Attention Deficit-Hyperactivity Disorder (ADHD).** The D4 receptor is known to be significant in ADHD; an association has been reproducibly demonstrated between the seven-repeat D4 VNTR variant and patients with ADHD. Recent preclinical testing has uncovered potential therapeutic benefits of the selective D4 agonist, A-412997, in cognitive tasks and animal models of ADHD. Animals treated with A-412997 showed cognitive improvements well below hyperlocomotive doses and, importantly, A-412997 did not show potential for abuse at any dose tested (Woolley et al., 2008). This is in marked contrast to the currently available drug therapies for ADHD treatment that have high abuse potential. While all published studies to date are preclinical, D4-selective agonists show significant promise for the next generation of ADHD therapy.

**DA Receptor Antagonists**

Just as enhancing DA neurotransmission is clinically important, inhibiting an over-active dopaminergic system can be useful. As with the DA receptor agonists, a lack of subtype-specific antagonists has limited the therapeutic utility of this group of ligands. Recent advances in defining GPCR structure, along with ligand-binding modeling, have advanced rational drug design, and selective antagonists are now available as experimental tools (Table 13–7). Many subtype-selective antagonists are in early stages of preclinical testing for therapeutic utility.

**DA Receptor Antagonists and Schizophrenia.** DA receptor antagonists are a mainstay in the pharmacotherapy of schizophrenia. While many neurotransmitter systems likely contribute to the complex pathology of schizophrenia (Chapter 16), DA dysfunction is considered the basis of this disorder. The DA hypothesis of schizophrenia has its origins in the characteristics of the drugs used to treat this disorder: all antipsychotic compounds used clinically have high affinity for DA receptors. Moreover, psychostimulants that increase extracellular DA levels can induce or worsen psychotic symptoms in schizophrenic patients. The advent of neuroimaging techniques for visualization of DA in human brain regions has led to new insights into the role of specific DA systems. DA hyperfunction in subcortical regions, most notably the striatum, has been associated with the positive symptoms of schizophrenia that respond well to antipsychotic treatment. In contrast, the prefrontal cortex of schizophrenic patients exhibits dopaminergic hypofunction, which has been associated with the more treatment-refractory negative/cognitive symptoms. The drugs currently used to treat schizophrenia are classified as either typical (also referred to as first generation) or atypical (second generation) antipsychotics. This nomenclature stems from the high efficacy and lack of extrapyramidal side effects observed with atypical antipsychotics. Some of the newer drugs in development do not fit into this classification scheme, including the D1-selective agonist, dihydrexidine. Dihydrexidine shows great promise to improve the refractory negative symptoms of schizophrenia, and may be especially useful in combination therapy with current antipsychotics that preferentially reduce positive symptoms by antagonizing D2 receptors (Mu et al., 2007).

**Antipsychotic Agents**

**Typical Antipsychotics.** The first antipsychotic drug used to treat schizophrenia was chlorpromazine (Thorazine). Despite its affinity for a wide array of neurotransmitter receptors, the antipsychotic
properties of chlorpromazine were attributed to its antagonism of DA receptors, especially the $D_2$ receptor. More $D_2$-selective ligands were developed to improve the antipsychotic properties, including haloperidol (HALDOL) and similar $D_2$-selective drugs. While all typical antipsychotics markedly improve positive symptoms, they are not very beneficial in the treatment of negative or cognitive symptoms. As promising as these drugs initially seemed, their debilitating side effects limited their utility and gave rise to the development of the next generation of antipsychotic drugs, the atypical agents.

**Atypical Antipsychotics.** This class of antipsychotic drugs originated with clozapine (FAZACLO) and is distinguished by a vastly improved side effect profile over the typical antipsychotics. The lack of extrapyramidal side effects has been attributed to a much lower affinity for the $D_2$ receptor compared to the typical antipsychotics. Atypical agents are also less likely to stimulate prolactin production. Clozapine has higher affinity for the $D_2$ receptor, which is highly expressed in the limbic system. Most atypical antipsychotics are low affinity antagonists at the $D_2$ receptor and high affinity antagonists or inverse agonists at the 5-HT$_{2A}$ receptor. While the precise role of 5-HT$_{2A}$ receptor binding in the efficacy of clozapine remains unclear, this dual DA-5-HT receptor blockade shaped the development of antipsychotics for several decades.

Aripiprazole (ABILIFY) has gained recent attention for causing even fewer side effects than earlier atypical antipsychotics. Aripiprazole diverges from the traditional atypical profile in two ways: first, it has higher affinity for $D_2$ receptors than for 5-HT$_{2A}$ receptors; secondly, and perhaps more importantly, it is a partial agonist, rather than an antagonist, at $D_2$ receptors. As a partial agonist, aripiprazole may diminish the subcortical DA hyperfunction by competing with DA for receptor binding, while simultaneously enhancing dopaminergic neurotransmission in the prefrontal cortex by acting as an agonist. The dual mechanism afforded by a partial agonist may thus treat both the positive and negative symptoms associated with schizophrenia.

**D$_3$ Receptor Antagonists and Drug Addiction.** Although much work remains to determine clinical utility, $D_3$-selective antagonists show promise in the treatment of addiction (Heidbreder, 2008). This interest stems from the high expression of the $D_3$ receptor in the limbic system, the reward center of the brain. Animal studies of highly $D_3$-selective antagonists BP-897 and SB-277011A have suggested a role for the $D_3$ receptor in the motivation to abuse drugs and in the potential for drug-abuse relapse.

**BIBLIOGRAPHY**

This page intentionally left blank
Drugs that act in the central nervous system (CNS) are invaluable therapeutically. They can, e.g., relieve pain, reduce fever, suppress disordered movements, induce sleep or arousal, reduce appetite, and allay the tendency to vomit. Selectively acting drugs can be used to treat anxiety, depression, mania, or schizophrenia and do so without altering consciousness (Chapters 15 and 16). Socially acceptable stimulants and anti-anxiety agents contribute to emotional stability, relief of anxiety, and pleasure. However, the excessive use of such drugs can affect lives adversely when uncontrolled, self-administration leads to physical dependence or to toxic side effects (Chapter 24). The nonmedical self-administration of CNS-active drugs—recreational pharmacology—is widespread.

The identification of targets for drugs that affect the nervous system and behavior presents extraordinary scientific challenges. Understanding the cellular and molecular basis for the complex and varied functions of the human brain is only the beginning. Complicating the effort is the fact that a CNS-active drug may act at multiple sites with disparate and even opposing effects. In addition, many CNS disorders involve multiple brain regions and pathways, which can frustrate efforts to use a single therapeutic agent. CNS pharmacologists have two overlapping goals: to use drugs to elucidate the mechanisms that operate in the normal CNS, and to develop drugs to correct pathophysiological events in the abnormal CNS. Advances in molecular biology and neurobiology are facilitating the development of drugs that can selectively treat diseases of the CNS.

This chapter introduces guidelines and fundamental principles for the comprehensive study of drugs that affect the CNS. Specific therapeutic approaches to neurological and psychiatric disorders are discussed in Chapters 15 to 17, 21, 22, and 24. For further detail, see the specialized texts by Cooper (2003), Siegel (2006), Nestler (2009), and their associates. For detailed information on specific receptors and ion channels see the official database of the IUPHAR Committee on Receptor Nomenclature and Drug Classification.

**ORGANIZATIONAL PRINCIPLES OF THE CNS**

The brain is a complex assembly of interacting neurons and nuclei that regulate their own and each other’s activities in a dynamic fashion, generally through chemical neurotransmission. It is useful to examine the major anatomical regions of the CNS and their associations with specific neurotransmitter systems and the effect of pharmacological agents thereon.

**Cerebral Cortex.** The two cerebral hemispheres constitute the largest division of the brain. Regions of the cortex are classified in several ways:

- by the modality of information processed (e.g., sensory, including somatosensory, visual, auditory, and olfactory, as well as motor and associational)
- by anatomical position (frontal, temporal, parietal, and occipital)
- by the geometric relationship between cell types in the major cortical layers (“cytoarchitectonic” classification)

The specialized functions of a cortical region arise from the interplay between connections with other regions of the cortex (corticocortical systems) and noncortical areas of the brain (subcortical systems) and a basic intracortical processing module of ~100 vertically connected cortical columns (Mountcastle, 1997). Varying numbers of adjacent columnar modules may be functionally linked into larger information-processing ensembles. The pathology of Alzheimer’s disease, e.g., destroys the integrity of the columnar modules and the corticocortical connections (Chapter 22). Cortical areas termed association areas process information from primary cortical sensory regions to produce higher cortical functions such as abstract thought, memory, and consciousness. The cerebral cortices also provide supervisory integration of the autonomic nervous system.
system and integrate somatic and vegetative functions, including those controlling the cardiovascular and gastrointestinal systems.

**Limbic System.** The limbic system is an archaic term for an assembly of brain regions (hippocampal formation, amygdaloid complex, septum, olfactory nuclei, basal ganglia, and selected nuclei of the diencephalon) grouped around the subcortical borders of the underlying brain core to which a variety of complex emotional and motivational functions have been attributed. Modern neuroscience tends to avoid this term because the ill-defined regions of the “limbic system” do not function consistently as a system. Parts of these limbic regions also participate individually in functions that can be more precisely defined. Thus, the basal ganglia or neostriatum (the caudate nucleus, putamen, globus pallidus, and lentiform nucleus) form an essential regulatory segment of the extrapyramidal motor system that complements the function of the pyramidal (or voluntary) motor system. Damage to the extrapyramidal system affects the ability to initiate voluntary movements and causes disorders characterized by involuntary movements, such as the tremors and rigidity of Parkinson disease or the uncontrollable limb movements of Huntington’s chorea (Chapter 22). Similarly, the hippocampus may be crucial to the formation of recent memory, since this function is lost in patients with extensive bilateral damage to the hippocampus. Memory is also disrupted by Alzheimer’s disease, which destroys the intrinsic structure of the hippocampus as well as parts of the frontal cortex.

**Diencephalon.** The thalamus lies in the center of the brain, beneath the cortex and basal ganglia and above the hypothalamus. The neurons of the thalamus are arranged in distinct clusters, or nuclei, which are either paired or midline structures. These nuclei act as relays between incoming sensory pathways and the cortex, between discrete regions of the thalamus and the hypothalamus, and between the basal ganglia and the association regions of the cerebral cortex. The thalamic nuclei and the basal ganglia also exert regulatory control over visceral functions; aphagia and adipsia, as well as general sensory neglect, follow damage to the corpus striatum or to selected circuits ending in the striatum. The hypothalamus is the principal integrating region for the autonomic nervous system and regulates body temperature, water balance, intermediary metabolism, blood pressure, sexual and circadian cycles, secretion from the adrenocortical system, sleep, and emotion.

**Midbrain and Brainstem.** The mesencephalon, pons, and medulla oblongata connect the cerebral hemispheres and thalamus-hypothalamus to the spinal cord. These “bridge portions” of the CNS contain most of the nuclei of the cranial nerves, as well as the major inflow and outflow tracts from the cortices and spinal cord. These regions contain the reticular activating system, an important but incompletely characterized region of gray matter linking peripheral sensory and motor events with higher levels of nervous integration. The major monoamine-containing neurons of the brain are found here. Together, these regions represent the points of central integration for coordination of essential reflexive acts, such as swallowing and vomiting, and those that involve the cardiovascular and respiratory systems; these areas also include the primary receptive regions for most visceral afferent sensory information. The reticular activating system is essential for the regulation of sleep, wakefulness, and level of arousal, as well as for coordination of eye movements. The fiber systems projecting from the reticular formation have been called nonspecific because the targets to which they project are relatively more diffuse in distribution than those of many other neuronal systems (e.g., specific thalamocortical projections). However, the chemically homogeneous components of the reticular system innervate targets in a coherent and functionally integrated manner despite their broad distribution.

**Cerebellum.** The cerebellum arises from the posterior pons behind the cerebral hemispheres. It is highly laminated and redundant in its detailed cytological organization. The lobules and folia of the cerebellum project onto specific deep cerebellar nuclei, which in turn make relatively selective projections to the motor cortex (by way of the thalamus) and to brainstem nuclei concerned with vestibular function (position-stabilization). In addition to maintaining the proper tone of antigravity musculature and providing continuous feedback during volitional movements of the trunk and extremities, the cerebellum also may regulate visceral functions (e.g., controlling heart rate, so as to maintain blood flow despite changes in posture).

**Spinal Cord.** The spinal cord extends from the caudal end of the medulla oblongata to the lower lumbar vertebrae. Within this mass of nerve cells and tracts, sensory information from skin, muscles, joints, and viscera is locally coordinated with motoneurons and with primary sensory relay cells that project to and receive signals from higher levels. The spinal cord is divided into anatomical segments (cervical, thoracic, lumbar, and sacral) that correspond to divisions of the peripheral nerves and spinal column (see Figure 8–1). Ascending and descending tracts of the spinal cord are located within the white matter at the perimeter of the cord, while intersegmental connections and synaptic contacts are concentrated within an H-shaped internal mass of gray matter. Sensory information flows into the dorsal cord, and motor commands exit via the ventral portion. The preganglionic neurons of the autonomic nervous system are found in intermediolateral columns of gray matter. Autonomic reflexes (e.g., changes in skin vasculature with alteration of temperature) can be elicited within local segments of the spinal cord, as shown by the maintenance of these reflexes after the cord has been severed.

**Microanatomy of the Brain**

Neurons operate either within layered structures such as the olfactory bulb, cerebral cortex, hippocampal formation, and cerebellum or in clustered groupings, defined collections of neurons that aggregate into nuclei. Specific connections between neurons within or across the macro-divisions of the brain are essential to the function of the brain. Through patterns of neuronal circuitry, individual neurons form functional ensembles to regulate the flow of information within and between the regions of the brain.

**Cellular Organization of the Brain.** Present understanding of the cellular organization of the CNS can be viewed from the perspective of the size, shape, location, and interconnections between neurons (Cooper et al., 2003; Shepherd, 2003).

**Cell Biology of Neurons.** Neurons are classified according to function (sensory, motor, or interneuron), location, the identity of the transmitter they synthesize and release or the class or classes of receptor expressed on the cell surface. Microscopic analysis of a neuron focuses on its general shape and in particular the complexity of the afferent receptive surfaces on the dendrites and cell body that receive synaptic contacts from other neurons. Neurons (Figure 14–1) exhibit
the cytological characteristics of highly active secretory cells with large nuclei: large amounts of smooth and rough endoplasmic reticulum; and frequent clusters of specialized smooth endoplasmic reticulum (Golgi complex), in which secretory products of the cell are packaged into membrane-bound organelles for transport from the perikaryon to the axon or dendrites. Neurons and their cellular extensions are rich in microtubules, which support the complex cellular structure and assist in the reciprocal transport of essential macromolecules and organelles between the cell body and distant axon or dendrites. The sites of interneuronal communication in the CNS are termed synapses. Although synapses are functionally analogous to "junctions" in the somatic motor and autonomic nervous systems, central junctions contain an array of specific proteins presumed to be the active region for transmitter release and response (Husi et al., 2000). Like peripheral "junctions," central synapses are denoted by accumulations of tiny (50-150 nm) synaptic vesicles. The proteins of these vesicles have specific roles in transmitter storage, vesicular docking onto presynaptic membranes, voltage- and Ca²⁺-dependent secretion, and recycling and restorage of released transmitter (Jahn, 2004, Murthy and Camilli, 2003; Nestler et al., 2009).

Support Cells. Neurons are not the only cells in the CNS. According to most estimates, neurons are outnumbered, perhaps by an order of magnitude, by various types of support cells. These include microglia, oligodendroglia, astrocytes, and the cells of the vascular elements comprising the intracerebral vasculature, the cerebrospinal fluid-forming cells of the choroid plexus found within the intracerebral ventricular system, and the meninges, which cover the surface of the brain and comprise the cerebrospinal fluid-containing envelope. Macrogia are the most abundant support cells; some are categorized as astrocytes (cells interposed between the vasculature and the neurons, often surrounding individual compartments of synaptic complexes). Astrocytes play a variety of metabolic support roles including furnishing energy intermediates and supplementary removal of neurotransmitters following release (Pellerin and Magistretti, 2003). The oligodendroglia, a second prominent category of macroglia, are myelin-producing cells. Myelin, made up of multiple layers of compacted membranes, insulates segments of axons bioelectrically and permit non-decremental propagation of action potentials. Microglia are relatively uncharacterized support cells believed to be of mesodermal origin and related to the macrophage/monocyte lineage (Carson, 2002). Some microglia reside within the brain, while additional cells of this class may be recruited to the brain during periods of inflammation following either microbial infection or brain injury. The response of the brain to inflammation differs strikingly from that of other tissues (Glass et al., 2010).

Blood-Brain Barrier. Apart from exceptional instances in which drugs are introduced directly into the CNS, the concentration of an agent in the blood after oral or parenteral administration may differ substantially from its concentration in the brain. The blood-brain barrier (BBB) is an important boundary between the periphery and the CNS that forms a permeability barrier to the passive diffusion of substances from the bloodstream into the CNS. Evidence for the existence of the BBB is provided by the greatly diminished rate of access of many chemicals from plasma to the brain and the localization of several drug export systems in the cells that constitute the BBB (Chapter 5). An exception exists for lipophilic molecules, which diffuse freely across the BBB and accumulate in the brain. This barrier is non-existent in the peripheral nervous system, and is much less prominent in the hypothalamus and in several small, specialized organs (the circumventricular organs) lining the third and fourth ventricles of the brain: the median eminence, area postrema, pineal gland, subfornical organ, and subcommissural organ. While the BBB may impose limitations on the diffusion of macromolecules
from the bloodstream into the brain, selective barriers to permeation into and out of the brain also exist for small, charged molecules such as neurotransmitters, their precursors and metabolites, and some drugs. These diffusional barriers are viewed as a combination of the partition of solute across the vasculature (which governs passage by definable properties such as molecular weight, charge, and lipophilicity) and the presence or absence of energy-dependent transport systems (Chapter 5). Important exceptions are the specific uptake transporters for amino acids. This accounts for the therapeutic utility of L-dopa (levodopa) used for treatment of Parkinson disease. The brain clears metabolites of transmitters into the fluid-containing lateral ventricles by excretion via the acid transport system of the choroid plexus. Substances that rarely gain access to the brain from the bloodstream often can reach the brain when injected directly into the cerebrospinal fluid. Under certain conditions, it may be possible to open the BBB, at least transiently, to permit the entry of chemotherapeutic agents. Cerebral ischemia and inflammation also modify the BBB, increasing access to substances that ordinarily would not affect the brain.

Response to Damage: Repair and Plasticity in the CNS

Because the neurons of the CNS are terminally differentiated cells, they do not undergo proliferative responses to damage, although recent evidence suggests the possibility of neural stem cell proliferation as a natural means for replacement of neurons in selected areas of the CNS and as a means of therapeutic repair (Aimone et al., 2010; Marchetto et al., 2010). In the CNS, unlike in the peripheral nervous system, glia-associated proteins are not uniformly upregulated following an injury. (Madinier A, et al., 2009). There are, in addition, proteins in myelin like Nogo-A that are potent inhibitors of axonal regeneration in the CNS (Giger et al., 2008).

INTEGRATIVE CHEMICAL COMMUNICATION IN THE CNS

The principal role of the CNS is to integrate information from a variety of external and internal sources, and to coordinate the needs of the organism with the demands of the environment. These integrative functions transcend individual transmitter systems and emphasize the means by which neuronal activity is normally coordinated. Only through a detailed understanding of these integrative functions, and their failure in certain pathophysiological conditions, can effective and specific therapeutic approaches be developed for neurological and psychiatric disorders. A central concept of neuropsychopharmacology is that drugs that influence behavior and improve the functional status of patients with neurological or psychiatric diseases act by enhancing or blunting the effectiveness of one or a combination of specific transmitters and channels.

Four research strategies provide the scientific substrates of neuropsychological phenomena: molecular (or biochemical), cellular, multicellular (or systems), and behavioral. Intensively exploited molecular and biochemical approaches have been the traditional focus for characterizing drugs that alter behavior. Molecular discoveries provide biochemical probes for identifying the appropriate neuronal sites and the mechanisms through which neuronal processes are modified. Identified targets for centrally acting drugs include ion channels that mediate change in excitability induced by neurotransmitters, neurotransmitter receptors to which drugs bind to elicit biological responses, and transport proteins that reaccumulate released transmitter. The membrane transporters, including those selective for norepinephrine, dopamine, or serotonin (NET, DAT, and SERT), accumulate released transmitter and package it for reuse. Inhibition of reuptake increases the concentration and dwell time of transmitter in the synaptic space; serotonin selective reuptake inhibitors used for the treatment of depression and cocaine, which inhibits the reuptake of DA, have dramatic effects. Inhibition of vesicular storage (e.g., inhibition of VMAT2 and storage of norepinephrine by reserpine) leads to depletion of releasable neurotransmitter.

Research at the cellular level identifies specific neurons and their most proximate synaptic connections that may mediate a behavior or the behavioral effects of a given drug. For example, research into the basis of emotion exploits both molecular and behavioral leads to identify the most likely brain sites at which behavioral changes pertinent to emotion can be analyzed. Such research provides clues as to the nature of the interactions in terms of interneuronal communication (i.e., excitation, inhibition, or more complex forms of synaptic interaction).

An understanding at the systems level is required to assemble the structural and functional properties of specific central transmitter systems, linking the neurons that make and release a given neurotransmitter to its behavioral effects. While many such transmitter-to-behavior linkages have been postulated, it has proven difficult to validate the essential involvement of specific transmitter-defined neurons in mediating specific mammalian behaviors. Research at the behavioral level may illuminate the integrative phenomena that link populations of neurons (often in an operationally or empirically defined manner) into extended specialized circuits or “systems” that integrate the physiological expression of a learned, reflexive, or spontaneously generated behavioral response. The entire concept of animal models of human psychiatric diseases rests on the assumption that scientists can appropriately infer from observations of behavior and physiology (heart rate, respiration, locomotion, etc.) that the states experienced by animals are equivalent to the emotional states experienced by human beings expressing similar physiological changes (Cowan et al., 2000, 2002).

CNS Transmitter Discovery Strategies. The earliest transmitters considered for central roles were acetylcholine (ACh) and norepinephrine (NE), largely because of their established roles in the...
somatodendritic motor and autonomic nervous systems. In the 1960s, serotonin (5-hydroxy tryptamine, 5-HT), epinephrine, and dopamine (DA) were investigated as potential CNS transmitters; although histochecmical, biochemical, and pharmacological data yielded results consistent with their roles as neurotransmitters, not all criteria were fully satisfied. In the early 1970s, the availability of selective and potent antagonists of gamma-aminobutyric acid (GABA), glycine, and glutamate, all known to be enriched in brain, led to their general acceptance as transmitters. At about the same time, a search for hypothalamic-hypophyseal factors led to an improvement in the technology to isolate, purify, sequence, and synthesize a growing family of neuropeptides (Hökfelt et al., 2003). These advances, coupled with the widespread application of immunohistochemistry, strongly supported the view that neuropeptides act as transmitters. Adaptation of bioassay technology developed in studies of pituitary secretions, and later, competitive binding assays with radioative ligands, gave rise to the discovery of endogenous peptide ligands for drugs acting at opiate receptors (Chapter 18). The search for endogenous factors whose receptors constituted drug binding sites later was extended to the benzodiazepine receptors and to a series of endogenous lipid amides as the natural ligands for cannabinoid receptors, termed the endocannabinoids (Piomelli, 2003).

Identification of Central Transmitters. An essential step in understanding the functional properties of neurotransmitters within the context of the circuitry of the brain is to identify substances that are transmitters at specific interneuronal connections. The criteria for the rigorous identification of central transmitters require the same data set used to establish the transmitters of the autonomic nervous system (Chapter 8).

1. The transmitter must be shown to be present in the presynaptic terminals of the synapse and in the neurons from which those presynaptic terminals arise.
2. The transmitter must be released from the presynaptic nerve concomitantly with presynaptic nerve activity.
3. When applied experimentally to target cells, the effects of the putative transmitter must be identical to the effects of stimulating the presynaptic pathway.
4. Specific pharmacological agonists and antagonists should mimic and antagonize, respectively, the measured functions of the putative transmitter with appropriate affinities and order of potency.

Other studies, especially those implicating peptides as neurotransmitters, suggest that many brain and spinal-cord terminals contain more than one transmitter substance (Hökfelt et al., 2003). Substances that co-exist in a given synapse are presumed to be released together. In some systems release has been shown to be frequency-dependent, with higher-frequency bursts mediating peptide release. Co-existing substances may either act jointly on the postsynaptic membrane, or may act presynaptically to affect release of transmitter from the presynaptic terminal. Clearly, if more than one substance transmits information, no single agonist or antagonist would be expected to faithfully mimic or fully antagonize activation of a given presynaptic element. Co-storage and co-release of ATP and NE are an example (Burnstock, 1995). In addition to being released as a co-transmitter with other biogenic amines, purines including ATP and adenosine have been shown to mediate diverse effects through interactions with distinct families of cell-surface purinergic receptors (Ralevic and Burnstock, 1998).

**Ion Channels.** The electrical excitability of neurons is achieved through modification of ion channels in neuronal plasma membranes. We now understand in considerable detail how three major cations, Na+, K+ and Ca2+, as well as Cl− anions, are regulated in their flow through highly discriminative ion channels (Figures 14–2 and 14–3). The relatively high extracellular concentration of Na+ (~140 mM) compared to its concentration intracellularly (~14 mM) means that increases in permeability to Na+ causes depolarization, ultimately leading to the generation of action potentials. In contrast, the intracellular concentration of K+ is relatively high (~120 mM, vs. 4 mM outside the cell) and increased permeability to K+ results in hyperpolarization. Changes in the concentration of intracellular Ca2+ (100 nM → 1 μM) affects multiple processes in the cell and are critical in the release of neurotransmitters. Cellular homeostatic mechanisms (Na+,K+-ATPase, Na+,Ca2+ exchanger, Ca2+-ATPases, etc.) maintain the basal concentrations of these ions, as does intracellular sequestration of releasable Ca2+ in storage vesicles.

The Cl− gradient across the plasma membrane (~116 mM outside vs 20 mM inside the cell) explains the fact that activation of Cl− channels causes an inhibitory postsynaptic potential (IPSP) that dampens neuronal excitability and inactivation of these channels can lead to hyperexcitability. There are three distinct types of Cl− channel (Figure 14–3). Ligand-gated channels are linked to inhibitory transmitters including GABA and glycine. CIC channels, of which nine subtypes have been cloned, affect Cl− flux, membrane potential, and the pH of intracellular vesicles. Cystic fibrosis transmembrane conductance regulated (CFTR) channels bind ATP and are regulated by phosphorylation of serine residues.

Voltage-dependent ion channels provide for rapid changes in ion permeability along axons and within dendrites and for excitation-secretion coupling that releases neurotransmitters from presynaptic sites (Catterall, 1993; Catterall and Epstein, 1992). The intrinsic membrane-embedded domains of the α-subunit of Na+ and Ca2+ channels are envisioned as four tandem
Figure 14–2. Structural similarities of voltage-dependent Na⁺, Ca²⁺, and K⁺ channels. A. The α subunit in both Ca²⁺ and Na⁺ channels contains four subunits, each with six transmembrane hydrophobic domains. The hydrophobic regions that connect segments five and six in each domain form the pore of the channel. Segment four in each domain includes the voltage-sensor. See Figure 20–2 for additional details. (Adapted with permission from Catterall W. From ionic currents to molecular mechanisms: The structure and function of voltage-gated sodium channels. Neuron, 2000, 26:13–25. Copyright © Elsevier.) B. The Ca²⁺ channel also requires several auxiliary small proteins (α₂, β, γ, and δ). The α₂ and δ subunits are linked by a disulfide bond. Regulatory subunits also exist for Na⁺ channels. C. Voltage-sensitive K⁺ channels (Kᵥ) and the rapidly activating K⁺ channel (Kₐ) share a similar putative hexaspanning structure similar in overall configuration to one repeat unit within the Na⁺ and Ca²⁺ channel structure, while the inwardly rectifying K⁺ channel protein (Kᵢ) retains the general configuration of just loops five and six. Regulatory β subunits (cystosolic) can alter Kᵥ channel functions. Channels of these two overall motifs can form heteromultimers.
repeats of a putative six-transmembrane domain (Figure 14–2), while the K+ channel family contains greater molecular diversity. One structural form of voltage-regulated K+ channels consists of subunits composed of a single putative six-transmembrane domain. The inward rectifier K+ channel structure, in contrast, has two membrane-spanning domains, retaining a general configuration corresponding to transmembrane spans 5 and 6 of voltage-dependent channels with the interposed “pore region” that penetrates only the exofacial surface membrane (Figure 14–2). Within the CNS, variants of the K+ channels (the delayed rectifier, the Ca2+-activated K+ channel, and the after-hyperpolarizing K+ channel) regulated by intracellular second messengers have been shown to underlie complex forms of synaptic modulation (Greengard, 2001).

Ligand-gated ion channels, regulated by the binding of neurotransmitters, form a distinct group of ion channels (Figure 14–4). The structurally defined channel molecules can be examined to determine how drugs, toxins, and imposed voltages alter neuronal excitability.

Ca2+ is an important signaling molecule present at a concentration of 1.25 mM in extracellular fluid and at very low concentrations (~100 nM) intracellularly in resting cells, rising to 1 μM upon excitation. Multiple classes of Ca2+ channel exist (Yu et al., 2005). Like Na+ channels, Ca2+ channels have a principal subunit called an α1 subunit as well as three or four additional subunits. The α1 subunit includes the conduction pore, voltage sensor, and gating apparatus as well as sites for channel regulation by drugs. They are structurally similar to the α-subunit of Na+ channels (Figure 14–2). A channel-mediated influx of Ca2+ can lead to muscle contraction, transmitter release, and alterations in gene expression. Ca2+ channels were originally classified according to electrophysical properties (Table 14–1). L-type Ca2+ channels are activated by large depolarization and can remain open for 500 milliseconds or longer. In contrast, T-type channels are activated by small depolarization and since they are subject to voltage-dependent inactivation, they are open only transiently.
P/Q, N and R channels comprise a sub family. They are not sensitive to L-type channels blockers and have been shown to be involved in the regulation of transmitter release. They are inhibited by peptide toxins including cone snail toxins (ω-conotoxins) and spider toxins (agatoxins).

Cyclic nucleotide–modulated channels consist of two groups:

- the cyclic nucleotide-gated (CNG) channels, which play important roles in sensory transduction for olfactory and photoreceptors
- the hyperpolarization-activated, cyclic nucleotide–gated (HCN) channels

CNG channels belong to the superfamily of pore-loop channels for cations and share domain structure with HCG channels and Eag-like K⁺ channels. Activation of CNG channels involves the binding of cGMP or cAMP to the C terminal region of the channel protein. These channels are multimeric channels composed of A and B subunits. Each subunit can bind a single molecule of cAMP or cGMP. The HCN channels are cation channels that open with hyperpolarization and close with depolarization; upon direct binding of cyclic AMP or cyclic GMP, the activation curves for the channels are shifted to more hyperpolarized potentials. These channels play essential roles in cardiac pacemaker cells and presumably in rhythmically discharging neurons. Similar channels respond to Ca²⁺/calmodulin (Biel and Michelakis, 2009). Activation of these channels offers a therapeutic target for the treatment of hyperalgesia seen following spinal cord ligation.

*Five classes of Ca²⁺ channel identified as L, P/Q, N, R and T channels exist, as defined in text.
Transient receptor potential (TRP) channels, are a family of hexaspanning receptors with a cation-permeable pore domain between the fifth and sixth transmembrane segments, and a common 25-amino acid TRP box C-terminal to the sixth transmembrane domain. TRP channels are responsive to multiple stimuli and play crucial roles in sensory physiology, including thermosensation, osmosensation, and taste. Members of the IRPV subfamily (vanilloid receptors) interact with numerous ligands, including the endogenous cannabinoid, anandamide, and the chili pepper ingredient, capsaicin (Ramsey et al., 2006).

**NEUROTRANSMITTER RECEPTOR-EFFECTOR COUPLING IN THE CNS**

A number of molecular mechanisms have been identified that link receptor occupancy to biological responses (Figure 14–5). The most commonly seen post-receptor events are changes in ion flux through channels formed by a multi-subunit receptor complex (Figures 14–2 and 14–3). The change in permeability is a characteristic of the specific receptor. For example, activation of N-AChR or NMDA receptors results in depolarization by increasing the permeability to Na⁺ (as well as Ca²⁺). GABA and glycine a receptor are generally hyperpolarizing.

*Figure 14–5. General Patterns of Signal Transduction in the Brain.* A. Neurotransmitter activation of a receptor that contains an integral ion channel. B. Neurotransmitter activation of G protein-coupled receptor. After activation, the βγ subunits of the G protein can directly regulate an ion channel (left), and the α subunit can activate second messenger-dependent signaling involving protein kinases and protein phosphatases, which can, in turn, affect ion channels and other neuronal processes (right). C. Neurotrophic factors promote receptor dimerization, which leads to activation of receptor protein tyrosine kinase activity and its sequelae. D. Steroid hormone activation of a cytoplasmic receptor. After the receptor-hormone complex forms, it enters the nucleus and regulates gene expression (see Figure 6–12). (Redrawn with permission from Nestler EJ, Hyman SE, Malenka RC (eds). *Molecular Neuropharmacology.* New York: McGraw-Hill, 2000, p 76. Copyright © 2009 by The McGraw-Hill Companies, Inc. All rights reserved.)
selectively increasing permeability to Cl\(^{-}\). Responses to receptors with a channel as part of its structure tends to be rapid since the effects are direct and generally do not require multiple steps or a series of protein-protein interactions leading to enzyme activation. Oligomeric ion channel receptors are composed of multiple subunits, each usually having six transmembrane domains (Figure 14–2). Ion channel receptors for neurotransmitters contain sites for reversible modulation by protein kinases and phosphoprotein phosphatases and sequences responsible for voltage-gating. Receptors with this structure include nicotinic cholinergic receptors; the receptors for the amino acids GABA, glycine, glutamate, and aspartate; and the 5-HT\(_3\) receptor (Figure 14–5A).

The second major group of receptors is the G-protein coupled receptors (GPCRs), which interact with heterotrimeric GTP-binding proteins (Chapter 3). GPCRs are heptaspanning membrane proteins with an extracellular amino terminus and an intracellular carboxy terminus (Figures 14–5B and 14–6). Comparison

**Figure 14–6. The \(\beta\) adrenergic receptor (\(\beta\)AR).** This two-dimensional bead-on-a string model illustrates features common to most heptaspanning GPCRs. Red lines mark 10-amino acid regions. The amino terminus (N) is extracellular and the carboxyl terminus (C) is intracellular; in between are 7 hydrophobic transmembrane (TM) domains and alternating intracellular and extracellular loops (e\(_{1,3}\) and i\(_{1,3}\)). Glycosylation sites are found near the N terminus; consensus sites for phosphorylation by PKA (arrows) are found in the i\(_3\) loop and the carboxy terminal tail. Multiple sites for \(\beta\)ARK occur throughout the carboxy terminal region. An aspartate residue in TM\(_3\) (asp113) interacts with the nitrogen of catecholamine agonists while two series (ser204, ser207) in TM\(_5\) interact with the hydroxyl groups on the phenyl ring of catecholamine agonists. A cysteine residue (cys 341) is a substrate for palmitoylation. Interaction of the palmitoyl group with membrane lipids reduces the flexibility of the carboxy tail. (Reprinted by permission from Macmillan Publishers Ltd: Rasmussen SGF, Choi H-J, Rosenbaum DM et al: Crystal structure of the human \(\beta2\) adrenergic G-protein-coupled receptor. *Nature* 450:383, 2007. Copyright \(\odot\) 2007.)
of multiple members of this receptor class reveals significant homology among the amino acids in the hydrophobic membrane spanning domains. Sites for N-linked glycosylation are found on the extracellular amino tail and sometimes on the second extracellular loop. There are also multiple potential sites for phosphorylation on the third intracellular loop and the carboxy tail. Finally, some members of this class of receptors are palmitoylated on the carboxy tail. When this occurs, the carboxy tail is pulled toward the membrane and becomes relatively fixed in position (Figure 14–6). GPCRs are associated with a broad spectrum of physiological effects including activation of K+ channels, activation of PLC-IP$_3$-Ca$^{2+}$ pathways and modulation of adenylyl cyclase activity. The interaction of GPCRs with effectors is regulated by a multiplicity of G-proteins, each a heterotrimer of $\alpha$ and $\beta\gamma$ subunits. The GTP-binding $\alpha$ subunits modulate the activities of numerous effectors (e.g., adenylyl cyclase, PLC). The $\beta\gamma$ subunits are also active, especially in the regulation of ion channels. G$_0$ is prominent in the CNS and in sensory neurons, G$_{gust}$ mediates stimulation of taste receptors, G$_{olf}$ mediates olfaction, and transducin mediates photo-transduction. The G protein activation-inactivation is described in Chapter 3.

Strategies involving mutagenesis have defined how activated receptors (themselves subject to reversible phosphorylation at one or more functionally distinct sites) can interact with heterotrimeric GTP-binding protein complex. GPCRs include muscarinic cholinergic receptors, subtypes of GABA and glutamate receptors, and many other aminergic and peptidergic receptors. Transfecting cells lacking GPCRs with mRNAs for GPCRs with no known ligands has led to the identification of novel neuropeptide ligands for these “orphan” receptors (Robas et al., 2003).

A third receptor motif is seen with a variety of growth factor receptors (GFR); these are typically monospanning membrane proteins that have an extracellular binding domain that regulates an intracellular catalytic activity, often a protein tyrosine kinase (Figure 14–5C). These receptors are generally active as dimers and possess intrinsic tyrosine kinase activity. Following binding of an agonist ligand, dimerization of the receptor occurs, resulting in receptor autophosphorylation. The phosphorylated receptor recruits cytoplasmic proteins leading to multiple protein-protein interactions and activation of signaling cascades (Chapter 3). Receptors with intrinsic guanylyl cyclase activity rather than protein kinase activity are a variation on this theme; an example is the atrial natriuretic peptide (ANP) receptor.

A distinct class of receptors transduces steroid hormone signaling. Steroid hormones cross cell membranes and bind to cytoplasmic receptors. After nuclear translocation these receptors bind DNA and function as transcriptional regulators (Figures 14–5D and 6–12).

Postsynaptic receptivity of CNS neurons is regulated dynamically in terms of the number of receptor sites and the threshold required to generate a response. Receptor number often depends on the concentration of agonist to which the target cell is exposed. Thus, chronic exposure to an agonist can lead to a reduction in responsiveness and in the number of receptors (desensitization and down-regulation) and consequently to subsensitivity or tolerance to the transmitter. Conversely, denervation or the administration of an antagonist can lead to supersensitive responses partially mediated by an increase in the number of receptors. For many GPCRs, down-regulation is achieved by the actions of receptor kinases (GRKs) that phosphorylate agonist occupied receptors leading in turn to internalization of the receptors (Chapter 3).

### CELL SIGNALING AND SYNAPTIC TRANSMISSION

Most cell-to-cell communication in the CNS involves chemical transmission (see Chapter 8). Chemical transmission requires several discreet specializations (Figure 14–7):

1. **Transmitter synthesis.** Small molecules like ACh and NE are synthesized in nerve terminals; peptides are synthesized in cell bodies and transported to nerve terminals.
2. **Transmitter storage.** Synaptic vesicles store transmitters, often in association with various proteins and frequently with ATP.
3. **Transmitter release.** Release of transmitter occurs by exocytosis. Depolarization results in an influx of Ca$^{2+}$, which in turn appears to bind to proteins called synaptotagmins. An active zone is established to which vesicles dock and then fuse with scaffolding proteins on the presynaptic membrane. After fusing with the membrane and exocytotic release of their contents, synaptic vesicle proteins are recycled through endocytosis (see Figures 8–2, 8–3, and 8–5).
4. **Transmitter recognition.** Receptors exist on postsynaptic cells, which recognize the transmitter. Binding of a neurotransmitter to its receptor initiates a signal transduction event, as previously described.
5. **Termination of action.** A variety of mechanisms terminate the action of synaptically released transmitter, including hydrolysis (for acetylcholine and
peptides) and reuptake into neurons by specific transporters such as NET, SERT, and DAT (for NE, 5-HT, DA) (see Chapters 5, 8, and 13). Inhibitors of NET, SERT, and DAT increase the dwell time and thus the effect of those transmitters in the synaptic cleft. Inhibitors of the uptake of NE and/or 5-HT are used to treat depression and other behavioral disorders, as described in Chapters 15 and 16.

Multiple transport proteins with selectivity for various transmitters have been cloned (Figure 14–8). In contrast to the GPCRs discussed earlier, these proteins have 12 hydrophobic membrane-spanning domains. This means that both the amino and carboxy termini are on the same, intracellular, side of the membrane. Like the GPCRs, these transporters have sites for glycosylation on the cytoplasmic side, primarily on the i2 loop, and sites for phosphorylation, primarily on the amino and carboxy tails. Comparison of the sequences of the transporters for NE and DA (Figure 14–8) reveals striking conservation in the TM domains.

**Neurohormones.** The anterior and posterior pituitary secrete a variety of hormones and releasing factors. Hypothalamic neurons affecting the anterior pituitary release their hormones into the hypothalamic–adenohypophyseal portal blood system, which delivers them to the anterior pituitary, where they regulate the release of trophic hormones (i.e., ACTH, FSH, GH, LH, prolactin) into the blood. Other hypothalamic neurons project onto the posterior pituitary, where they release their peptide contents, oxytocin and arginine vasopression (anti-diuretic hormone, or ADH) into the systemic circulation (Figure 14–9 and Chapters 25 and 38).

Cytochemical evidence indicates that the same substances that are secreted as hormones from the posterior pituitary also mediate transmission at these sites. Thus, the designation hormone relates...
to the site of release at the posterior pituitary and does not necessarily describe all of the actions of the peptides.

**Neuromodulators.** The distinctive feature of a modulator is that it originates from non-synaptic sites, yet influences the excitability of nerve cells. Substances such as CO and ammonia, arising from active neurons or glia, are potential modulators acting through non-synaptic actions. Similarly, circulating steroid hormones, steroids produced in the nervous system (i.e., neurosteroids), locally released adenosine, and other purines, eicosanoids, and nitric oxide (NO) are regarded as modulators and/or neurotransmitters (discussed later).

**Neurotrophic Factors.** Neurotrophic factors are substances produced within the CNS by neurons, astrocytes, microglia, or transiently invading peripheral inflammatory or immune cells that assist neurons in their attempts to repair damage. The binding of neurotrophic factors to their receptors generally promotes receptor dimerization and protein tyrosine kinase activity in the intracellular domains of the receptors (Figure 14–5C). Seven categories of neurotrophic peptides are recognized:

1. classic neurotrophins (nerve growth factor, brain-derived neurotrophic factor, and the related neurotrophins)
2. neuroopoietic factors, which have effects both in brain and in myeloid cells (e.g., cholinergic differentiation factor [also called leukemia inhibitory factor], ciliary neurotrophic factor, and some interleukins)
3. growth factor peptides, such as epidermal growth factor, transforming growth factors α and β, glial cell–derived neurotrophic factor, and activin A
4. fibroblast growth factors
5. insulin-like growth factors

**Figure 14–8. Structure of the rat 5-HT transport protein.** Both the N terminus (NH₃⁺) and C terminus (COO⁻) are intracellular. These proteins typically have 12 hydrophobic, membrane-spanning domains with intervening extracellular and intracellular loops. The second extracellular loop is the largest and contains several potential glycosylation sites (indicated with tree-like symbols). Amino acid residues which are homologous to those in the DA transporter (DAT) and the NE transporter (NET) are colored, as noted. The most highly conserved regions of these transporters are located in the transmembrane domains; the most divergent areas occur in the N and C termini. (Courtesy of Dr. Beth J. Hoffman, Vertex Pharmaceuticals, San Diego.)
6. platelet-derived growth factors
7. axon guidance molecules, some of which also affect cells of the immune system

Drugs designed to elicit the formation and secretion of these products or to emulate their actions may provide useful adjuncts to rehabilitative treatments (Huang and Reichardt, 2001).

**CENTRAL NEUROTRANSMITTERS**

The view that synapses are drug-modifiable control points within neuronal networks requires explicit delineation of the sites at which given neurotransmitters may operate and the degree of specificity with which such sites may be affected. One principle that underlies the following summaries of individual transmitter substances is the chemical-specificity hypothesis often ascribed to Dale: that a given neuron releases the same transmitter substance at each of its synaptic terminals. Because of the growing indications that some neurons contain more than one transmitter substance (Hökfelt et al., 2000), Dale’s hypothesis has been modified: A given neuron secretes the same set of transmitters from all of its terminals. Even this formulation may require revision. For example, it is not clear whether a neuron that secretes a given peptide will process the precursor peptide to the same end product at all of its synaptic terminals.

Neurotransmitters are discussed next as groups of substances within chemical categories: amino acids, amines, and neuropeptides. Other substances that may participate in central synaptic transmission include purines (such as adenosine and ATP), NO (Boehning and Snyder, 2003), and arachidonic acid derivatives (Piomelli, 2003).

**Amino Acids.** The CNS contains uniquely high concentrations of certain amino acids, notably glutamate and gamma-aminobutyric acid (GABA), that potently alter neuronal firing. Their ubiquitous distribution within the brain and the consistent observation that they produced prompt, powerful, and readily reversible but redundant effects on every neuron tested seemed out of keeping with the extreme heterogeneity of distribution and responsivity seen for other putative transmitters. The dicarboxylic amino acids (e.g., glutamate and aspartate) produced near universal excitation, while the monocarboxylic amino acids (e.g., GABA, glycine, β-alanine, and taurine) consistently caused inhibition. Following the emergence of selective antagonists, identification of selective receptors and receptor subtypes became possible. These data, together with the development of methods for mapping ligands and their receptors, led to widespread acceptance that the amino acids GABA, glycine, and glutamate are CNS transmitters.

**GABA.** Substantial data supports the idea that GABA mediates the inhibitory actions of local interneurons in the brain and may also mediate presynaptic inhibition within the spinal cord. Presumptive GABA-containing inhibitory synapses have been demonstrated most clearly between cerebellar Purkinje neurons and their targets in Deiter’s nucleus; between small interneurons and the major output cells of the cerebellar cortex, olfactory bulb, cuneate nucleus, hippocampus, and lateral septal nucleus; and between the vestibular nucleus and trochlear motoneurons. GABA also mediates inhibition within the cerebral cortex and between the caudate nucleus and the substantia nigra. GABA-containing neurons and nerve terminals have been localized with immunocytochemical methods that visualize glutamic acid decarboxylase, the enzyme that catalyzes the synthesis of GABA from glutamic acid, or by in situ hybridization of the mRNA for this protein. GABA-containing neurons frequently co-express one or more neuropeptides.

The most useful compounds for confirmation of GABA-mediated effects have been bicuculline and picrotoxin (Figure 14–10); however, many convulsants whose actions previously were unexplained...
Figure 14–10. Amino acid transmitters and congeners.
(including penicillin and pentylenetetrazol) are relatively selective antagonists of the action of GABA. Useful therapeutic effects have not yet been obtained through the use of agents that mimic GABA (such as muscimol), inhibit its active reuptake (such as 2,4-diaminobutyrate, nipecotic acid, and guvacine), or alter its turnover (such as aminoxyacetic acid).

GABA receptors have been divided into three main types: A, B, and C.

- The most prominent GABA-receptor subtype, the GABAA receptor, is a ligand-gated Cl⁻ ion channel, an “ionotropic receptor.”
- The GABAB receptor is a GPCR.
- The GABAC receptor is a transmitter-gated Cl⁻ channel.

GABAA receptor subunit proteins have been well characterized due to their abundance. The receptor also has been extensively characterized as the site of action of many neuroactive drugs, notably benzodiazepines, barbiturates, ethanol, anesthetic steroids, and volatile anesthetics (Figure 14–11).

Based on sequence homology to the first reported GABAA subunit cDNAs, multiple subunits have been cloned, including 6α, 4β, and 3γ subunits. They appear to be expressed in multiple multimeric, pharmacologically distinctive combinations. In addition to these subunits, which are products of separate genes, splice variants for several subunits have been described.

The GABAA receptor is probably pentameric or tetrameric in structure with subunits that assemble together around a central pore typical for other ionotropic receptors. The major form of the GABAA receptor contains at least three different subunits α, β, and γ, with likely stoichiometry of 2α, 2β, 1γ. All three subunits are required to interact with benzodiazepines with the profile expected of a native GABAA receptor. The distribution of different subunit combinations of GABAA and their functions in the mammalian brain are summarized in Table 14–2 (Fritschy and Mohler, 1995).

The GABAB or metabotropic GABA receptor interacts with Gi to inhibit adenylyl cyclase, activate K⁺ channels, and reduce Ca²⁺ conductance. Presynaptic GABAB receptors function as autoreceptors, inhibiting GABA release, and may play the same role on neurons releasing other transmitters. Functional GABAB receptors are heterodimers made up of GABABR1 and GABABR2 subunits (Bettler et al., 2004). The GABAC receptor is less widely distributed than the A and B subtypes. GABA is more potent by an order of magnitude at GABAC than at GABAA receptors, and a number of GABAA agonists (e.g., baclofen) and modulators (e.g., benzodiazepines and barbiturates) seem not to interact with GABAC receptors. GABAC

BZ, benzodiazepines.
receptors are found in the retina, spinal cord, superior colliculus, and pituitary (Olsen and Betz, 2005).

**Glycine.** Many of the features described for the GABA<sub>α</sub> receptor family also apply to the inhibitory glycine receptor, which is prominent in the brainstem and spinal cord. Multiple subunits assemble into a variety of glycine receptor subtypes. These pharmacological subtypes are detected in brain tissue with particular neuroanatomical and neurodevelopmental profiles. As with the GABA<sub>α</sub> receptor, the complete functional significance of glycine receptor subtypes is not known. There is evidence for clustering of glycine receptors by the anchoring protein gephyrin (Sola et al., 2004). An additional role for glycine is as a co-agonist at NMDA receptors, at which both glutamate and glycine must be present for activation to occur.

**Glutamate and Aspartate.** Glutamate and aspartate are found in very high concentrations in brain, and both amino acids have powerful excitatory effects on neurons in virtually every region of the CNS. Their widespread distribution initially obscured their roles as transmitters, but there now is broad acceptance that glutamate and possibly aspartate are the principal fast (“classical”) excitatory transmitters throughout the CNS (Bleich et al., 2003; Conn, 2003). Multiple subtypes of receptors for excitatory amino acids have been cloned, expressed, and characterized pharmacologically, based on the relative potencies of synthetic agonists and the discovery of potent and selective antagonists (Kotecha and MacDonald, 2003). Glutamate receptors are classed functionally either as ligand-gated ion channel (“ionotropic”) receptors or as “metabotropic” GPCRs (Table 14–3).

Neither the precise number of subunits that assembles to generate a functional glutamate ionotropic receptor ion channel in vivo nor the intramembranous topography of each subunit has been established unequivocally. The ligand-gated ion channels are further classified according to the identity of agonists that selectively activate each receptor subtype, and are broadly divided into N-methyl-D-aspartate

<sup>a</sup>Glutamate is the principal agonist at both ionotropic and Metabotropic receptors for glutamate and aspartate.

CNQX, 6-Cyano-7-nitroquinolinic acid; NBQX, 1,2,3,4-Tetrahydro-6-nitro-2,3-dioxo-benzof[\]quinolinic acid; D-AP5, D-2-amino-5-phosphonovaleric acid; AIDA, 1-aminoindan-1,5-dicarboxylic acid; CBPG, (S)-(-)-2-(3′-carboxybicyclo(1.1.1)pentyl)-glycine; EGLU, (2S)-α-ethylglutamic acid; PCCG-4, phenylcarboxyclopropylglycine; MAP4, (S)-amino-2-methyl-4-phosphonobutanoic acid; MPPG, (RS)-α-methyl-4-phosphonophenylglycine; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; ATPA, 2-amino-3(3-hydroxy-5-tert-butylisoxazol-4-yl)propanoic acid; NMDA, N-methyl-D-aspartate; 3,5-DHPG, 3,5-dihydroxyphenylglycine; DCG-IV, dicarboxyclopropylglycine; L-AP-4, L-2-amino-4-phosphonobutiric acid; (S)-3,4-DCPG, (S)-3,4-dicarboxyphenylglycine.
(NMDA) receptors and non-NMDA receptors. The non-NMDA receptors include the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainic acid (KA) receptors (Table 14–3). Selective antagonists for these receptors are now available. In the case of NMDA receptors, agonists include open-channel blockers such as phencyclidine (PCP or “angel dust”), antagonists such as 5,7-dichlorokynurenic acid, which act at an allosteric glycine-binding site, and the novel antagonist ifenprodil, which may act as a closed-channel blocker. In addition, the activity of NMDA receptors is sensitive to pH and to modulation by a variety of endogenous agents including Zn²⁺, some neurosteroids, arachidonic acid, redox reagents, and polyamines such as spermine. Additional diversity of glutamate receptors arises by alternative splicing or by single-base editing of mRNAs encoding the receptors or receptor subunits. Alternative splicing has been described for metabotropic receptors and for subunits of NMDA, AMPA, and kainate receptors. For some subunits of AMPA and kainate receptors, the RNA sequence differs from the genomic sequence in a single codon of the receptor subunit that markedly affects the Ca²⁺ permeability of the receptor channel (Conn and Pin, 1997). AMPA and kainate receptors mediate fast depolarization at glutamatergic synapses in the brain and spinal cord. NMDA receptors are involved in normal synaptic transmission, but activation of NMDA receptors is usually associated more closely with the induction of various forms of synaptic plasticity rather than with fast point-to-point signaling in the brain. AMPA or kainate receptors and NMDA receptors may be co-localized at many glutamatergic synapses.

Activation of NMDA receptors is obligatory for the induction of a type of long-term potentiation (LTP) that occurs in the hippocampus. NMDA receptors normally are blocked by Mg²⁺ at resting membrane potentials. Thus, activation of NMDA receptors requires not only binding of synaptically released glutamate, but simultaneous depolarization of the postsynaptic membrane. This is achieved by activation of AMPA/kainate receptors at nearby synapses involving inputs from different neurons. AMPA receptors also are dynamically regulated to affect their sensitivity to the synergism with NMDA. Thus, NMDA receptors may function as coincidence detectors, being activated only when there is simultaneous firing of two or more neurons. A well-characterized phenomenon involving NMDA receptors is the induction of LTP. LTP refers to a prolonged (hours to days) increase in the size of a postsynaptic response to a presynaptic stimulus of given strength. NMDA receptors also can induce long-term depression (LTD; the converse of LTP) at CNS synapses. The frequency and pattern of synaptic stimulation may dictate whether a synapse undergoes LTP or LTD (Nestler et al., 2009). It is believed that NMDA-dependent LTP and LTD reflect the insertion and internalization of AMPA receptors, possibly mediated by CaM-kinase II and calcineurin/protein phosphatase 1, respectively (Figure 14–12).

**Figure 14–12. Major forms of NMDA receptor-dependent LTP and LTD.**

**A.** NMDA receptor-dependent LTP requires postsynaptic NMDA receptor activation leading to a rise in Ca²⁺ and activation of CaM kinase II (CaMKII). AMPA receptor insertion into the postsynaptic membrane is a major mechanism underlying LTP expression. **B.** NMDA receptor-dependent LTD is triggered by Ca²⁺ entry through postsynaptic NMDA receptor channels, leading to increases in the activity of the protein phosphatases calcineurin and PP1. LTD occurs when postsynaptic AMPA receptors are internalized. (Redrawn with permission from Nestler EJ, Hyman SE, Malenka RC (eds). *Molecular Neuropharmacology*. New York: McGraw-Hill, 2000, p 132. Glutamate Excitotoxicity. High concentrations of glutamate lead to neuronal cell death by mechanisms that have only recently begun to be clarified (Figure 14–13). The cascade of events leading to neuronal death is thought to be triggered by excessive activation of NMDA or AMPA/kinase receptors, allowing significant influx of Ca$^{2+}$ into neurons. Glutamate-mediated excitotoxicity may underlie the damage that occurs after ischemia or hypoglycemia in the brain, during which a massive release and impaired reuptake of glutamate in the synapse leads to excess stimulation of glutamate receptors and subsequent cell death. NMDA receptor antagonists can attenuate neuronal cell death induced by activation of these receptors (Haeberlein and Lipton, 2009). Because of their widespread distribution in the CNS, glutamate receptors have become targets for diverse therapeutic interventions. For example, a role for disordered glutamatergic transmission in the etiology of chronic neurodegenerative diseases and in schizophrenia has been postulated (Chapters 16 and 22).

Acetylcholine. Based on a non-homogeneous distribution within the CNS and the observation that peripheral cholinergic drugs could produce marked behavioral effects after central administration, many investigators addressed the possibility that ACh might also be a central neurotransmitter. In the late 1950s, Eccles and colleagues identified ACh as a neurotransmitter for the excitation of spinal cord Renshaw interneurons by the recurrent axon collaterals of spinal motoneurons. Subsequently, the capacity of ACh to elicit neuronal discharge has been replicated on scores of CNS cells (Shepherd, 2003). Eight major clusters of ACh neurons and their pathways have been characterized (Cooper et al., 2003; Nestler et al., 2009; Shepherd, 2003). For additional details, see Chapter 9.
Non-selective agonists include carbachol, pilocarpine, and oxotremorine. Non-selective antagonists include atropine and scopolamine. McN-A-3436 is a selective agonist at the M<sub>1</sub> receptor. 4-DAMP is 4-diphenylacetoxy-N-methylpiperidine.

In most regions of the CNS, the effects of ACh result from interaction with a mixture of nicotinic and muscarinic receptors. Nicotinic ACh receptors are found in autonomic ganglia, the adrenal gland, and in the CNS. Activation by ACh results in a rapid increase in the influx of Na<sup>+</sup> and Ca<sup>2+</sup> and subsequent depolarization. Nicotinic cholinergic receptors appear to desensitize rapidly. The receptors are composed by five heterologous subunits arranged around a central pore (see Figure 14–4). A total of 17 subunits, including 10 α, 4 β, as well as 6, ε, and γ subunits, have been identified. The nicotinic receptor at the neuromuscular junction has the composition α<sub>1</sub>βεδγ. However, some α subunits, including α7, α8, and ε9, can form functional homo-oligomers. For additional information on neuronal nicotinic ACh receptors, see Chapter 11.

There are five subtypes of muscarinic receptors, all of which are expressed in the brain. M<sub>1</sub>, M<sub>4</sub>, and M<sub>5</sub> couple to G<sub>q</sub> while the M<sub>2</sub> and M<sub>3</sub> receptors couple to G<sub>i</sub> (Table 14–4). Several presumptive cholinergic pathways have been proposed in addition to that of the motoneuron-Renshaw cell.

**Catecholamines.** The brain contains separate neuronal systems that utilize three different catecholamines—dopamine, norepinephrine, and epinephrine. Each system is anatomically distinct and serves separate, functional roles within its field of innervation (Nestler et al., 2009).

**Dopamine.** Although DA was originally regarded only as a precursor of NE, assays of distinct regions of the CNS revealed that the distributions of DA and NE are markedly different. In fact, more than half the CNS content of catecholamine is DA and extremely large amounts of DA are found in the basal ganglia. There are three major DA-containing pathways in the CNS (Figure 14–14):

- the nigrostriatal pathway
- the mesocortical pathway, where neurons in the ventral tegmental nucleus project to a variety of midbrain structures and to the frontal cortex
- the tuberoinfundibular pathway, which delivers DA to cells in the anterior pituitary

Initial pharmacological studies discriminated between two subtypes of DA receptors: D<sub>1</sub> (which couples to G<sub>S</sub> to stimulate adenylyl cyclase) and D<sub>2</sub> (which couples to G<sub>i</sub> to inhibit adenylyl cyclase). Subsequent studies identified three additional genes encoding subtypes of DA receptors: the D<sub>2</sub> receptor, which is related to the D<sub>1</sub> receptor; and the D<sub>3</sub> and D<sub>4</sub> receptors, which are part of what is called the D<sub>2</sub> receptor family. There are also two isoforms of the D<sub>2</sub> receptor that differ in the predicted length of their third intracellular loops (Nestler et al., 2009). The D<sub>2</sub>L and D<sub>2</sub>R receptors activate the G<sub>S</sub>-adenyl cyclase-cyclic AMP-PKA system. The D<sub>1</sub> receptors couple to multiple effector systems, including inhibition of adenylyl cyclase activity, suppression of Ca<sup>2+</sup> currents, and activation of K<sup>+</sup> currents. The effector systems to which the D<sub>2</sub>L and D<sub>2</sub>R receptors couple have not been unequivocally defined (Greengard, 2001) (Table 14–5). DA-containing pathways and receptors have been implicated in the pathophysiology of schizophrenia and Parkinson disease and in the side effects seen following pharmacotherapy of these disorders (Chapters 16 and 22).

**Norepinephrine.** There are relatively large amounts of NE within the hypothalamus and in certain parts of the limbic system, such as the central nucleus of the amygdala and the dentate gyrus of the

**Figure 14–14.** The three major dopaminergic projections in the CNS. 1. The mesostriatal (or nigrostriatal) pathway. Neurons in the substantia nigra pars compacta (SNc) project to the dorsal striatum (upward dashed blue arrows); this is the pathway that degenerates in Parkinson disease. 2. Neurons in the ventral tegmental area project to the ventral striatum (nucleus accumbens), olfactory bulb, amygdala, hippocampus, orbital and medial prefrontal cortex, and cingulate gyrus (solid blue arrows). 3. Neurons in the arcuate nucleus of the hypothalamus project by the tuberoinfundibular pathway in the hypothalamus, from which DA is delivered to the anterior pituitary (red arrows).
Hippocampus. However, this catecholamine also is present in significant, although lower, amounts in most brain regions. Detailed mapping studies indicate that noradrenergic neurons of the locus ceruleus innervate specific target cells in a large number of cortical, subcortical, and spinomedullary fields (Nestler et al., 2009). NE has been established as the transmitter at synapses between presumptive noradrenergic pathways and a wide variety of target neurons. For example, stimulation of the locus ceruleus depresses the spontaneous activity of target neurons in the cerebellum; this is associated with a slowly developing hyperpolarization and a decrease in membrane conductance (Aston-Jones et al., 2001; Nestler et al., 2009).

Multiple types and subtypes of adrenergic receptors (α₁, α₂, and β) and their subtypes have been described in the CNS; all are GPCRs (Table 14–6). As expected, β receptors couple to Gₛ and

tence to adenyl cyclase. $\alpha_1$ Adrenergic receptors are coupled to $G_{q}$, resulting in stimulation of phospholipase C, and are associated predominantly with neurons. $\alpha_2$ Adrenergic receptors are found on glial and vascular elements, as well as on neurons; they couple to $G_{i}$ and thence to inhibition of adenyl cyclase activity. $\alpha_2$ Receptors on noradrenergic target neurons of the neocortex and thalamus respond to NE with prazosin-sensitive, depolarizing responses due to decreases in K$^+$ conductance. However, stimulation of $\alpha_2$ receptors also can augment cyclic AMP accumulation in neocortical slices in response to concurrent stimulation of the $G_{q}$ pathway, possibly an example of $G_{i}-G_{q}$ cross-talk involving Ca$^{2+}$/calmodulin and/or PKC (Ostrom et al., 2003). $\alpha_2$ Adrenergic receptors are prominent on noradrenergic neurons, where they presumably couple to $G_{q}$, inhibit adenyl cyclase, and mediate a hyperpolarizing response due to enhancement of an inwardly rectifying K$^+$ channel. As in the periphery, $\alpha_2$ receptors are located presynaptically, where they function as inhibitory autoreceptors. There is also evidence for postsynaptic $\alpha_2$ receptors that modulate sympathetic tone. Effects mediated through $\alpha_2$ receptors on blood pressure have been reported. It is believed, e.g., that the antihypertensive effects of the $\alpha_2$ selective agonist clonidine are due to stimulation of $\alpha_2$ receptors in the lower brainstem.

**Epinephrine.** Neurons in the CNS that contain epinephrine were recognized only after the development of sensitive enzymatic assays and immunocytochemical staining techniques for phenylethanolamine-N-methyltransferase, the enzyme that converts NE into epinephrine. Epinephrine-containing neurons are found in the medullary reticular formation and make restricted connections to pontine and diencephalic nuclei, eventually coursing as far rostrally as the paraventricular nucleus of the thalamus. Their physiological properties have not been unambiguously identified.

**5-Hydroxytryptamine (Serotonin).** In mammals, 5-HT containing neurons are found in nine nuclei lying in or adjacent to the midline (raphe) regions of the pons and upper brainstem. Cells receiving cytochemically demonstrable 5-HT input, such as the suprachiasmatic nucleus, ventrolateral geniculate body, amygdala, and hippocampus, exhibit a uniform and dense investment of serotonergic terminals.

Molecular biological approaches have led to identification of 14 distinct mammalian 5-HT receptor subtypes (Table 14–7). These subtypes exhibit characteristic ligand-binding profiles, couple to different intracellular signaling systems, exhibit subtype-specific distributions within the CNS, and mediate distinct behavioral effects of 5-HT. Most 5-HT receptors are GPCRs coupling to a variety of G-protein $\alpha$ subunits. The 5-HT$_1$ receptor, however, is a ligand-gated ion channel with structural similarity to the $\alpha$-subunit of the nicotinic acetylcholine receptor. As seen with subtypes of glutamate receptors, mRNA editing has also been observed for the 5-HT$_{2C}$ receptor (Niswender et al., 2001); the resulting isoforms differ in agonist affinity and distribution in the brain.

The family of 5-HT$_1$ receptors is composed of at least five receptor subtypes (Table 14–7) that are linked to inhibition of adenyl cyclase activity or to regulation of K$^+$ or Ca$^{2+}$ channels. 5-HT$_{1A}$ Receptors are abundantly expressed on 5-HT neurons in the dorsal raphe nucleus, where they are thought to be involved in temperature regulation. They also are found in regions of the CNS associated with mood and anxiety such as the hippocampus and amygdala. Activation of 5-HT$_{1A}$ receptors opens an inwardly rectifying K$^+$ conductance, which leads to hyperpolarization and neuronal inhibition. These receptors can be activated by drugs including buspirone, which is used for the treatment of anxiety and also used off-label for panic disorders. In contrast, 5-HT$_{1B}$ receptors are activated by low concentrations of sumatriptan, which is currently prescribed for acute management of migraine headaches (Chapters 13 and 34). The 5-HT$_{1C}$ receptor class has three subtypes: 5-HT$_{1A}$, 5-HT$_{1B}$, and 5-HT$_{1C}$; these receptors couple to pertussis-toxin-insensitive G proteins (e.g., $G_{q}$ and $G_{12}$) and link to activation of PLC. Based on ligand binding and mRNA in situ hybridization patterns, 5-HT$_{2A}$ receptors are enriched in forebrain regions such as the neocortex and olfactory tuber, as well as in several nuclei arising from the brainstem. The 5-HT$_{2C}$ receptor, which is very similar in sequence and pharmacology to the 5-HT$_{2A}$ receptor, is expressed abundantly in the choroid plexus, where it may modulate cerebrospinal fluid production. Many of the effects of antidepressants are thought to be a consequence of increased stimulation of 5-HT receptors following inhibition of 5-HT reuptake by SERT. On the other hand, inhibition of 5-HT$_{3}$ receptors may account for the increased weight gain associated with neuroleptics used to treat schizophrenia.

5-HT$_{3}$ receptors function as ligand-gated ion channels; these receptors were first recognized in the peripheral autonomic nervous system. Within the CNS, they are expressed in the area postrema and solitary tract nuclei, where they couple to potent depolarizing responses that show rapid desensitization to continued 5-HT exposure. Actions of 5-HT at central 5-HT$_{1}$ receptors can lead to emesis and anti-nociceptive actions, and 5-HT$_{3}$ antagonists are beneficial in the management of chemotherapy-induced emesis (Chapter 46).

Within the CNS, 5-HT$_{2}$ receptors occur on neurons within the inferior and superior colliculi and in the hippocampus. Activation of 5-HT$_{2}$ receptors stimulates the $G_{q}$-adenyl cyclase-cyclic AMP pathway. Other 5-HT receptors are less well studied in the CNS. The 5-HT$_{4}$ and 5-HT$_{7}$ receptors also couple to $G_{i}$; their affinity for clozapine may contribute to its antipsychotic efficacy (Chapter 16).

The hallucinogen lysergic acid diethylamide (LSD) is a potent partial agonist at 5-HT$_{2}$ receptors. When applied iontophoretically, LSD inhibits the firing of raphe (5-HT) neurons. The inhibitory effect of LSD on raphe neurons offers a plausible explanation for its hallucinogenic effects, namely that these effects result from depression of activity in a system that tonically inhibits visual and other sensory inputs. However, typical LSD-induced behaviors are seen in animals with destroyed raphe nuclei or after blockade of the synthesis of 5-HT by p-chlorophenylalanine (Aghajanian and Marek, 1999; Nichols, 2004).

**Histamine.** Histamine and antihistamines have long been known to produce significant effects on animal behavior. Biochemical detection of histamine synthesis by neurons and direct cytochemical localization of these neurons have defined a histaminergic system in the CNS. Most of these neurons are located in the ventral posterior hypothalamus; they give rise to long ascending and descending tracts that are typical of the patterns characteristic of other aminergic systems. Based on the presumptive central effects of histamine antagonists, the histaminergic system is thought to affect arousal, body temperature, and vascular dynamics. Four subtypes of histamine receptors have been described; all are GPCRs (Figure 14–15). H$_{1}$ receptors, the most prominent, are located on glia and vessels as well as on neurons and act to mobilize Ca$^{2+}$ in receptive cells through the $G_{q}$-PLC pathway.
**Peptides.** The discovery during the 1980s of numerous novel peptides in the CNS, each capable of regulating neuronal function, produced considerable excitement and an imposing catalog of substances as well as potential medications based upon interaction with peptide receptors (Darlison and Richter, 1999; Hökfelt et al., 2003). In addition, certain peptides previously thought to be restricted to the GI tract or to endocrine glands have been found in the CNS. Most of these peptides bind to GPCRs. Many of the effects are modulatory rather than causing direct excitation or inhibition. Myriad peptide neurotransmitters or neuromodulators have been described (Table 14–11). Relatively detailed neuronal maps are available that identify immunoreactivity to peptide-specific antisera. While some CNS peptides may function on their own, most are now thought to act primarily in concert with co-existing transmitters, both amines and amino acids.

Neuropeptides are processed and stored in large, dense-core vesicles (LDCVs; see Figure 14–7). The peptides may be co-localized and released together with small molecule transmitters, such as a biogenic amine. Multiple peptides may be co-localized within the same neuron. As noted, some neurons may contain two or more transmitters, including peptides, and their release can be independently regulated.

In contrast to the biogenic amines or amino acids, peptide synthesis requires transcription of DNA into mRNA and translation of mRNA into protein. This takes place primarily in perikarya and the resulting peptide is then transported to nerve terminals. Single genes can, through the post-translational action of peptidases, give rise to multiple neuropeptides. For example, proteolytic processing of proopiomelanocortin (POMC) gives rise to, among other things, ACTH, α and γ MSH, β-MSH, and β-endorphin (Figure 14–16). In addition, alternative splicing of RNA transcripts may result in distinct mRNA species. For example, calcitonin and calcitonin gene-related peptide (CGRP) are derived in specific tissues from the same primary transcript.

**Organization by Function.** Since most peptides were identified initially on the basis of bioassays, their names reflect these biologically assayed functions (e.g., thyrotropin-releasing hormone and vasoactive intestinal polypeptide). These names become trivial when more ubiquitous distributions and additional functions are discovered. Some general integrative role might be hypothesized for widely separated neurons (and other cells) that make the same peptide. However, a more parsimonious view is that each peptide has unique messenger roles at the cellular level that are used repeatedly in biologically similar pathways within functionally distinct systems.

Most neuropeptide receptors are GPCRs. In comparison to GPCRs for smaller ligands such as biogenic amines and amino acids, the extracellular domains of neuropeptide receptors play a larger role in ligand binding. As seen with other transmitter systems, there are often multiple subtypes of receptor for the same peptide transmitter (Table 14–9). For example, there are five subtypes of receptor for somatostatin and all inhibit adenylyl cyclase through an interaction with G<sub>i</sub>; they differ in their interaction with various somatostatin analogs. The cloning of the major members of the opioid-peptide receptors has revealed unexpected, and as yet unexplained, homologies with receptors for somatostatin, angiotensin, and other peptides. Multiple melanocortin receptors exist that respond to various peptides derived from POMC. Not surprisingly, the receptor on adrenal

---

**Figure 14–15. Main signaling pathways for histamine receptors.** Histamine can couple to a variety of G protein-linked signal transduction pathways via four different receptors. The H<sub>1</sub> receptor and some H<sub>4</sub> receptors activate phosphatidylinositol turnover via G<sub>q11</sub>. The other receptors couple either positively (H<sub>2</sub> receptor) or negatively (H<sub>3</sub> and H<sub>4</sub> receptor) to adenylyl cyclase activity via G<sub>i</sub> and G<sub>o</sub>.
cortical cells responds to ACTH, while that on melanocytes responds to α-MSH. Further evidence for complexity comes from the realization that agonists at subtypes of melanocortin receptors are associated with a variety of biological effects including skin darkening (MCR1), decreased appetite (MCR3 and/or MCR4), and sexual arousal (MCR4).

Although most peptide receptors are GPCRs, exceptions do exist. The amiloride-sensitive FMRF amide (phe-met-arg-phe-amide) receptor is a peptide-gated ion channel. The large number of neuropeptides and peptide receptors has led to increased interest in identifying therapeutic agents. Examples include experimental substance P antagonists as antidepressants or to treat anxiety, and antagonists of CRH for stress related disorders.

**Comparison with Other Transmitters.** Peptides differ in several important respects from the monoamine and amino acid transmitters. Peptide synthesis takes place in the rough endoplasmic reticulum. The propeptide is cleaved (processed) to the secreted form as secretory vesicles are transported from the perinuclear cytoplasm to the nerve terminal. Active mechanisms for the local synthesis of peptides have not been described; thus, peptidergic nerve terminals depend on distant sites of synthesis. As for structure-activity relationships for peptide transmitters, linear chains of amino acids can assume many conformations at their receptors, making it difficult to define the sequences and their steric relationships that are critical for activity. Until recently, it was difficult to develop non-peptidic synthetic agonists or antagonists that interact with specific peptide receptors. Such agents now are being developed for many neuropeptides (Hökfelt et al., 2003). Natural products have not been good sources of drugs that affect peptidergic transmission. Only one plant alkaloid, morphine, has been found to act selectively at peptidergic synapses. Fortunately for pharmacologists, morphine was discovered before the endorphins, or rigid

Other Regulatory Substances

Cannabinoids. Delta-9-tetrahydrocannabinol (THC) is one of several active substances in marijuana (Figure 14–17). It has dramatic short-term effects, including causing feelings of euphoria and altered sensory perception. After chronic or long-term use, withdrawal symptoms include irritability and sleep disturbances. The primary pharmacologic effects of THC follow its interaction with CB$_1$ receptors in the CNS and CB$_2$ receptors in the periphery. CB$_1$ receptors are found primarily in the basal ganglia, hippocampus, cerebellum, and cerebral cortex. They are also expressed in some non-neuronal cells and tissues, including leukocytes and testis. CB$_2$ receptors are expressed in the spleen, tonsils, bone marrow, and on peripheral blood leukocytes. The natural endogenous ligands for these receptors are arachidonic acid derivatives including anandamide and 2-arachidonyl glycerol (Figure 14–17). Both CB$_1$ and CB$_2$ receptors are linked to $G_i$ and inhibition of adenylyl cyclase activity. Activation of CB$_1$ receptors results in inhibition of glutamate release. Efforts to develop CB$_1$ antagonists like rimonabant have focused on possible treatments for drug addiction and obesity. Efforts are also underway to develop agonists that interact with CB$_1$ and CB$_2$ receptors for the relief of pain. THC (dronabinol, MARINOL) is sometimes used in the control of nausea and moderate pain (Chapter 46).

Purines. Adenosine, ATP, UDP, and UTP have roles as extracellular signaling molecules (Robertson et al., 2001; Siegel et al., 2006). High concentrations of ATP are found in adrenergic storage vesicles and ATP is released along with catecholamines and the other contents
of adrenergic storage granules. Intracellular nucleotides may also reach the cell surface by other means (Lazarowski et al., 2003), including as a consequence of cellular hypoxia or cell death, and extracellular adenosine can result from cellular release and metabolism of ATP (Jackson and Raghvendra, 2004). The concentration of ATP may greatly exceed the concentration of adenosine and, given the presence of nucleotidases, it can be difficult to unambiguously distinguish between effects of, e.g., adenosine and ATP.

Extracellular nucleotides and adenosine act on a family of purinergic receptors that is divided into two classes, P1 and P2 (Table 14–10). P1 receptors are GPCRs that interact with adenosine; two of these receptors (A1 and A3) couple to Gi and two (A2a and A2b) couple to Gs; methylxanthines antagonize A1 and A3 receptors. Activation of A1 receptors is associated with inhibition of adenylyl cyclase, activation of K+ currents, and in some instances, with activation of PLC; stimulation of A2 receptors activates adenylyl cyclase. The P2 class includes a large number of P2X receptors that are ligand-gated ion channels and the P2Y receptors, a similarly large subclass of GPCRs that couple to Gq or Gi and their associated effectors. The P2Y14 receptor is expressed in the CNS; it interacts with UDP-glucose and may couple to Gq. The P2Y14 receptor is important clinically, since inhibition of this receptor in platelets inhibits platelet aggregation.

Although many of these receptors have been detected in brain, most of the current interest stems from pharmacological rather than physiological observations. Adenosine can act presynaptically throughout the cortex and hippocampal formation to inhibit the release of amine and amino acid transmitters. ATP-regulated responses have been linked pharmacologically to a variety of pathophysiological functions, including anxiety, stroke, and epilepsy. A1 antagonists are being investigated as potential therapeutic agents to enhance awareness and learning. A2 receptors and dopamine D2 receptors appear to be functionally antagonistic, leading to investigation of A2a antagonists as adjunctive therapy for Parkinson disease (Jacobson and Gao, 2006).

**Lipid Mediators.** Substances identified as physiological regulators in systems throughout the body have been examined for their roles within the CNS. Arachidonic acid, normally stored within the cell membrane as a glycerol ester, can be liberated during phospholipid hydrolysis (by pathways involving phospholipases A2, C, and D). Phospholipases are activated via a variety of receptors (Chapter 3). Arachidonic acid can be converted to highly reactive regulators by three major enzymatic pathways (Chapter 33): cyclooxygenases (leading to prostaglandins and thromboxanes), lipoxygenases

glutamate (NMDA)-mediated neurotoxicity and LTP. Neuronal NOS (nNOS) is activated following NMDA-mediated receptor mediated increases in intracellular Ca\(^{2+}\). NO diffuses freely across membranes, acting primarily to stimulate soluble guanylyl cyclase, which catalyzes the formation of cyclic GMP. Formation of NO can also result in S-nitrosylation of cysteine residues in a variety of proteins including G proteins and ion channels. Other gases may also act as intracellular messengers. One candidate is carbon monoxide (CO), which is generated in neurons by three isoforms of hemeoxygenase (HO), isoform 2 predominating in neurons. Like NO, CO stimulates soluble guanylyl cyclase.

**Cytokines.** Cytokines are a large and diverse family of polypeptide regulators that are produced widely throughout the body by cells of diverse embryological origin. The effects of cytokines are regulated by the conditions imposed by other cytokines, interacting as a network with variable effects leading to synergistic, additive, or opposing actions. Tissue-produced peptides, termed chemokines, serve to attract immune and inflammatory cells into interstitial spaces. These special cytokines have received attention as potential regulators of nervous system inflammation (as in early stages of dementia, following infection with human immunodeficiency virus, and during recovery from traumatic injury). Some of the more conventional neuronal- and glial-derived growth-enhancing and growth-retarding factors have been identified earlier. The fact that neurons and astrocytes may be induced under some pathophysiological conditions to express cytokines or other growth factors further blurs the dividing line between neurons and glia (Campbell, 2004; Wang et al., 2002).

### ACTIONS OF DRUGS IN THE CNS

**Specificity and Nonspecificity of CNS Drug Actions**

The effect of a drug in the CNS is considered to be specific when it affects an identifiable molecular mechanism unique to target cells that bear receptors for that drug. Conversely, a drug is regarded as being nonspecific when it produces effects at a variety of different target cells, thus affecting a diverse set of neurobiological systems. This distinction is often affected by the dose-response relationship of the drug and the cell or mechanisms under scrutiny. Even a drug that is highly specific when tested at low concentrations may exhibit nonspecific actions at higher doses. In general, the more potent a drug at its desired target, the lower the probability that it will have off-target effects. Conversely, even drugs that have a broad spectrum of activity may not act identically at all levels of the CNS. For example, sedatives, hypnotics, and general anesthetics would have very limited utility if central neurons that control the respiratory and cardiovascular systems were especially sensitive to their actions. Although relief of pain is the goal when administering an opiate, one must also contend with potential off-target effects including respiratory depression and constipation.

**General (Nonspecific) CNS Depressants**

This category includes the anesthetic gases and vapors, the aliphatic alcohols, and some hypnotic-sedative drugs. These agents share the capacity to depress excitable tissue at all levels of the CNS, leading to a decrease in the amount of transmitter released by the nerve impulse, as well as to general depression of postsynaptic responsiveness and ion flux. At sub-anesthetic concentrations, these agents

(e.g., ethanol) can exert relatively specific effects on certain groups of neurons, which may account for differences in their behavioral effects, especially the propensity to produce dependence.

**General (Nonspecific) CNS Stimulants**

The drugs in this category include pentylenetetrazol and related agents that are capable of powerful excitation of the CNS, and the methylxanthines, which have a much weaker stimulant action. Stimulation may be accomplished by one of two general mechanisms: (1) blockade of inhibition or (2) direct neuronal excitation that may involve increased transmitter release or more prolonged transmitter action, as occurs when the reuptake of a released transmitter is inhibited.

**Drugs That Selectively Modify CNS Function**

The agents in this group may cause either depression or excitation. In some instances, a drug may produce both effects simultaneously on different systems. Some agents in this category have little effect on the level of excitability in doses that are used therapeutically. The principal classes of these CNS drugs are anticonvulsants, drugs used in treating Parkinson disease, opioid and non-opioid analgesics, appetite suppressants, anti-emetics, analgesic-antipyretics, certain stimulants, antidepressants, anti-manic and anti-psychotic agents, tranquilizers, sedatives and hypnotics, and medications employed in the treatment of Alzheimer’s disease (cholinesterase inhibitors and anti-glutamate neuroprotectants). Although selectivity of action may be remarkable, a drug usually affects several CNS functions to varying degrees. When only one constellation of effects is wanted in a therapeutic situation, the remaining effects of the drug are regarded as limitations in selectivity (i.e., unwanted side effects or off-target effects). The specificity of a drug’s action is frequently overestimated. This is partly due to the fact that drugs are often identified with the effect that is implied by the class name.

**General Characteristics of CNS Drugs**

Combinations of centrally acting drugs frequently are administered to therapeutic advantage (e.g., an anticholinergic drug and levodopa for Parkinson disease). However, other combinations of drugs may be detrimental because of potentially dangerous additive or mutually antagonistic effects. The effects of a CNS drug may be additive with the physiological state and the effects of other depressant and stimulant drugs. For example, anesthetics are less effective in a hyperexcitable subject than in a normal patient; the converse is true for stimulants. In general, the depressant effects of drugs from different categories are additive (e.g., the potentially fatal combination of barbiturates or benzodiazepines with ethanol), as are the effects of stimulants. Therefore, respiration depressed by morphine is further impaired by depressant drugs, while stimulant drugs can augment the excitatory effects of morphine to produce vomiting and convulsions.

Antagonism between depressants and stimulants is variable. Some instances of true pharmacological antagonism among CNS drugs are known; for example, opioid antagonists can selectively antagonize the effects of opioid analgesics. However, the antagonism exhibited between two CNS drugs is most often physiological in nature. For example, an individual whose CNS is depressed by an opiate cannot be returned entirely to normal by stimulation with caffeine.

The selective effects of drugs on specific neurotransmitter systems may be additive or competitive. The potential for drug interactions must be considered whenever such drugs are concurrently administered. To minimize such interactions, a drug-free period may be required when modifying therapy; in fact, development of desensitized and supersensitive states with prolonged therapy may limit the speed with which one drug may be halted and another started. An excitatory effect is commonly observed with low concentrations of certain depressant drugs due either to depression of inhibitory systems or to a transient increase in the release of excitatory transmitters. Examples include the stage of excitement seen during induction of general anesthesia. The excitatory phase typically occurs with low concentrations of the depressant; uniform depression ensues with increasing drug concentration. The excitatory effects can be minimized, when appropriate, by pretreatment with a depressant drug that is devoid of such effects (e.g., benzodiazepines in preanesthetic medication). Acute, excessive stimulation of the cerebrospinal axis normally is followed by depression, which is in part a consequence of neuronal fatigue and exhaustion of stores of transmitters. Postictal depression is additive with the effects of depressant drugs. Acute, drug-induced depression generally is not followed by stimulation. However, chronic drug-induced sedation or depression may be followed by prolonged hyperexcitability upon abrupt withdrawal of the medication (barbiturates or alcohol). This type of hyperexcitability can be controlled effectively by the same or another depressant drug (Chapters 17, 23, and 24).

**Organization of CNS-Drug Interactions.** The structural and functional properties of neurons provide a means to specify the possible sites at which drugs could interact, specifically or generally, in the CNS. In this scheme, drugs that affect neuronal energy metabolism, membrane integrity, or transmembrane ionic equilibria would be generally acting compounds. Similarly general in action would be drugs that affect molecular motors and thereby affect the transport of materials from cell bodies to nerve terminals and back. These general effects may exhibit different dose-response or time-response relationships based, e.g., on neuronal properties such as rate of firing, dependence of discharge on external stimuli or internal pacemakers, resting ionic fluxes, or axon length. In contrast, when the actions of a drug can be related to specific aspects of the metabolism, release, or function of a neurotransmitter, then the site, specificity, and mechanism of action of the drug can be defined by systematic studies of dose-response and time-response relationships.

Transmitter-dependent actions of drugs can be grouped into presynaptic and postsynaptic categories. The presynaptic category includes the events in the perikaryon and nerve terminal that regulate transmitter synthesis (including the acquisition of adequate substrates and co-factors), storage, release, and metabolism. Transmitter concentrations can be lowered by blockade of synthesis, inhibition of storage, or both. The amount of transmitter released per impulse generally is stable but may be subject to regulation. The effective concentration of transmitter may be increased by inhibition of metabolic enzymes or by blockade of re-uptake transporters. The transmitter that is released at a synapse also can exert actions on the terminal from which it was released by interacting with receptors at these sites (autoreceptors). Activation of presynaptic autoreceptors can inhibit or stimulate the rate of release of transmitter and thereby provide a feedback mechanism that controls the concentration of transmitter in the synaptic cleft.
NEUROTRANSMISSION AND THE CENTRAL NERVOUS SYSTEM

The postsynaptic category includes all the events that follow release of the transmitter in the vicinity of the postsynaptic receptor. Examples include the molecular mechanisms by which receptor occupancy alters the properties of the membrane of the postsynaptic cell (shifts in membrane potential), as well as more enduring biochemical actions (e.g., changes in second messenger concentrations, protein kinase and phosphoprotein phosphatase activities, and phosphoprotein formation). Direct postsynaptic effects of drugs generally require relatively high affinity for the receptors or resistance to metabolic degradation. Each of these presynaptic or postsynaptic actions is potentially highly specific and can be envisioned as restricted to a single, chemically defined subset of CNS cells.

Convergence, Synergism, and Antagonism Result from Transmitter Interactions. Although the power of the reductionist approach to clone cDNAs for receptors or receptor subunits and to determine their properties by expression in cells that do not normally express the receptor or subunit cannot be underestimated, the simplicity of cell culture models may not reproduce the nuances of receptor function in vivo and may divert attention from the complexity of the intact CNS. A given neurotransmitter may interact simultaneously with all of the various isoforms of its receptor on neurons that also are under the influence of multiple other afferent pathways and their transmitters. Thus, the use of model systems to predict the behavioral or therapeutic consequences of drugs in humans may fail as a consequence of the complexity of the interactions possible, including differences between normal and diseased tissue.

CNS Drug Discovery. As is evident from the chapters to follow, a large number of agents have been developed to treat neuropsychiatric diseases. With few exceptions these agents offer primarily symptomatic improvement; few are truly disease modifying. For example, the use of L-dopa to treat Parkinson disease alleviates the symptoms effectively but the disease continues to progress. Similarly, although antipsychotics and antidepressants are often efficacious, the symptoms tend to recur. Moreover, many drugs developed to treat CNS diseases are not uniformly effective: Approximately one-third of patients with severe depression are “treatment-resistant.” CNS diseases are complex, with multiple symptoms, some of which, like the negative symptoms of schizophrenia, tend to be resistant to treatment. Furthermore, the complexity of the brain and its neuronal pathways results in significant risk of side effects, even when the most biochemically selective agent is administered. Particularly disquieting side effects include tardive dyskinesias that can result from prolonged treatment with antipsychotics and the hypnotic effects of agents used for the treatment of seizure disorders.

The lack of disease-modifying treatments for CNS diseases represents a very significant unmet medical need and makes the discovery of such agents a high priority. Drug discovery is generally a high-risk/high-reward effort (Chapter 1) and CNS-active agents are no exception. Overall, the probability of success in developing a drug from the time a compound enters into clinical trials is ~10%; the success rate for CNS drugs is somewhat lower. Myriad factors contribute to the increased difficulty and reduced probability of success in efforts to develop drugs to treat CNS disease. Factors that reduce the probability of success include the complexity of neural pathways governing behavior and its pathology, and the permeability barriers that restrict access of drugs to CNS sites (including the blood-brain barrier and drug export systems; see Chapters 2 and 5). For example, a drug that affects serotonergic transmission may affect 14 5-HT receptor subtypes that are involved in a plethora of biological systems. Moreover, animal models of CNS diseases are often incompletely validated and an effect in an animal model may not be predictive of efficacy in human disease. For instance, a number of agents reduce the size of the infarct when given to animals following occlusion of the middle cerebral artery, yet none of these agents has shown positive results in human clinical trials. A number of agents that inhibit the reuptake of 5-HT and NE are effective in treating depression. In a number of animal models of depression, these agents produce an effect after a single dose, which corresponds nicely with the time course for the inhibition of neurotransmitter reuptake in experimental animals, whereas, a period of several weeks is typically required to see a therapeutic effect in humans. Given this discrepancy, one can understand the reluctance of pharmaceutical companies to invest in clinical trials of new antidepressants on the basis of effects in animal models.

Clinical trials represent another area of challenge in developing new therapies for CNS diseases. For example, testing an agent to treat depression likely requires a trial lasting 6 or more weeks and the placebo response rate may exceed 50%. Such conditions necessitate large, prolonged, and therefore expensive trials. Studies of treatments for neurodegenerative disease are even more difficult. With current diagnostic capabilities, it is difficult to detect a significant change in the rate of progression of cognitive decline in patients with Alzheimer’s disease in less than a year. One way to circumvent the long time necessary to detect a biological meaningful result is through the use of surrogate markers (e.g., a decrease in serum cholesterol for improved cardiovascular morbidity and mortality). Regrettably, there are relatively few useful surrogate markers for CNS diseases.

Impact of Genomics on CNS Drug Discovery. The sequencing of the human genome has the potential to significantly change drug discovery in the CNS. Thus, genetic testing may predict the likelihood that a given individual will develop a particular disease, will respond to a particular therapy, or will suffer side effects from a particular treatment paradigm. Genetic testing may be particularly important in the case of CNS diseases, where the etiology is likely to be multigenic. Molecular approaches will likely speed development of more and improved animal models that better mimic human disease.

BIBLIOGRAPHY

This page intentionally left blank
Depression and anxiety disorders are the most common mental illnesses, each affecting in excess of 10-15% of the population at some time in their lives. Both anxiety and depressive disorders are amenable to pharmacological treatments that have been developed since the 1950s. With the discovery of more selective and safer drugs, the use of antidepressants and anxiolytics has moved from the domain of psychiatry to other medical specialties, including primary care. The relative safety of the majority of commonly used antidepressants and anxiolytics notwithstanding, their optimal use requires a clear understanding of their mechanisms of action, pharmacokinetics, potential drug interactions, and the differential diagnosis of psychiatric illnesses.

A confluence of symptoms of depression and anxiety may affect an individual patient; some of the drugs discussed here are effective in treating both disorders, suggesting common underlying mechanisms of pathophysiology and response to pharmacotherapy. In large measure, our current understanding of pathophysiological mechanisms underlying depression and anxiety has been inferred from the mechanisms of action of psychopharmacological compounds (Chapter 14). While depression and anxiety disorders comprise a wide range of symptoms, including changes in mood, behavior, somatic function, and cognition, some progress has been made in developing animal models that respond with some sensitivity and selectivity to antidepressant or anxiolytic drugs (Cryan and Holmes, 2005; Miller et al., 2010). Recent work has focused on identifying endophenotypes associated with psychiatric diseases, with the goals of understanding their underlying pathophysiology and targeting them pharmacologically (Cannon and Keller, 2006). Although animal models are useful for investigating pharmacological mechanisms of action and providing initial evidence of efficacy, the development of antidepressant and anxiolytic drugs depends on clinical trials. However, it is not uncommon for psychopharmacological agents to fail to show efficacy in clinical trials; in large measure this is due to significant placebo effects and the lack of objective and firm end points. In spite of these limitations, the last half century has seen notable advances in the discovery and development of drugs for treating depression and anxiety.

**CHARACTERIZATION OF DEPRESSIVE AND ANXIETY DISORDER**

**Symptoms of Depression**

Depression, in general, is classified as major depression (i.e., unipolar depression) or bipolar depression (i.e., manic depressive illness); bipolar depression and its treatment are discussed in Chapter 16. Lifetime risk of unipolar depression is ~15%. Females are affected twice as frequently as males (Kessler et al., 1994). Depressive episodes are characterized by depressed or sad mood, pessimistic worry, diminished interest in normal activities, mental slowing and poor concentration, insomnia or increased sleep, significant weight loss or gain due to altered eating and activity patterns, psychomotor agitation or retardation, feelings of guilt and worthlessness, decreased energy and libido, and suicidal ideation, occurring most days for a period of at least 2 weeks. In some cases, the primary complaint of patients involves somatic pain or other physical symptoms and can present a diagnostic challenge for primary care physicians. Depressive symptoms also can occur secondary to other illnesses such as hypothyroidism, Parkinson’s disease, and inflammatory conditions. Further, depression often complicates the management of other medical conditions (e.g., severe trauma, cancer, diabetes, and cardiovascular...
disease, especially myocardial infarction) (Andrews and Nemeroff, 1994).

Depression is underdiagnosed and undertreated (Suominen et al., 1998). This is of particular concern due to the inherent risk of suicide associated with depression. Approximately 10-15% of those with severe depression attempt suicide at some time (Chen and Dilsaver, 1996). Thus, it is important that symptoms of depression be recognized and treated in a timely manner. Furthermore, the response to treatment must be assessed and decisions made regarding continued treatment with the initial drug, dose adjustment, adjunctive therapy, or alternative medication.

Symptoms of Anxiety

Anxiety disorders encompass a constellation of symptoms, and include generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, separation anxiety disorder, social phobia, specific phobias, and acute stress (Atack, 2003). In general, symptoms of anxiety that lead to pharmacological treatment are those that interfere significantly with normal function. Symptoms of anxiety also are often associated with depression and other medical conditions.

Anxiety is a normal human emotion that serves an adaptive function from a psychobiological perspective. However, in the psychiatric setting, feelings of fear or dread that are unfocused (e.g., generalized anxiety disorder) or out of scale with the perceived threat (e.g., specific phobias) often require treatment. Drug treatment includes acute drug administration to manage episodes of anxiety, and chronic or repeated treatment to manage unrelieved and continuing anxiety disorders.

ANTIDEPRESSANT DRUGS

Mechanisms of Action. Many different antidepressants have established track records of efficacy for treating major depression (Millan, 2006). However, they all suffer some limitations in efficacy, since at least 20% of all depressed patients are refractory to multiple different antidepressants at adequate doses (Rush et al., 2006). The most commonly used medications, often referred to as second-generation antidepressants, are the selective serotonin reuptake inhibitors (SSRIs) and the serotonin-norepinephrine reuptake inhibitors (SNRIs), which have greater efficacy and safety compared to most older drugs (i.e., first-generation antidepressants). Relatively selective norepinephrine reuptake inhibitors also have been developed as antidepressants (e.g., maprotiline, reboxetine).

In monoamine systems, reuptake of the transmitter is the main mechanism by which neurotransmission is terminated; thus, inhibition of reuptake can enhance neurotransmission, presumably by slowing clearance of the transmitter from the synapse and prolonging the dwell-time of the transmitter in the synapse. Enhancing neurotransmission may subsequently lead to adaptive changes (described later). Reuptake inhibitors inhibit either SERT, the neuronal serotonin (5-hydroxytryptamine; 5-HT) transporter; NET, the neuronal norepinephrine (NE) transporter; or both (Figure 15–1). Similarly, the first-generation drugs, which include monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants (TCAs), also enhance monoaminergic neurotransmission: the MAOIs by inhibiting monoamine metabolism and thereby enhancing neurotransmitter storage in secretory granules, the TCAs by inhibiting 5-HT and norepinephrine reuptake. While efficacious, these first-generation agents exhibit side effects and drug and food interactions that limit their use relative to the newer drugs. Table 15–1 summarizes the actions of the most widely used antidepressants.

All drugs commonly used to treat depression share, at some level, primary effects on serotoninergic or noradrenergic neurotransmitter systems (Shelton and Lester, 2006). In general, antidepressants enhance serotoninergic or noradrenergic transmission, although the nature of this effect may change with chronic treatment (Shelton, 2000). The dependence of many current treatments on serotoninergic or noradrenergic mechanisms is highlighted by clinical studies employing monoamine depletion strategies. For example, tryptophan depletion that acutely reduces 5-HT neurotransmission results in a relatively brisk relapse (within 5-10 hours) of the symptoms of depression in patients who had shown remission on an SSRI but not a NE reuptake inhibitor (Delgado et al., 1991). Conversely, catecholamine depletion by blocking the rate-limiting enzyme for the synthesis of NE and dopamine (DA) results in a relapse of symptoms in patients who had recently remitted on an NE reuptake inhibitor, but not an SSRI (Miller et al., 1996). Sites of interaction of antidepressant drugs with noradrenergic and serotoninergic neurons are depicted in Figure 15–1.

Long-term effects of antidepressant drugs evoke adaptive or regulatory mechanisms that enhance the effectiveness of therapy. These responses include increased adrenergic or serotoninergic receptor density or sensitivity, increased receptor-G protein coupling and cyclic nucleotide signaling, induction of neurotrophic factors, and increased neurogenesis in the hippocampus (Schmidt and Duman, 2007). Persistent antidepressant effects depend on the continued inhibition of 5-HT or NE transporters, or enhanced serotoninergic or noradrenergic neurotransmission achieved by an alternative pharmacological mechanism. For example, chronic treatment with some antidepressants that interact directly with monoamine transporters (e.g., SSRIs, SNRIs, or NE reuptake inhibitors) reduces the expression and activity of 5-HT or NE transporters in the brain, which results in enhanced serotoninergic or noradrenergic neurotransmission (Benmansour et al., 1999; Zhao et al., 2008). Compelling evidence suggests that sustained signaling via NE or 5-HT increases the
expression of specific downstream gene products, particularly brain-derived neurotrophic factor (BDNF), which appears to be related to the ultimate mechanism of action of these drugs (Sen et al., 2008). Unfortunately, neither earlier theories of monoaminergic receptor down-regulation and altered signaling nor current theories of neurogenesis and modulation of neurotrophic factors has yet led to new antidepressant treatments. Chronic treatment with a number of antidepressants desensitizes presynaptic autoreceptors and heteroreceptors, producing long-lasting changes in monoaminergic neurotransmission. Post-receptor effects of antidepressant treatment, including modulation of GPCR signaling and activation of protein kinases and ion channels, are involved in the mediation of the long-term effects of antidepressant drugs. Note that NE and 5-HT also affect each other’s neurons.

Clinical Considerations with Antidepressant Drugs

Following initiation of antidepressant drug treatment there is generally a “therapeutic lag” lasting 3-4 weeks before a measurable therapeutic response becomes evident. This is the reason that electroconvulsive therapy may be the treatment of choice for agitated, depressed patients with a high risk of suicide. Some patients may respond to antidepressant treatment sooner than 3-4 weeks; others may require > 8 weeks for an adequate response. Some symptoms respond more rapidly and are predictive of a more global response (Katz et al., 2004). Approximately two-thirds of depressed patients will show a 50% decrease in depressive symptoms over the course of an 8-week antidepressant trial; one-third will experience a complete remission with a single antidepressant (Rush et al., 2006). In general, if a patient does not respond to a given antidepressant after an 8-week trial on an adequate dose, then switching to

Figure 15–1. Sites of action of antidepressants. Schematics representing noradrenergic (top) and serotonergic (bottom) nerve terminals. SSRIs, SNRIs, and TCAs increase noradrenergic or serotonergic neurotransmission by blocking the norepinephrine or serotonin transporter at presynaptic terminals (NET, SERT). MAOIs inhibit the catabolism of norepinephrine and serotonin. Some antidepressants such as trazodone and related drugs have direct effects on serotonergic receptors that contribute to their clinical effects. Chronic treatment with a number of antidepressants desensitizes presynaptic autoreceptors and heteroreceptors, producing long-lasting changes in monoaminergic neurotransmission. Post-receptor effects of antidepressant treatment, including modulation of GPCR signaling and activation of protein kinases and ion channels, are involved in the mediation of the long-term effects of antidepressant drugs. Note that NE and 5-HT also affect each other’s neurons.

*Note:* Most of the drugs are hydrochloride salts, but SURMONTIL and LUVOX are maleates; CELEXA is a hydrobromide, and REMERON is a free-base. Selegiline is approved for early Parkinson disease, but may have antidepressant effects, especially at daily doses 20 mg, and is under investigation for administration by transdermal patch. *Both higher and lower doses are sometimes used, depending on an individual patient’s needs and response to the drug; see the literature and FDA-approved dosage recommendations.*

O, oral tablet or capsule; I, injectable; NE, norepinephrine; 5-HT, serotonin, DA, dopamine; 0, negligible; 0/+ , minimal; +, mild; 2+, moderate; 3+, moderately severe; 4+, severe. Other significant side effects for individual drugs are described in the text.
Another antidepressant with a different mechanism of action is a reasonable next step (e.g., SSRI to SNRI). If a partial response has been observed, other drugs may be added to the primary SSRI or SNRI medications; these additive medications include the antidepressant drug bupropion, thyroid hormone (triiodothyronine), or an atypical antipsychotics (aripiprazole or olanzapine) (Shelton, 2007). After the successful initial treatment phase, a 6-12 month maintenance treatment phase is typical, after which the drug is gradually withdrawn. If a patient has experienced two separate episodes of major depression or is chronically depressed (i.e., > 2 years), lifelong treatment with an antidepressant is advisable. Certain psychotherapies such as cognitive behavioral therapy or behavioral activation therapy are suitable options for many patients and may reduce the risk for relapse (DeRubeis et al., 2008). Finally, in addition to electroconvulsive therapy, other non-pharmacological interventions have been developed; these include transmagnetic stimulation of the brain and deep brain stimulation (Rakofsky et al., 2009).

The challenge of management of the depressive episode through the “therapeutic lag” is compounded by the early emergence of side effects. Most of the adverse reactions are well tolerated. A significant aspect of effective management of depression is informing the patient about the time course of both the therapeutic and side effects of medications and encouraging persistence with treatment.

Another important issue in the use of antidepressants is a phenomenon known as the “switch” from a depressed episode to a manic or hypomanic episode (Goldberg and Truman, 2003), a significant challenge in managing bipolar illness. For this reason, antidepressants are not recommended as monotherapy for bipolar illness. However, patients with bipolar illness may present with major depressive episodes early in the course of their illness. SSRIs and bupropion may be somewhat less likely to induce the switch from depression to mania than antidepressants from other pharmacological classes.

A controversial issue regarding the use of all antidepressants is their relationship to suicide (Mann et al., 2006). Data establishing a clear link between antidepressant treatment and suicide are lacking. In general, for reasons of safety, suicidal patients are not enrolled in clinical trials designed to seek approval for marketing a new medication. Thus, the FDA uses “suicidality” (i.e., suicidal ideation or suicide attempts and self-injurious behavior) as a proxy for risk of suicide. The FDA has issued a “black box” warning regarding the use of SSRIs and a number of other antidepressants in children and adolescents, particularly during the early phase of treatment, due to the possibility of an association between antidepressant treatment and suicide. However, there is strong epidemiological evidence that the rate of suicide has been decreasing since the time that SSRIs were first prescribed and then gained widespread usage; these data, however, cannot demonstrate a causal relationship. An analysis of health records of over 65,000 patients undergoing different types of pharmacological treatment for depression found no suggestion of increases in suicide or suicide attempts (Simon et al., 2006). Relevant to this point is the observation that an increase in suicide occurred for children and adolescents after regulatory authorities in the U.S. and Europe issued public health warnings about a possible association between antidepressants and suicidal ideation and acts, perhaps due to a reduction in the use of antidepressants in these patient populations after the announcement (Gibbons et al., 2007). Most clinicians agree that for seriously depressed patients, the risk of not being on an effective antidepressant drug outweighs the risk of being treated with one. Of course, clinical common sense also demands that special attention be paid to potentially suicidal patients regardless of their medication status. In addition, patients and family members should be warned to look for the exacerbation of symptoms such as insomnia, agitation, anxiety, or either the onset or worsening of suicidal thoughts and behaviors, particularly early in the course of therapy.

Monoamine Oxidase Inhibitors

The first class of drugs with relatively specific antidepressant effects were the MAOIs (Hollister, 1981). Iproniazid, which was developed initially for the treatment of tuberculosis, was found to have mood-elevating effects in patients with tuberculosis. Subsequently, iproniazid was shown to inhibit MAO, leading to the development of additional MAOIs including phenelzine, isocarboxazid, and tranylcypromine. As irreversible inhibitors of both MAO-A and MAO-B, these drugs have pronounced effects on the body’s ability to metabolize endogenous monoamines (e.g., 5-HT, NE, and DA) and exogenous monoamines (e.g., tyramine). The protection of exogenous monoamines leads to significant drug and food interactions. More recently, reversible and selective inhibitors of MAO-A and MAO-B have been developed (Livingston and Livingston, 1996), and these have fewer side effects and fewer interactions with food and other drugs. The MAO-B selective inhibitor selegiline is used in the treatment of Parkinson disease; selective inhibitors of MAO-A, such as moclobemide, are effective antidepressants but are not approved for use in the U.S.

Tricyclic Antidepressant and Selective Reuptake Inhibitors

The initial development of the TCAs resulted from psychopharmacological characterization of a series of structural analogs that had been developed as potential antihistamines, sedatives, analgesics, and antiparkinson drugs (Hollister, 1981). One of the compounds, imipramine, which has a phenothiazine-like structure, modified behavior in animal models. Unlike the phenothiazines, imipramine had limited efficacy in schizophrenic patients, but improved symptoms of depression. Imipramine and related TCAs became the mainstay of drug treatment of depression until the later development of the SSRIs.

TCAs with a tertiary-amine side chain, including amitriptyline, doxepin, and imipramine, inhibit both norepinephrine and serotonin uptake, while clomipramine is somewhat selective for inhibition of serotonin uptake. Chemical modification of the TCA structure led to the earliest SSRI zimelidine which, while effective, was withdrawn from the market due to serious adverse effects. Fluoxetine and fluvoxamine were the first widely used SSRIs. At the
same time, selective inhibitors of norepinephrine reuptake entered clinical development; while not approved for use in the U.S. for the treatment of depression, one norepinephrine reuptake inhibitor, atomoxetine, is used for the treatment of attention deficit hyperactivity disorder. Subsequent drug development efforts focused on serotonin and norepinephrine reuptake inhibitors (SNRIs), resulting in venlafaxine and duloxetine, which lack the complex receptor pharmacology exhibited by the TCAs.

Selective Serotonin Reuptake Inhibitors
A number of SSRIs were introduced from 1984-1997, including fluoxetine, paroxetine, sertraline, citalopram, escitalopram, and fluvoxamine; the FDA has approved fluvoxamine for treatment of obsessive-compulsive disorder and social anxiety disorder, but not depression. Citalopram is labeled for use in premenstrual dysphoric disorder. All of the SSRIs show a clear improvement in safety margin compared to the TCAs and are much safer in overdose, and in clinical practice have affected a broad range of psychiatric, behavioral, and medical conditions, for which they are used, on and off label. The SSRIs are effective in treating major depression. In typical studies, only about two-thirds of SSRI-treated patients, compared to about one-third of placebo-treated patients, exhibit a 50% reduction of depressive symptoms during a 6-8 week trial. SSRI treatment results in ~ 35% of patients enjoying a remission, as defined by a Hamilton Depression Rating Score < 7, indicative of a complete resolution of symptoms, compared to 25% of patients who experience a remission with placebo treatment (Rush et al., 2006).

In addition to use as an antidepressant, SSRIs also are anxiolytics with demonstrated efficacy in the treatment of generalized anxiety, panic, social anxiety, and obsessive-compulsive disorders. Sertraline and paroxetine also have been approved for the treatment of posttraumatic stress disorder (PTSD), although treatment of this condition remains highly challenging. SSRIs also are used for treatment of premenstrual dysphoric syndrome and for preventing vasovagal symptoms in post-menopausal women (although the SNRI venlafaxine is the most extensively studied drug for this problem).

Mechanism of Action. SERT mediates the reuptake of serotonin into the presynaptic terminal; neuronal uptake is the primary process by which neurotransmission via 5-HT is terminated (Figure 15–1). Thus, treatment with an SSRI initially blocks reuptake and results in enhanced and prolonged serotonergic neurotransmission. SSRIs used clinically are relatively selective, that is, 10-fold or more, for inhibition of SERT relative to NET (Table 15–2). Increased synaptic availability of serotonin stimulates a large number of postsynaptic 5-HT receptor subtypes, as well as somatodendritic and presynaptic terminal receptors that regulate serotonergic neuron activity and serotonin release.

SSRI treatment causes stimulation of 5-HT$_{1A}$ and 5-HT$_7$ autoreceptors on cell bodies in the raphe nucleus and of 5-HT$_{1D}$ autoreceptors on serotonergic terminals, and this reduces serotonin synthesis and release toward pre-drug levels. With repeated treatment with SSRIs, there is a gradual down-regulation and desensitization of these autoreceptor mechanisms. In addition, down-regulation of postsynaptic 5-HT$_{1A}$ receptors may contribute to antidepressant efficacy directly or by influencing the function of noradrenergic and other neurons via serotonergic heteroreceptors. Other postsynaptic 5-HT receptors likely remain responsive to increased synaptic concentrations of 5-HT and contribute to the therapeutic effects of the SSRIs.

Later-developing effects of SSRI treatment also may be important in mediating ultimate therapeutic responses. These include sustained increases in cyclic AMP signaling and phosphorylation of the nuclear transcription factor CREB, as well as increases in the expression of trophic factors such as BDNF. In addition, SSRI treatment increases neurogenesis from progenitor cells in the dentate nucleus of the hippocampus and subventricular zone (Santarelli et al., 2003). In animals models, some behavioral effects of SSRIs depend on increased neurogenesis (probably via increased expression of BDNF and its receptor TrkB), suggesting a role for this mechanism in the antidepressant effects. Recent evidence indicates the presence of neural progenitor cells in the human hippocampus, providing some support for the relevance of this mechanism to the clinical situation (Manganas et al., 2007). Further, repeated treatment with SSRIs reduces the expression of SERT, resulting in reduced clearance of released 5-HT and increased serotonergic neurotransmission. These changes in transporter expression parallel behavioral changes observed in animal models, suggesting some role for this regulatory mechanism in the late-developing effects of SSRIs (Zhao et al., 2009). These persistent behavioral changes depend on increased serotonergic neurotransmission, similar to what has been demonstrated clinically using depletion strategies (Delgado et al., 1991).

Serotonin-Norepinephrine Reuptake Inhibitors
Many older TCAs block both SERT and NET, but at a high side effect burden. Four medications with a non-tricyclic structure that inhibit the reuptake of both 5-HT and norepinephrine have been approved for use in the U.S. for treatment of depression, anxiety disorders, and pain: venlafaxine and its demethylated metabolite, desvenlafaxine; duloxetine; and milnacipran (approved only for fibromyalgia pain in the U.S.). Off-label uses include stress urinary incontinence (duloxetine), autism, binge eating disorders, hot flashes, pain syndromes, premenstrual dysphoric disorders, and post-traumatic stress disorders (venlafaxine).

The rationale behind the development of these newer agents was that targeting both SERT and NET, analogous to the effects of some TCAs, might improve overall treatment response. Meta-analyses provide some support for this hypothesis (Entsuah et al., 2001). Specifically, the remission rate for venlafaxine appears slightly better than for SSRIs in head-to-head trials. However, many

Values shown are experimentally determined constants (Kᵢ values, nM) for inhibiting the function of human NET, SERT, and DAT expressed in cell lines. Drugs shown include clinically used antidepressants, important metabolites, and experimental drugs not used clinically. Selectivity is defined as ratio of the relevant Kᵢ values (SERT/NET, NET/SERT, NET/DAT). Bupropion is selective for the DAT relative to the NET and SERT.

Source: Data are adapted from Frazer (1997), Owens et al. (1997), and Leonard and Richelson (2000).
of the studies included in the meta-analyses used a daily venlafaxine dose of 150 mg, which would have modest effects on noradrenergic neurotransmission. Duloxetine, in addition to being approved for use in the treatment of depression and anxiety, also is used for treatment of fibromyalgia and neuropathic pain associated with peripheral neuropathy.

**Mechanism of Action.** SNRIs inhibit both SERT and NET (Table 15–2). Depending on the drug, the dose, and the potency at each site, SNRIs cause enhanced serotonergic and/or noradrenergic neurotransmission. Similar to the action of SSRIs, the initial inhibition of SERT induces activation of 5-HT1A and 5-HT1D autoreceptors. This action decreases serotonergic neurotransmission by a negative feedback mechanism until these serotonergic autoreceptors are desensitized. Then, the enhanced serotonin concentration in the synapse can interact with postsynaptic 5-HT receptors.

**Serotonin Receptor Antagonists**

Several antagonists of the 5-HT2 family of receptors are effective antidepressants, although most agents of this class affect other receptor classes as well. The class includes two pairs of close structural analogues, trazodone and nefazodone, as well as mirtazapine (Remeron, others) and mianserin (not marketed in the U.S.).

The efficacy of trazodone may be somewhat more limited than the SSRIs; however, low doses of trazodone (50–100 mg) have been used widely both alone and concurrently with SSRIs or SNRIs to treat insomnia. When used to treat depression, trazodone typically is started at 150 mg/day in divided doses with 50 mg increments every 3-4 days. The maximally recommended dose is 400 mg/day for outpatients and 600 mg/day for inpatients.

Both mianserin and mirtazapine are quite sedating and are treatments of choice for some depressed patients with insomnia. The recommended initial dosing of mirtazapine is 15 mg/day with a maximal recommended dose of 45 mg/day. Since the t1/2 is 16-30 hours, the recommended interval for dose changes is no less than 2 weeks.

**Mechanism of Action.** The most potent pharmacological effects of trazodone are blockade of the 5-HT2 and α1 adrenergic receptors. Trazodone also inhibits the serotonin transporter, but is markedly less potent for this action relative to its blockade of 5-HT2A receptors. Similarly, the most potent pharmacological action of nefazodone also is the blockade of the 5-HT2 family of receptors.

Both mirtazapine and mianserin potently block histamine H1 receptors. They also have some affinity for α2 adrenergic receptors, which is claimed to be related to their therapeutic efficacy, but this point is questionable. Their affinities for 5-HT2A, 5-HT2C, and 5-HT3 receptors are high, though less so than for histamine H1 receptors. Both of these drugs have been shown in double-blind, placebo-controlled studies to increase the antidepressant response when combined with SSRIs compared to the action of the SSRIs alone. The exact monoamine receptor accounting for the effects of mirtazapine and mianserin is not clear, although the data from clinical trials suggest that olanzapine, aripiprazole, and quetiapine enhance the therapeutic effects of SSRIs or SNRIs, an important hint that their unique capacity to block the 5-HT2A receptor is the most potent shared pharmacological action amongst these antidepressant and antipsychotic drugs.

**Bupropion**

Bupropion (Wellbutrin, others) is discussed separately because it appears to act via multiple mechanisms. It enhances both noradrenergic and dopaminergic neurotransmission via reuptake inhibition (Table 15–2); in addition, its mechanism of action may involve the presynaptic release of NE and DA (Foley et al., 2006). Bupropion is indicated for the treatment of depression, prevention of seasonal depressive disorder, and as a smoking cessation treatment (under the Zyban brand). Bupropion has effects on sleep EEG that are opposite those of most antidepressant drugs. Bupropion may improve symptoms of attention deficit hyperactivity disorder (ADHD) and has been used off-label for neuropathic pain and weight loss. Clinically, bupropion is widely used in combination with SSRIs to obtain a greater antidepressant response; however, there are very limited clinical data providing strong support for this practice.

**Mechanism of Action.** Bupropion appears to inhibit NET. It also blocks the DAT but its effects on this transporter are not particularly potent in animal studies. In addition, it has effects on VMAT2, the vesicular monoamine transporter (see Figure 15–6). The hydroxybupropion metabolite may contribute to the therapeutic effects of bupropion: this metabolite appears to have a similar pharmacology and is present in substantial levels.

**Atypical Antipsychotics**

In addition to their use in schizophrenia, bipolar depression, and major depression with psychotic disorders, atypical antipsychotics have gained further, off-label use for major depression without psychotic features (Jarema, 2007). In fact, both aripiprazole (Abilify) added to SSRIs and SNRIs and a combination of olanzapine and the SSRI fluoxetine (Symbyax) have been approved by the FDA for treatment-resistant major depression (i.e., following an inadequate response to at least two different antidepressants).

The initial recommended dose of aripiprazole is 2-5 mg/day with a recommended maximal dose of 15 mg/day following increments of no more than 5 mg/day every week. The olanzapine-fluoxetine combination is available in fixed-dose combinations of either 6 or 12 mg of olanzapine and 25 or 50 mg of fluoxetine. Quetiapine (Seroquel) may have either primary antidepressant actions on its own or adjunctive benefit for treatment-resistant depression; it is used off-label for insomnia. Quetiapine also is currently under review by the FDA for additional indications in major depression and generalized anxiety disorder.

**Mechanism of Action.** The mechanism of action and adverse effects of the atypical antipsychotics are described in detail in Chapter 16. The side effects seen with atypical antipsychotics in patients with schizophrenia may not exactly translate to patients with major depression, due to a predisposition toward metabolic syndrome in patients with schizophrenia. The major risks of these agents are weight gain and metabolic syndrome, a greater problem for quetiapine and olanzapine than for aripiprazole.

**Tricyclic Antidepressants**

Due to their potential to cause serious side effects, the TCAs generally are not used as first-line drugs for the treatment of depression. Nevertheless, these drugs have established value for the treatment of major depression (Hollister, 1981). TCAs and first-generation
antipsychotics are synergistic for the treatment of psychotic depression. Tertiary amine TCAs (e.g., doxepin, amitriptyline) have been used for many years in relatively low doses for treating insomnia. In addition, because of the role of norepinephrine and serotonin in pain transmission, these drugs are commonly used to treat a variety of pain conditions.

**Mechanism of Action.** The inspiration for the development of both SSRIs and SNRIs derived from the appreciation that a salient pharmacological action of TCAs is antagonism of serotonin and norepinephrine transporters (Table 15–2). The antidepressant action of TCAs was discovered during clinical trials in schizophrenic patients; imipramine had little effect on psychotic symptoms but had beneficial effects on depressive symptoms (Hollister, 1981). In addition to inhibiting NET somewhat selectively (desipramine, nortriptyline, protriptyline, amoxapine) or both SERT and NET (imipramine, amitriptyline), these drugs also block other receptors (H₁, 5-HT₂, α₁, and muscarinic). Given the superior activity of clomipramine over SSRIs, some combination of these additional pharmacological actions may contribute to the therapeutic effects of TCAs. One TCA, amoxapine, also is a dopaminergic receptor antagonist; its use, unlike that of other TCAs, poses some risk for the development of extrapyramidal side effects such as tardive dyskinesia.

**Monoamine Oxidase Inhibitors**

MAOIs have efficacy equivalent to that of the TCAs but are rarely used because of their toxicity and major drug and food interactions (Hollister, 1981). The MAOIs approved for treatment of depression include tranylcypromine (PARNATE, others), phenelzine (NARDIL), and isocarboxazid (MARPLAN). Selegiline (EMSAM) is available as a transdermal patch and approved for use in the treatment of depression; transdermal delivery may reduce the risk for diet-associated hypertensive reactions (described later).

**Mechanism of Action.** The MAOIs nonselectively and irreversibly inhibit both MAO-A and MAO-B, which are located in the mitochondria and metabolize (inactivate) monoamines, including 5-HT and NE (Chapter 8). Selegiline inhibits MAO-B at lower doses, with effects on MAO-A at higher doses. Selegiline also is a reversible inhibitor of monoamine oxidase, which may reduce the potential for serious adverse drug and food interactions. While both MAO-A and MAO-B are involved in metabolizing 5-HT, only MAO-B is found in serotonergic neurons (Chapter 13).

**Pharmacokinetics**

The metabolism of most antidepressants is mediated by hepatic CYPs (see Table 15–3). Some antidepressants inhibit the clearance of other drugs by the CYP system, as discussed in the following section, and this possibility of drug interactions should be a significant factor in considering the choice of agents.

**Selective Serotonin Reuptake Inhibitors.** All of the SSRIs are orally active and possess elimination half-lives consistent with once-daily dosing (Hiemke and Hartter, 2000). In the case of fluoxetine, the combined action of the parent and the desmethyl metabolite norfluoxetine allows for a once weekly formulation (PROZAC WEEKLY). CYP2D6 is involved in the metabolism of most SSRIs and the SSRIs are at least moderately potent inhibitors of this isoenzyme (Table 15–3). This creates a significant potential for drug interaction for post-menopausal women taking the breast cancer drug and estrogen antagonist, tamoxifen (Chapter 62); the parent molecule is converted to a more active metabolite by CYP2D6, and SSRIs may inhibit this activation and diminish the therapeutic activity of tamoxifen. Since venlafaxine and desvenlafaxine are weak inhibitors of CYP2D6, these antidepressants are not contraindicated in this clinical situation. However, care should be used in combining SSRIs with drugs that are metabolized by CYPs 1A2, 2D6, 2C9, and 3A4 (e.g., warfarin, tricyclic antidepressants, paclitaxel).

**Serotonin-Norepinephrine Reuptake Inhibitors.** Both immediate release and extended-release (tablet or capsule) preparations of venlafaxine (EFFEXOR XR, others) produces steady state levels of drug in plasma within 3 days. The elimination half-lives for the parent venlafaxine and its active and major metabolite desmethyl venlafaxine are 5 and 11 hours, respectively. Desmethylvenlafaxine is eliminated by hepatic metabolism and by renal excretion. Venlafaxine dose reductions are suggested for patients with renal or hepatic impairment. Duloxetine has a t 1/2 of 12 hours. Duloxetine is not recommended for those with end-stage renal disease or hepatic insufficiency.

**Serotonin Receptor Antagonists.** Mirtazapine has an elimination t 1/2 of 16-30 hours. Thus, dose changes are suggested no more often than 1-2 weeks. Clearance of mirtazapine is decreased in the elderly and in patients with moderate to severe renal or hepatic impairment. Pharmacokinetics and adverse effects of mirtazapine may have an enantiomer-selective component (Brockmöller et al., 2007). Steady-state trazodone is observed within 3 days following either a twice or three times daily dosing regimen. Nefazodone has a t 1/2 of only 2-4 hours; its major metabolite hydroxynefazodone has a t 1/2 of 1.5-4 hours.

**Bupropion.** The terminal phase of bupropion elimination has a t 1/2 of 21 hours. The elimination of bupropion involves both hepatic and renal routes. Patients with severe hepatic cirrhosis should receive a maximum dose of 150 mg every other day while consideration for a decreased dose should also be made in cases of renal impairment.

**Tricyclic Antidepressants.** The TCAs, or their active metabolites, have plasma exposure half-lives of 8-80 hours; this makes once-daily dosing possible for most of the compounds (Rudorfer and Potter, 1999). Steady-state concentrations occur within several days to several weeks of beginning treatment. TCAs are largely eliminated by hepatic CYPs (see Table 15–3). Determination of plasma levels may be useful in identifying patients who appear to have toxic effects and may have excessively high levels of the drug, or those in whom lack of absorption or noncompliance is suspected. Dosage adjustments of TCAs are typically made according to patient’s clinical response, not based on plasma levels. Nonetheless, monitoring the plasma exposure has an important relationship to treatment response: there is a relatively narrow therapeutic window, as discussed below.

About 7% of patients metabolize TCAs slowly due to a variant CYP2D6 isoenzyme, causing a 30-fold difference in plasma concentrations among different patients given the same TCA dose. To avoid toxicity in “slow metabolizers,” plasma levels should be monitored and doses adjusted downward.

**Monoamine Oxidase Inhibitors.** MAOIs are metabolized by acetylation, although the end products are incompletely characterized.

Values shown are elimination $t_{1/2}$ values for a number of clinically used antidepressant drugs; numbers in parentheses are $t_{1/2}$ values of active metabolites. Fluoxetine (2D6), fluvoxamine (1A2, 2C8, 3A3/4), paroxetine (2D6), and nefazodone (3A3/4) are potent inhibitors of CYPs; sertraline (2D6), citalopram (2C19), and venlafaxine are less potent inhibitors. Plasma concentrations are those observed at typical clinical doses. Information was obtained from manufacturers’ summaries and Appendix II, which the reader should consult for important details.

A significant portion of the population (50% of the Caucasian population and an even higher percentage among Asians) are “slow acetylators” and will exhibit elevated plasma levels. The nonselective MAOIs used in the treatment of depression are irreversible (sometimes called “suicide”) inhibitors; thus, it takes up to 2 weeks for MAO activity to recover, even though the parent drug is excreted within 24 hours (Livingston and Livingston, 1996). Recovery of normal enzyme function is dependent on synthesis and transport of new
MAO to monoaminergic nerve terminals. Despite this irreversible enzyme inhibition, MAOIs require daily dosing.

**Adverse Effects**

**Selective Serotonin Reuptake Inhibitors.** The SSRIs, unlike the TCAs, do not cause major cardiovascular side effects. The SSRIs are generally free of antimuscarinic side effects (dry mouth, urinary retention, confusion), do not block histamine or α-adrenergic receptors, and are not sedating (Table 15–4). The favorable side effect profile of the SSRIs may lead to better patient compliance compared to that for the TCAs.

SSRIs are not free from side effects, however. Excessive stimulation of brain 5-HT₂ receptors may result in insomnia, increased anxiety, irritability, and decreased libido, effectively worsening prominent depressive symptoms. Excess activity at spinal 5-HT₂ receptors causes sexual side effects including erectile dysfunction.

Values are experimentally determined potencies (Kᵢ values, nM) for binding to receptors that contribute to common side effects of clinically used antidepressant drugs: muscarinic cholinergic receptors (e.g., dry mouth, urinary retention, confusion), histamine H₁ receptors (sedation), and α₁ adrenergic receptors (orthostatic hypotension, sedation).

*Source:* Data adapted from Leonard and Richelson (2000).
anorgasmia, and ejaculatory delay; these effects may be more prominent with paroxetine (Vaswani et al., 2003). Stimulation of 5-HT3 receptors in the CNS and periphery contributes to GI effects, which are usually limited to nausea but may include diarrhea and emesis. Some patients experience an increase in anxiety, especially with the initial dosing of SSRIs. With continued treatment, some patients also report a dullness of intellectual abilities and concentration. In addition, a phenomenon of a residual “flat effect” can occur in an otherwise successful treatment with SSRIs. A number of these side effects may be difficult to distinguish from symptoms of depression.

In general, there is not a strong relationship between SSRI serum concentrations and therapeutic efficacy. This finding is not surprising given that most antidepressant studies have been conducted at doses/plasma exposures which saturate the brain SERT, consistent with the flat dose or exposure/efficacy relationships observed. Thus, dosage adjustments are based more on evaluation of clinical response and management of side effects than on measurements of plasma drug concentrations.

Sudden withdrawal of antidepressants can precipitate a withdrawal syndrome. For SSRIs or SNRIs, the symptoms of withdrawal may include dizziness, headache, nervousness, nausea, and insomnia. This withdrawal syndrome appears most intense for paroxetine and venlafaxine compared to other antidepressants due to their relatively short half-lives and, in the case of paroxetine, lack of active metabolites. On the other hand, the active metabolite of fluoxetine, norfluoxetine, has such a long t½ (1–2 weeks) that few patients experience any withdrawal symptoms when discontinuing fluoxetine.

Unlike the other SSRIs, paroxetine is associated with an increased risk of congenital cardiac malformations. Epidemiological data suggest that paroxetine might increase the risk of congenital cardiac malformations when administered in the first trimester of pregnancy. Venlafaxine also is associated with an increased risk of perinatal complications. Therefore, these drugs should not be used in pregnant women; careful consideration should be given to using these medications in women of reproductive potential, and these subjects should be advised to avoid pregnancy while they are taking the drugs.

Serotonin-Norepinephrine Reuptake Inhibitors. The SNRIs have desirable safety advantages over the TCAs (Table 15–4). SNRIs have a side effect profile similar to that of the SSRIs, including nausea, constipation, insomnia, headaches, and sexual dysfunction. The immediate release formulation of venlafaxine can induce sustained diastolic hypertension (systolic blood pressure > 90 mm Hg at consecutive weekly visits) in 10–15% of patients at higher doses; this risk is reduced with the extended-release form. This effect of venlafaxine may not be associated simply with inhibition of NET, since duloxetine does not share this side effect.

Serotonin Receptor Antagonists. The main side effects of mirtazapine, seen in >10% of the patients in clinical trials, are somnolence, increased appetite, and weight gain. A rare side effect of mirtazapine is agranulocytosis. In the 2 patients having this side effect during the pre-marketing phase in nearly 2800 patients, bone marrow function recovered when mirtazapine treatment was discontinued. Trazodone use is associated with priapism in rare instances; this should be considered a medical emergency and surgical intervention may be required. Nefazodone was voluntarily withdrawn from the market in Europe and the U.S. after rare cases of liver failure were associated with its use. Generic nefazodone is still available in the U.S.

Bupropion. At doses higher than that recommended for depression (450 mg/day), the risk of seizures increases significantly. The use of extended release formulations often blunts the maximum concentration observed after dosing and minimizes the chance of reaching drug levels associated with an increased risk of seizures.

Tricyclic Antidepressants. TCAs are potent antagonists at histamine H1 receptors; H1 receptor antagonism contributes to the sedative effects of TCAs (Table 15–4). Antagonism of muscarinic acetylcholine receptors contributes to cognitive dulling as well as a range of adverse effects mediated by the parasympathetic nervous system (blurred vision, dry mouth, tachycardia, constipation, difficulty urinating). Some tolerance does occur for these anticholinergic effects, which are mitigated by titration strategies to reach therapeutic doses over a reasonable period of time. Antagonism of α1 adrenergic receptors contributes to orthostatic hypotension and sedation. Weight gain is another side effect of this class of antidepressants.

TCAs also have quinidine-like effects on cardiac conduction that can be life threatening with overdose and limit the use of TCAs in patients with coronary heart disease. This is the primary reason that no more than a one-week supply should be provided to a new patient; even during maintenance treatment, only a very limited supply should be available to the patient at any given time. Like other antidepressant drugs, TCAs also lower the seizure threshold.

Monoamine Oxidase Inhibitors. Hypertensive crisis resulting from food or drug interactions is one of the life-threatening toxicities associated with use of the MAOIs. Foods containing tyramine are a contributing factor. MAO-A within the intestinal wall and MAO-A and MAO-B in the liver normally degrade dietary tyramine. However, when MAO-A is inhibited, the ingestion of certain aged cheeses, red wines, sauerkraut, fava beans, and a variety of other tyramine-containing foods leads to accumulation of tyramine in adrenergic nerve endings and neurotransmitter vesicles and induces norepinephrine and epinephrine release. The released catecholamines stimulate postsynaptic receptors in the periphery, increasing blood pressure to dangerous levels. These episodes can be reversed by antihypertensive medications. Even when the patient is highly vigilant, dietary indiscretions or use of prescription or over-the-counter medications that contain sympathomimetic compounds may occur, resulting in a potentially life-threatening elevation of blood pressure. In comparison to tranylcypromine and isocarboxazid, the selegiline transdermal patch is better tolerated and safer. Another serious, life-threatening issue with chronic administration of MAOIs is hepatotoxicity.

MAO-B inhibitors are efficacious in treating depression. However, MAO-B inhibitors such as selegiline (with oral formulations) are effective in treating depression only when given at doses that block both MAO-A and MAO-B. Thus, these data emphasize the importance of enhancing the synaptic availability of 5-HT and NE as important mediating events for many antidepressant drugs. While not available in the U.S., reversible inhibitors of MAO-A (RIMAs, such as moclobemide) have been developed. Since these drugs are selective for MAO-A, significant MAO-B activity remains. Further, since the inhibition of MAO-A by RIMAs is reversible and competitive, as concentrations of tyramine rise, enzyme inhibition is surmounted. Thus, RIMAs produce antidepressant effects with reduced risk of tyramine-induced hypertensive crisis.
Drug Interactions

Selective Serotonin Reuptake Inhibitors. Most antidepressants, including the SSRIs, exhibit drug-drug interactions based on their routes of metabolism CYPs. Paroxetine and, to a lesser degree, fluoxetine are potent inhibitors of CYP2D6 (Hiemke and Hartter, 2000). The other SSRIs, outside of fluvoxamine, are at least moderate inhibitors of CYP2D6. This inhibition can result in disproportionate increases in plasma concentrations of drugs metabolized by CYP2D6 when doses of these drugs are increased. Fluvoxamine directly inhibits CYP1A2 and CYP2C19; fluoxetine and fluvoxamine also inhibit CYP3A4. A prominent interaction is the increase in TCA exposure that may be observed during co-administration of TCAs and SSRIs.

Another important drug-drug interaction with SSRIs occurs via a pharmacodynamic mechanism. MAOIs enhance the effects of SSRIs due to inhibition of serotonin metabolism. Administration of these drugs together can produce synergistic increases in extracellular brain serotonin, leading to the serotonin syndrome. Symptoms of the serotonin syndrome include hyperthermia, muscle rigidity, myoclonus, tremors, autonomic instability, confusion, irritability, and agitation; this can progress toward coma and death. Other drugs that may induce the serotonin syndrome include substituted amphetamines such as methylenedioxymethamphetamine (Ecstasy), which directly releases serotonin from nerve terminals. The primary treatment is stopping all serotonergic drugs, administering nonselective serotonin antagonists, and supportive measures.

Since currently available MAOIs bind irreversibly to MAO and block the enzymatic metabolism of monoamnergic neurotransmitters, SSRIs should not be started until at least 14 days following discontinuation of treatment with an MAOI; this allows for synthesis of new MAO. For all SSRIs but fluoxetine, at least 14 days should pass prior to beginning treatment with an MAOI following the end of treatment with an SSRI. Since the active metabolite norfluoxetine has a t_{1/2} of 1-2 weeks, at least 5 weeks should pass between stopping fluoxetine and beginning an MAOI.

Serotonin-Norepinephrine Reuptake Inhibitors. While 14 days are suggested to elapse from ending MAOI therapy and starting venlafaxine treatment, an interval of only 7 days after stopping venlafaxine is considered safe before beginning an MAOI. Duloxetine has a similar interval to initiation following MAOI therapy, but requires only a 5-day waiting period to begin MAOI treatment after ending duloxetine. Failure to observe these required waiting periods can result in the serotonin syndrome, as noted above for SSRIs.

Serotonin Receptor Antagonists. Trazodone dosing may need to be lowered when given together with drugs that inhibit CYP3A4. Mirtazapine is metabolized by CYPs 2D6, 1A2, and 3A4, but does not potently inhibit any of these isoenzymes. Trazodone and nefazodone are weak inhibitors of serotonin uptake and should not be administered with MAOIs due to concerns about the serotonin syndrome. However, it is unclear whether these drugs appreciably block brain SERT at doses used in the treatment of depression.

Bupropion. The major route of metabolism for bupropion is CYP2B6. While there does not appear to be any evidence for metabolism by CYP2D6 and this drug is frequently administered with SSRIs, the potential for interactions with drugs metabolized by CYP2D6 should be kept in mind until the safety of the combination is firmly established.

Tricyclic Antidepressants. Drugs that inhibit CYP2D6, such as SSRIs, may increase plasma exposures of TCAs. Other drugs that may act similarly are phenothiazine antipsychotic agents, type 1C anti-arrhythmic drugs, and other drugs with antimuscarinic, antihistaminic, and α adrenergic antagonistic effects. TCAs can potentiate the actions of sympathomimetic amines and should not be used concurrently with MAOIs or within 14 days of stopping MAOIs.

Monoamine Oxidase Inhibitors. A large number of drug-drug interactions lead to contraindications for simultaneous use with MAOIs. CNS depressants including meperidine and other narcotics, alcohol, and anesthetic agents should not be used with MAOIs. Meperidine and other opioid agonists in combination with MAOIs also induce the serotonin syndrome. As discussed earlier, SSRIs and SNRIs are contraindicated in patients on MAOIs, and vice versa, to avoid the serotonin syndrome. In general, other antidepressants such as TCAs and bupropion also should be avoided in patients taking an MAOI.

Anxiolytic Drugs

A variety of agents and drug classes provide anxiolytic effects. The primary treatments for anxiety-related disorders include the SSRIs, SNRIs, benzodiazepines, the azapirone buspirone, and beta adrenergic antagonists (Atack, 2003). Historically, TCAs, particularly clomipramine, and MAOIs have been used for the treatment of some anxiety-related disorders, but their use has been supplanted by drugs with lower toxicity. Specific issues relating to mechanism of action, adverse effects, pharmacokinetics, and drug interactions are discussed earlier and in Chapters 16 and 17.

The SSRIs and the SNRI venlafaxine (discussed earlier) are well tolerated with a reasonable side effect profile; in addition to their documented antidepressant activity, they also have anxiolytic activity with chronic treatment. The benzodiazepines are effective anxiolytics as both acute and chronic treatment. There is concern regarding their use because of their potential for dependence and abuse as well as negative effects on cognition and memory. Buspirone, like the SSRIs, is effective following chronic treatment. In acts, at least in part, via the serotonergic system, where it is a partial agonist at 5-HT_{1A} receptors. Buspirone also has antagonistic effects at dopamine D_{2} receptors, but the relationship between this effect and its clinical actions is uncertain. β adrenergic antagonists, particularly those with higher lipophilicity (e.g., propranolol and nadolol) are occasionally used for performance anxiety such as fear of public speaking; their use is limited due to significant side effects such as hypotension.

The antihistamine hydroxyzine and various sedative-hypnotic agents have been used as anxiolytics, but are generally not recommended because of their side effect profiles. Hydroxyzine, which produces short-term sedation, has been used in patients that cannot use other types of anxiolytics (e.g., those with a history of drug or alcohol abuse where benzodiazepines would be avoided). Chloral hydrate has been used for situational anxiety, but there is a narrow dose range where anxiolytic effects are observed in the absence of significant sedation, and, therefore, the use of chloral hydrate is not recommended.

Clinical Considerations with Anxiolytic Drugs. The choice of pharmacological treatment for anxiety is dictated by the specific anxiety-related disorders and the clinical need for acute anxiolytic effects (Millan, 2003). Among the commonly used anxiolytics, only the
benzodiazepines and β adrenergic antagonists are effective acutely; the use of β adrenergic antagonists is generally limited to treatment of situational anxiety. Chronic treatment with SSRIs, SNRIs, and buspirone is required to produce and sustain anxiolytic effects. When an immediate anxiolytic effect is desired, benzodiazepines are typically selected.

Benzodiazepines, such as alprazolam, chlordiazepoxide, clonazepam, clorazepate, diazepam, lorazepam, and oxazepam, are effective in the treatment of generalized anxiety disorder, panic disorder, and situational anxiety. In addition to their anxiolytic effects, benzodiazepines produce sedative, hypnotic, anesthetic, anticonvulsant, and muscle relaxant effects. The benzodiazepines also impair cognitive performance and memory, adversely affect motor control, and potentiate the effects of other sedatives including alcohol. The anxiolytic effects of this class of drugs are mediated by allosteric interactions with the pentameric benzodiazepine-GABAA receptor complex, in particular those GABA<sub>α</sub> receptors comprised of α2, α3, and α5 subunits (Chapters 14 and 17). The primary effect of the anxiolytic benzodiazepines is to enhance the inhibitory effects of the neurotransmitter GABA.

One area of concern regarding the use of benzodiazepines in the treatment of anxiety is the potential for habituation, dependence, and abuse. Patients with certain personality disorders or a history of drug or alcohol abuse are particularly susceptible. However, the risk of dependence must be balanced with the need for treatment, since benzodiazepines are effective in both short- and long-term treatment of patients with sustained or recurring bouts of anxiety. Further, premature discontinuation of benzodiazepines, in the absence of other pharmacological treatment, results in a high rate of relapse. Withdrawal of benzodiazepines after chronic treatment, particularly those with short durations of action, can include increased anxiety and seizures. For this reason, it is important that discontinuation be carried out in a gradual manner.

Benzodiazepines cause many adverse effects, including sedation, mild memory impairments, decreased alertness, and slowed reaction time (which may lead to accidents). Memory problems can include visual-spatial deficits, but will manifest clinically in a variety of ways, including difficulty in word-finding. Occasionally, paradoxical reactions can occur with benzodiazepines such as increases in anxiety, sometimes reaching panic attack proportions. Other pathological reactions can include irritability, aggression, or behavioral disinhibition. Amnesic reactions (i.e., loss of memory for particular periods) can also occur. Benzodiazepines should not be used in pregnant women; there have been rare reports of craniofacial defects. In addition, benzodiazepines taken prior to delivery may result in sedated, under-responsive newborns and prolonged withdrawal reactions. In the elderly, benzodiazepines increase the risk for falls and must be used cautiously. These drugs are safer than classical sedative-hypnotics in overdosage and typically are fatal only if combined with other CNS depressants.

Benzodiazepines have at least some abuse potential, although their capacity for abuse is considerably below that of other classical sedative-hypnotic agents. When these agents are abused, it is generally in a multi-drug abuse pattern. In fact, the primary reason for misuse of these agents often is failed attempts to control anxiety. Tolerance to the anxiolytic effects develops with chronic administration, with the result that some patients escalate the dose of benzodiazepines over time. Ideally, benzodiazepines should be used for short periods of time and in conjunction with other medications (e.g., SSRIs) or evidence-based psychotherapies (e.g., cognitive behavioral therapy for anxiety disorders).

SSRIs and the SNRI venlafaxine are first-line treatments for most types of anxiety disorders, except when an acute drug effect is desired; fluvoxamine is approved only for obsessive-compulsive disorder. As for their antidepressant actions, the anxiolytic effects of these drugs become manifest following chronic treatment. Other drugs with actions on serotonergic neurotransmission, including trazodone, nefazodone, and mirtazapine, also are used in the treatment of anxiety disorders. Details regarding the pharmacology of these classes of were presented earlier.

Both SSRIs and SNRIs are beneficial in specific anxiety conditions such as generalized anxiety disorder, social phobias, obsessive-compulsive disorder, and panic disorder. These effects appear to be related to the capacity of serotonin to regulate the activity of brain structures such as amygdala and locus coeruleus that are thought to be involved in the genesis of anxiety. Interestingly, the SSRIs and SNRIs often will produce some increases in anxiety in the short-term that dissipate with time. Therefore, the maxim “start low and go slow” is indicated with anxious patients; however, many patients with anxiety disorders ultimately will require doses that are about the same as those required for the treatment of depression. Anxious patients appear to be particularly prone to severe discontinuation reactions with certain medications such as venlafaxine and paroxetine; therefore, slow off-tapering is required.

Buspirone is used in the treatment of generalized anxiety disorder (Goodman, 2004). Like the SSRIs, buspirone requires chronic treatment for effectiveness. Also, like the SSRIs, buspirone lacks many of the other pharmacological effects of the benzodiazepines: it is not an anticonvulsant, muscle relaxant, or sedative, and it does not impair psychomotor performance or result in dependence. Buspirone is primarily effective in the treatment of generalized anxiety disorder, but not for other anxiety disorders. In fact, patients with panic disorder often note an increase in anxiety acutely following initiation of buspirone treatment; this may be the result of the fact that buspirone causes increased firing rates of the locus coeruleus, which is thought to underlie part of the pathophysiology of panic disorder.

**CLINICAL SUMMARY**

Mood and anxiety disorders are the most common psychiatric illnesses and are encountered frequently by clinicians in all disciplines. Depression represents a spectrum of conditions with a range of severities and a high frequency of comorbidities. Depressive conditions range from mild, self-limiting conditions to extremely severe illnesses that can include a high suicidal potential, psychosis, and serious functional impairment. Whereas the likelihood of receiving treatment for depression or anxiety has improved, problems remain with regard to duration, dosing, and adherence to treatment. Unfortunately, persons with depressive or anxiety disorders continue to suffer considerable delays in diagnosis and adequate treatment. Prominently used agents inhibit transmitter reuptake via SERT and NET.

Current antidepressant and anxiolytic treatment strategies are imperfect. Many patients have significant residual symptoms after pharmacotherapy. Fortunately, antidepressant/anxiolytic drug development is expanding beyond standard 5-HT and NE uptake inhibitors. New antidepressant medications include triple (5-HT, NE, and DA)
reuptake inhibitors, agents combining inhibition of 5-HT reuptake and modulation of 5-HT receptors, antagonists of CNS peptides (e.g., corticotropin-releasing hormone-1 receptor and neurokinin-1), modulators of cyclic nucleotide signaling, $\sigma_1$ and $\sigma_2$ receptor ligands, melatonin receptors (particularly, combined 5-HT receptor antagonists/melatonin receptor agonists), and glutamate receptor antagonists (Zarate, Jr. et al., 2006).

Drugs that target NMDA, AMPA, and metabotropic glutamate receptors are very promising. Other targets, such as specific 5-HT receptor agonists, partial agonists, or antagonists, and GABA $\alpha$ receptor agonists may prove useful in the future for anxiety. Modulating the endocannabinoid signaling system is also promising with regard to both antidepressant and anxiolytic actions. Finally, there is increasing evidence that some naturally occurring products such as S-adenosylmethionine, l-methylfolate, N-acetyl cysteine, and omega-3 fatty acids may be useful in depression and anxiety.

**BIBLIOGRAPHY**

Pharmacotherapy of Psychosis and Mania
Jonathan M. Meyer

16

TREATMENT OF PSYCHOSIS

Psychosis is a symptom of mental illnesses characterized by a distorted or non-existent sense of reality. Psychotic disorders have different etiologies, each of which demands a unique treatment approach. Common psychotic disorders include mood disorders (major depression or mania) with psychotic features, substance-induced psychosis, dementia with psychotic features, delirium with psychotic features, brief psychotic disorder, delusional disorder, schizoaffective disorder, and schizophrenia. Schizophrenia has a worldwide prevalence of 1% and is considered the prototypic disorder for understanding the phenomenology of psychosis and the impact of antipsychotic treatment, but patients with schizophrenia exhibit features that extend beyond those seen in other psychotic illnesses. Hallucinations, delusions, disorganized speech, and disorganized or agitated behavior comprise the types of psychotic symptoms found individually, or rarely together, in all psychotic disorders, and are typically responsive to pharmacotherapy. In addition to positive symptoms, schizophrenia patients also suffer from negative symptoms (apathy, avolition, alogia), and cognitive deficits, particularly deficits in working memory, processing speed, social cognition, and problem solving that test 1.5-2 standard deviations below population norms (Green et al., 2004). Cognitive dysfunction is the strongest predictor of functional impairment among schizophrenia patients, yet negative symptoms and cognitive deficits show limited improvement with antipsychotic treatment (Buchanan et al., 2007). That schizophrenia is not identical to other psychoses is important for appreciating the differential impact of antipsychotic medications on psychotic symptomatology, and for understanding the rationale for non-dopaminergic antipsychotic drugs based on the underlying pathophysiology of schizophrenia (Carpenter and Koenig 2008).

The Dopamine Hypothesis. The development of our understanding of the neurobiology and pharmacotherapy of psychoses profited from the synthesis of chlorpromazine in 1950 and of haloperidol in 1958. The DA hypothesis of psychosis derived from the fortuitous discovery of chlorpromazine’s therapeutic efficacy in schizophrenia, and the subsequent elucidation by Carlsson that postsynaptic DA D2 receptor antagonism was the common mechanism that explained antipsychotic properties. Reserpine, derived from Rauwolfia, exhibited antipsychotic properties by decreasing dopaminergic neurotransmission; however, unlike D2 receptor antagonists, reserpine exerted its effects through depletion of monoamines from presynaptic nerve terminals. The dopamine theory of psychosis was reinforced by the high risk for drug-induced psychosis among substances that directly increased synaptic dopamine availability, including cocaine, amphetamines, and the Parkinson’s disease treatment L-dopa (Carlsson, 1978).

The dopamine (DA) overactivity hypothesis has led to the development of the first therapeutic class of antipsychotic agents, now referred to as typical or first-generation antipsychotic drugs. These medications differed in potency, but shared the common mechanism of significant DA D2 blockade and associated risk for extrapyramidal side effects. In the past, the term “neuroleptic” was also employed to refer to typical antipsychotic drugs, literally meaning to “take hold of the nerves” in Greek, but this has been dropped from contemporary usage (as has the term “major tranquilizer”) in favor of “antipsychotic drug,” a term that more accurately reflects the primary clinical use of these agents. While the DA hypothesis is an advance over earlier conceptualizations of psychosis, it has limitations, and does not account for the cognitive deficits associated with schizophrenia that appear to be related to decreased DA signaling in the prefrontal cortex. The DA hypothesis also does not explain the psychotomimetic effects of agonists of other pathways (e.g., d-lysergic acid, a potent serotonin 5-HT2 receptor agonist), or the effects of phencyclidine and ketamine, antagonists of the N-methyl-D-aspartate (NMDA)
glutamate receptor. Advances in treatment have emerged from exploration of alternative (non-dopaminergic) mechanisms for psychosis and from experience with atypical antipsychotic agents such as clozapine. These newer antipsychotics potently antagonize the 5-HT₂ receptor, while blocking D₂ receptors less potently than older typical antipsychotic agents, resulting in the atypical clinical profile of antipsychotic efficacy with limited extrapyramidal side effects. Also promising are medications that target glutamate and 5-HT₇ receptor subtypes, receptors for γ-aminobutyric acid (GABA) and acetylcholine (both muscarinic and nicotinic), and even peptide hormone receptors (e.g., oxytocin) (Carpenter and Koenig, 2008).

**Review of Relevant Pathophysiology**

Not all psychosis is schizophrenia, and the pathophysiology relevant to effective schizophrenia treatment may not apply to other psychotic disorders. The effectiveness of dopamine D₂ antagonists for the positive symptoms of psychosis seen in most psychotic disorders suggests a common etiology for these symptoms related to excessive dopaminergic neurotransmission in mesolimbic dopamine pathways. In substance-induced psychotic disorders, the substance may directly increase postsynaptic DA activity through increased presynaptic neurotransmitter release (amphetamine), inhibition of presynaptic DA reuptake (methylphenidate, cocaine, and amphetamine), or increased DA availability (L-dopa). The NMDA antagonists phenecyclidine and ketamine indirectly act to stimulate DA availability by decreasing the glutamate-mediated tonic inhibition of DA release in the mesolimbic DA pathway.

The psychoses related to delirium and dementia, particularly dementia of the Alzheimer type, may share a common etiology: the deficiency in cholinergic neurotransmission, either due to anticholinergic properties of medications (Chew et al., 2008), age- or disease-related neuronal loss, or both (Barten and Albright, 2008; Hshieh et al., 2008). Among hospitalized elderly patients, increased plasma concentrations of anticholinergic medications are directly associated with increased delirium risk (Flacker and Lipsitz, 1999); however, unlike in Alzheimer’s dementia, where psychotic symptoms are directly related to cholinergic neuronal loss and may respond to acetylcholinesterase therapy, delirium may have numerous precipitants besides medication-associated anticholinergic properties, all of which require specific treatment (e.g., infection, electrolyte imbalance, metabolic derangement) in addition to removal of offending anticholinergic medications.

Schizophrenia is a neurodevelopmental disorder with complex genetics and incompletely understood pathophysiology. Certain environmental exposures confer an increased risk of developing schizophrenia, including fetal second-trimester viral and nutritional insults, birth complications, and substance abuse in the late teen or early adult years (Fanous and Kendler, 2008). Rather than being the result of a single gene defect, mutations or polymorphisms of many genes appear to contribute to the risk for schizophrenia. Implicated are genes that regulate neuronal migration and synaptogenesis (neuregulin 1), synaptic DA availability (Val108/158)/Met polymorphism of catechol-O-methyltransferase, which increases DA catabolism), glutamate and DA neurotransmission (dystrobrevin binding protein 1 or dysbindin, particularly with schizophrenia patients with prominent negative symptoms), nicotinic neurotransmission (α7-receptor polymorphisms), and cognition (disrupted-in-schizophrenia-1) (Porteous, 2008). Schizophrenia patients also have increased rates of genome-wide DNA microduplications termed copy number variants (Need et al., 2007) and epigenetic changes, including disruptions in DNA methylation patterns in various brain regions (Porteous, 2008). This genetic variability is consistent with the clinical disease heterogeneity, and suggests that any one specific mechanism is unlikely to account for large amounts of disease risk.

In addition to increased mesolimbic DA activity related to positive symptoms, schizophrenia patients have decreased DA D₁ activity in the dorsolateral and ventromedial prefrontal cortex (PFC) that is associated with cognitive deficits and negative symptoms (Buchanan et al., 2007).

Cognitive dysfunction is the greatest predictor of poor functional outcome in schizophrenia and shows limited response to antipsychotic treatment. Experimental studies have provided new insights into the mechanisms of cognitive dysfunction. Glutamate NMDA receptor stimulation is involved in tonic inhibition of mesolimbic DA release, but facilitates mesocortical DA release (Sodhi et al., 2008). Ketamine infusion studies in animals and healthy volunteers demonstrate that decreased NMDA function results in a picture that more accurately encompasses all aspects of schizophrenia, including positive, negative, and cognitive symptoms, and social withdrawal. Several of the newer antipsychotic drugs remediate not only the positive psychotic symptoms but also the cognitive disruption induced by ketamine and other potent NMDA antagonists such as MK-801 (dizocilpine). These results have prompted the clinical investigation of agents without affinity for DA receptors, but with potent agonist properties at metabotropic glutamate receptor subtypes (Patil et al., 2007).

**Review of Psychosis Pathology and the General Goals of Pharmacotherapy**

Common to all psychotic disorders are positive symptoms, which may include hallucinatory behavior, disturbed thinking, and behavioral dyscontrol. For many psychotic disorders the state of psychosis is transient, and antipsychotic drugs are only administered during and shortly after periods of symptom exacerbation. Patients with delirium, dementia, mania or major depressive disorder with psychotic features, substance-induced psychoses, and brief psychotic disorder will typically receive short-term antipsychotic treatment that is discontinued after resolution of psychotic symptoms, although the duration may vary considerably based upon the etiology. In the majority
of substance-induced psychoses, removal of the offending agent results in prompt improvement of psychotic symptoms with no further need for antipsychotic therapy. This may not apply to advanced Parkinson’s disease patients, for whom L-dopa cannot be stopped and for whom ongoing antipsychotic treatment may be necessary (Chapter 22). Patients with psychosis related to mood disorders, in particular manic patients, may have antipsychotic treatment extended for several months after resolution of the psychosis, since antipsychotic medications are effective in controlling mania symptoms. Chronic psychotic symptoms in dementia patients may also be amenable to drug therapy, but potential benefits must be balanced with the documented risk of mortality and cerebrovascular events associated with the use of antipsychotic medications in this patient population (Jeste et al., 2008).

Delusional disorder, schizophrenia, and schizoaffective disorder are chronic diseases that require long-term antipsychotic treatment, although there are few reliable studies of treatment outcomes for delusional disorder patients. Individuals with monosymptomatic delusions (e.g., paranoia, marital infidelity) do not have neurocognitive dysfunction and may continue to perform work and social functions unaffected by their illness, aside from behavioral consequences related to the specific delusional belief (American Psychiatric Association, 2000). These patients often have limited or no psychiatric contact outside of mandated legal interventions, thus limiting the opportunity for clinical trials. For schizophrenia and schizoaffective disorder, the goal of antipsychotic treatment is to maximize functional recovery by decreasing the severity of positive symptoms and their behavioral influence, improving negative symptoms, decreasing social withdrawal, and remediating cognitive dysfunction. That only 15% of chronic schizophrenia patients are employed in any capacity and 11% are married has been attributed to the relatively limited effect of treatment on core negative and cognitive symptoms of the illness (Lieberman et al., 2005). Nonetheless, continuous antipsychotic treatment reduces 1-year relapse rates from 80% among unmedicated patients, to ~15%. Poor adherence to antipsychotic treatment increases relapse risk, and is often related to adverse drug events, cognitive dysfunction, substance use, and limited illness insight.

Regardless of the underlying pathology, the immediate goal of antipsychotic treatment is a decrease in acute symptoms that induce patient distress, particularly behavioral symptoms (e.g., hostility, agitation) that may present a danger to the patient or others. The dosing, route of administration, and choice of antipsychotic depend on the underlying disease state, clinical acuity, drug-drug interactions with concomitant medications, and patient sensitivity to short- or long-term adverse effects. With the exception of clozapine’s superior efficacy in treatment-refractory schizophrenia (Leucht et al., 2009), neither the clinical presentation nor biomarkers predict the likelihood of response to a specific antipsychotic class or agent. As a result, avoidance of adverse effects based upon patient and drug characteristics, or exploitation of certain medication properties (e.g., sedation related to histamine H₁ or muscarinic antagonism) are the principal determinants for choosing initial antipsychotic therapy.

All commercially available antipsychotic drugs reduce dopaminergic neurotransmission (Figure 16–1). This finding implicates D₂ blockade (or, in the case of aripiprazole, modulation of DA activity) as the primary therapeutic mechanism. Chlorpromazine and other early low-potency typical antipsychotic agents are also profoundly sedating, a feature that used to be considered relevant to their therapeutic pharmacology. The development of the high-potency antipsychotic agent haloperidol, a drug with limited H₁ and M₁ affinity and significantly less sedative effects, and the clinical efficacy of intramuscular forms of nonsedating newer antipsychotic drugs, aripiprazole and ziprasidone, demonstrate that sedation is not necessary for antipsychotic activity, although at times desirable.

### Short-Term Treatment

#### Delirium and Dementia

Disease variables have considerable influence on selection of antipsychotic agents. Psychotic symptoms of delirium or dementia are generally treated with low medication doses, although doses may have to be repeated at frequent intervals initially to achieve adequate behavioral control (Lacasse et al., 2006). Despite widespread clinical use, not a single antipsychotic drug has received approval for dementia-related psychosis. Moreover, all antipsychotic drugs carry warnings that they may increase mortality in this setting (Jeste et al., 2008). Because anticholinergic drug effects may worsen delirium (Hshieh et al., 2008) and dementia, high-potency typical antipsychotic drugs (e.g., haloperidol) or atypical antipsychotic agents with limited antimuscarinic properties (e.g., risperidone) are often the drugs of choice (Jeste et al., 2008; Lacasse et al., 2006).

The best-tolerated doses in dementia patients are one-fourth of adult schizophrenia doses (e.g., risperidone 0.5-1.5 mg/day), although extrapyramidal neurological symptoms (EPS), orthostasis, and sedation are particularly problematic in this patient population (Chapter 22). Significant antipsychotic benefits are usually seen in acute psychosis within 60-120 minutes after drug administration. Delirious or demented patients may be reluctant or unable to swallow tablets, so oral dissolving tablet (ODT) preparations for risperidone, aripiprazole, and olanzapine, or liquid concentrate forms of risperidone or aripiprazole, are options. The dissolving tablets adhere
but may be apparent as early as day 2. Unlike patients with delirium, dementia, substance-induced psychosis, and brief psychotic disorder, patients with mania may need to continue on antipsychotic treatment for many months after the resolution of psychotic and manic symptoms, typically in combination with a mood stabilizer such as lithium or valproic acid preparations (e.g., divalproex). Oral aripiprazole and olanzapine have indications as monotherapy for bipolar disorder maintenance treatment (Keck et al., 2007; Tohen et al., 2003), but the use of olanzapine has decreased dramatically due to concerns over adverse metabolic effects (e.g., weight gain, hyperlipidemia, hyperglycemia). Long-acting injectable risperidone also has indications for maintenance monotherapy (and adjunctively with lithium or valproate) in bipolar I disorder patients. Combining an antipsychotic agent with a mood stabilizer often improves control of manic symptoms, and further reduces the risk of relapse (Scherk et al., 2007).

Weight gain from the additive effects of antipsychotic agents and mood stabilizers (lithium, valproic acid) presents a significant clinical problem (Meyer, 2002).

Mania. All atypical antipsychotic agents with the exception of clozapine and iloperidone have indications for acute mania, and doses are titrated rapidly to the maximum recommended dose over the first 24-72 hours of treatment. Acute mania patients with psychosis require very high daily doses, typically close to or at the maximum FDA-approved dose (Scherk et al., 2007). Typical antipsychotic drugs are also effective in acute mania, but often eschewed due to the risk for EPS. Clinical response (decreased psychomotor agitation and irritability, increased sleep, and reduced or absent delusions and hallucinations) usually occurs within 7 days, but may be apparent as early as day 2. Unlike patients with delirium, dementia, substance-induced psychosis, and brief psychotic disorder, patients with mania may need to continue on antipsychotic treatment for many months after the resolution of psychotic and manic symptoms, typically in combination with a mood stabilizer such as lithium or valproic acid preparations (e.g., divalproex). Oral aripiprazole and olanzapine have indications as monotherapy for bipolar disorder maintenance treatment (Keck et al., 2007; Tohen et al., 2003), but the use of olanzapine has decreased dramatically due to concerns over adverse metabolic effects (e.g., weight gain, hyperlipidemia, hyperglycemia). Long-acting injectable risperidone also has indications for maintenance monotherapy (and adjunctively with lithium or valproate) in bipolar I disorder patients. Combining an antipsychotic agent with a mood stabilizer often improves control of manic symptoms, and further reduces the risk of relapse (Scherk et al., 2007). Weight gain from the additive effects of antipsychotic agents and mood stabilizers (lithium, valproic acid) presents a significant clinical problem (Meyer, 2002).
Antipsychotic agents with greater weight-gain liabilities (e.g., olanzapine, clozapine) should be avoided unless patients are refractory to preferred treatments. The recommended duration of treatment after resolution of bipolar mania varies considerably, but as symptoms permit, a gradual drug taper can frequently be attempted after 4 months of treatment.

**Major Depression.** Patients with major depressive disorder with psychotic features require lower than average doses of antipsychotic drugs, given in combination with an antidepressant (Rothschild et al., 2004). Extended antipsychotic treatment is not usually required, but certain atypical antipsychotic agents provide adjunctive antidepressant benefit. It is worth noting that mood disorder patients may be more susceptible to EPS and other adverse drug events due to the fact that many of these individuals either have never taken antipsychotic drugs before (“drug-naïve”) or have had only limited lifetime exposure to antipsychotic drugs. Regardless of the indication for therapy, clinicians must be alert to the emergence of adverse effects to avoid patient rejection of ongoing treatment.

With few exceptions (e.g., loxapine, where the active metabolite amoxapine is a heterocyclic antidepressant), most antipsychotic drugs show limited antidepressant benefit as monotherapy agents. However, clinical data demonstrate efficacy of atypical antipsychotic agents as adjunct therapy in treatment-resistant depression. The clinical efficacy may be related to the fact that almost all atypical antipsychotic medications are potent 5-HT	extsubscript{2A} antagonists, with 5-HT	extsubscript{2A} occupancies exceeding 80% at modest dosages (Figure 16–2) (Mamo et al., 2007). Both 5-HT	extsubscript{2A} and 5-HT	extsubscript{2C} receptors are G-protein coupled, with stimulation resulting in increased production of intracellular inositol trisphosphate (IP	extsubscript{3}) (Marek et al., 2003). In vitro assays demonstrate that atypical agents are inverse agonists at both receptor subtypes, capable of lowering basal IP levels (Rausser et al., 2001; Weiner et al., 2001). For the purposes of functional description, the term antagonism will be used throughout this chapter with respect to actions at these two serotonin receptor subtypes, even though the underlying mechanism is inverse agonism (Chapter 3). 5-HT	extsubscript{2A} and 5-HT	extsubscript{2C} antagonism not only facilitates DA release but again at low doses (2-15 mg). Unlike other atypical antipsychotic agents, aripiprazole’s highest affinities at low doses (<15 mg) are for D	extsubscript{2} and D	extsubscript{3} receptors, at which it is a partial agonist, with only 50% of 5-HT	extsubscript{2A} receptor occupancy (olanzapine, Panel A) and risperidone (Panel B) and efficacy at lower D	extsubscript{2} receptor occupancy (olanzapine, Panel A). Aripiprazole is a partial D	extsubscript{2} agonist that can achieve only 75% functional blockade (Figure 16–3).

---

**Figure 16–2. Receptor occupancy and clinical response for antipsychotic agents.** Typically, in D	extsubscript{2} receptor occupancy by the drug >60% provides antipsychotic effects, receptor occupancy >80% causes extrapyramidal symptoms (EPS). Atypical agents combine weak D	extsubscript{2} receptor blockade with more potent 5-HT	extsubscript{2A} antagonism/inverse agonism. Inverse agonism at 5-HT	extsubscript{2} receptor subtypes may contribute to the reduced EPS risk of olanzapine (Panel A) and risperidone (Panel B) and efficacy at lower D	extsubscript{2} receptor occupancy (olanzapine, Panel A). Aripiprazole is a partial D	extsubscript{2} agonist that can achieve only 75% functional blockade (Figure 16–3).
**Schizophrenia.** The immediate goals of acute antipsychotic treatment are the reduction of agitated, disorganized, or hostile behavior, decreasing the impact of hallucinations, the improvement of organization of thought processes, and the reduction of social withdrawal. Doses used are often higher than those required for maintenance treatment of stable patients. Despite considerable debate, newer atypical antipsychotic agents are not more effective in the treatment of positive symptoms than typical agents (Rosenheck et al., 2006; Sikich et al., 2008), although there may be small but measurable differences in effects on negative symptoms and cognition (Leucht et al., 2009).

Newer, atypical antipsychotic agents do offer a better neurological side-effect profile than typical antipsychotic drugs. Clinically effective doses of atypical agents show markedly reduced EPS risk (or nearly absent in the case of quetiapine and clozapine) compared to typical antipsychotic agents. Excessive D₂ blockade, as is often the case with the use of high-potency typical agents (e.g., haloperidol), not only increases risk for motor neurological effects (e.g., muscular rigidity, bradykinesia, tremor, akathisia), but also slows mentation (bradyphrenia), and interferes with central reward pathways, resulting in patient complaints of anhedonia. Rarely used are low-potency typical agents (e.g., chlorpromazine), which also have high affinities for H₁, M, and α₁ receptors that cause many undesirable effects (sedation, anticholinergic properties, orthostasis). Concerns regarding QTₘ prolongation (e.g., thioridazine) further limit their clinical usefulness. In acute psychosis, sedation may be desirable, but the use of a sedating antipsychotic drug may interfere with a patient’s cognitive function and social reintegration. Clinicians often prefer using nonsedating antipsychotic agents, and add low doses of benzodiazepines as necessary. As a result of the improved neurological risk profile and aggressive marketing, atypical antipsychotic agents have essentially replaced typical antipsychotic drugs in clinical practice in the U.S.

Since schizophrenia requires long-term treatment, antipsychotic agents with greater metabolic liabilities, especially weight gain (discussed later), should be avoided as first-line therapies (Meyer et al., 2008). Ziprasidone and aripiprazole are the most weight and metabolically neutral atypical agents, with asenapine and iloperidone also having favorable metabolic profiles. Ziprasidone and aripiprazole are available in IM form, thus permitting continuation of same drug treatment initiated parenterally in the emergency room.

Schizophrenia patients have a 2-fold higher prevalence of metabolic syndrome and type 2 diabetes mellitus (DM) and 2-fold greater cardiovascular (CV) related mortality rates than the general population (Meyer and Nasrallah 2009). For this reason, consensus guidelines recommend baseline determination of serum glucose, lipids, weight, blood pressure, and when possible, waist circumference and personal and family histories of metabolic and CV disease (American Diabetes Association et al., 2004). This cardiometabolic risk assessment should be performed for all schizophrenia patients despite the low metabolic risk for certain agents. With the low EPS risk among atypical antipsychotic agents, prophylactic use of anti-parkinsonian medications (e.g., benzotropine, trihexyphenidyl) is not necessary; however, acute dystonic reactions can occur (see Table 16–4), typically among patients who have never before taken antipsychotic drugs, adolescents, and young adults. Lower dosages are recommended in these individuals. Drug-induced parkinsonism can also occur, especially among elderly patients exposed to antipsychotic agents that have high D₂ affinity (e.g., typical antipsychotic drugs, risperidone, paliperidone); recommended doses are ~50% of those used in younger schizophrenia patients. (See also “Use in Pediatric Populations” and “Use in Geriatric Populations” later in the chapter.)

**Long-Term Treatment**

The need for long-term treatment poses issues almost exclusively to the chronic psychotic illnesses, schizophrenia and schizoaffective disorder, although long-term antipsychotic treatment is sometimes used for manic patients, for ongoing psychosis in dementia patients, for L-dopa psychosis, and for adjunctive use in SSRI-unresponsive major depression. Safety concerns combined with limited long-term efficacy data have dampened enthusiasm for extended antipsychotic drug use in dementia patients (Jeste et al., 2008). The goal should be to optimize clinical and behavioral aspects of treatment in order to minimize the need for antipsychotic drugs in the dementia population. Justification for ongoing use, based on documentation of patient response to tapering of antipsychotic medication, is often mandated in long-term care settings. L-dopa psychosis represents a thorny clinical problem, as clinicians are caught between the Scylla of treatment-induced psychotic symptoms and the Charybdis of motoric worsening as a result of exposure to antipsychotic drugs. Parkinson disease patients who present with L-dopa psychosis usually have advanced disease and cannot tolerate reductions in dopamine agonist treatment without significant motoric worsening and on-off phenomena (Chapter 22). They are exquisitely sensitive to minute amounts of D₂ blockade (Zahodne and Fernandez, 2008). Clozapine, used in doses ranging from 6.25-50 mg/day, has the most extensive clinical evidence base. The necessity for routine hematological...
monitoring for agranulocytosis has prompted the use of low doses of quetiapine, itself a very weak D₂ antagonist, although the evidence for quetiapine’s efficacy in L-dopa psychosis is not compelling. Anecdotal evidence also exists for using low doses of the D₂ partial agonist aripiprazole (1-5 mg/day) in L-dopa psychosis (Zahodne and Fernandez, 2008).

The choice of antipsychotic agents for long-term schizophrenia treatment is based primarily on avoidance of adverse effects and, when available, prior history of patient response. Since schizophrenia spectrum disorders are lifelong diseases, treatment acceptability is paramount to effective illness management. Whether atypical antipsychotic agents are superior to typical antipsychotic agents has been the subject of significant and contentious debate. Large meta-analyses of predominantly industry-funded studies find only minute differences in relapse risk (Leucht et al., 2003). Atypical antipsychotic agents offer significant advantages related to reduced neurological risk, with long-term tardive dyskinesia rates < 1%, or approximately one-fifth to one-tenth of that seen with typical antipsychotic drugs (for haloperidol, the annual incidence of tardive dyskinesia is 4-5% in non-geriatric adult patients; lifetime risk ~20%). This advantage of the atypical agents is magnified in elderly patients, in whom tardive dyskinesia incidence is 5-fold greater than in younger patients, and for whom annual tardive dyskinesia rates with typical antipsychotic agents exceed 20% per year. The decreased affinity for D₂ receptors among atypical agents has also translated into reduced concerns over hyperprolactinemia with most atypical antipsychotic agents, although risperidone and paliperidone (9-OH risperidone) are exceptions; both agents cause dose-dependent increases in prolactin (see “Adverse Effects and Drug Interactions” later in the chapter).

While concerns over EPS and tardive dyskinesia have abated with the introduction of the atypical antipsychotic agents into clinical practice, there has been increased concern over metabolic effects of antipsychotic treatment: weight gain, dyslipidemia (particularly hypertriglyceridemia), and an adverse impact on glucose-insulin homeostasis, including new-onset type 2 DM, and diabetic ketoacidosis (DKA), with reported fatalities from the latter (American Diabetes Association et al., 2004). Clozapine and olanzapine have the highest metabolic risk and are only used as last resort. Olanzapine has been relegated in most treatment algorithms to third-tier status, and is considered only after failure of more metabolically benign agents such as aripiprazole, ziprasidone, asenapine, iloperidone, risperidone, and paliperidone.

Acutely psychotic patients usually respond within hours after drug administration, but weeks may be required to achieve maximal drug response, especially for negative symptoms, which respond much less robustly to drug therapy. While 6 weeks of therapy has been considered an adequate antipsychotic trial, analyses of symptom response in clinical trials indicate that the majority of response to any antipsychotic treatment in acute schizophrenia is seen by week 4 (Agid et al., 2003; Emsley et al., 2006). Failure of response after 2 weeks should prompt a clinical reassessment, including determination of medication adherence, before a decision is made to increase the current dose or consideration of switching to another agent. First-episode schizophrenia patients often respond to modest doses, and more chronic patients may require doses that exceed recommended ranges. While the acute behavioral impact of treatment is seen within hours to days, long-term studies indicate improvement may not plateau for 6 months, underscoring the importance of ongoing antipsychotic treatment in functional recovery for schizophrenia patients.

Usual dosages for acute and maintenance treatment are noted in Table 16–1. Dosing should be adjusted based on clinically observable signs of antipsychotic benefit and adverse effects. For example, higher EPS risk is noted for risperidone doses that exceed 6 mg/day in non-elderly adult schizophrenia patients. However, in the absence of EPS, increasing the dose from 6-8 mg would be a reasonable approach in a patient with ongoing positive symptoms, albeit with appropriate monitoring for emerging EPS symptoms. Treatment-limiting adverse effects may include weight gain, sedation, orthostasis, and EPS, which to some degree can be predicted based on the potencies of the selected agent to inhibit neurotransmitter receptors (Table 16–2). The detection of dyslipidemia or hyperglycemia is based on laboratory monitoring (Table 16–1). Certain adverse effects such as hyperprolactinemia, EPS, orthostasis, and sedation may respond to dose reduction, but metabolic abnormalities improve only with discontinuation of the offending agent and a switch to a more metabolically benign medication. The decision to switch stable schizophrenia patients with antipsychotic-related metabolic dysfunction solely for metabolic benefit must be individualized, based on patient preferences, severity of the metabolic disturbance, likelihood of metabolic improvement with

**Dosage Forms:** O, tablet; S, solution; IM, acute intramuscular; ODT, orally dissolving tablet.

Note that doses in first-episode, younger, or antipsychotic-naïve patients are lower than for chronic schizophrenia patients. Dose in elderly schizophrenia patients is approximately 50% of that used in younger adults with schizophrenia; dosing for dementia-related psychosis is approximately 25%.

*Due to orthostasis risk, dose titration of iloperidone is 1 mg bid on day 1, increasing to 2, 4, 6, 8, 10, and 12 mg bid on days 2, 3, 4, 5, 6, and 7 (as needed). Safety data exist for daily doses up to 16 mg bid.

*Paliperidone palmitate dosing: in acute schizophrenia, deltoid IM loading doses of 234 mg at day 1 and 156 mg at day 8 provide paliperidone levels equivalent to 6 mg oral paliperidone during the first week, and peaking on day 15 at a level comparable to 12 mg oral paliperidone. No oral antipsychotic needed in first week. Maintenance IM doses can be given in deltoid or gluteus every 4 weeks after day 8. Maintenance dose options: 39, 78, 117, 156, or 234 mg every 4 weeks. Failure to give initiation doses (except for those switching from depot) will result in subtherapeutic levels for months.

*Not available in the U.S.

*Oral dose must be given with food (500 kcal) to facilitate absorption. Food increases the absorption of single doses of 20-, 40-, and 80-mg capsules by 48%, 87%, and 101%, respectively.

\(^a\)Data are averaged \(K_i\) values (nM) from published sources determined by competition with radioligands for binding to the indicated cloned human receptors. Data derived from receptor binding to human or rat brain tissue is used when cloned human receptor data is lacking.

\(^b\)Not available in the U.S.

antipsychotic switching, and history of response to prior agents. Patients with refractory schizophrenia on clozapine are not good candidates for switching because they are resistant to other medications (see the definition of refractory schizophrenia later in this section).

There are many reasons for psychotic relapse or inadequate response to antipsychotic treatment in schizophrenia patients. Examples are ongoing substance use, psychosocial stressors, inherent refractory illness, and poor medication adherence. Outside of controlled settings, the problem of medication nonadherence remains a significant barrier to successful treatment, yet one that is not easily assessed. Serum drug levels can be obtained for most antipsychotic medications, but there is limited dose-response data for atypical antipsychotic agents (except for clozapine), leaving clinicians little guidance about the interpretation of antipsychotic drug levels. Even low or undetectable levels may not reflect nonadherence, but rather can be the result of genetic variation or induction of hepatic CYPs that decrease drug availability, such as the high prevalence of CYP2D6 ultrarapid metabolizers among individuals from North Africa and the Middle East. Nevertheless, the common problem of medication nonadherence among schizophrenia patients has led to the development of long-acting injectable (LAI) antipsychotic medications, often referred to as depot antipsychotics. They are more widely used in the E.U. Only < 5% of U.S. patients receive depot antipsychotic treatment. There are currently four available LAI forms in the U.S.: decanoate esters of fluphenazine and haloperidol, risperidone-impregnated microspheres, and paliperidone palmitate. Patients receiving LAI antipsychotic medications show consistently lower relapse rates compared to patients receiving comparable oral forms and may suffer fewer adverse effects. LAI risperidone and paliperidone palmitate are currently the only atypical antipsychotic agents in depot form. However, clinical trials of LAI aripiprazole and olanzapine are in progress and these agents should become available in the near future. LAI risperidone is administered as biweekly intramuscular (IM) injections of 25-50 mg. Based on extensive kinetic modeling of clinical data, paliperidone palmitate therapy in acute schizophrenia is initiated with IM deltoid loading doses of 234 mg at day 1 and 156 mg at day 8 to provide serum paliperidone levels equivalent to 6 mg oral paliperidone during the first week, obviating the need for oral antipsychotic supplementation. Serum paliperidone levels from these two injections peak on day 15 at a level comparable to 12 mg oral paliperidone. Maintenance IM doses are given in deltoid or gluteus muscle every 4 weeks after day 8. Unlike acute IM preparations or paliperidone palmitate, all other LAI antipsychotic medications require several weeks to attain therapeutic levels and months to reach steady state, necessitating the use of oral medications for the initial 4 weeks of treatment.

Lack of response to adequate antipsychotic drug doses for adequate periods of time may indicate treatment-refractory illness. Refractory schizophrenia is defined using the Kane criteria: failed 6-week trials of two separate agents and a third trial of a high-dose typical antipsychotic agent (e.g., haloperidol or fluphenazine 20 mg/day). In this patient population, response rates to typical antipsychotic agents, defined as 20% symptom reduction using standard rating scales (e.g., Positive and Negative Syndrome Scale [PANSS]), are 0%, and for any atypical antipsychotic except clozapine, are < 10% (Leucht et al., 2009). Due to the long titration involved to minimize orthostasis, and to sedation and other tolerability issues, adequate clozapine trials often require 6 months, but response rates in 26-week-long studies are consistently 60% in refractory schizophrenia patients. The therapeutic clozapine dose for a specific patient is not predictable, but various studies have found correlations between trough serum clozapine levels > 327-504 ng/mL and likelihood of clinical response. When therapeutic serum concentrations are reached, response to clozapine occurs within 8 weeks.

In addition to agranulocytosis risk that mandates routine ongoing hematological monitoring, clozapine has numerous other adverse effects. Examples are high metabolic risk, dose-dependent lowering of the seizure threshold, orthostasis, sedation, anticholinergic effects (especially constipation), and salivation related to muscarinic agonism at M₄ receptors. As a result, clozapine use is limited to refractory schizophrenia patients.

Electroconvulsive therapy is considered a treatment of last resort in refractory schizophrenia and is rarely employed. Despite widespread clinical use of combining several antipsychotic agents, there is virtually no data supporting this practice, and metabolic risk increases with use of multiple antipsychotic agents (Correll et al., 2007). In one of few instances where a sound pharmacological rationale exists for combination treatment, the addition of a potent D₂ antagonist (e.g., risperidone, haloperidol) to maximally tolerated doses of clozapine (a weak D₂ blocker), the results have been decidedly mixed. That multiple antipsychotic agents (“polypharmacy”) are commonly used in clinical practice attests to the limitations of current treatment. Lastly, antipsychotic drug therapy is the foundation of schizophrenia treatment, yet adequate management of schizophrenia patients requires a multimodal approach that also includes psychosocial, cognitive, and vocational rehabilitation to promote functional recovery.

Pharmacology of Antipsychotic Agents

Chemistry. In the past, the chemical structure of selected agents was informative regarding their antipsychotic activity, since most were derived from phenothiazine or butyrophenone structures. Phenothiazines have a tricyclic structure in which two benzene rings are linked by a sulfur and a nitrogen atom (Table 16–1). The chemically related thioxanthenes have a carbon in place of the nitrogen at position 10 with the R₁ moiety linked through a double bond. Substitution of an electron-withdrawing group at position 2 increases the antipsychotic efficacy of phenothiazines (e.g., chlorpromazine). The nature of the substituent at position 10 also influences pharmacological activity, and the phenothiazines and thioxanthenes can be divided into three groups on the basis of substitution at this site. Those with an aliphatic side chain include chlorpromazine and are relatively low in potency. Those with a piperidine ring in the side chain include thioridazine, which has lower EPS risk, possibly due to increased central
antimuscarinic activity, but is rarely used due to concerns over QTc prolongation and risk of torsade de pointes. Several potent phenothiazine antipsychotic compounds have a piperazine group in the side chain (fluphenazine, perphenazine, and trifluoperazine) and have reduced affinity for H$_1$, M, and $\alpha_2$ receptors. Those with a free hydroxyl can also be esterified to long-chain fatty acids to produce LAI antipsychotic medications (e.g., fluphenazine decanoate). Thioxanthenes also have aliphatic or piperazine side-chain substituents. Piperazine-substituted thioxanthenes include the high potency agent thiothixene. Since thioxanthenes have an olefinic double bond between the central-ring C10 and the side chain, geometric isomers exist. The cis isomers are more active. The antipsychotic phenothiazines and thioxanthenes have three carbon atoms interposed between position 10 of the central ring and the first amino nitrogen atom of the side chain at this position; the amine is always tertiary. Antihistaminic phenothiazines (e.g., promethazine) or strongly anticholinergic phenothiazines have only two carbon atoms separating the amino group from position 10 of the central ring. Metabolic N-dealkylation of the side chain or increasing the size of amino N-alkyl substituents reduces antidopaminergic and antipsychotic activity. Additional tricyclic antipsychotic agents are the benzepines, containing a 7-member central ring, of which loxapine (a dibenzoxazepine) and clozapine (a dibenzodiazepine) are available in the U.S. Clozapine-like atypical antipsychotic agents may lack a substituent on the aromatic ring (e.g., quetiapine, a dibenzothiazepine), have an analogous methyl substituent (olanzapine), or have an electron-donating substituent at position 8 (e.g., clozapine). In addition to their moderate potencies at DA receptors, clozapine-like agents interact with varying affinities at several other classes of receptors ($\alpha_1$, $\alpha_2$, adrenergic, 5-HT$_{1A}$, 5-HT$_{2A}$, 5-HT$_{2C}$, M, H$_1$). The prototypical butyrophenone (phenylbutylpiperidine) antipsychotic is haloperidol, originally developed as a substituted derivative of the phenylpiperidine analgesic meperidine. An analogous compound, droperidol, is a very short-acting and highly sedating agent that was used almost exclusively for emergency sedation and anesthesia until QTc and torsade de pointes concerns substantially curtailed its use and the use of the related diphenylbutylpiperidine pimozide. Several other classes of heterocyclic compounds have antipsychotic effects, of which only the indo l molindone has generated any interest due to its unusual association with modest weight loss (Sikich et al., 2008a). The enantiomeric, substituted benzamides are another group of heterocyclic compounds that are relatively selective antagonists at central D$_2$ receptors and have antipsychotic activity. Examples (not available in the U.S.) include sulpiride and its congener, amisulpride.

The introduction of clozapine stimulated research into agents with antipsychotic activity and low EPS risk. This search led to a series of atypical antipsychotic agents with certain pharmacological similarities to clozapine: namely lower affinity for D$_2$ receptors than typical antipsychotic drugs and high 5-HT$_2$ antagonist effects. The currently available atypical antipsychotic medications include the structurally related olanzapine, quetiapine, and clozapine; the benzisoxazoles risperidone, its active metabolite paliperidone, and iloperidone; ziprasidone (a benzisothiazolpiperazinylindolone derivative); asenapine (a dibenzo-oxepino pyrrole), and aripiprazole (a quinololone derivative); Table 16–1.

Presently, antipsychotic agents include many different chemical structures with a range of activities at different neurotransmitter receptors (e.g., 5-HT$_{2A}$ antagonism, 5-HT$_{1A}$ partial agonism). As a result, structure-function relationships that were relied upon in the past have become less important. Instead, receptor-function relationships and functional assays are more clinically relevant. Aripiprazole represents a good example of how an examination of the structure provides little insight into its mechanism, which is based on dopamine partial agonism (discussed later). Detailed knowledge of receptor affinities (Table 16–2) and the functional effect at specific receptors (e.g., full, partial or inverse agonism or antagonism) can provide important insight into the therapeutic and adverse effects of antipsychotic agents. Nevertheless, there are limits. For example, it is not known which properties are responsible for clozapine’s unique effectiveness in refractory schizophrenia, although many hypotheses exist. Other notable antipsychotic properties not fully explained by receptor parameters include the reduced seizure threshold, the unexpected extent of prolactin elevation for risperidone and paliperidone, the effects of antipsychotic agents on metabolic function, and the increased risk for cerebrovascular events and mortality among dementia patients (see “Adverse Effects and Drug Interactions” later in the chapter).

**Mechanism of Action.** While emerging data indicate that stimulation of glutamate or muscarinic receptors may confer antipsychotic properties, no clinically available effective antipsychotic is devoid of D$_2$ antagonistic activity. This reduction in dopaminergic neurotransmission is presently achieved through one of two mechanisms: D$_2$ antagonism or partial D$_2$ agonism, of which aripiprazole is the only current example. Another partial agonist, bifeprunox, completed clinical trials but failed to gain FDA approval.

Aripiprazole has an affinity for D$_2$ receptors only slightly less than DA itself, but its intrinsic activity is ~25% that of dopamine. As depicted in Figure 16–3, when dopamine is given in increasing concentrations in an *in vitro* model, 100% stimulation of the available D$_2$ receptors occurs (as measured by forskolin-stimulated cyclic AMP accumulation). In the absence of DA, aripiprazole produces a maximal level of D$_2$ activity ~25% that of DA (Burris et al., 2002). The potent D$_2$ antagonist haloperidol is capable of reducing dopamine’s effect to zero, but when DA is incubated with increasing concentrations of aripiprazole, maximal inhibition of D$_2$ activity did not exceed 25% of the DA response, that is, the level of agonism provided by aripiprazole. Aripiprazole’s capacity to stimulate D$_2$ receptors in brain areas where synaptic DA levels are limited (e.g., PFC neurons) or decrease dopaminergic activity when dopamine concentrations are high (e.g., mesolimbic cortex) is thought to be the basis for its clinical effects in schizophrenia. Evidence for its partial DA agonist properties is seen clinically as a reduction in
Thus, it inhibits effects of DA and reduces stimulation at the D_2 receptor only to the extent of its own capacity as an agonist. Haloperidol, an antagonist without agonist activity, completely antagonizes D_2 receptor activation. Here, receptor activity was measured as inhibition of forskolin-induced cAMP accumulation in CHO cells transfected with human D_{2L} DNA. (Adapted from Burris et al., 2002.)

Figure 16–3. Aripiprazole activity at D_2 receptors in the presence or absence of dopamine. Aripiprazole is a partial D_2 agonist; thus it inhibits effects of DA and reduces stimulation at the D_2 receptor only to the extent of its own capacity as an agonist. Haloperidol, an antagonist without agonist activity, completely antagonizes D_2 receptor activation. Here, receptor activity was measured as inhibition of forskolin-induced cAMP accumulation in CHO cells transfected with human D_{2L} DNA. (Adapted from Burris et al., 2002.)

Serum prolactin levels. Unlike other antipsychotic agents, in which striatal D_2 occupancy (i.e., reduction in postsynaptic D_2 signal) > 78% is associated with EPS, aripiprazole requires significantly higher D_2 occupancy levels. Even with 100% receptor occupancy, aripiprazole’s intrinsic dopaminergic agonism can generate a 25% postsynaptic signal, implying a maximal 75% reduction in DA neurotransmission, below the 78% threshold that triggers EPS in most individuals, although rare reports of acute dystonia exist, primarily in antipsychotic-naïve, younger patients.

Animal models of antipsychotic activity have evolved over a half-century of antipsychotic drug development to incorporate emerging knowledge of psychosis pathophysiology. Prior to the elucidation of D_2 antagonism as a common mechanism for antipsychotic agents, early behavioral paradigms exploited known animal effects that predicted clinical efficacy. As expected, these models, including catalepsy induction and blockade of apomorphine-induced stereotypic behavior, were subsequently found to be dependent on potent D_2 receptor antagonism (Lieberman et al., 2008). Clozapine failed these early trials and was not suspected to possess antipsychotic activity until experimental human use in the mid-1960s revealed it to be an effective treatment for schizophrenia, particularly in patients who had failed other antipsychotic medications, and with virtually absent EPS risk. By 1989, the pharmacological basis for some of these atypical properties, namely clinical efficacy without EPS induction, was found to result from a significantly weaker D_3 antagonism than existing antipsychotic agents, combined with potent 5-HT_2 antagonism. Subsequent research demonstrated that 5-HT_2A receptor antagonism is responsible for facilitation of dopamine release in both mesocortical and nigrostriatal pathways. The behavioral pharmacology of 5-HT_2A antagonism and related 5-HT_2C and 5-HT_1A receptor agonism has since been characterized, and relevant animal behavioral assays developed. Clozapine possesses activity at numerous other receptors including antagonism and agonism at various muscarinic receptor subtypes and antagonism at dopamine D_4 receptors; however, subsequent D_3 antagonists that did not also have D_2 antagonism lacked antipsychotic activity. Clozapine’s active metabolite, N-desmethylclozapine, is a potent muscarinic M_1 agonist (Li et al., 2005). Although N-desmethylclozapine failed clinical trials as schizophrenia monotherapy, it increased interest in cholinergic agonists as primary treatments or adjunctive cognitive enhancing medications for schizophrenia. Important targets of agents in preclinical and clinical drug development include M_1 agonism (Janowsky and Davis 2009), M_4 agonism (Chan et al., 2008), and α7- and α4β2-nicotinic receptor agonism (Buchanan et al., 2007).

The glutamate hypofunction hypothesis of schizophrenia has led to novel animal models that examine the influence of proposed antipsychotic agents, including those in clinical development with agonist properties at metabotropic glutamate receptors mGlu2 and mGlu4 (Patil et al., 2007) and other subtypes. Atypical antipsychotic drugs are better than typical antipsychotic medications at reversing the negative symptoms, cognitive deficits and social withdrawal induced by glutamate antagonists. At the present time, however, it is unclear whether glutamate agonist that lack direct D_2 antagonist properties will prove as effective as serotonin-dopamine antagonists for schizophrenia treatment, or whether glutamate agonist mechanisms might be more useful when combined with D_2 modulation, much in the same manner as 5-HT_2A antagonism. Schizophrenia patients also exhibit specific neurophysiological abnormalities. For example, a disruption in the normal processing of sensory and cognitive information is exhibited in various preconscious inhibitory processes, including deficiencies in sensorimotor gating as assessed by prepulse inhibition (PPI) of the acoustic startle reflex. PPI is the automatic suppression of startle magnitude that occurs when the louder acoustic stimulus is preceded 30-500 ms by a weaker prepulse (Swerdlov et al., 2006). In schizophrenia patients, PPI is increased more robustly with atypical than typical antipsychotic agents, and in animal models, atypical antipsychotic agents are also more effective at opposing PPI disruption from NMDA antagonists. Increased understanding of the pharmacological basis for neurophysiological deficits provides another means for developing antipsychotic treatments that are specifically effective for schizophrenia and may not necessarily apply to other forms of psychosis.

Dopamine Receptor Occupancy and Behavioral Effects. Dopaminergic projections from the midbrain terminate on septal nuclei, the olfactory tubercle and basal forebrain, the amygdala, and other structures within the temporal and prefrontal cerebral lobes and the hippocampus. The dopamine hypothesis has focused considerable attention on the mesolimbic and mesocortical systems as possible sites where antipsychotic effects are mediated. Recent research confirms that excessive dopaminergic functions in the limbic system are central to the positive
symptoms of psychosis. The behavioral effects and the time course of antipsychotic response parallel the rise in D₂ occupancy and include calming of psychomotor agitation, decreased hostility, decreased social isolation, and less interference from disorganized or delusional thought processes and hallucinations.

Levels of central D₃ occupancy estimated by positron emission tomography (PET) brain imaging in patients treated with antipsychotic drugs support conclusions arising from laboratory studies that receptor occupancy predicts clinical efficacy, EPS, and serum level-clinical response relationships. Occupation of > 78% of D₂ receptors in the basal ganglia is associated with a risk of EPS across all dopamine antagonist antipsychotic agents, while occupancies in the range of 60-75% are associated with antipsychotic efficacy (Figure 16–2) (Kapur et al., 2000b). With the exception of aripiprazole, all atypical antipsychotic drugs at low doses have much greater occupancy of 5-HT₂A receptors (e.g., 75-99%) than typical agents (Table 16–2). Among atypical agents, clozapine has the highest ratio of 5-HT₂A/D₂ binding. Clozapine’s D₂ occupancy 12-hours post-dose ranges from 51-63% (Kapur et al., 1999), providing evidence for its limited EPS risk. The trough D₂ occupancy for quetiapine is even lower (< 30%), but PET studies obtained 2-3 hours after dosing reveal D₂ receptor occupancies in the expected therapeutic range (54-64%), albeit transiently. Ziprasidone absorption is sensitive to the presence of food, but PET studies demonstrate that clinical efficacy occurs when D₂ occupancy exceeds 60%, which corresponds to a minimum daily dose of 120 mg (with food) (Mamo et al., 2004).

Among the typical antipsychotic drugs, receptor occupancy is best studied for haloperidol. Haloperidol has complex metabolism and is susceptible to modulation by CYP inhibitors, inducers, and CYP polymorphisms (Table 16–3), complicating the establishment of dose-response relationships in patients. Nonetheless, the use of serum levels can predict D₂ occupancy (Fitzgerald et al., 2000):

\[
\% \text{ D}_2 \text{ receptor occupancy} = 100 \times \left(\frac{\text{Plasma haloperidol ng/mL}}{0.40 \text{ ng/mL} + \text{Plasma haloperidol ng/mL}}\right)
\]

Similar formulas also exist for several atypical antipsychotic drugs, although their plasma concentrations are rarely measured in the clinical setting.

\textit{D}_3 \text{ and D}_4 \text{ Receptors in the Basal Ganglia and Limbic System.} The discovery that D₃ and D₄ receptors are preferentially expressed in limbic areas has led to efforts to identify selective inhibitors for these receptors that might have antipsychotic efficacy and low EPS risk. As previously noted, clozapine has modest selectivity for D₄ receptors, which are preferentially localized in cortical and limbic brain regions in relatively low abundance, and are up-regulated after repeated administration of most typical and atypical antipsychotic drugs (Tarazi et al., 2001). These receptors may contribute to clinical antipsychotic actions, but agents that are D₄ selective (e.g., sonepiprazole) or mixed D₃/5-HT₂A antagonists (e.g., fananserin) lack antipsychotic efficacy in clinical studies. In contrast to effects on D₁ and D₂ receptors, long-term administration of typical and atypical antipsychotic drugs does not alter D₃ receptor levels in rat forebrain regions (Tarazi et al., 2001). These findings suggest that D₃ receptors are unlikely to play a pivotal role in antipsychotic drug actions, perhaps because their avidity for endogenous DA prevents their interaction with antipsychotic agents. The subtle and atypical functional activities of cerebral D₃ receptors suggest that D₃ agonists rather than antagonists may have useful psychotrophic effects, particularly in antagonizing stimulant-reward and dependence behaviors. Aripiprazole possesses affinity and intrinsic activity at D₃ receptors equivalent to that at D₂; the clinical advantage of this property is not readily apparent, although preclinical data suggest some effects on substance use.

\textit{The Role of Non-Dopamine Receptors for Atypical Antipsychotic Agents.} The concept of atypicality was initially based on clozapine’s absence of EPS within the therapeutic range, combined with a prominent role of 5-HT₁ receptor antagonism. As subsequent agents were synthesized using clozapine’s 5-HT₁/D₂ ratio as a model, most of which possessed greater D₂ affinity and EPS risk than clozapine, there has been considerable debate on the definition of an atypical antipsychotic agent and its necessary properties. Aripiprazole in particular is problematic for the model based on ratios of 5-HT₁ to D₂; since its action as partial agonist necessitates very high D₂ affinity. Loxapine is another problematic agent for the model since its receptor pharmacology suggests atypical properties based on 5-HT₁/D₂ ratio; however, in clinical practice its use was associated with the expected higher level of EPS characteristic of typical antipsychotic drugs, perhaps related to the additive D₂ antagonist properties of the active metabolite amoxapine. These dilemmas have lead some to suggest abandonment or modification of the atypical/typical antipsychotic terminology, perhaps in lieu of the designation by generation (e.g., first, second, etc.), as is used with antibiotics, or some other organizing scheme (Gründler et al., 2009). Nonetheless, the term “atypical” persists in common usage and designates lesser (but not absent) EPS risk and other decreased effects of excessive D₂ antagonism, or more accurately, reduction in D₂-mediated neurotransmission.

The neuropharmacology and behavioral pharmacology of 5-HT₂ antagonism provide insights into the advantageous properties of medications with these effects (Marek et al., 2003). Antipsychotic agents with appreciable 5-HT₂ affinity have significant effects at both 5-HT₂A and 5-HT₂C receptors with individual medications varying in their relative potencies at each subtype (Tarazi et al., 2002). As discussed previously, atypical antipsychotic agents exhibit potent functional antagonism at both subtypes of 5-HT₂ receptors, but \textit{in vitro} assays suggest that these effects result from inverse agonism at these G-coupled receptors.

5-HT₂A receptors are widely distributed, but antagonism exerts the greatest effect on prefrontal and basal ganglia DA release and midbrain noradrenergic outflow, with recent data implicating 5-HT₂A receptor polymorphisms in differential antidepressant response (McMahon et al., 2006). There are significant interrelationships between serotonin receptors, with evidence from animal studies that stimulation of either 5-HT₁A or 5-HT₂C receptors antagonizes the behavioral effects of 5-HT₂A agonists (Marek et al., 2003). This can be seen with agents that have direct effects on 5-HT₂A activity and also in studies of NMDA antagonists where there are opposing modulatory effects of 5-HT₂A and 5-HT₂C stimulation. By virtue of their impact on noradrenergic neurotransmission, 5-HT₂A antagonists...

pass many preclinical in vivo assays of antidepressant activity; conversely, 5-HT_{2C} antagonists exhibit a similar spectrum of antidepressant properties, although pure 5-HT_{2A} or 5-HT_{2C} agents are, by themselves, not effective antidepressants in human trials (Marek et al., 2003). Data also indicate that 5-HT_{2C} agonism decreases mesolimbic DA neurotransmission, a mechanism that is being explored in clinical trials of vabicaserin, a pure 5-HT_{2C} agonist. At the cellular level, stimulation of 5-HT_{2A} and 5-HT_{1A} receptors causes depolarization and hyperpolarization, respectively, of cortical pyramidal cells (Marek et al., 2003). No atypical antipsychotic agent is a potent agonist of 5-HT_{1A} receptors, but several, including clozapine, idalopridine, and aripiprazole are partial agonists. The extent to which this contributes to any clinical effect is unknown, but more potent selective 5-HT_{1A} agonists have anxiolytic effects and appear to exert procognitive effects in schizophrenia patients when added to existing antipsychotic treatment.

Based upon trials of the selective α_{2} adrenergic antagonist idazoxan, researchers have postulated effects of α_{2} blockade on mood, but ongoing research into this mechanism has not been promising. Risperidone is the one antipsychotic with relatively high affinity for α_{2} adrenergic receptors, at which it is an antagonist; however, the clinical correlate of this unique profile is unclear. Any benefit on major depressive symptoms from low-dose risperidone augmentation of SSRI antidepressants is more likely conveyed by effects at the 5-HT_{2A} receptor, at which risperidone has >100-fold greater potency than at α_{2} adrenergic receptors.

**Tolerance and Physical Dependence.** As defined in Chapter 24, antipsychotic drugs are not addicting; however, tolerance to the anticholinergic and anticholinergic effects of antipsychotic agents usually develops over days or weeks. Loss of efficacy with prolonged treatment is not known to occur with antipsychotic agents; however, tolerance to antipsychotic drugs and cross-tolerance among the agents are demonstrable in both clinical and biochemical experiments in animals, particularly those directed toward evaluation of the blockade of dopaminergic receptors in the basal ganglia (Tarazi et al., 2001). This form of tolerance may be less prominent in limbic and cortical areas of the forebrain. One correlate of tolerance in striatal dopaminergic systems is the development of receptor supersensitivity (mediated by upregulation of supersensitive DA receptors) referred to as D_{2}^{*} receptors (Lieberman et al., 2008). These changes may underlie the clinical phenomenon of withdrawal-emergent dyskinesias and may contribute to the pathophysiology of tardive dyskinesia. This may also partly explain the ability of certain chronic schizophrenia patients to tolerate high doses of potent DA antagonists with limited EPS.

**Absorption, Distribution, and Elimination.** The pharmacokinetic constants for these drugs may be found in Appendix II. Table 16–3 outlines the metabolic pathways of atypical antipsychotic agents available in the U.S. and selected typical agents in common use. Most antipsychotic drugs are highly lipophilic, highly membrane-or protein-bound, and accumulate in the brain, lung, and other tissues with a rich blood supply. They also enter the fetal circulation and breast milk. Despite half-lives that may be short, the biological effects of single doses of most antipsychotic medications usually persist for at least 24 hours, permitting once-daily dosing for many agents once the patient has adjusted to initial side effects.

Elimination from the plasma may be more rapid than from sites of high lipid content and binding, notably the CNS, as evidenced by PET pharmacokinetic studies that demonstrate half-lives in the CNS that exceed those in plasma. For example, mean single-dose plasma half-lives of olanzapine and risperidone are 24.2 and 10.3 hours respectively, whereas a 50% reduction from peak striatal D_{2} receptor occupancy requires 75.2 hours for olanzapine and 66.6 hours for risperidone (Tauscher et al., 2002). Similar discrepancies are seen between the time course of plasma levels and occupancy of extrastriatal D_{2} and 5-HT_{3A} receptors (Tauscher et al., 2002). Metabolites of long acting injectable medications have been detected in the urine several months after drug administration was discontinued. Slow removal of drug may contribute to the typical delay of exacerbation of psychosis after stopping drug treatment. Depot decanoate esters of fluphenazine and haloperidol, paliperidone palmitate, as well as risperidone-impregnated microspheres, are absorbed and eliminated much more slowly than are oral preparations. For example, the t_{1/2} of oral fluphenazine is ∼20 hours while the IM decanoate ester has a t_{1/2} of 14.3 days; oral haloperidol has a t_{1/2} of 24-48 hours in CYP2D6-extensive metabolizers (de Leon et al., 2004), while haloperidol decanoate has a t_{1/2} of 21 days (Altamura et al., 2003); paliperidone palmitate has a t_{1/2} of 25-49 days compared to an oral paliperidone t_{1/2} of 23 hours. Clearance of fluphenazine and haloperidol decanoate following repeated dosing can require 6-8 months. Effects of LAI risperidone (RISPERDAL CONSTA) are delayed for 4 weeks because of slow biodegradation of the microspheres and persist for at least 4-6 weeks after the injections are discontinued (Altamura et al., 2003). The dosing regimen recommended for starting patients on LAI paliperidone generates therapeutic levels in the first week, obviating the need for routine oral antipsychotic supplementation.

With the exception of asenapine, paliperidone and ziprasidone, all antipsychotic drugs undergo extensive phase 1 metabolism by CYPs and subsequent phase 2 glucuronidation, sulfation, and other conjugations (Table 16–3). Hydrophilic metabolites of these drugs are excreted in the urine and to some extent in the bile. Most oxidized metabolites of antipsychotic drugs are biologically inactive; a few (e.g., P88 metabolite of iloperidone, hydroxy metabolite of haloperidol 9-OH risperidone, N-desmethylclozapine, and dehydroaripiprazole) are active. These active metabolites may contribute to biological activity of the parent compound and complicate correlating serum drug levels with clinical effects. The active metabolite of risperidone, paliperidone (9-OH risperidone), is already the product of oxidative metabolism, and 59% is excreted unchanged in urine with a lesser amount (32%) excreted as metabolites or via phase 2 metabolism (∼10%). Ziprasidone’s primary metabolic pathway is through the aldehyde oxidase system that is neither saturable nor inhibitable by commonly encountered xenobiotics, with ∼one-third of ziprasidone’s metabolism through CYP3A4 (Meyer, 2007). Asenapine is metabolized primarily through glucuronidation (UGT4), with a minor contribution from CYP1A2. The potential for drug-drug interactions is covered in “Adverse Effects and Drug Interactions” later in the chapter.
Absorption for most agents is quite high, and concurrent administration of anticholinergic anti-parkinsonian agents does not appreciably diminish intestinal absorption. Most orally-disintegrating tablets (ODT) and liquid preparations provide similar pharmacokinetics since there is little mucosal absorption and effects depend on swallowed drug. Asenapine remains the only exception. It is only available as an ODT preparation administered sublingually, and all absorption occurs via oral mucosa, with bioavailability of 35% by this route. If swallowed, the first pass effect is > 98%, indicating that drug swallowed with oral secretions is not bioavailable. Intramuscular administration avoids much of the first-pass enteric metabolism and provides measurable concentrations in plasma within 15-30 minutes. Most agents are highly protein bound, but this protein binding may include glycoprotein sites. Kinetic studies indicate that antipsychotic drugs do not significantly displace other pre-albumin- or albumin-bound medications. Antipsychotic medications are predominantly highly lipophilic with apparent volumes of distribution as high as 20 L/kg.

### Therapeutic Uses

The use of antipsychotic medications for the treatment of schizophrenia spectrum disorders, for mania treatment, and as adjunctive use for treatment-resistant major depression has been discussed previously. Antipsychotic agents are also utilized in several nonpsychotic neurological disorders and as antiemetics.

**Anxiety Disorders.** There are two anxiety disorders in which double-blind, placebo-controlled trials have shown benefit of adjunctive treatment with antipsychotic drugs: obsessive compulsive disorder (OCD) and post-traumatic stress disorder (PTSD). While SSRI antidepressants remain the only psychotropic medication with FDA approval for PTSD treatment, adjunctive low-dose quetiapine, olanzapine, and particularly risperidone significantly reduce the overall level of symptoms in SSRI-resistant PTSD (Bartzokis et al., 2005). OCD patients with limited response to the standard 12-week regimen of high dose SSRI also benefit from adjunctive risperidone (mean dose 2.2 mg), even in the presence of comorbid tic disorders (McDougle et al., 2000). For generalized anxiety disorder, double-blind placebo controlled clinical trials demonstrate efficacy for quetiapine as monotherapy, and for adjunctive low-dose risperidone.

**Tourette’s Disorder.** The ability of antipsychotic drugs to suppress tics in patients with Tourette’s disorder has been known for decades, and relates to reduced D₂ neurotransmission in basal ganglia sites. In prior decades, the use of low-dose, high-potency typical antipsychotic agents (e.g., haloperidol, pimozide) was the treatment of choice, but these nonpsychotic patients were extremely sensitive to the impact of DA blockade on cognitive processing speed, and on reward centers. Safety concerns regarding pimozide’s QTc prolongation and increased risk for ventricular arrhythmias have large ended its clinical use. While lacking FDA approval for tic disorders, risperidone and aripiprazole have indications for child and adolescent schizophrenia and bipolar disorder (acute mania) treatment, and these agents (as well as ziprasidone) have published data supporting their use for tic suppression. Given the enormous sensitivity of preadolescent and teenage patients to antipsychotic-induced weight gain, aripiprazole has an advantage in this patient population due to somewhat lower risk for weight gain, and low risk for hyperprolactinemia or concerns over QTc effects.

**Huntington’s Disease.** Huntington’s disease is another neuropsychiatric condition, which, like tic disorders, is associated with basal ganglia pathology. DA blockade can suppress the severity of choreoathetotic movements, but is not strongly endorsed due to the risks associated of excessive DA antagonism that outweigh the marginal benefit. Inhibition of the vesicular monoamine transporter type 2 (VMAT2) with tetrabenazine has replaced DA receptor blockade in the management of chorea (Chapter 22).

**Autism.** Autism is a disease whose neuropathology is incompletely understood, but in some patients is associated with explosive behavioral outbursts, and aggressive or self-injurious behaviors that may be stereotypical. Risperidone has FDA approval for irritability associated with autism in child and adolescent patients ages 5-16, with common use for disruptive behavior problems in autism and other forms of mental retardation. Initial risperidone daily doses are 0.25 mg for patients weighing < 20 kg, and 0.5 mg for others, with a target dose of 0.5 mg/day in those < 20 kg weight, and 1.0 mg/day for other patients, with a range 0.5-3.0 mg/day.

**Anti-emetic Use.** Most antipsychotic drugs protect against the nausea- and emesis-inducing effects of DA agonists such as apomorphine that act at central DA receptors in the chemoreceptor trigger zone of the medulla. Antipsychotic drugs are effective antiemetics already at low doses. Drugs or other stimuli that cause emesis by an action on the nodose ganglion, or locally on the GI tract, are not antagonized by antipsychotic drugs, but potent piperazines and butyrophenones are sometimes effective against nausea caused by vestibular stimulation. The commonly used antiemetic phenothiazines are weak DA antagonists (e.g., prochlorperazine) without antipsychotic activity, but can be associated with EPS or akathisia.

### Adverse Effects and Drug Interactions

**Adverse Effects Predicted by Monoamine Receptor Affinities**

**Dopamine D₂ Receptor.** With the exception of the D₂ partial agonist aripiprazole (and the commercially unavailable agent bifeprunox), all other antipsychotic agents possess D₂ antagonist properties, the strength of which determines the likelihood for EPS, akathisia, long-term tardive dyskinesia risk, and hyperprolactinemia. The manifestations of EPS are described in Table 16-4, along with the usual treatment approach. Acute dystonic reactions occur in the early hours and days of treatment with highest risk among younger patients (peak incidence ages 10-19), especially antipsychotic-naive individuals, in response to abrupt decreases in nigrostriatal D₂ neurotransmission. The dystonia typically involves head and neck muscles, the tongue, and in its severest form, the oculogyric crisis, extraocular muscles, and is very frightening to the patient.
Parkinsonism resembling its idiopathic form occurs when striatal D₂ occupancy exceeds 78%, and often responds to dose reduction or switching to an antipsychotic with weaker D₂ antagonism. In situations where this is neither possible nor desirable, antiparkinsonian medication may be employed. Clinically, there is a generalized slowing and impoverishment of volitional movement (bradykinesia) with masked facies and reduced arm movements during walking. The syndrome characteristically evolves gradually over days to weeks as the risk of acute dystonia diminishes. The most noticeable signs are slowing of movements, and sometimes rigidity and variable tremor at rest, especially involving the upper extremities. “Pill-rolling” movements and other types of resting tremor (at a frequency of 3-5 Hz, as in Parkinson’s disease) may be

<sup>a</sup>Treatment: diphenhydramine 25-50 mg IM, or benztriptene 1-2 mg IM. Due to long antipsychotic t<sub>1/2</sub> may need to repeat, or follow with oral medication.

<sup>b</sup>Propranolol often effective in relatively low doses (20–80 mg/day in divided doses). β<sub>1</sub>-Selective adrenergic receptor antagonists are less effective. Non-lipophilic β adrenergic antagonists have limited CNS penetration and are of no benefit (e.g., atenolol).

<sup>c</sup>Use of amantadine avoids anticholinergic effects of benztriptene or diphenhydramine.

<sup>d</sup>Despite the response to dantrolene, there is no evidence of abnormal Ca<sup>2+</sup> transport in skeletal muscle; with persistent antipsychotic effects (e.g., long-acting injectable agents), bromocriptine may be tolerated in large doses (10-40 mg/day). Anti-parkinsonian agents are not effective.
seen, although they are less prominent in antipsychotic-induced than in idiopathic parkinsonism. Bradykinesia and masked facies may be mistaken for clinical depression. Elderly patients are at greatest risk.

The treatment of acute dystonia and antipsychotic-induced parkinsonism involves the use of anti-parkinsonian agents, although dose reduction should be considered as the initial strategy for parkinsonism. Muscarinic cholinergic receptors modulate nigrostriatal DA release, with blockade increasing synaptic DA availability. Important issues in the use of anticholinergics include the negative impact on cognition and memory, peripheral antimuscarinic adverse effects (e.g., urinary retention, dry mouth, cycloplegia, etc.), and the relative risk of exacerbating tardive dyskinesia. In patients receiving chronic anticholinergic therapy, there are also short-term risks of cholinergic rebound following abrupt anticholinergic withdrawal, which may include sleep disturbance (vivid dreams, nightmares) and also increased EPS if the patient continues to receive antipsychotic treatment. For parenteral administration, diphenhydramine (25-50 mg IM) and benztropine (1-2 mg IM) are the agents most commonly used. Diphenhydramine is an antihistamine that also possesses anticholinergic properties. Benztropine combines a benzhydryl group with a tropane group to create a compound which is more anticholinergic than trihexyphenidyl but less antihistaminic than diphenhydramine. The clinical effect of a single dose lasts 5 hours, thereby requiring 2 or 3 daily doses. Dosing usually starts at 0.5-1 mg bid, with a daily maximum of 6 mg, although slightly higher doses are used in rare circumstances. The piperidine compound trihexyphenidyl was one of the first synthetic anticholinergic agents available, and replaced the belladonna alkaloids for treatment of PD in the 1940s due to its more favorable side effect profile. Trihexyphenidyl inhibits the presynaptic DA reuptake transporter, and therefore has a concomitant higher risk of abuse than the antihistamines or benztropine. Trihexyphenidyl has good GI absorption, achieving peak plasma levels in 1-2 hours, with a serum \( t_{1/2} \) of 10-12 hours, generally necessitating multiple daily dosing to achieve satisfactory clinical results. The total daily dosage range is 5-15 mg, given 2-3 times a day as divided doses. Piperidin (Akie-tn) is another drug in this class.

Amanadine (Symmetrel), originally marketed as an antiviral agent toward influenza A, represents the most commonly used non-anticholinergic medication for antipsychotic-induced parkinsonism. Its mechanism of action is unclear but appears to involve presynaptic DA reuptake blockade, facilitation of DA release, postsynaptic DA agonism, and receptor modulation. These properties are sufficient to reduce symptoms of drug-induced parkinsonism, and only rarely have been reported to exacerbate psychotic symptoms. Amanadine is well absorbed after oral administration, with peak levels achieved 1-4 hours after ingestion; clearance is renal, with > 90% recovered unmetabolized in the urine. The plasma \( t_{1/2} \) is 12-18 hours in healthy young adults, but is sufficiently longer in those with renal impairment and the elderly that a 50% dose reduction is recommended. Starting dosage is 100 mg orally bid in healthy adults, which may be increased to 200 mg bid. A dose of 100 mg bid yields peak plasma levels of 0.5-0.8 \( \mu g/mL \) and trough levels of 0.3 \( \mu g/mL \). Toxicity is seen at serum levels of 1.0-5.0 \( \mu g/mL \). Amanadine’s primary advantage, especially in older patients, is avoidance of adverse CNS and peripheral anticholinergic effects.

Tardive dyskinesia is a situation of increased nigrostriatal dopaminergic activity as the result of postsynaptic receptor supersensitivity and up-regulation from chronically high levels of postsynaptic D\(_2\) blockade (and possible direct toxic effects of high-potency DA antagonists). Tardive dyskinesia occurs more frequently in older patients, and the risk may be somewhat greater in patients with mood disorders than in those with schizophrenia. Its prevalence averages 15-25% in young adults treated with typical antipsychotic agents for more than a year. The annual incidence was 3-5% with typical antipsychotic drugs, with a somewhat smaller annual rate of spontaneous remission, even with continued treatment. The risk is one-fifth to one-tenth that of a atypical antipsychotic drug.

Tardive dyskinesia is characterized by stereotyped, repetitive, painless, involuntary, quick choreiform (tic-like) movements of the face, eyelids (blinks or spasm), mouth (grimaces), tongue, extremities, or trunk. There are varying degrees of slower athetosis (twisting movements), while tardive dystonia and tardive akathisia are rarely encountered as use of high-dose, high-potency typical antipsychotic medications has abated. The movements all disappear in sleep (as do many other extrapyramidal syndromes), vary in intensity over time, and are dependent on the level of arousal or emotional distress, sometimes reappearing during acute psychiatric illnesses following prolonged disappearance. The dyskinetic movements can be suppressed partially by use of a potent DA antagonist, but such interventions over time may worsen the severity, as this was part of the initial pharmacological insult. Switching patients from potent D\(_2\) antagonists to weaker agents, especially clozapine has at times proven effective. When possible, drug discontinuation may be beneficial, but usually cannot be offered to schizophrenic patients. Trials of the antioxidant vitamin E have proved ineffective and are not recommended, especially in light of adverse cardiovascular effects from chronic vitamin E exposure.

Unlike antipsychotic-induced parkinsonism and acute dystonia, the phenomenology and treatment of akathisia suggests involvement of structures outside the nigrostriatal pathway. Akathisia was seen quite commonly during treatment with high doses of high potency typical antipsychotic drugs, but also can be seen with atypical agents, including those with weak D\(_2\) affinities (e.g., quetiapine), and aripiprazole. Among the predominantly antipsychotic drug-naive population with major depression in clinical studies with adjunctive aripiprazole, akathisia incidence was 23% using a starting dose of 5 mg, suggesting that dopaminergic partial agonism, rather than antagonism, may be etiologic for this medication (Berman et al., 2007; Marcus et al., 2008). Despite the association with D\(_2\) blockade, akathisia does not have a robust response to anti-parkinsonian drugs, so other treatment strategies must be employed, including the use of high-potency benzodiazepines (e.g., clonazepam), nonselective \( \beta \) blockers with good CNS penetration (e.g., propranolol), and also dose reduction, or switching to another...
antipsychotic agent. That clonazepam and propranolol have significant cortical activity and are ineffective for other forms of EPS, points to an extrastriatal origin for akathisia symptoms.

The rare neuroleptic malignant syndrome (NMS) resembles a very severe form of parkinsonism, with signs of autonomic instability (hyperthermia and labile pulse, blood pressure, and respiration rate), stupor, elevation of creatine kinase in serum, and sometimes myoglobinemia with potential nephrotoxicity. At its most severe, this syndrome may persist for more than a week after the offending agent is discontinued, and is associated with mortality. This reaction has been associated with various types of antipsychotic agents, but its prevalence may be greater when relatively high doses of potent agents are used, especially when they are administered parenterally. Aside from cessation of antipsychotic treatment and provision of supportive care, including aggressive cooling measures, specific pharmacological treatment is unsatisfactory, although administration of dantrolene and the dopaminergic agonist bromocriptine may be helpful. While dantrolene also is used to manage the syndrome of malignant hyperthermia induced by general anesthetics, the neuroleptic-induced form of hyperthermia probably is not associated with a defect in Ca²⁺ metabolism in skeletal muscle. There are anecdotal reports of NMS with atypical antipsychotic agents, but this syndrome is now rarely seen in its full presentation.

Hyperprolactinemia results from blockade of the pituitary actions of the tuberoinfundibular dopaminergic neurons; these neurons project from the arcuate nucleus of the hypothalamus to the median eminence, where they deliver DA to the anterior pituitary via the hypophyseoportal blood vessels. D₂ receptors on lactotropes in the anterior pituitary mediate the tonic prolactin-inhibiting action of DA. Correlations between the D₂ potency of antipsychotic drugs and prolactin elevations are excellent. With the exception of risperidone and paliperidone, atypical antipsychotic agents show limited (asenapine, iloperidone, olanzapine, quetiapine, ziprasidone) to almost no effects (clozapine, aripiprazole) on prolactin secretion.

The hyperprolactinemia from antipsychotic drugs is rapidly reversible when the drugs are discontinued. Hyperprolactinemia can directly induce breast engorgement and galactorrhea. Approximately 33% of human breast cancers are prolactin-dependent in vitro, a factor of potential importance if the prescription of these drugs is contemplated in a patient with previously detected breast cancer. By suppressing the secretion of gonadotropins and sex steroids, hyperprolactinemia can cause amenorrhea in women and sexual dysfunction or infertility in men. The development of amenorrhea is of concern as it represents low serum estradiol levels and ongoing risk for bone density loss. The development of amenorrhea becomes a sensitive marker for sex hormone levels, and should prompt clinical action, while asymptomatic measurable increases in serum prolactin levels do not necessarily merit any intervention. Dose reduction can be tried to decrease serum prolactin levels, but caution must be exercised to keep treatment within the antipsychotic therapeutic range. When switching from offending antipsychotic agents is not feasible, bromocriptine can be employed. There is also anecdotal evidence that aripiprazole augmentation may be effective.

All DA antagonist antipsychotic drugs possess antiemetic properties by virtue of their actions at the medullary chemoreceptor trigger zone (Figure 46–4). The D₂ partial agonists aripiprazole (and bifeprunox), however, can be associated with nausea. For aripiprazole this effect was noted in clinical trials of oral medication for acute mania, bipolar maintenance, or schizophrenia (nausea incidence 15% for aripiprazole vs. 11% for placebo; vomiting incidence 11% for aripiprazole vs. 6% for placebo), and also in studies of pediatric bipolar mania in patients ages 10-17 (nausea incidence 11%) and in acute IM trials for agitation in schizophrenia or acute mania (nausea incidence 9%). Bifeprunox possessed a level of intrinsic DA agonism that was slightly greater than that for aripiprazole (25-28%), but was significant enough to cause clinical problems with nausea and vomiting, that a 10-day titration from an initial starting dose of 0.125 mg was necessary to reach the proposed effective dosage range of 10-30 mg (Glick and Peselow, 2008).

H₁ Receptors. Central antagonism of H₁ receptors is associated with two major adverse effects: sedation and weight gain via appetite stimulation. Examples of sedating antipsychotic drugs include low-potency typical agents such as chlorpromazine and thioridazine, and the atypical agents clozapine and quetiapine. The sedating effect is easily predicted by their high H₁ receptor affinities (Table 16–2). Some tolerance to the sedative properties will develop, a fact that must be kept in mind when switching patients to nonsedating agents.

There is an extended-release quetiapine preparation available, with markedly reduced Cmax compared to the immediate-release form. Immediate-release quetiapine generates peak serum levels > 800 ng/mL within 2 hours of ingestion, while the extended release preparation has Cmax ~50% lower, with peak serum levels seen 4-8 hours after ingestion. In clinical practice the onset of sedation for extended-release quetiapine is delayed for at least 3 hours after oral administration, and subjectively the sedation is much less profound than with the immediate-release form (Mamo et al., 2008).

Rapid discontinuation of sedating antihistaminic antipsychotic drugs is inevitably followed by significant complaints of rebound insomnia and sleep disturbance. If discontinuation of sedating antipsychotic treatment is deemed necessary, except for emergency cessation of clozapine for agranulocytosis, the medication should be tapered slowly over 4-8 weeks, and the clinician should be prepared to utilize a sedative when the end of the titration is reached. Generous dosing of another antihistamine (hydroxyzine), or the anticholinergic antihistamine diphenhydramine are reasonable replacement sedative medications, but others can used, including benzodiazepines, non-benzodiazepine hypnotics that act at specific benzodiazepine sites (e.g., zolpidem, eszopiclone), and sedating antidepressants (e.g., trazodone). Sedation may be useful during acute psychosis, but excessive sedation can interfere with patient evaluation, may prolong emergency room and psychiatric hospital stays unnecessarily, and is poorly tolerated among elderly dementia and delirium patients, so appropriate caution must be exercised with the choice of agent and the dose.

Weight gain is a significant problem during long-term use of antipsychotic drugs and represents a major barrier to medication adherence, as well as a significant threat to the physical and emotional
health of the patient. Weight gain has effectively replaced concerns over EPS as the adverse effect causing the most consternation among patients and clinicians alike. Appetite stimulation is the primary mechanism involved, with little evidence to suggest that decreased activity (due to sedation) is a main contributor to antipsychotic-related weight gain (Gothelf et al., 2002). Recent animal studies indicate that medications with significant H1 antagonism induce appetite stimulation through effects at hypothalamic sites (Kim et al., 2007). The low-potency phenothiazine chlorpromazine, and the atypical antipsychotic drugs olanzapine and clozapine, are the agents of highest risk, but weight gain of some extent is seen with nearly all antipsychotic drugs, partly related to the fact that acutely psychotic patients may lose weight; in placebo-controlled acute schizophrenia trials, the placebo cohort inevitably loses weight (Meyer, 2001). For clozapine and olanzapine, massive weight gains of 50 kg or more are not uncommon, and mean annual weight gains of 13 kg are reported in schizophrenia clinical trials, with 20% of subjects gaining ≥20% of baseline weight. High-potency typical antipsychotic drugs (e.g., haloperidol, fluphenazine), and newer atypical antipsychotics aripiprazole, ziprasidone, and asenapine, are associated with mean annual weight gains <2 kg in schizophrenia patients, with mean gains of 2.5-3 kg noted for iloperidone, risperidone, and quetiapine (Meyer, 2001). For unknown reasons, molindone is associated with modest weight loss. Younger and antipsychotic drug-naïve patients are much more sensitive to the weight gain from all antipsychotic agents, including those which appear roughly weight neutral in adult studies, leading some to conjecture that DA blockade may also play a small additive role in weight gain. 5-HT2C antagonism is also thought to play an additive role in promoting weight gain for medications that possess high H1 affinities (e.g., clozapine, olanzapine), but appears to have no effect in the absence of significant H1 blockade, as seen with ziprasidone, a weight-neutral antipsychotic drug with extremely high 5-HT2C affinity. Switching to more weight-neutral medications can achieve significant results; however, when not feasible or when unsuccessful, behavioral strategies must be employed, and should be considered for all chronically mentally ill patients given the high obesity prevalence in this patient population. 

M1 Receptors. Muscarinic antagonism is responsible for the central and peripheral anticholinergic effects of medications. Most of the atypical antipsychotic drugs, including risperidone, paliperidone, asenapine, iloperidone, ziprasidone, and aripiprazole, have no muscarinic affinity and no appreciable anticholinergic effects, while clozapine and low-potency phenothiazines have significant anticholinergic adverse effects (Table 16–2). Quetiapine has modest muscarinic affinity, but its active metabolite norquetiapine is likely responsible for anticholinergic complaints (Jensen et al., 2008). Clozapine is particularly associated with significant constipation, perhaps due to the severely ill population under treatment. Routine use of stool softeners, and repeated inquiry into bowel habits are necessary to prevent serious intestinal obstruction from undetected constipation. In general, avoidance of anticholinergic medications obviates the need to secondarily treat problems related to central or peripheral antagonism. Medications with significant anticholinergic properties should be particularly avoided in elderly patients, especially those with dementia or delirium.

α1 Receptors. α1 Adrenergic antagonism is associated with risk of orthostatic hypotension and can be particularly problematic for elderly patients who have poor vasomotor tone. Compared to high-potency typical agents, low-potency typical agents have significantly greater affinities for α1 receptors and greater risk for orthostasis. While risperidone has a Kᵢ that indicates greater α1-adrenergic affinity than chlorpromazine, thioridazine, clozapine, and quetiapine, in clinical practice risperidone is used at 0.01-0.005 times the dosages of these medications, and thus causes a relatively lower incidence of orthostasis in non-elderly patients. Since clozapine-treated patients have few other antipsychotic options, the potent mineralocorticoid fludrocortisone is sometimes tried at the dose of 0.1 mg/day as a volume expander.

Adverse Effects Not Predicted by Monoamine Receptor Affinities

Adverse Metabolic Effects. Such effects have become the area of greatest concern during long-term antipsychotic treatment, paralleling the overall concern for high prevalence of pre-diabetic conditions and type 2 diabetes mellitus, and 2-fold greater CV mortality among patients with schizophrenia (Meyer and Nasrallah, 2009). Aside from weight gain, the two predominant metabolic adverse seen with antipsychotic drugs are dyslipidemia, primarily elevated serum triglycerides, and impairments in glycemic control.

Low-potency phenothiazines were known to elevate serum triglyceride values, but this effect was not seen with high-potency agents (Meyer and Koro, 2004). As atypical antipsychotic drugs became more widely used, significant increases in fasting triglyceride levels were noted during clozapine and olanzapine exposure, and to a lesser extent, with quetiapine (Meyer et al., 2008). Mean increases during chronic treatment of 50-100 mg/dL are common, with serum triglyceride levels exceeding 7000 mg/dL in some patients. Effects on total cholesterol and cholesterol fractions are significantly less, but show expected associations related to agents of highest risk: clozapine, olanzapine, and quetiapine. Risperidone and paliperidone have fewer effects on serum lipids, while aripiprazole, iloperidone, and ziprasidone appear to have none (Meyer and Koro, 2004). Weight gain in general may induce deleterious lipid changes, but there is compelling evidence to indicate that antipsychotic-induced hypertriglyceridemia is a weight-independent adverse event that temporally occurs within weeks of starting an offending medication, and which similarly resolves within 6 weeks after medication discontinuation. The finding that
serum triglycerides may change 70-80 mg/dL during a period when weight has changed relatively little propelled the search for adiposity-independent physiological mechanisms to explain this phenomenon.

In individuals not exposed to antipsychotic drugs, elevated fasting triglycerides are a direct consequence of insulin resistance since insulin-dependent lipases in fat cells are normally inhibited by insulin. As insulin resistance worsens, inappropriately high levels of lipolysis lead to the release of excess amounts of free fatty acids that are hepatically transformed into triglyceride particles (Smith, 2007). Elevated fasting triglyceride levels thus become a sensitive marker of insulin resistance, leading to the hypothesis that the triglyceride increases seen during antipsychotic treatment are the result of derangements in glucose-insulin homeostasis. The ability of antipsychotic drugs to induce hyperglycemia was first noted during low-potency phenothiazine treatment, with chlorpromazine occasionally exploited for this specific property as adjunctive presurgical treatment for insulinoma. As atypical antipsychotic drugs found widespread use, numerous case series documented the association of new-onset diabetes and diabetic ketoacidosis associated with treatment with atypical antipsychotic drugs, with most of cases observed during clozapine and olanzapine therapy (Jin et al., 2002, 2004). Analysis of the FDA MedWatch database found that reversibility was high upon drug discontinuation (~78%) for olanzapine- and clozapine-associated diabetes and ketoacidosis, supporting the contention of a drug effect. Comparable rates for risperidone and quetiapine were significantly lower. The mechanism by which antipsychotic drugs disrupt glucose-insulin homeostasis is not known, but recent in vivo animal experiments document immediate dose-dependent effects of clozapine and olanzapine on whole-body and hepatic insulin sensitivity (Houseknecht et al., 2007).

Antipsychotic-induced weight gain, and other diabetes risk factors (e.g., age, family history, gestational diabetes, obesity, race, ethnicity, smoking) all contribute to metabolic dysfunction. There may also be inherent disease-related mechanisms that increase risk for metabolic disorders among patients with schizophrenia, but the medication itself is the primary modifiable risk factor. As a result, all atypical antipsychotic drugs have a hyperglycemia warning in the drug label in the U.S., although there is essentially no evidence that aseptidant agents are associated with treatment with increased risk for ventricular arrhythmia. Thioridazine has been shown to inhibit Na+ channels at high dosages, but other antipsychotics treated patients is unclear in the absence of large autopsy samples. The true incidence of drug-induced ventricular arrhythmia can only be estimated, due partly to underreporting, and the fact that drug-induced torsade de pointes is rarely captured with confirmatory EKG (Nielsen and Toft, 2009).

Multiple ion channels are involved in the depolarization and repolarization of cardiac ventricular cells, which are discussed in detail in Chapter 29. Myocyte depolarization is seen as the QRS complex on EKG, and is primarily mediated by ion channels that permit rapid Na+ influx. Antagonism of these voltage-gated Na+ channels causes QRS widening and an increase in the PR interval, with increased risk for ventricular arrhythmia. Thioridazine has been shown to inhibit Na+ channels at high dosages, but other antipsychotic medications have not (Nielsen and Toft, 2009). Repolarization is mediated in part by K+ efflux via two channels: the rapid Ik, and the slow Ik, channel. The Ik channel is encoded by the human-ether-a-related-go-go gene (HERG), polymorphisms of which are involved in the congenital long QT syndrome associated with syncope and SCD. Many antipsychotic drugs block the Ik channel to an extent comparable with that seen in congenital long QT syndrome. Antagonism of Ik, channels is the mechanism responsible for most cases of drug-induced QT prolongation, and is the suspected mechanism for the majority of antipsychotic-induced sudden cardiac deaths (Nielsen and Toft, 2009).

Aside from individual agents, where anecdotal and pharmacosurveillance data indicate risk for torsade de pointes (e.g., thioridazine, pimozide), most of the commonly used newer antipsychotic agents are associated with known risk for ventricular arrhythmias, including risperidone in overdose up to 12,000 mg. One exception is sertindole, an agent not available in the U.S. that was withdrawn in 1998 based on anecdotal reports of torsade de pointes, and then reintroduced in Europe in 2006 with strict EKG monitoring guidelines (Nielsen and Toft, 2009). Although in vitro data revealed sertindole’s affinity for the K+ rectifier channel, several epidemiological studies published over the past decade were unable to confirm an

**Adverse Cardiac Effects.** Ventricular arrhythmias and sudden cardiac death (SCD) are a concern with the use of antipsychotic agents. Most of the older antipsychotic agents (e.g., thioridazine) inhibit cardiac K+ channels, and all antipsychotic medications marketed in the U.S. carry a class label warning regarding QTc prolongation. A black box warning exists for thioridazine, mesoridazine, pimozide, IM droperidol, and IV (but not oral or IM) haloperidol due to reported cases of torsade de pointes and subsequent fatal ventricular arrhythmias (discussed next and in Chapter 29). Although the newer atypical agents are thought to have less effects on heart electrophysiology compared to the typical agents, a recent retrospective analysis found a dose-dependent increased risk for SCD among antipsychotic users of newer and older agents alike compared to antipsychotic nonusers, with a relative risk of 2 (Ray et al., 2009).

Cardiac arrhythmia is the most common etiology for SCD, but it is important to determine whether the arrhythmia is primary or secondary to structural changes related to cardiomyopathy, myocarditis, or acute myocardial infarction. Secondary ventricular arrhythmia is probably the most frequent form of fatal tachyarhythmia, but the exact distribution of SCD deaths by etiology among antipsychotic-treated patients is unclear in the absence of large autopsy samples. The true incidence of drug-induced ventricular arrhythmia can only be estimated, due partly to underreporting, and the fact that drug-induced torsade de pointes is rarely captured with confirmatory EKG (Nielsen and Toft, 2009).
increased risk of sudden death due to sertindole exposure, thereby providing justification for its reintroduction. Aside from sertindole, the apparent safety of newer antipsychotic medications appears at odds with retrospective findings of SCD among antipsychotic users (Ray et al., 2009), thus confronting the clinician with contradictory information regarding antipsychotic drug-related SCD risk, and leading to conflicting clinical recommendations. Currently, there are no data that would suggest a benefit of routine EKG monitoring for prevention of SCD among antipsychotic drug users.

Other Adverse Effects. Seizure risk is an unusual adverse effect of antipsychotic drugs, with anecdotal reports of uncertain causality present for many agents. In the U.S., there is a class label warning for seizure risk on all antipsychotic agents, with reported incidences well below 1%. Among commonly used newer antipsychotic drugs, only clozapine has a dose-dependent seizure risk, with an incidence of 3.5% per year. The structurally related olanzapine had an incidence of 0.9% in premarketing studies. Seizure disorder patients who commence antipsychotic treatment must receive adequate prophylaxis, with consideration given to avoiding carbamazepine and phenytoin due to their capacity to induce CYPs and P-glycoprotein. Carbamazepine is also contraindicated during clozapine treatment due to its bone marrow effects, particularly leucopenia. Redistribution and increased spacing of doses to minimize high peak serum clozapine levels can help, but patients may eventually require antiseizure medication. Valproic acid derivatives (e.g., divalproex sodium) are often used, but will compound clozapine-associated weight gain.

Clozapine possesses a host of unusual adverse effects aside from seizure induction, the most concerning of which is agranulocytosis. Clozapine’s introduction in the U.S. was based on its efficacy in refractory schizophrenia, but came with FDA-mandated CBC monitoring that is overseen by industry-created registries. Now that several generic forms of clozapine are available in addition to proprietary CLOZARIL, clinicians must verify with each manufacturer the history of prior exposure. The overall agranulocytosis incidence is slightly under 1%, with highest risk during the initial 6 months of treatment, peaking at months 2-3 and diminishing rapidly thereafter. The mechanism is immune mediated, and patients who have verifiable clozapine-related agranulocytosis should not be rechallenged. Increased risk is associated with certain HLA types and advanced age. An extensive algorithm guiding clinical response to agranulocytosis, and lesser forms of neutropenia, is available from manufacturer web sites, and must be followed, along with the current recommended CBC monitoring frequency.

While rarely used due to its risk of QTc prolongation, thioridazine is also associated with pigmentary retinopathy at daily doses ≥ 800 mg/day. Low-potency phenothiazines are associated with the development of photosensitivity, which necessitated warnings regarding sun exposure. Phenothiazines are also associated with development of a cholestatic picture on laboratory assessments (e.g., elevated alkaline phosphatase), and rarely elevations in hepatic transaminases.

Increased Mortality in Dementia Patients. Perhaps the least understood adverse effect is the increased risk for cerebrovascular events and all-cause mortality among elderly dementia patients exposed to antipsychotic medications. All antipsychotic agents carry a mortality warning in the drug label regarding their use in dementia patients. The cerebrovascular adverse event rates in 10-week dementia trials range from 0.4-0.6% for placebo to 1.3-1.5% for risperidone, olanzapine and aripiprazole (Jeste et al., 2008). The mortality warning indicates a 1.6-1.7 fold increased mortality risk for drug versus placebo. Mortality is due to heart failure, sudden death, or pneumonia. The underlying etiology for antipsychotic-related cerebrovascular and mortality risk is unknown, but the finding of virtually equivalent mortality risk for typical agents compared to atypical antipsychotic drugs (including aripiprazole) suggests an impact of reduced D2 signaling regardless of individual antipsychotic mechanisms.

Overdose with typical antipsychotic agents is of particular concern with low-potency agents (e.g., chlorpromazine) due to the risk of torsades de pointes, sedation, anticholinergic effects, and orthostasis. Patients who overdose on high-potency typical antipsychotic drugs (e.g., haloperidol) and the substituted benzenes are at greater risk for EPS due to the high D2 affinity, but also must be observed for EKG changes. Overdose experience with newer agents, including ziprasidone, indicates a much lower risk for torsade de pointes ventricular arrhythmias compared to older antipsychotic medications; however, combinations of antipsychotic agents with other medications can lead to fatality, primarily through respiratory depression (Ciranni et al., 2009).

Drug-Drug Interactions. Antipsychotic agents are not significant inhibitors of CYP enzymes with a few notable exceptions (chlorpromazine, perphenazine, and thioridazine inhibit CYP 2D6) (Otani and Aoshima, 2000). The plasma half-lives of a number of these agents are altered by induction or inhibition of hepatic CYPs and by genetic polymorphisms that alter specific CYP activities (Table 16–3). While antipsychotic drugs are highly protein bound, there is no evidence of significant displacement of other protein bound medications, so dosage adjustment is not required for anticonvulsants, warfarin, or other agents with narrow therapeutic indices. With respect to drug-drug interactions, it is important to consider the effects of environmental exposures (smoking, nutraceuticals, grapefruit juice), and changes in these behaviors.

Changes in smoking status can be especially problematic for clozapine-treated patients, and will alter serum levels by 50% or more. Within 2 weeks of smoking discontinuation (e.g., hospitalization in nonsmoking environment), the absence of aryl hydrocarbons will cause upregulated CYP1A2 activity to return to baseline levels, with a concomitant rise in serum clozapine concentrations (Rostami-Hodjegan et al., 2004). For smoking patients with high serum clozapine levels, this loss of enzyme induction may result in nonlinear increases in clozapine levels, with potentially catastrophic results. Conversely, patients discharged from nonsmoking wards to the community will be expected to resume smoking behavior, with an expected 50% decrease in clozapine levels. Monitoring of serum clozapine concentrations, anticipation of changes in smoking habits,
While breast milk presents an important source of protective antibodies, neonatal hepatic catabolic activity in the first 2 postpartum months. Use in conjunction with highest placental passage ratio, exhibit a trend towards greater levels after 12 months of exposure significantly lower than peak levels, and close to baseline. Delayed sexual maturation was not seen in adolescents in clinical trials with risperidone, but should nevertheless be monitored.

**Use in Geriatric Populations.** The increased sensitivity to EPS, orthostasis, sedation, and anticholinergic effects are important issues for the geriatric population, and often dictate the choice of antipsychotic medication. Avoidance of drug-drug interactions is also important, as older patients on numerous concomitant medications have multiple opportunities for interactions. Dose adjustment can be offset known drug-drug interactions, but clinicians must be attentive to changes in concurrent medications and the potential pharmacokinetic consequences. Vigilance must also be maintained for the additive pharmacodynamic effects of α, adrenergic, antihistaminic, and anticholinergic properties of other agents. Elderly patients have an increased risk for tardive dyskinesia and parkinsonism, with TD rates ~5-fold higher than those seen with younger patients. With typical antipsychotics, the reported annual TD incidence among elderly patients in 20-25% compared to 4-5% for younger patients. With atypical antipsychotics, the annual TD rate in elderly patients is much lower (2-3%). Increased risk for cerebrovascular events and all-cause mortality is also seen in elderly patients with dementia (see “Increased Mortality in Dementia Patients”). Compared to younger patients, antipsychotic-induced weight gain is lower in elderly patients.

**Use During Pregnancy and Lactation.** Antipsychotic agents carry pregnancy class B or C warnings. Human data from anecdotal case reports and manufacturer registries indicate limited or no patterns of toxicity and no consistent increased rates of malformations. Nonetheless, the use of any medication during pregnancy must be balanced by concerns over fetal impact, especially first-trimester exposure, and the mental health of the mother. Haloperidol is often cited as the agent with the best safety record based on decades of accumulated human exposure reports, but newer antipsychotic drugs, such as risperidone, have not generated any signals of concern (Viguera et al., 2009). As antipsychotic drugs are designed to cross the blood-brain barrier, all have high rates of placental passage. Placental passage ratios are estimated to be highest for olanzapine (72%), followed by haloperidol (42%), risperidone (49%), and quetiapine (24%). Neonates exposed to olanzapine, the atypical agent with highest placental passage ratio, exhibit a trend towards greater neonatal intensive care unit admission (Viguera et al., 2009). Use in lactation presents a separate set of concerns due to the low level of infant hepatic catabolic activity in the first 2 postpartum months. While breast milk presents an important source of protective antibodies for the baby, the inability of the newborn to adequately metabolize xenobiotics presents a significant risk for antipsychotic drug toxicity. The available data do not provide adequate guidance on choice of agent.

**Major Drugs Available in the Class**

In the U.S., atypical antipsychotic drugs have largely replaced older agents, primarily due to their more favorable EPS profile, although typical agents are widely used throughout the world. Table 16–1 describes the acute and maintenance doses for adult schizophrenia treatment based on consensus recommendations.

Acute IM forms exist for many typical antipsychotic drugs, and also for aripiprazole, ziprasidone, and olanzapine, with the latter being the most sedating due to its antihistaminic and anticholinergic properties. The standard IM doses are 9.75 mg for aripiprazole, 10 mg for olanzapine, and 20 mg for ziprasidone (Altamura et al., 2003). The 20-mg IM ziprasidone dose generates serum levels that exceed those from 160 mg/day orally, but has not been associated with reports of torsade de pointes or cardiac dysrhythmia. There are numerous LAI (long-acting injectable) formulations of typical antipsychotics, but in the U.S., the only available LAI typical agents are fluphenazine and haloperidol (as decanoate esters), with usual dosages 12.5-25 mg IM every 2 weeks and 50-200 mg (not to exceed 100 mg as the initial dose) IM monthly, respectively. Haloperidol decanoate has more predictable kinetics, while fluphenazine decanoate’s serum level can increase within days after administration and induce adverse effects (Altamura et al., 2003). EPS remains a significant barrier for using these agents. LAI risperidone was studied at doses of 25, 50, and 75 mg IM biweekly, but the higher dose was found to be without increased efficacy and with greater EPS rates. Current available doses, all distributed as complete, single-dose kits, are 12.5, 25, 37.5, and 50 mg, given as a 2-mL water-based injection. LAI risperidone is impregnated into organic microspheres that require several weeks to liberate free drug. The impact of any dosage change (or missed dose) of LAI risperidone is seen 4 weeks later. LAI paliperidone has recently become available, and dosing is initiated with two loading IM deltoid injections given at days 1 (234 mg) and 8 (156 mg), followed by injections every 4 weeks starting at day 36. This loading strategy can be omitted if transitioning patients from another LAI antipsychotic, with LAI paliperidone given in lieu of the next injection, and the every 4 weeks thereafter. The package insert provides detailed information on dose equivalency with oral paliperidone, and on handling missed injections. ODT forms are available for aripiprazole, clozapine, olanzapine, and risperidone, and are the only form for asenapine. These ODT preparations are commonly used in emergency and inpatient settings where patients may be prone to chewing or spitting out oral tablets.

**Clinical Summary: Treatment of Psychosis**

The pharmacological profile of newer, atypical antipsychotic drugs has expanded the uses of antipsychotic medications during the last decade to include adjunctive use for major depression and bipolar depression, with...
supporting data for certain anxiety disorders. Considerable debate exists over the clinical superiority touted for the newer antipsychotic drugs for the treatment of schizophrenia compared to older, typical agents. What is clear is that the more favorable therapeutic indices of newer agents (e.g., fewer neurological adverse effects) permit clinicians to avoid the effects of excessive antagonism of D2 dopamine receptors. Aside from refractory schizophrenia, where clozapine exhibits superior effectiveness, drug choice primarily revolves around the avoidance of adverse effects, concerns regarding drug-drug interactions, and the availability of acute injectable, long-acting injectable, or orally dissolving tablet forms. Atypical antipsychotic drugs have generated considerable interest in non-dopaminergic mechanisms of action, including the useful property of 5-HT2A antagonism. The greater understanding of schizophrenia pathophysiology has furthered investigation into glutamatergic and cholinergic agents, some of which have advanced to later-stage clinical trials. Knowledge of receptor binding affinities combined with neuroimaging data on CNS receptor occupancy provide a guide to gauging the risk of most adverse effects of a particular drug. However, the pathophysiology for adiposity-independent effects on glucose-insulin homeostasis seen with certain antipsychotic medications has yet to be elucidated. Given the inherent cardiometabolic risk factors common among the severely mentally ill, close medical monitoring during long-term antipsychotic therapy is considered the standard of care, regardless of the metabolic risk of the specific antipsychotic agent. Judicious use of antipsychotic drugs with more favorable risk profiles is the primary guide to medication choice.

TREATMENT OF MANIA

Mania is a period of elevated, expansive or irritable mood with co-existing symptoms of increased energy and goal-directed activity, and decreased need for sleep (discussed later). Mania represents one pole of what had been termed manic-depressive illness, but is now referred to as bipolar disorder (American Psychiatric Association, 2000). As with psychosis, mania may be induced by medications (e.g., DA agonists, antidepressants, stimulants) or substances of abuse, primarily cocaine and amphetamines, although periods of substance-induced mania should not be relied upon solely to make a diagnosis of bipolar disorder. Nonetheless, there is recognition that patients who develop antidepressant-induced mania do have a bipolar diathesis even with no prior independent history of mania, and should be followed carefully, especially if antidepressant treatment is again considered during periods of major depression.

Mania is distinguished from its less severe form, hypomania, by the fact that hypomania, by definition, does not result in functional impairment or hospitalization, and is not associated with psychotic symptoms. Patients who experience periods of hypomania and major depression have bipolar II disorder, those with mania at any time, bipolar I, and those with hypomania, but less severe forms of depression, cyclothymia (American Psychiatric Association, 2000). The prevalence of bipolar I disorder is roughly 1% of the population, and the prevalence of all forms of bipolar disorder 3-5%.

Genetics studies of bipolar disorder have yielded several loci of interest associated with disease risk and predictors of treatment response, but the data are not yet at the phase of clinical application. Unlike schizophrenia, where the biological understanding of monoamine neurotransmission has permitted synthesis of numerous effective compounds, no medication has yet been designed to treat the full spectrum of bipolar disorder based on preformed biological hypotheses of the illness, although candidate medications have passed certain in vitro and in vivo assays. Lithium carbonate was introduced fortuitously in 1949 for the treatment of mania (Cade, 1949) and approved for this purpose in the U.S. in 1970. While many classes of agents demonstrate efficacy in acute mania, including lithium, antipsychotic drugs, and certain anticonvulsants, no medication has surpassed lithium’s efficacy for prophylaxis of future manic and depressive phases of bipolar disorder, and no other medication has demonstrated lithium’s reduction in suicidality among bipolar patients.

Pharmacological Properties of Agents for Mania

Antipsychotic Agents. The chemistry and pharmacology of antipsychotic medications are addressed earlier in this chapter.

Anticonvulsants. The pharmacology and chemistry of the anticonvulsants with significant data for acute mania (valproic acid compounds, carbamazepine) and for bipolar maintenance (lamotrigine) are covered extensively in Chapter 21. These compounds are of diverse chemical classes, but share the common property of functional blockade of voltage-gated Na+ channels, albeit with differing binding sites. Valproate exhibits non-specific binding to voltage-gated Na+ channels, while carbamazepine (and its congeners) and lamotrigine have specific high affinity for the open-channel configuration of the alpha subunit (Söderpalm, 2002). These anticonvulsants have varying affinities for voltage-dependent Ca2+ channels, and differ in their ability to facilitate GABA-ergic (valproate) or
inhibit glutamatergic neurotransmission (lamotrigine). The extent to which any of these actions is necessary for antimanic or mood stabilizing activity is unknown, but the failure of phenytoin, gabapentin, and topiramate to be effective antimanic and mood-stabilizing medications suggests that potent blockade of voltage-gated Na+ channels (which gabapentin and topiramate lack) is necessary but not sufficient, since phenytoin is very active at these channels.

**Lithium.** Lithium (Li+) is the lightest of the alkali metals (group Ia); the salts of this monovalent cation share some characteristics with those of Na+ and K+. Li+ is readily assayed in biological fluids and can be detected in brain tissue by magnetic resonance spectroscopy (Soares et al., 2000). Traces of the ion occur normally in animal tissues, but it has no known physiological role. Lithium carbonate and lithium citrate currently are used therapeutically in the U.S.

**Mechanism of Action.** Therapeutic concentrations of Li+ have almost no discernible psychotropic effects in individuals without psychiatric symptoms. There are numerous molecular and cellular actions of Li+, some of which overlap with identified properties of other mood-stabilizing agents (particularly valproate), and are discussed below. An important characteristic of Li+ is that, unlike Na+ and K+, Li+ develops a relatively small gradient across biological membranes. Although it can replace Na+ in supporting a single action potential in a nerve cell, it is not a substrate for the Na+ pump and therefore cannot maintain membrane potentials. It is uncertain whether therapeutic concentrations of Li+ (0.5-1.0 mEq/L) affect the transport of other monovalent or divalent cations by nerve cells.

**Hypotheses for the Mechanism of Action of Lithium, and Relationship to Anticonvulsants.** Plausible hypotheses focus on lithium’s impact on monoamines implicated in the pathophysiology of mood disorders, and on second-messenger and other intracellular molecular mechanisms involved in signal transduction, gene regulation, and cell survival (Quiroz et al., 2004). In animal brain tissue, lithium at concentrations of 1-10 mEq/L inhibits the depolarization-provoked and Ca2+-dependent release of NE and DA, but not 5-HT, from nerve terminals. Li+ may even transiently enhance release of 5-HT, especially in the limbic system, but has limited effects on catecholamine-sensitive adenyl cyclase activity or on the binding of ligands to monoamine receptors in brain tissue, although it does influence response of 5-HT autoreceptors to agonists (Lenox and Wang, 2003). Li+ modifies some hormonal responses mediated by adenyl cyclase or PLC in other tissues, including the actions of vasopressin and thyroid-stimulating hormone on their peripheral target tissues (Quiroz et al., 2004). Li+ can inhibit the effects of receptor-blocking agents that cause supersensitivity in such systems. In part, the actions of Li+ may reflect its ability to interfere with the activity of both stimulatory and inhibitory G proteins (Gs and Gi) by keeping them in their inactive εβγ trimeric state (Jope, 1999).

Considered by many as relevant for lithium’s therapeutic efficacy is its inhibition of inositol monophosphatase and interference with the phosphatidylinositol pathway (Figure 16–1), leading to decreased cerebral inositol concentrations (Williams et al., 2002). Phosphatidylinositol (PI) is a membrane lipid that is phosphorylated to form phosphatidylinositol biphosphate (PIP2). Activated phospholipase C cleaves PIP2 into diacylglycerol and inositol 1,4,5-trisphosphate (IP3), with the latter stimulating Ca2+ release from cellular stores. IP3 is dephosphorylated to inositol monophosphate (IP) and thence to inositol by inositol monophosphatase. Within its range of therapeutic concentrations, Li+ uncompetitively inhibits this last step (Chapter 3), with resultant decrease in available inositol for resynthesis into PIP2 (Shaldubina et al., 2001). The inositol depletion effect can be detected in vivo with magnetic resonance spectroscopy (Manji and Lenox, 2000). A recent genome-wide association study has implicated diacylglycerol kinase in the etiology of bipolar disorder, strengthening the association between Li+ actions and PI metabolism (Baum et al., 2008). Further support for the role of inositol signaling in mania rests on the finding that valproate, and valproate derivatives, decrease intracellular inositol concentrations (Shaltiel et al., 2007). Unlike Li+, valproate decreases inositol through inhibition of myo-inositol-1-phosphate synthase. Carbamazepine exposure in cultured sensory neurons alters the dynamic behavior of neuron growth cones, effects that are remediated through inositol supplementation, implicating inositol depletion as a mechanism underlying carbamazepine’s mood stabilizing properties (Williams et al., 2002).

Stimulation of NMDA receptors results in IP3 accumulation in primate brain, leading some to postulate that lithium’s activity in the inositol pathway might also relate to glutamatergic effects (Dixon and Hokin, 1998). Subsequent experiments demonstrated the ability of acute high lithium levels to increase synaptic glutamate in mice and non-human primates, primarily through inhibition of glutamate reuptake at presynaptic nerve terminals by lowering the Vmax of glutamate transport, but not glutamate binding to the transporter (Dixon and Hokin, 1998). The impact of supratherapeutic Li+ on synaptic glutamate may be implicated in lithium-induced neurotoxicity during overdose; conversely, chronic Li+ administration at therapeutic CNS concentrations results in increased glutamate uptake and increased levels of glutamate in presynaptic synaptosomes (Dixon and Hokin, 1998). This effect occurs at therapeutic Li+ serum concentrations, leading to speculation that the neuroprotective effects of Li+ seen in models of excitotoxic cell death may be mediated through modulation of synaptic glutamate availability (Bauer et al., 2003).

Li+ treatment also leads to consistent decreases in the functioning of protein kinases in brain tissue, including PKC, particularly isoforms α and β (Jope, 1999; Manji and Lenox, 2000; Quiroz et al., 2004). Among other proposed antimanic or mood-stabilizing agents, this effect is also shared with valproic acid (particularly for PKC) but not with carbamazepine (Manji and Lenox, 2000). Long-term treatment of rats with lithium carbonate or valproate decreases cytoplasm-to-membrane translocation of PKC and reduces PKC stimulation–induced release of 5-HT from cerebral cortical and hippocampal tissue. Excessive PKC activation can disrupt prefrontal cortical regulation of behavior, but pretreatment of monkeys and rats with lithium carbonate or valproate blocks the impairment in working memory induced by activation of PKC in a manner also seen with the PKC inhibitor chelerythrine (Yildiz et al., 2008). The impact of Li+ or valproate on PKC activity may secondarily alter the release of amine neurotransmitters and hormones as well as the activity of tyrosine hydroxylase (Manji and Lenox, 2000). A major substrate for cerebral PKC is the myristoylated alanine-rich C-kinase substrate (MARCKS) protein, which has been implicated in synaptic and neuronal plasticity. The expression of MARCKS protein is reduced by...
Absorption, Distribution, and Elimination. Li⁺ is absorbed readily and almost completely from the GI tract. Complete absorption occurs in ~ 8 hours, with peak plasma concentrations occurring 2-4 hours after an oral dose (Sproule, 2002). Slow-release preparations of lithium carbonate minimize early peaks in plasma concentrations, and to some extent may decrease local GI adverse effects, but the increased trough levels may increase the risk for, and the extent of, nephrogenic diabetes insipidus (Schou et al., 1982). Li⁺ initially is distributed in the extracellular fluid, and gradually accumulates in various tissues; it does not bind appreciably to plasma proteins. The concentration gradient across plasma membranes is much smaller than those for Na⁺ and K⁺. The final volume of distribution (0.7-0.9 L/kg) approaches that of total body water and is lower than agents that are lipophilic and protein bound. Passage through the blood-brain barrier is slow, and when a steady state is achieved, the concentration of Li⁺ in the cerebrospinal fluid and in brain tissue is ~ 40-50% of the concentration in plasma. The kinetics of Li⁺ can be monitored in human brain with magnetic resonance spectroscopy (Soares et al., 2000).

Approximately 95% of a single dose of Li⁺ is eliminated in the urine. From one- to two-thirds of an acute dose is excreted during a 6-12 hour initial phase of excretion, followed by slow excretion over the next 10-14 days (Goodnick and Schorr-Cain, 1991). The elimination t½ averages 20-24 hours, obviating the need for multiple daily dosing. Once-daily dosing not only improves adherence, but is also associated with decreased polyuria (Schou et al., 1982). With repeated administration, Li⁺ excretion increases during the first 5-6 days until a steady state is achieved after ~5 half-lives. When Li⁺ is stopped, there is a rapid phase of renal excretion followed by a slow 10- to 14-day phase. Since 80% of the filtered Li⁺ is reabsorbed by the proximal renal tubules, clearance of Li⁺ by the kidney is ~20% of that for creatinine, 15-30 mL/min (Goodnick and Schorr-Cain 1991; Hopkins and Gelenberg 2000); this rate is somewhat lower in elderly patients (10-15 mL/min) (Juurlink et al., 2004; Tueth et al., 1998). Loading with Na⁺ produces a small enhancement of Li⁺ excretion, but Na⁺ depletion promotes a clinically important degree of Li⁺ retention. Although the pharmacokinetics of Li⁺ varies considerably among subjects, the volume of distribution and clearance are relatively stable in an individual patient.

Li⁺ is completely filtered, and 80% is reabsorbed in the proximal tubules (Goodnick and Schorr-Cain, 1991). Li⁺ competes with Na⁺ for reabsorption, and Li⁺ retention can be increased by Na⁺ loss related to diuretic use, or febrile, diarrheal, or other GI illness. Heavy sweating leads to a preferential secretion of Li⁺ over Na⁺ (Jefferson et al., 1982); however, the repletion of excessive sweating using free water without electrolytes can cause hyponatremia, and promote Li⁺ retention. Thiazide diuretics deplete Na⁺ and can cause significant reductions in Li⁺ clearance that result in toxic levels. The K⁺-sparing diuretics triamterene, spironolactone, and amiloride have modest effects on the excretion of Li⁺, with concomitantly smaller increases in serum levels. Loop diuretics such as furosemide seem to have limited impact on Li⁺ levels (Juurlink et al., 2004). Renal excretion can be increased by administration of osmotic diuretics or acetazolamide, but not sufficiently for the management of acute Li⁺ intoxication. Through alteration of renal perfusion, some nonglomerular anti-inflammatory agents can facilitate renal proximal tubular resorption of Li⁺ and thereby increase serum concentrations (Phelan et al., 2003). This interaction appears to be particularly prominent with indomethacin, but also may occur with ibuprofen, naproxen, and COX-2 inhibitors, and possibly less so with sulindac and aspirin (Phelan et al., 2003). Angiotensin-converting enzyme inhibitors, particularly the renally cleared lisinopril, also cause Li⁺ retention, with isolated reports of toxicity among stable lithium-treated patients switched from fosinopril to lisinopril (Meyer et al., 2005).

Less than 1% of ingested Li⁺ leaves the human body in the feces; 4-5% is secreted in sweat (Sproule, 2002). Li⁺ is secreted in saliva in concentrations about twice those in plasma, while its concentration in tears is about equal to that in plasma. As noted under “Pregnancy and Lactation” later in the chapter, Li⁺ is secreted in human milk, but serum levels in breast-fed infants are ~20% that of
Serum Level Monitoring and Dose. Because of the low therapeutic index for Li+, periodic determination of serum concentrations is crucial. Li+ cannot be used with adequate safety in patients who cannot be tested regularly. Concentrations considered to be effective and acceptably safe are between 0.6 and 1.5 mEq/L. The range of 1.0-1.5 mEq/L is favored for treatment of acutely manic or hypomanic patients (Sproule, 2002). Somewhat lower values (0.6-1.0 mEq/L) are considered adequate and are safer for long-term prophylaxis. Serum concentrations of Li+ have been found to follow a clear dose-effect relationship between 0.4 and 1.0 mEq/L, but with a corresponding dose-dependent rise in polyuria and tremor as indices of adverse effects. Nonetheless, patients who maintain trough levels of 0.8-1.0 mEq/L experience decreased relapse risk compared to those maintained at lower serum concentrations. There are patients who may do well with serum levels of 0.5-0.8 mEq/L, but there are no current clinical or biological predictors to permit a priori identification of these individuals. Individualization of serum levels is often necessary to obtain a favorable risk-benefit relationship.

The concentration of Li+ in blood usually is measured at a trough of the daily oscillations that result from repetitive administration (i.e., from samples obtained 10-12 hours after the last oral dose of the day). Peaks can be two or three times higher at a steady state. When the peaks are reached, intoxication may result, even when concentrations in morning samples of plasma at the daily nadir are in the acceptable range of 0.6-1 mEq/L. Single daily doses generate relatively large oscillations of plasma Li+ concentration but lower mean trough levels than with multiple daily dosing, and are associated with a reduction in the extent and risk for polyuria (Schou et al., 1982); moreover, single nightly dosing means that peak serum levels occur during sleep, so complaints regarding CNS adverse effects are minimized. While relatively uncommon, GI complaints are one compelling reason for multiple daily dosing or using delayed release Li+ preparations, bearing in mind the increased polyuria risk from these strategies.

Therapeutic Uses

Drug Treatment of Bipolar Disorder. Treatment with Li+ ideally is conducted in patients with normal cardiac and renal function. Occasionally, patients with severe systemic illnesses are treated with Li+, provided that the indications are compelling, but the need for diuretics, nonsteroidal anti-inflammatory agents, or other medications that pose potential kinetic problems often precludes lithium use in those with multiple medical problems. Treatment of acute mania and the prevention of recurrences of bipolar illness in adults or adolescents are uses approved by the FDA. Li+ is the only mood stabilizer with data on suicide reduction in bipolar patients (Cipriani et al., 2005 Goodwin et al., 2003; Tondo et al., 2001), and Li+ also has abundant efficacy data for augmentation in unipolar depressive patients who are inadequate responders to antidepressant therapy (Bschor et al., 2002).

Drug Treatment of Mania. The modern treatment of the manic, depressive, and mixed-mood phases of bipolar disorder was revolutionized by the introduction of Li+ in 1949, its gradual acceptance worldwide by the 1960s, and late official acceptance in the U.S. in 1970, initially for acute mania only, and later primarily for prevention of recurrences of mania. While Li+, valproate, and carbamazepine have efficacy in acute mania, in clinical practice these are usually combined with atypical antipsychotic drugs, even in manic patients without psychotic features, due to their delayed onset of action. Li+, carbamazepine, and valproic acid preparations are only effective with daily dosing that maintains adequate serum levels, and require serum level monitoring. Mania patients are often irritable and poorly cooperative with medication administration and phlebotomy, thus, atypical antipsychotic drugs may be the sole initial therapy, and have proven efficacy as monotherapy (Scherk et al., 2007); moreover, acute IM forms of olanzapine, ziprasidone, and aripiprazole can be used to achieve rapid control of psychosis and agitation. Benzodiazepines are often used adjunctively for agitation and sleep induction.

Li+ is effective in acute mania, but is rarely employed as a sole treatment for reasons noted above, and because 5-7 days are required for clinical effect. A 600-mg loading dose of Li+ can be given to hasten the time to steady state, and can also be used to predict dosage requirements based on the 24-hour serum Li+ result, with a very high correlation coefficient (r = 0.972) (Cooper et al., 1973). Acutely manic patients may require higher dosages to achieve therapeutic serum levels, and downward adjustment may be necessary once the patient is euthymic. When adherence with oral capsules or tablets is an issue, the liquid Li+ citrate can be used. Each 5 mL of lithium citrate syrup provides 8.12 mEq of Li+, equivalent to 300 mg of lithium carbonate.

The anticonvulsant sodium valproate provides more rapid antimanic effects than Li+, with therapeutic benefit seen within 3-5 days. The most common form of valproate in use is divalproex sodium, preferred over valproic acid due to lower incidence of GI and other adverse effects. Divalproex is initiated at 25 mg/kg once daily and titrated to effect or the desired serum concentration. Serum concentrations of 90-120 μg/mL show the best response in clinical studies (Bowden et al., 2006). With immediate release forms of valproic acid and divalproex sodium, 12-hour troughs are used to guide treatment. With the extended-release divalproex preparation, patients respond best when the 24-hour trough levels are in the high therapeutic range (Bowden et al., 2006).

Carbamazepine is effective for acute mania. Immediate release forms of carbamazepine cannot be loaded or rapidly titrated over 24 hours as with valproate due to the development of neurological adverse effects such as dizziness or ataxia, even within the
therapeutic range (6-12 μg/mL) (Post et al., 2007); the extended-release form of carbamazepine was FDA-approved for acute mania in 2005. The extended-release form is better tolerated compared to older preparations, and effective as monotherapy with once-daily dosing (Weisler et al., 2006). Carbamazepine response rates are lower than those for valproate compounds or Li+, with mean rates of 45-60% cited in the literature (Post et al., 2007). Nevertheless, certain individuals respond to carbamazepine after failing Li+ and valproate. Initial doses are 400 mg/day, with the larger dose given at bedtime due to the sedating properties of carbamazepine. Titration proceeds by 200-mg increments every 24-48 hours based on clinical response and serum trough levels. Due to increased risk of Stevens-Johnson syndrome in Asian individuals (especially those from China, Hong Kong, Malaysia, and the Philippines where HLA-B*1502 prevalence is > 15%), HLA testing must be performed prior to treatment in populations at risk.

Lamotrigine has no role in acute mania due to the slow, extended titration necessary to minimize risk of Stevens-Johnson syndrome (Hahn et al., 2004).

**Prophylactic Treatment of Bipolar Disorder.** The choice of ongoing prophylaxis is determined by the need for continued antipsychotic drug use and for use of a mood-stabilizing agent. Both aripiprazole and olanzapine are effective as monotherapy for mania prophylaxis, but olanzapine use is eschewed out of concern for metabolic effects, and aripiprazole shows no benefit for prevention of depressive relapse.

In the pivotal maintenance trials, the mean endpoint aripiprazole dose was 27.9 mg (Keck et al., 2007), and mean olanzapine dose 16.2 mg (Tohen et al., 2003). In 2009, LAI risperidone was also approved for bipolar maintenance treatment to be used adjunctively with Li+ or valproate, or as monotherapy. If used as monotherapy, coverage with an oral antipsychotic is necessary for the first 4 weeks after the initial injection. When antipsychotic drugs have been employed as adjunctive agents, the optimal duration treatment is unclear, but most clinicians will continue with combination treatment for 2-4 months after the acute manic phase has been controlled. Clozapine can be beneficial in refractory mania patients as adjunctive therapy and as monotherapy (Hummel et al., 2002).

The overriding concern guiding bipolar treatment is the high recurrence rate. Individuals who experience mania have an 80-90% lifetime risk of subsequent manic episodes. As with schizophrenia, lack of insight, poor psychosocial support, and substance abuse all interfere with treatment adherence. While the anticonvulsants lamotrigine, carbamazepine, and divalproex have data supporting their use in bipolar prophylaxis, only concern has consistently been shown to reduce the risk of suicide compared to non-lithium users (Cipriani et al., 2005; Tondo et al., 2001), and compared to bipolar patients on valproate acid derivatives (Goodwin et al., 2003). Early case series and retrospective clinical literature indicated preferential benefit of valproate over concern in rapid-cycling patients, but a recent recent trial failed to substantiate this effect, and found no significant differences in time to relapse between the two agents (Calabrese et al., 2005b). Based largely on subanalyses of acute mania trials, there are also claims that valproate may be superior to concern for patients experiencing mixed episodes, but the lack of prospective data from randomized trials also raises questions about the validity of these findings. Lamotrigine was effective in two large, 18-month long maintenance trials for bipolar patients whose most recent mood episode was manic or depressed, with greater effect on depressive relapse (Bowden et al., 2003; Calabrese et al., 2003). The ability to provide prophylaxis for future depressive episodes combined with data in acute bipolar depression (Hahn et al., 2004) has made lamotrigine a useful choice for bipolar treatment, given that bipolar I and II patients spend large amounts of time in depressive phases (32% and 50%, respectively) (Judd et al., 2003).

Bipolar disorder is a lifetime illness with high recurrence rates. Individuals who experience an episode of mania should be educated about the probable need for ongoing treatment. Stopping mood stabilizer therapy can be considered in patients who have experienced only one lifetime manic episode, particularly when there may have been a pharmacological precipitant (e.g., substance or antidepressant use), and who have been euthymic for extended periods. For bipolar II patients, the impact of hypomania is relatively limited, so the decision to recommend prolonged maintenance treatment with a mood stabilizer is based on clinical response and risk:benefit ratio. Discontinuation of maintenance Li+ treatment in bipolar I patients carries a high risk of early recurrence and of suicidal behavior over a period of several months, even if the treatment had been successful for several years. Recurrence is much more rapid than is predicted by the natural history of untreated bipolar disorder, in which cycle lengths average ~1 year. This risk may be moderated by slow, gradual removal of Li+, while rapid discontinuation should be avoided unless dictated by medical emergencies.

**Other Uses of Lithium.** Li+ has been shown to be effective as adjunct therapy in treatment-resistant major depression (Bschor et al., 2002). Clinical data also support Li+ use as monotherapy for unipolar depression. Meta-analyses indicate that lithium’s benefit on suicide reduction extends to unipolar mood disorder patients (Cipriani et al., 2005; Tondo et al., 2001). While maintenance Li+ levels of 0.6-1.0 mEq/L are used for bipolar prophylaxis, a lower range (0.4-0.8 mEq/L) is recommended for antidepressant augmentation.

Based on its neuroprotective properties, there has been consideration of Li+ treatment for conditions associated with excitotoxic and apoptotic cell death, such as stroke and spinal cord injury, as well as in neurodegenerative disorders, including dementia of the Alzheimer type, stroke, Parkinson’s disease, Huntington’s disease, amyotrophic lateral sclerosis, progressive supranuclear palsy, and spinocerebellar ataxia type I (Aghdam and Barger 2007; Bauer et al., 2003; Chuang, 2004).

**Interactions with Other Drugs.** Interactions between Li+ and diuretics (especially thiazides spironolactone and amiloride), angiotensin-converting enzyme inhibitors, and nonsteroidal anti-inflammatory agents have been discussed earlier. Amiloride has been used
safely to reverse the syndrome of nephrogenic diabetes insipidus associated with Li+ therapy, but requires careful monitoring and Li+ dosage reduction to prevent lithium toxicity (Kosten and Forrest, 1986).

Adverse Effects

CNS Effects. The most common CNS effect of Li+ in the therapeutic dose range is fine postural hand tremor, indistinguishable from essential tremor. Severity and risk for tremor are dose-dependent, with incidence ranging from 15-70%. Some tolerance may develop over time, but tremor may be sufficiently bothersome to require intervention. In addition to the avoidance of caffeine and other agents that increase tremor amplitude, therapeutic options include dose reduction (bearing in mind the increased relapse risk with lower serum Li+ levels), or in those without contraindications for β-adrenergic blockade, use of propranolol, starting at 20 mg/day in divided doses, and gradually increased until the desired clinical effect is achieved (typically at doses ≤ 160 mg/day). Valproate treatment has a similar problem, and the approach to valproate-induced tremor is identical. At peak serum (and CNS) levels, some individuals may complain of incoordination, ataxia, or slurred speech, all of which can be avoided by dosing Li+ at bedtime. Patients may also complain of mental fatigue or cognitive dulling at higher serum Li+ levels, but this should be carefully assessed to determine whether this reflects a true side effect or a desire to regain the mental high from hypomania.

Li+ routinely causes EEG changes characterized by diffuse slowing, widened frequency spectrum, and potentiation with disorganization of background rhythm. Seizures have been reported in non-epileptic patients with therapeutic plasma concentrations of Li+. Li+ treatment has also been associated with increased risk of post-ECT confusion, and is generally tapered off prior to a course of ECT.

Li+ (and valproate) treatment results in significant weight gain, a problem that is magnified by concurrent use of antipsychotic drugs. Mean weight gain at one year in prospective Li+ trials ranges from −1 kg to +4 kg, but the proportion of individuals who gain > 5% of baseline weight is 13-62% (Keck and McElroy, 2003). Although the mechanism is unclear, central appetite stimulation at hypothalamic sites is the most plausible explanation (Keck and McElroy, 2003).

Renal Effects. Long-term renal effects of Li+ treatment are an important concern. The kidneys’ ability to concentrate urine decreases during Li+ therapy, and ~60% of individuals exposed to Li+ experience some form of polyuria and compensatory polydipsia. The mechanism of polyuria is unclear, but the result is decreased vasopressin stimulation of renal reabsorption of water, and the clinical picture of nephrogenic diabetes insipidus. Mean 24-hour urinary volumes of 3 L/day are common among long-term Li+ users, but Li+ discontinuation or a switch to single daily dosing may reverse the impact on renal concentrating ability in patients with < 5 years of Li+ exposure (Kusalic and Engelsmann, 1996). Patients exposed to multiple daily dosing or sustained-release Li+ preparations are at greatest risk for renal effects. Renal function should be monitored with biyearly serum blood urea nitrogen and creatinine levels, calculation of estimated GFR using standard formulas (Morriss and Benjamin, 2008), and annual measurement of 24-hour urinary volume. Reassessment of Li+ treatment, more frequent renal function tests, and possible nephrology consultation should be considered when estimated GFR < 60 mL/min on several periodic measurements, daily urinary volume exceeds 4 L, or serum creatinine continues to rise on three separate occasions (Morriss and Benjamin, 2008).

Thyroid and Endocrine Effects. A small number of patients on Li+ develop a benign, diffuse, nontender thyroid enlargement suggestive of compromised thyroid function, although many of these patients will have normal thyroid function. Measurable effects of Li+ on thyroid indices are seen in a fraction of patients: 7-10% develop overt hypothyroidism (Jefferson, 2000), and 23% have subclinical disease, with women at 3-9 times greater risk (Kleiner et al., 1999). There appears to be no plateau in the incidence of hypothyroidism in studies covering up to 10 years’ exposure; thus, ongoing monitoring of TSH and free T4 is recommended throughout the course of Li+ treatment. The development of hypothyroidism is easily treated through exogenous replacement, and is not a reason to discontinue Li+ therapy. Rare reports of hyperthyroidism during Li+ treatment also exist (Jefferson, 2000).

EKG Effects. The prolonged use of Li+ causes a benign and reversible T-wave flattening in ~20% of patients and the appearance of U waves, effects unrelated to depletion of Na+ or K+. At therapeutic concentrations there are rare reports of Li+-induced effects on cardiac conduction and pacemaker automaticity, effects that become pronounced during overdose and lead to sinus bradycardia, atrioventricular blocks, and possible cardiovascular compromise. Routine EKG monitoring is not recommended in younger patients, but may be considered in older patients, particularly those with a history of arrhythmia or coronary heart disease.

Skin Effects. Allergic reactions such as dermatitis, folliculitis, and vasculitis can occur with Li+ administration. Worsening of acne vulgaris, psoriasis, and other dermatological conditions is a common problem that is usually treatable by topical measures, but in a small number may improve only upon discontinuation of Li+. Some patients on Li+ (and valproate) may experience alopecia; daily supplementation with a multivitamin containing at least 100 μg of selenium and 15 mg of zinc may be beneficial.

Pregnancy and Lactation. Li+ is classified as risk category D (see Appendix I). The use of Li+ in early pregnancy may be associated with an increase in the incidence of cardiovascular anomalies of the newborn, especially Ebstein’s malformation (Freeman and Freeman, 2006). The basal risk of Ebstein’s anomaly of ~1 per 20,000 live births may rise several-fold with first-trimester Li+ exposure, but probably not above 1 per 2500. Moreover, the defect typically is detectable in utero by ultrasonography and often is surgically correctable after birth. Although the anticonvulsants valproic acid and carbamazepine are also pregnancy risk category D, these agents are associated with irreversible neural tube defects. In balancing the risk vs. benefit of using Li+ in pregnancy, it is important to evaluate the risk of inadequate prophylaxis for the bipolar disorder patient, and subsequent risk that mania poses for the patient and fetus. In patients who choose to forgo medication exposure during the first trimester, potentially safer treatments for acute mania include antipsychotic drugs or ECT (Dodd and Berk, 2006; Yonkers et al., 2004).

In pregnancy, maternal polyuria may be exacerbated by Li+. Concomitant use of Li+ with medications that waste Na+ or a low-Na+ diet during pregnancy can contribute to maternal and neonatal
Li+ intoxication. Li+ freely crosses the placenta, and fetal or neonatal Li+ toxicity may develop when maternal blood levels are within the therapeutic range. Fetal Li+ exposure is associated with neonatal goiter, CNS depression, hypotonia (“floppy baby” syndrome), and cardiac murmur. Most recommend withholding lithium therapy for 24-48 hours before delivery, and this is considered standard practice to avoid the potentially toxic increases in maternal and fetal serum Li+ levels associated with postpartum diuresis. This brief period of discontinuation results in a mean decrease of 0.28 mEq/L in maternal Li+ concentrations (Newport et al., 2005). The physical and CNS sequelae of late-term neonatal Li+ exposure are reversible once Li+ exposure has ceased, and no long-term neurobehavioral consequences are observed (Viguera et al., 2007).

**Other Effects.** A benign, sustained increase in circulating polymorphonuclear leukocytes (12,000-15,000 cells/mm³) occurs during the chronic use of Li+ and is reversed within a week after termination of treatment. Some patients complain of a metallic taste, making food less palatable. Myasthenia gravis may worsen during treatment with Li+.

**Acute Toxicity and Overdose.** The occurrence of toxicity is related to the serum concentration of Li+ and its rate of rise following administration. Acute intoxication is characterized by vomiting, profuse diarrhea, coarse tremor, ataxia, coma, and convulsions. Symptoms of milder toxicity are most likely to occur at the absorptive peak of Li+ and include nausea, vomiting, abdominal pain, diarrhea, sedation, and fine tremor. The more serious effects involve the nervous system and include mental confusion, hyperreflexia, gross tremor, dysarthria, seizures, and cranial nerve and focal neurological signs, progressing to coma and death. Sometimes both cognitive and motor neurological damage may be irreversible, with persistent cerebellar tremor being the most common (El-Mallakh, 1986). Other toxic effects are cardiac arrhythmias, hypotension, and albuminuria.

**Treatment of Lithium Intoxication.** There is no specific antidote for Li+ intoxication, and treatment is supportive, including intubation if indicated, and continuous cardiac monitoring. Levels ≥ 1.5 mEq/L are considered toxic, but inpatient medical administration is usually not indicated (in the absence of symptoms) until levels exceed 2 mEq/L. Care must be taken to assure that the patient is not Na+ and water depleted. Dialysis is the most effective means of removing Li+ and is necessary in severe poisonings, that is, in patients exhibiting symptoms of toxicity or patients with serum Li+ concentrations ≥ 3 mEq/L in acute overdoses. A review of 213 case reports of acute Li+ toxicity between 1948 and 1984, found that complete recovery occurred with an average maximal level of 2.5 mEq/L, permanent neurological symptoms with mean levels of 3.2 mEq/L, and death with mean maximal levels of 4.2 mEq/L (El-Mallakh, 1986). The most common neurological sequelae are due to cerebellar damage, and manifest clinically as ataxia, tremor, dysarthria, and dysmetria (Mangano et al., 1997).

**Use in Pediatric and Geriatric Populations**

**Pediatric Use.** The anticonvulsants all have pediatric indications for epilepsy, but only Li+ has FDA approval for child/adolescent bipolar disorder for ages ≥ 12 years (Tueth et al., 1998). Recently, aripiprazole and risperidone were FDA-approved for acute mania in children and adolescents ages 10-17. Children and adolescents have higher volumes of body water and higher GFR than adults. The resulting shorter t½ of Li+ demands dosing increases on a mg/kg basis, and multiple daily dosing is often required. In children ages 6-12 years, a dose of 30 mg/kg/day given in three divided doses will produce a Li+ concentration of 0.6-1.2 mEq/L in 5 days (Danielyan and Kowatch, 2005), although ongoing dosing is always guided by serum levels and clinical response. Use in children under 12 represents an off-label use for Li+ and care givers should be alert to evidence of the development of toxicity. As with adults, ongoing monitoring of renal and thyroid function is important, along with clinical inquiry into extent of polyuria.

A limited number of controlled studies suggest that valproate has efficacy comparable to that of Li+ for mania in children or adolescents (Danielyan and Kowatch, 2005). As with Li+, weight gain and tremor can be problematic; moreover, there are reports of hyperammonemia in children with urea-cycle disorders. Ongoing monitoring of platelets and liver function tests, in addition to serum drug levels, is recommended. There have been no controlled studies of carbamazepine for the treatment of children and adolescents with mania, although there is substantial safety data for epilepsy indications in this age group.

**Geriatric Use.** The majority of older patients on Li+ therapy are those maintained for years on the medication. Less than 10% of individuals with bipolar disorder experience their first manic episode at age 50 or above. Elderly patients frequently take numerous medications for other illnesses and the potential for contraindications or drug-drug interactions is substantial. For patients naïve to Li+, these issues can be addressed relatively easily prior to commencement of Li+ treatment. The more difficult clinical decision revolves around switching treatment in stable patients who have taken Li+ for years or decades with excellent clinical response. In addition, age-related reductions in total body water and creatinine clearance reduce the safety margin for Li+ treatment in older patients. Targeting lower maintenance serum levels (0.6-0.8 mEq/L) may reduce the risk of toxicity. As GFR drops below 60 mL/min, strong consideration must be given to a search for alternative agents, despite lithium’s therapeutic advantages (Morris and Benjamin, 2008). Li+ toxicity occurs more frequently in elderly patients, in part as the result of concurrent use of loop diuretics and angiotensin-converting enzyme inhibitors (Juurlink et al., 2004). Anticonvulsants, especially extended-release divalproex, are a reasonable alternative to Li+. Elderly patients who are drug-naïve may be more sensitive to CNS adverse effects of all types of medications used for acute mania, especially parkinsonism and tardive dyskinesia from D2 antagonism, confusion from antipsychotic medications with antimuscarinic properties, and ataxia or sedation from Li+ or anticonvulsants.

**Major Drugs Available in the Class**

**Formulations.** Most Li+ preparations currently used in the U.S. are tablets or capsules of lithium carbonate in strengths of 150, 300, and 600 mg. Slow-release preparations of lithium carbonate also are available in strengths of 300 and 450 mg, as is lithium citrate syrup (with 8 mEq of Li+5 mL citrate liquid, equivalent to 300 mg of lithium carbonate). Salts other than the carbonate have been used, but the carbonate salt is favored for tablets and capsules because it is relatively less
hygroscopic and less irritating to the gut than other salts, especially the chloride. Since slow-release forms carry an increased risk for polyuria, their use should be limited to patients who experience GI side effects related to rapid absorption.

**Novel Treatments for Psychosis and Mania**

There are several molecular targets for antipsychotic drug development, including glutamate, serotonergic, and cholinergic receptor systems. The glutamate hypofunction hypothesis for schizophrenia has opened the door to exploration of metabotropic glutamate receptor agonists, and agonists at co-transmitter sites. The glutamate receptor family is divided into the excitatory ionotropic receptors, broadly distributed in the CNS, and metabotropic glutamate receptors that exert modulatory functions (Chapter 14). The former are not viable targets for drug activity due to the global impact on CNS function that may result. Metabotropic glutamate receptors show significant promise, with agents synthesized based on the distribution of the three receptor groups (Krivoy et al., 2008).

The mGlu 2/3 receptor agonist LY2140023 showed efficacy in a 4-week phase 2 schizophrenia monotherapy trial (Patil et al., 2007), and while subsequent data were problematic, similar compounds are still in development.

Glycine is a co-transmitter at glutamate receptors whose synaptic action is terminated by presynaptic reuptake transporters. There are two human forms of the glycine reuptake pump: GlyT1, which is localized to cortical areas; and GlyT2, which is concentrated in spinal cord. The GlyT1 inhibitor SSR504734 was as effective as haloperidol in blocking PCP-induced CNS metabolic changes in rats. Larusidone is a novel 5-HT/DA antagonist that filed for FDA approval in late 2009. Larusidone possesses potent activity at 5-HT1 receptors, actions that, based on preclinical and early clinical studies, may be associated with cognitive benefits (Meyer et al., 2009). Muscarinic receptor modulators at M1 and M4 sites have passed several preclinical antipsychotic tests (Chan et al., 2008; Janowsky and Davis, 2009), and xanomeline, an M1/M4 agonist, has shown antipsychotic and procognitive affects in a 4-week, double-blind placebo-controlled schizophrenia trial (Shekhar et al., 2008). Certain targets (e.g., α7 and α4β2 nicotinic receptors) are being exploited solely for the purposes of cognitive enhancement in schizophrenia, and may not confer antipsychotic activity (Buchanan et al., 2007).

The expanded role for atypical antipsychotics in bipolar treatment is primarily in acute mania, although quetiapine possesses unique effectiveness for bipolar depression based on antidepressant properties conferred by the metabolite norquetiapine. Improved understanding of the biological basis for Li+ and anticonvulsant actions in mania has generated several possible targets. No agents acting on IP3 have been developed, but several inhibitors of GSK-3β that are 3-benzofuranyl-1-indolylmaleimide compounds have been identified, with one showing activity in a murine mania model (Kozikowski et al., 2007). PKC inhibition has emerged as the most viable novel candidate for antimanic activity, based on several positive tamoxifen trials in acute mania (Einat et al., 2007; Yildiz et al., 2008; Zarate et al., 2007). There is still no medication that possesses lithium’s unique broad spectrum of pharmacological activities for bipolar disorder, and particular aspects of lithium’s actions that are addressed in a limited fashion by current medications (e.g., lamotrigine and quetiapine for bipolar depression), or not at all (e.g., neuroprotection), remain important targets for novel treatments (Quiroz et al., 2004).

**Clinical Summary: Treatment of Mania**

Despite decades of data substantiating the superior efficacy of Li+ in bipolar patients, including suicide reduction, Li+ remains underutilized. Long-term studies spanning 10 or more years demonstrate that while polyuria may be relatively common, significant declines in renal function and renal failure are rare during Li+ treatment. Many agents are effective for acute mania, but long-term treatment requires careful consideration of extent and severity of prior depressive episodes, past history of treatment response, concurrent medical illness and medication use, patient preference, and concerns over particular adverse effects (e.g., weight gain). Combining mood stabilizers and antipsychotic agents shows greater benefit for acute mania than monotherapy of either agent class, but may be associated with increased long-term weight gain. A realistic discussion with patients regarding long-term side effects for various treatments and clinical outcomes is paramount to improve adherence. Serum level monitoring is necessary for Li+, valproate acid compounds, and carbamazepine. Lamotrigine may be particularly useful in type II bipolar patients, where mania prophyaxis is not a concern. The clinical data make a compelling argument for Li+ as the treatment of choice in bipolar I disorder. Ongoing research into lithium’s mechanism of action may yield new agents without lithium’s adverse effect profile, and genetic predictors of Li+ response.

Many agents can depress the function of the central nervous system and produce calming or drowsiness (sedation). The CNS depressants discussed in this chapter include benzodiazepines, other benzodiazepine receptor agonists (the “Z compounds”), barbiturates, and sedative-hypnotic agents of diverse chemical structure. Older sedative-hypnotic drugs depress the CNS in a dose-dependent fashion, progressively producing a spectrum of responses from mild sedation to coma and death.

A sedative drug decreases activity, moderates excitement, and calms the recipient, whereas a hypnotic drug produces drowsiness and facilitates the onset and maintenance of a state of sleep that resembles natural sleep in its electroencephalographic characteristics and from which the recipient can be aroused easily.

Sedation is a side effect of many drugs that are not general CNS depressants (e.g., antihistamines and antipsychotic agents). Although such agents can intensify the effects of CNS depressants, they usually produce more specific therapeutic effects at concentrations far lower than those causing substantial CNS depression. For example, they cannot induce surgical anesthesia in the absence of other agents. The benzodiazepine sedative-hypnotics resemble such agents; although coma may occur at very high doses, neither surgical anesthesia nor fatal intoxication is produced by benzodiazepines in the absence of other drugs with CNS-depressant actions; an important exception is midazolam, which has been associated with decreased tidal volume and respiratory rate. Moreover, specific antagonists of benzodiazepines exist. This constellation of properties sets the benzodiazepine receptor agonists apart from other sedative-hypnotic drugs and imparts a measure of safety such that benzodiazepines and the newer Z compounds have largely displaced older agents for the treatment of insomnia and anxiety.

The sedative-hypnotic drugs that do not specifically target the benzodiazepine receptor belong to a group of agents that depress the CNS in a dose-dependent fashion, progressively producing calming or drowsiness (sedation), sleep (pharmacological hypnosis), unconsciousness, coma, surgical anesthesia, and fatal depression of respiration and cardiovascular regulation. They share these properties with a large number of chemicals, including general anesthetics (Chapter 19) and aliphatic alcohols, most notably ethanol (Chapter 23). Only two landmarks on the continuum of CNS depression produced by increasing concentrations of these agents can be defined with a reasonable degree of precision: surgical anesthesia, a state in which painful stimuli elicit no behavioral or autonomic response (Chapter 19), and death, resulting from sufficient depression of medullary neurons to disrupt coordination of cardiovascular function and respiration. The “end points” at lower concentrations of CNS depressants are defined with less precision—in terms of deficits in cognitive function (including attention to environmental stimuli) or motor skills (e.g., ataxia) or of the intensity of sensory stimuli needed to elicit some reflex or behavioral response. Other important indices of decreased CNS activity, such as analgesia and seizure suppression, do not necessarily fall along this continuum; they may not be present at sub-anesthetic concentrations of a CNS depressant drug (e.g., a barbiturate), or they may be achieved with minimal sedation or other evidence of CNS depression (e.g., with low doses of opioids, phenytoin, or ethosuximide).

History. Since antiquity, alcoholic beverages and potions containing laudanum and various herbs have been used to induce sleep. In the middle of the nineteenth century, bromide was the first agent to be introduced specifically as a sedative-hypnotic. Chloral hydrate, paraldehyde, urethane, and sulfonal came into use before the introduction of barbital in 1903 and phenobarbital in 1912. Their success spawned the synthesis and testing of >2500 barbiturates, of which ~50 were distributed commercially. The barbiturates were so dominant that less than a dozen other sedative-hypnotics were marketed successfully before 1960.

The partial separation of sedative-hypnotic-anesthetic from anticonvulsant properties embodied in phenobarbital led to
searches for agents with more selective effects on CNS functions. As a result, relatively non-sedating anticonvulsants, notably phenytoin and trimethadione, were developed in the late 1930s and early 1940s (Chapter 21). The advent of chlorpromazine and meprobamate in the early 1950s, with their taming effects in animals, and the development of increasingly sophisticated methods for evaluating the behavioral effects of drugs set the stage in the 1950s for the synthesis of chlordiazepoxide by Sternbach and the discovery of its unique pattern of actions by Randall. The introduction of chlordiazepoxide into clinical medicine in 1961 ushered in the era of benzodiazepines. Most of the benzodiazepines that have reached the marketplace were selected for high anxiolytic potency in relation to their depression of CNS function. However, all benzodiazepines possess sedative-hypnotic properties to varying degrees; these properties are exploited extensively clinically, especially to facilitate sleep. Mainly because of their remarkably low capacity to produce fatal CNS depression, the benzodiazepines have displaced the barbiturates as sedative-hypnotic agents.

**BENZODIAZEPINES**

All benzodiazepines in clinical use have the capacity to promote the binding of the major inhibitory neurotransmitter $\gamma$-aminobutyric acid (GABA) to the GABA$_A$ subtype of GABA receptors, which exist as multi-subunit, ligand-gated chloride channels, thereby enhancing the GABA-induced ionic currents through these channels (see Figure 14–11). Pharmacological data suggest heterogeneity among sites of binding and action of benzodiazepines; biochemical and molecular biological investigations reveal the numerous varieties of subunits that make up the GABA-gated chloride channels expressed in different neurons. Since receptor subunit composition appears to govern the interaction of various allosteric modulators with these channels, there has been a surge in efforts to find agents displaying different combinations of benzodiazepine-like properties that may reflect selective actions on one or more subtypes of GABA receptors. These efforts led to the development of zolpidem (AMBIEN), an imidazopyridine, the pyrazolopyrimidines zaleplon (SONATA) and the cyclopyrrolones eszopiclone (LUNESTA); these so-called “Z compounds” all apparently exert sedative-hypnotic effects by interacting with a subset of benzodiazepine binding sites.

Although the benzodiazepines exert qualitatively similar clinical effects, important quantitative differences in their pharmacodynamic spectra and pharmacokinetic properties have led to varying patterns of therapeutic application. A number of distinct mechanisms of action are thought to contribute to the sedative-hypnotic, muscle-relaxant, anxiolytic, and anticonvulsant effects of the benzodiazepines, and specific subunits of the GABA$_A$ receptor are responsible for specific pharmacological properties of benzodiazepines. While only the benzodiazepines used primarily for hypnosis are discussed in detail, this chapter describes the general properties of the group and important differences among individual agents (see also Chapters 15 and 21).

**Chemistry.** The structures of the benzodiazepines in use in the U.S. are shown in Table 17–1, as are those of a few related compounds discussed later.

The term benzodiazepine refers to the portion of the structure composed of a benzene ring (A) fused to a seven-membered diazepine ring (B). Since all the important benzodiazepines contain a 5-aryl substituent (ring C) and a 1,4-diazepine ring, the term has come to mean the 5-aryl-1,4-benzodiazepines. Various modifications in the structure of the ring systems have yielded compounds with similar activities, including 1,5-benzodiazepines (e.g., clobazam) and compounds in which the fused benzene ring is replaced with heteroaromatic systems such as thieno- (e.g., brotizolam). The chemical nature of substituents at positions 1 to 3 can vary widely and can include triazolo or imidazo rings fused at positions 1 and 2. Replacement of ring C with a keto function at position 5 and a methyl substituent at position 4 is an important structural feature of the benzodiazepine receptor antagonist flumazenil (ROMAZICON).

In addition to various benzodiazepine or imidazobenzodiazepine derivatives, a large number of non-benzodiazepine compounds compete with classic benzodiazepines or flumazenil for binding at specific sites in the CNS. These include representatives from the $\beta$-carbolines (containing an indole nucleus fused to a pyridine ring), imidazopyridines (e.g., zolpidem, discussed later), imidazopyrimidines, imidazoxinolones, and cyclopyrrolones (e.g., eszopiclone).

**Pharmacological Properties**

Virtually all effects of the benzodiazepines result from their actions on the CNS. The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Only two effects of these drugs result from peripheral actions: coronary vasodilation, seen after intravenous administration of therapeutic doses of certain benzodiazepines, and neuromuscular blockade, seen only with very high doses.

A number of benzodiazepine-like effects have been observed in vivo and in vitro and have been classified as full agonistic effects (i.e., faithfully mimicking agents such as diazepam with relatively low fractional occupancy of binding sites) or partial agonistic effects (i.e., producing less intense maximal effects or requiring relatively high fractional occupancy compared with agents such as diazepam). Some compounds produce...
effects opposite to those of diazepam in the absence of benzodiazepine-like agonists and have been termed inverse agonists; partial inverse agonists also have been recognized (Chapters 2 and 3). The vast majority of effects of agonists and inverse agonists can be reversed or prevented by the benzodiazepine antagonist flumazenil, which competes with agonists and inverse agonists for binding to the GABA<sub>A</sub> receptor.

**Central Nervous System.** While benzodiazepines affect activity at all levels of the neuraxis, some structures are affected preferentially. The benzodiazepines do not produce the same degrees of neuronal depression produced...
by barbiturates and volatile anesthetics. All the benzodiazepines have similar pharmacological profiles. Nevertheless, the drugs differ in selectivity, and the clinical usefulness of individual benzodiazepines thus varies considerably.

As the dose of a benzodiazepine is increased, sedation progresses to hypnosis and then to stupor. The clinical literature often refers to the “anesthetic” effects and uses of certain benzodiazepines, but the drugs do not cause a true general anesthesia because awareness usually persists, and immobility sufficient to allow surgery cannot be achieved. However, at “preanesthetic” doses, there is amnesia for events subsequent to administration of the drug.

Although considerable attempts have been made to separate the anxiolytic actions of benzodiazepines from their sedative-hypnotic effects, distinguishing between these behaviors still is problematic. Measurements of anxiety and sedation are difficult in humans, and the validity of animal models for anxiety and sedation is uncertain. The existence of multiple benzodiazepine receptors may in part explain the diversity of pharmacological responses in different species.

Animal Models of Anxiety. In animal models of anxiety, most attention has focused on the ability of benzodiazepines to increase locomotor, feeding, or drinking behavior that has been suppressed by novel or aversive stimuli. In one paradigm, animal behaviors that previously had been rewarded by food or water are punished periodically by an electric shock. The time during which shocks are delivered is signaled by some auditory or visual cue, and untreated animals stop performing almost completely when the cue is perceived. The difference in behavioral responses during the punished and unpunished periods is eliminated by benzodiazepine receptor agonists, usually at doses that do not reduce the rate of unpunished responses or produce other signs of impaired motor function. Similarly, rats placed in an unfamiliar environment exhibit markedly reduced exploratory behavior (neophobia), whereas animals treated with benzodiazepines do not. Opioid analgesics and antipsychotic drugs do not increase suppressed behaviors, and phenobarbital and meprobamate usually do so only at doses that also reduce spontaneous or unpunished behaviors or produce ataxia.

The difference between the dose required to impair motor function and that necessary to increase punished behavior varies widely among the benzodiazepines and depends on the species and experimental protocol. Although such differences may have encouraged the marketing of some benzodiazepines as selective sedative-hypnotic agents, they have not predicted with any accuracy the magnitude of sedative effects among those benzodiazepines marketed as anxiolytic agents.

Tolerance to Benzodiazepines. Studies on tolerance in laboratory animals often are cited to support the belief that disinhibitory effects of benzodiazepines are distinct from their sedative-ataxic effects. For example, tolerance to the depressant effects on rewarded or neutral behavior occurs after several days of treatment with benzodiazepines; the disinhibitory effects of the drugs on punished behavior are augmented initially and decline after 3–4 weeks (File, 1985). Although most patients who ingest benzodiazepines chronically report that drowsiness wanes over a few days, tolerance to the impairment of some measures of psychomotor performance (e.g., visual tracking) usually is not observed. Whether tolerance develops to the anxiolytic effects of benzodiazepines remains a subject of debate. Many patients can maintain themselves on a fairly constant dose; increases or decreases in dosage appear to correspond with changes in problems or stresses. On the other hand, some patients either do not reduce their dosage when stress is relieved or steadily escalate dosage. Such behavior may be associated with the development of drug dependence (Chapter 24).

Some benzodiazepines induce muscle hypotonia without interfering with normal locomotion and can decrease rigidity in patients with cerebral palsy. In contrast to effects in animals, there is only a limited degree of selectivity in humans. Clonazepam in non-sedative doses does cause muscle relaxation, but diazepam and most other benzodiazepines do not. Tolerance occurs to the muscle relaxant and ataxic effects of these drugs.

Experimentally, benzodiazepines inhibit seizure activity induced by either pentylenetetrazol or picrotoxin, but strychnine- and maximal electroshock-induced seizures are suppressed only at doses that also severely impair locomotor activity. Clonazepam, nitrazepam, and nordazepam have more selective anticonvulsant activity than most other benzodiazepines. Benzodiazepines also suppress photic seizures in baboons and ethanol-withdrawal seizures in humans. However, the development of tolerance to the anticonvulsant effects has limited the usefulness of benzodiazepines in the treatment of recurrent seizure disorders in humans (Chapter 21).

Although analgesic effects of benzodiazepines have been observed in experimental animals, only transient analgesia is apparent in humans after intravenous administration. Such effects actually may involve the production of amnesia. Unlike barbiturates, benzodiazepines do not cause hyperalgesia.

Effects on the Electroencephalogram (EEG) and Sleep Stages. The effects of benzodiazepines on the waking EEG resemble those of other sedative-hypnotic drugs. Alpha activity is decreased, but there is an increase in low-voltage fast activity. Tolerance occurs to these effects.

Benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings and the time spent in stage 0 (a stage of wakefulness). Time in stage 1 (descending drowsiness) usually is decreased, and there is a prominent decrease in the time spent in slow-wave sleep (stages 3 and 4). Most benzodiazepines increase the time from onset of spindle sleep to the first burst of rapid-eye-movement (REM) sleep, and the time spent in REM sleep usually is shortened. However, the number of cycles of REM sleep usually is increased, mostly late in the sleep time. Zolpidem and zaleplon suppress REM sleep to a lesser extent than do benzodiazepines and thus may be superior to benzodiazepines for use as hypnotics (Dujardin et al., 1998).

Despite the shortening of stage 4 and REM sleep, benzodiazepine administration typically increases total sleep time, largely by increasing the time spent in stage 2 (which is the major fraction of non-REM sleep). The effect is greatest in subjects with the shortest baseline total sleep time. In addition, despite the increased number of
REM cycles, the number of shifts to lighter sleep stages (1 and 0) and the amount of body movement are diminished. Nocturnal peaks in the secretion of growth hormone, prolactin, and luteinizing hormone are not affected. During chronic nocturnal use of benzodiazepines, the effects on the various stages of sleep usually decline within a few nights. When such use is discontinued, the pattern of drug-induced changes in sleep parameters may “rebound,” and an increase in the amount and density of REM sleep may be especially prominent. If the dosage has not been excessive, patients usually will note only a shortening of sleep time rather than an exacerbation of insomnia.

Although some differences in the patterns of effects exerted by the various benzodiazepines have been noted, their use usually imparts a sense of deep or refreshing sleep. It is uncertain to which effect on sleep parameters this feeling can be attributed. As a result, variations in the pharmacokinetic properties of individual benzodiazepines appear to be much more important determinants of their effects on sleep than are any potential differences in their pharmacodynamic properties.

**Molecular Targets for Benzodiazepine Actions in the CNS.**

Benzodiazepines appear to exert most of their effects by interacting with inhibitory neurotransmitter receptors directly activated by GABA (Chapter 14). The ionotropic GABA_A receptors consist of five subunits that co-assemble to form an integral chloride channel (Figure 14–11). GABA_A receptors are responsible for most inhibitory neurotransmission in the CNS. Benzodiazepines act at GABA_A receptors by binding directly to a specific site that is distinct from that of GABA binding. Unlike barbiturates, benzodiazepines do not activate GABA_A receptors directly; rather, benzodiazepines act allosterically by modulating the effects of GABA. Benzodiazepines and GABA analogs bind to their respective sites on brain membranes with nanomolar affinity. Benzodiazepines modulate GABA binding, and GABA alters benzodiazepine binding in an allosteric fashion.

Benzodiazepines and related compounds can act as agonists, antagonists, or inverse agonists at the benzodiazepine-binding site on GABA_A receptors. Agonists at the binding site increase, and inverse agonists decrease, the amount of chloride current generated by GABA_A-receptor activation. Agonists at the benzodiazepine binding site shift the GABA concentration-response curve to the left, whereas inverse agonists shift the curve to the right. Both these effects are blocked by antagonists at the benzodiazepine binding site.

In the absence of an agonist or inverse agonist for the benzodiazepine binding site, an antagonist for this binding site does not affect GABA_A receptor function. One such antagonist, flumazenil, is used clinically to reverse the effects of high doses of benzodiazepines. The behavioral and electrophysiological effects of benzodiazepines also can be reduced or prevented by prior treatment with antagonists at the GABA binding site (e.g., bicuculline).

The strongest evidence that benzodiazepines act directly on GABA_A receptors comes from recombinant expression of cDNAs encoding subunits of the receptor complex, which resulted in high-affinity benzodiazepine binding sites and GABA-activated chloride conductances that were enhanced by benzodiazepine receptor agonists (Burt, 2003). The properties of the expressed receptors generally resemble those of GABA_A receptors found in most CNS neurons. Each GABA_A receptor is believed to consist of a pentamer of homologous subunits. Thus far 16 different subunits have been identified and classified into seven subunit families: six α, three β, three γ, and single δ, ε, π, and θ subunits. Additional complexity arises from RNA splice variants of some of these subunits (e.g., γ2 and α6). The exact subunit structures of native GABA receptors still are unknown, but it is thought that most GABA receptors are composed of α, β, and γ subunits that co-assemble with some uncertain stoichiometry. The multiplicity of subunits generates heterogeneity in GABA_A receptors and is responsible, at least in part, for the pharmacological diversity in benzodiazepine effects in behavioral, biochemical, and functional studies. Studies of cloned GABA_A receptors have shown that the co-assembly of a γ subunit with α and β subunits confers benzodiazepine sensitivity to GABA_A receptors (Burt, 2003). Receptors composed solely of α and β subunits produce functional GABA_A receptors that also respond to barbiturates, but they neither bind nor are affected by benzodiazepines. Benzodiazepines are believed to bind at the interface between α and γ subunits, and both subunits determine the pharmacology of the benzodiazepine binding site (Burt, 2003). For example, receptors containing the α1 subunit are pharmacologically distinct from receptors containing α2, α3, or α5 subunits (Pritchett and Seeburg, 1990), reminiscent of the pharmacological heterogeneity detected with radioligand-binding studies using brain membranes. Receptors containing the α6 subunit do not display high-affinity binding of diazepam and appear to be selective for the benzodiazepine receptor inverse agonist RO 15-4513, which has been tested as an alcohol antagonist (Lüddens et al., 1990). The subtype of γ subunit also modulates benzodiazepine pharmacology, with lower-affinity binding observed in receptors containing the γ1 subunit. Although theoretically ~1 million different GABA_A receptors could be assembled from all these different subunits, constraints for the assembly of these receptors apparently limit their numbers (Sieghart et al., 1999).

An understanding of which GABA_A receptor subunits are responsible for particular effects of benzodiazepines *in vivo* has emerged. The mutation to arginine of a histidine residue at position 101 of the GABA_A receptor α1 subunit renders receptors containing that subunit insensitive to the GABA-enhancing effects of diazepam (Kleingoor et al., 1993). Mice bearing these mutated subunits fail to exhibit the sedative, the amnesic, and in part the anticonvulsant effects of diazepam while retaining sensitivity to the anxiolytic, muscle-relaxant, and ethanol-enhancing effects. Conversely, mice bearing the equivalent mutation in the α2 subunit of the GABA_A receptor are insensitive to the anxiolytic effects of diazepam (Burt, 2003). The attribution of specific behavioral effects of benzodiazepines to individual receptor subunits will aid in the development of new compounds exhibiting fewer undesired side effects.

Electrophysiological studies *in vitro* have shown that the enhancement of GABA-induced chloride currents by benzodiazepines results primarily from an increase in the frequency of bursts of chloride channel opening produced by submaximal amounts of GABA (Twyman et al., 1989). Inhibitory synaptic transmission measured after stimulation of afferent fibers is potentiated by benzodiazepines at therapeutically relevant concentrations. Prolongation of spontaneous miniature inhibitory postsynaptic currents (IPSCs) by benzodiazepines also has been observed. Although sedative barbiturates also enhance such chloride currents, they do so by prolonging the duration of individual channel-opening events. Macroscopic measurements of GABA_A receptor-mediated currents indicate that benzodiazepines shift the GABA concentration-response curve to the left without increasing the maximum current evoked with GABA. These findings collectively are consistent with
a model in which benzodiazepines exert their major actions by increasing the gain of inhibitory neurotransmission mediated by GABA<sub>α</sub> receptors.

GABA<sub>α</sub> receptor subunits also may play roles in the targeting of assembled receptors to their proper locations in synapses. In knockout mice lacking the γ<sub>2</sub> subunit, GABA<sub>α</sub> receptors did not localize to synapses, although they were formed and translocated to the cell surface (Essrich et al., 1998). The synaptic clustering molecule gephyrin also plays a role in receptor localization.

**GABA<sub>α</sub> Receptor-Mediated Electrical Events: in vivo Properties.** The remarkable safety of the benzodiazepines is likely related to the fact that their effects *in vivo* depend on the presynaptic release of GABA; in the absence of GABA, benzodiazepines have no effects on GABA<sub>α</sub> receptor function. Although barbiturates also enhance the effects of GABA at low concentrations, they directly activate GABA receptors at higher concentrations, which can lead to profound CNS depression (discussed later). Further, the behavioral and sedative effects of benzodiazepines can be ascribed in part to potentiation of GABA-ergic pathways that serve to regulate the firing of neurons containing various monoamines (Chapter 14). These neurons are known to promote behavioral arousal and are important mediators of the inhibitory effects of fear and punishment on behavior. Finally, inhibitory effects on muscular hypertonia or the spread of seizure activity can be rationalized by potentiation of inhibitory GABA-ergic circuits at various levels of the neuraxis. In most studies conducted *in vivo* or *in situ*, the local or systemic administration of benzodiazepines reduces the spontaneous or evoked electrical activity of major (large) neurons in all regions of the brain and spinal cord. The activity of these neurons is regulated in part by small inhibitory interneurons (predominantly GABA-ergic) arranged in feedback and feedforward types of circuits. The magnitude of the effects produced by benzodiazepines varies widely depending on such factors as the types of inhibitory circuits that are operating, the sources and intensity of excitatory input, and the manner in which experimental manipulations are performed and assessed. For example, feedback circuits often involve powerful inhibitory synapses on the neuronal soma near the axon hillock, which are supplied predominantly by recurrent pathways. The synaptic or exogenous application of GABA to this region increases chloride conductance and can prevent neuronal discharge by shunting currents that otherwise would depolarize the membrane of the initial segment. Accordingly, benzodiazepines markedly prolong the period after brief activation of recurrent GABA-ergic pathways during which neither spontaneous nor applied excitatory stimuli can evoke neuronal discharge; this effect is reversed by the GABA<sub>α</sub> receptor antagonist bicuculline (see Figure 14–10).

The macromolecular complex containing GABA-regulated chloride channels also may be a site of action of general anesthetics, ethanol, inhaled drugs of abuse, and certain metabolites of endogenous steroids (Whiting, 2003). Among the latter, allopregnanolone (3α-hydroxy, 5α-dihydroprogesterone) is of particular interest. This compound, a metabolite of progesterone that can be formed in the brain from precursors in the circulation and also synthesized by glial cells, produces barbiturate-like effects, including promotion of GABA-induced chloride currents and enhanced binding of benzodiazepines and GABA-receptor agonists. As with the barbiturates, higher concentrations of the steroid activate chloride currents in the absence of GABA, and its effects do not require the presence of a γ subunit in GABA<sub>α</sub> receptors expressed in transfected cells. Unlike the barbiturates, however, the steroid cannot reduce excitatory responses to glutamate (discussed later). These effects are produced very rapidly and apparently are mediated by interactions at sites on the cell surface. A congener of allopregnanolone (alfaxalone) was used previously outside the U.S. for the induction of anesthesia.

**Respiration.** Hypnotic doses of benzodiazepines are without effect on respiration in normal subjects, but special care must be taken in the treatment of children (Kriel et al., 2000) and individuals with impaired hepatic function, such as alcoholics (Guglielmetti et al., 1999). At higher doses, such as those used for preanesthetic medication or for endoscopy, benzodiazepines slightly depress alveolar ventilation and cause respiratory acidosis as the result of a decrease in hypoxic rather than hypercapnic drive; these effects are exaggerated in patients with chronic obstructive pulmonary disease (COPD), and alveolar hypoxia and CO subscripts 2 narcosis may result. These drugs can cause apnea during anesthesia or when given with opioids. Patients severely intoxicated with benzodiazepines only require respiratory assistance when they also have ingested another CNS-depressant drug, most commonly ethanol.

In contrast, hypnotic doses of benzodiazepines may worsen sleep-related breathing disorders by adversely affecting control of the upper airway muscles or by decreasing the ventilatory response to CO subscripts 2. The latter effect may cause hypoventilation and hypoxemia in some patients with severe COPD, although benzodiazepines may improve sleep and sleep structure in some instances. In patients with obstructive sleep apnea (OSA), hypnotic doses of benzodiazepines may decrease muscle tone in the upper airway and exaggerate the impact of apneic episodes on alveolar hypoxia, pulmonary hypertension, and cardiac ventricular load. Many clinicians consider the presence of OSA to be a contraindication to the use of alcohol or any sedative-hypnotic agent, including a benzodiazepine; caution also should be exercised with patients who snore regularly, because partial airway obstruction may be converted to OSA under the influence of these drugs. In addition, benzodiazepines may promote the appearance of episodes of apnea during REM sleep (associated with decreases in oxygen saturation) in patients recovering from a myocardial infarction; however, no impact of these drugs on survival of patients with cardiac disease has been reported.

**Cardiovascular System.** The cardiovascular effects of benzodiazepines are minor in normal subjects except in severe intoxication; the adverse effects in patients with obstructive sleep disorders or cardiac disease were noted above. In preanesthetic doses, all benzodiazepines decrease blood pressure and increase heart rate. With midazolam, the effects appear to be secondary to a decrease in peripheral resistance, but with diazepam, they are secondary to a decrease in left ventricular work and cardiac output. Diazepam increases coronary flow, possibly by an action to increase interstitial concentrations of adenosine, and the accumulation of this cardio depressant metabolite also may explain the negative inotropic effects of the drug. In large doses, midazolam decreases cerebral blood flow and oxygen assimilation considerably (Nugent et al., 1982).

**GI Tract.** Benzodiazepines are thought by some gastroenterologists to improve a variety of “anxiety related” gastrointestinal disorders. There is a paucity of evidence for direct actions. Benzodiazepines partially protect against stress ulcers in rats, and diazepam markedly decreases nocturnal gastric secretion in humans. Other
Intermediate-acting agents (t 1/2 6-24 hours), including benzodiazepines. Absorption, Fate, and Excretion. The physicochemical and pharmacokinetic properties of the benzodiazepines greatly affect their clinical utility. They all have high lipid–water distribution coefficients in the non-ionized form; nevertheless, lipophilicity varies >50-fold according to the polarity and electronegativity of various substituents.

All the benzodiazepines are absorbed completely, with the exception of clorazepate; this drug is decarboxylated rapidly in gastric juice to N-desmethyldiazepam (nordazepam), which subsequently is absorbed completely. Drugs active at the benzodiazepine receptor may be divided into four categories based on their elimination t 1/2:

- **Ultra-short-acting benzodiazepines**
- **Short-acting agents** (t 1/2 <6 hours), including triazolam, the non-benzodiazepine zolpidem (t 1/2 ~2 hours), and eszopiclone (t 1/2 5-6 hours)
- **Intermediate-acting agents** (t 1/2 6-24 hours), including estazolam and temazepam
- **Long-acting agents** (t 1/2 >24 hours), including flurazepam, diazepam, and quazepam

Flurazepam itself has a short t 1/2 (~2.3 hours), but a major active metabolite, N-des-alkyl-flurazepam, is long-lived (t 1/2 47-100 hours), which complicates the classification of individual benzodiazepines.

The benzodiazepines and their active metabolites bind to plasma proteins. The extent of binding correlates strongly with lipid solubility and ranges from ~70% for alprazolam to nearly 99% for diazepam. The concentration in the cerebrospinal fluid is approximately equal to the concentration of free drug in plasma. While competition with other protein-bound drugs may occur, no clinically significant examples have been reported.

The plasma concentrations of most benzodiazepines exhibit patterns that are consistent with two-compartment models (Chapter 2), but three-compartment models appear to be more appropriate for the compounds with the highest lipid solubility. Accordingly, there is rapid uptake of benzodiazepines into the brain and other highly perfused organs after intravenous administration (or oral administration of a rapidly absorbed compound); rapid uptake is followed by a phase of redistribution into tissues that are less well perfused, especially muscle and fat. Redistribution is most rapid for drugs with the highest lipid solubility. In the regimens used for nighttime sedation, the rate of redistribution sometimes can have a greater influence than the rate of biotransformation on the duration of CNS effects (Dettli, in Symposium, 1986a). The kinetics of redistribution of diazepam and other lipophilic benzodiazepines are complicated by enterohepatic circulation. The volumes of distribution of the benzodiazepines are large and in many cases are increased in elderly patients. These drugs cross the placental barrier and are secreted into breast milk.

The benzodiazepines are metabolized extensively by hepatic CYPs, particularly CYPs 3A4 and 2C19. Some benzodiazepines, such as oxazepam, are conjugated directly and are not metabolized by these enzymes (Tanaka, 1999). Erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone, and grapefruit juice are inhibitors of CYP3A4 (Chapter 6) and can affect the metabolism of benzodiazepines (Dresser et al., 2000). Because active metabolites of some benzodiazepines are biotransformed more slowly than are the parent compounds, the duration of action of many benzodiazepines bears little relationship to the t 1/2 of elimination of the parent drug that was administered, as noted above for flurazepam. Conversely, the rate of biotransformation of agents that are inactivated by the initial reaction is an important determinant of their duration of action; these agents include oxazepam, lorazepam, temazepam, triazolam, and midazolam.

Metabolism of the benzodiazepines occurs in three major stages. These and the relationships between the drugs and their metabolites are shown in Table 17–2.

For benzodiazepines that bear a substituent at position 1 (or 2) of the diazepine ring, the initial and most rapid phase of metabolism involves modification and/or removal of the substituent. With the exception of triazolam, alprazolam, estazolam, and midazolam, which contain either a fused triazolo or a imidazolo ring, the eventual products are N-desalkylated compounds that are biologically active. One such compound, nordazepam, is a major metabolite common to the biotransformation of diazepam, clorazepate, and prazepam; it also is formed from demoxepam, an important metabolite of chlordiazepoxide.

The second phase of metabolism involves hydroxylation at position 3 and also usually yields an active derivative (e.g., oxazepam from nordazepam). The rates of these reactions are usually very much slower than the first stage (t 1/2 >40–50 hours) such that appreciable accumulation of hydroxylated products with intact substituents at position 1 does not occur. There are two significant exceptions to this rule: (1) small amounts of temazepine accumulate during the chronic administration of diazepam and (2) following the replacement of S with O in quazepam, most of the resulting 2-oxoquazepam is hydroxylated slowly at position 3 without removal of the N-alkyl group. However, only small amounts of the 3-hydroxyl derivative accumulate during chronic administration of quazepam because this compound is conjugated at an unusually rapid rate. In contrast, the N-desalkylflurazepam that is formed by the “minor” metabolic pathway does accumulate during quazepam administration, and it contributes significantly to the overall clinical effect.

The third major phase of metabolism is the conjugation of the 3-hydroxyl compounds, principally with glucuronic acid; the t 1/2 of these reactions usually are ~6–12 hours, and the products invariably are inactive. Conjugation is the only major route of metabolism for oxazepam and lorazepam and is the preferred pathway for temazepam because of the slower conversion of this compound to oxazepam. Triazolam and alprazolam are metabolized principally by initial hydroxylation of the methyl group on the fused triazolo ring; the absence of a chlorine residue in ring C of alprazolam slows this reaction significantly. The products, sometimes referred to as α-hydroxylated compounds, are quite active but are metabolized very
rapidly, primarily by conjugation with glucuronic acid, such that there is no appreciable accumulation of active metabolites. The fused triazolo ring in estazolam lacks a methyl group and is hydroxylated to only a limited extent; the major route of metabolism involves the formation of the 3-hydroxyl derivative. The corresponding hydroxyl derivatives of triazolam and alprazolam also are formed to a significant extent. Compared with compounds without the triazolo ring, the rate of this reaction for all three drugs is unusually swift, and the 3-hydroxyl compounds are rapidly conjugated or oxidized further to benzophenone derivatives before excretion.

Midazolam is metabolized rapidly, primarily by hydroxylation of the methyl group on the fused imidazo ring; only small amounts of 3-hydroxyl compounds are formed. The α-hydroxylated compound, which has appreciable biological activity, is eliminated with a t$_{1/2}$ of 1 hour after conjugation with glucuronic acid. Variable and sometimes substantial accumulation of this metabolite has been noted during intravenous infusion (Oldenhof et al., 1988).

The aromatic rings (A and C) of the benzodiazepines are hydroxylated only to a small extent. The only important metabolism at these sites is reduction of the 7-nitro substituents of clonazepam, nitrazepam, and flunitrazepam; the t$_{1/2}$ of these reactions are usually 20-40 hours. The resulting amines are inactive and are acetylated to varying degrees before excretion.

Because the benzodiazepines apparently do not significantly induce the synthesis of hepatic CYPs, their chronic administration usually does not result in the accelerated metabolism of other substances or of the benzodiazepines. Cimetidine and oral contraceptives inhibit N-dealkylation and 3-hydroxylation of benzodiazepines. Ethanol, isoniazid, and phenytoin are less effective in this regard. These reactions usually are reduced to a greater extent in elderly

*a Compounds enclosed in boxes are marketed in the U.S. The approximate half-lives of the various compounds are denoted in parentheses; S (short-acting), t$_{1/2}$ < 6 hours; I (intermediate-acting), t$_{1/2}$ = 6-24 hours; L (long-acting), t$_{1/2}$ = >24 hours. All compounds except clorazepate are biologically active; the activity of 3-hydroxydesalkylflurazepam has not been determined. Clonazepam (not shown) is an N-desalkyl compound, and it is metabolized primarily by reduction of the 7-NO$_2$ group to the corresponding amine (inactive), followed by acetylation; its t$_{1/2}$ is 20-40 hours. †See text for discussion of other pathways of metabolism. |
patients and in patients with chronic liver disease than are those involving conjugation.

**Pharmacokinetics and the Ideal Hypnotic.** An ideal hypnotic agent would have a rapid onset of action when taken at bedtime, a sufficiently sustained action to facilitate sleep throughout the night, and no residual action by the following morning. Among the benzodiazepines that are used commonly as hypnotic agents, triazolam theoretically fits this description most closely. Because of the slow rate of elimination of desalkylflurazepam, flurazepam (or quazepam) might seem to be unsuitable for this purpose. In practice, there appear to be some disadvantages to the use of agents that have a relatively rapid rate of disappearance, including the early-morning insomnia that is experienced by some patients and a greater likelihood of rebound insomnia on drug discontinuation (Gillin et al., 1989; Roth and Roehrs, 1992). With careful selection of dosage, flurazepam and other benzodiazepines with slower rates of elimination than triazolam can be used effectively. The biotransformation and pharmacokinetic properties of the benzodiazepines have been reviewed (Laurijssens and Greenblatt, 1996).

**Therapeutic Uses**

The therapeutic uses and routes of administration of individual benzodiazepines that are marketed in the U.S. are summarized in Table 17–3. Most benzodiazepines can be used interchangeably. For example, diazepam can be used for alcohol withdrawal, and most benzodiazepines work as hypnotics. In general, the therapeutic uses of a given benzodiazepine depend on its t1/2 and may not match the FDA-approved indications. Benzodiazepines that are useful as anticonvulsants have a long t1/2, and rapid entry into the brain is required for efficacy in treatment of status epilepticus. A short elimination t1/2 is desirable for hypnotics, although this carries the drawback of increased abuse liability and severity of withdrawal after drug discontinuation. Anti-anxiety agents, in contrast, should have a long t1/2 despite the drawback of the risk of neuropsychological deficits caused by drug accumulation.

**Untoward Effects.** At the time of peak concentration in plasma, hypnotic doses of benzodiazepines can be expected to cause varying degrees of light-headedness, lassitude, increased reaction time, motor incoordination, impairment of mental and motor functions, confusion, and anterograde amnesia. Cognition appears to be affected less than motor performance. *All of these effects can greatly impair driving and other psychomotor skills, especially if combined with ethanol.* When the drug is given at the intended time of sleep, the persistence of these effects during the waking hours is adverse. These dose-related residual effects can be insidious because most subjects underestimate the degree of their impairment. Residual daytime sleepiness also may occur, even though successful drug therapy can reduce the daytime sleepiness resulting from chronic insomnia (Dement, 1991). The intensity and incidence of CNS toxicity generally increase with age; both pharmacokinetic and pharmacodynamic factors are involved (Monane, 1992).

Other relatively common side effects of benzodiazepines are weakness, headache, blurred vision, vertigo, nausea and vomiting, epigastric distress, and diarrhea; joint pains, chest pains, and incontinence are much rarer. Anticonvulsant benzodiazepines sometimes actually increase the frequency of seizures in patients with epilepsy. The possible adverse effects of alterations in the sleep pattern are discussed later.

**Adverse Psychological Effects.** Benzodiazepines may cause paradoxical effects. Flurazepam occasionally increases the incidence of nightmares—especially during the first week of use—and sometimes causes garrulousness, anxiety, irritability, tachycardia, and sweating. Amnesia, euphoria, restlessness, hallucinations, sleep-walking, sleep-talking, other complex behaviors, and hypomanic behavior have been reported to occur during use of various benzodiazepines. The release of bizarre uninhibited behavior has been noted in some users, whereas hostility and rage may occur in others; collectively, these are sometimes referred to as disinhibition or dyscontrol reactions. Paranoia, depression, and suicidal ideation also occasionally may accompany the use of these agents. Such paradoxical or disinhibition reactions are rare and appear to be dose related. Because of reports of an increased incidence of confusion and abnormal behaviors, triazolam has been banned in the U.K., although the FDA declared triazolam to be safe and effective in low doses of 0.125–0.25 mg. Surveys in the U.K. after the ban found that patients did not have fewer side effects with replacement treatments (Hindmarch et al., 1993), which is consonant with controlled studies that do not support the conclusion that such reactions occur more frequently with any one benzodiazepine than with others (Jonas et al., 1992; Rothschild, 1992).

Chronic benzodiazepine use poses a risk for development of dependence and abuse (Woods et al., 1992), but not to the same extent as seen with older sedatives and other recognized drugs of abuse (Uhlenhuth et al., 1999). Abuse of benzodiazepines includes the use of flunitrazepam (rohypnol; not licensed for use in the U.S.) as a “date-rape drug” (Woods and Winger, 1997). Mild dependence may develop in many patients who have taken therapeutic doses of benzodiazepines on a regular basis for prolonged periods. Withdrawal symptoms may include temporary intensification of the problems that originally prompted their use (e.g., insomnia or anxiety). Dysphoria, irritability, sweating, unpleasant dreams, tremors, anorexia, and faintness or dizziness also may occur, especially when withdrawal of the benzodiazepine occurs abruptly (Petrusson, 1994). Hence, it is prudent to taper the dosage gradually when therapy is to be discontinued. Despite their adverse effects, benzodiazepines are relatively safe drugs. Even huge doses are rarely fatal unless other drugs are taken concomitantly. Ethanol is a common contributor to deaths involving benzodiazepines, and true coma is uncommon in the absence of another CNS depressant. Although overdosage with a benzodiazepine rarely causes severe cardiovascular or respiratory depression, therapeutic doses can further compromise respiration in patients with COPD or obstructive sleep apnea (see “Respiration” earlier in the chapter).

A wide variety of serious allergic, hepatotoxic, and hematologic reactions to the benzodiazepines may occur, but the incidence is quite low; these reactions have been associated with the use of flurazepam, triazolam, and temazepam. Large doses taken just before or during labor may cause hypothermia, hypotonia, and mild respiratory

*a IM, intramuscular injection; IV, intravenous administration; qd, once a day; bid, twice a day; tid, three times a day; qid, four times a day. b The therapeutic uses are identified as examples to emphasize that most benzodiazepines can be used interchangeably. In general, the therapeutic uses of a given benzodiazepine are related to its t₁/₂ and may not match the marketed indications. The issue is addressed more extensively in the text. c Half-life of active metabolite may differ. See Appendix II for additional information. d For additional dosage information, see Chapter 13 (anesthesia), Chapter 17 (anxiety), and Chapter 19 (seizure disorders). e Approved as a sedative-hypnotic only for management of alcohol withdrawal; doses in a nontolerant individual would be smaller. f Recommended doses vary considerably depending on specific use, condition of patient, and concomitant administration of other drugs.
depression in the neonate. Abuse by the pregnant mother can result in a withdrawal syndrome in the newborn.

Except for additive effects with other sedative or hypnotic drugs, reports of clinically important pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent. Ethanol increases both the rate of absorption of benzodiazepines and the associated CNS depression. Valproate and benzodiazepines in combination may cause psychotic episodes. Pharmacokinetic interactions were discussed earlier.

**Novel Benzodiazepine Receptor Agonists**

Hypnotics in this class are commonly referred to as “Z compounds”. They include zolpidem (AMBIEN), zaleplon (SONATA), zopiclone (not marketed in the U.S.), and eszopiclone (LUNESTA), which is the S(+) enantiomer of zopiclone. Although the Z compounds are structurally unrelated to each other and to benzodiazepines, their therapeutic efficacy as hypnotics is due to agonist effects on the benzodiazepine site of the GABA<sub>A</sub> receptor. Compared to benzodiazepines, Z compounds are less effective as anticonvulsants or muscle relaxants, which may be related to their selective affinity for GABA<sub>A</sub> receptors containing the α1 subunit. Over the last decade, Z compounds have largely replaced benzodiazepines in the treatment of insomnia. Z compounds were initially promoted as having less potential for dependence and abuse than traditional benzodiazepines. However, based on post-marketing clinical experience with zopiclone and zaleplon, tolerance and physical dependence can be expected during long-term use of Z compounds, especially with higher doses (Zammit, 2009). Reports of abuse of Z compounds are on the rise worldwide (Victorri-Vigneau, 2007). Zopiclone and its isomers are classified as schedule IV drugs in the U.S. The clinical presentation of overdose with Z compounds is similar to that of benzodiazepine overdose and can be treated with the benzodiazepine antagonist flumazenil.

Zaleplon and zolpidem are effective in relieving sleep-onset insomnia. Both drugs have been approved by the FDA for use for up to 7-10 days at a time. Zaleplon and zolpidem have sustained hypnotic efficacy without occurrence of rebound insomnia on abrupt discontinuation (Mitler, 2000; Walsh et al., 2000). Zaleplon and zolpidem have similar degrees of efficacy. Zolpidem has a t<sub>1/2</sub> of ~2 hours, which is sufficient to cover most of a typical 8-hour sleep period, and is presently approved for bedtime use only. Zaleplon has a shorter t<sub>1/2</sub> of ~1 hour, which offers the possibility for safe dosing later in the night, within 4 hours of the anticipated rising time. As a result, zaleplon is approved for use immediately at bedtime or when the patient has difficulty falling asleep after bedtime. Because of its short t<sub>1/2</sub>, zaleplon has not been shown to be different from placebo in measures of duration of sleep and number of awakenings. Zaleplon and zolpidem differ in residual side effects; late-night administration of zolpidem has been associated with morning sedation, delayed reaction time, and anterograde amnesia, whereas zaleplon does not differ from placebo.

**Zaleplon.** Zaleplon (SONATA, generic) is a non-benzodiazepine and is a member of the pyrazolopyrimidine class of compounds.

Zaleplon preferentially binds to the benzodiazepine-binding site on GABA<sub>A</sub> receptors containing the α1 receptor subunit. Zaleplon is absorbed rapidly and reaches peak plasma concentrations in ~1 hour. Its bioavailability is ~30% because of presystemic metabolism. Zaleplon has a volume of distribution of ~1.4 L/kg and plasma-protein binding of ~60%. Zaleplon is metabolized largely by aldehyde oxidase and to a lesser extent by CYP3A4. Its oxidative metabolites are converted to glucuronides and eliminated in urine. Less than 1% of zaleplon is excreted unchanged in urine. None of zaleplon’s metabolites are pharmacologically active.

Zaleplon (usually administered in 5-, 10-, or 20-mg doses) has been studied in clinical trials of patients with chronic or transient insomnia (Dooley and Plosker, 2000), focusing on the drug’s effects in decreasing sleep latency. Zaleplon-treated subjects with either chronic or transient insomnia have experienced shorter periods of sleep latency than have placebo-treated subjects.

**Zolpidem.** Zolpidem (AMBIEN, others) is a non-benzodiazepine sedative-hypnotic drug. It is classified as an imidazopyridine:

Although the actions of zolpidem are due to agonist effects on GABA<sub>A</sub> receptors and generally resemble those of benzodiazepines, it produces only weak anticonvulsant effects in experimental animals, and its relatively strong sedative actions appear to mask anxiolytic effects in various animal models of anxiety (Langtry and Benfield, 1990). Although chronic administration of zolpidem to rodents produces neither tolerance to its sedative effects nor signs of withdrawal when the drug is discontinued and flumazenil is injected (Perrault et al., 1992), tolerance and physical dependence have been observed with chronic administration of zolpidem to baboons (Griffiths et al., 1992). During U.S. clinical trials, withdrawal effects within 48 hours of drug discontinuation occurred at an
incidence of 1% or less. Post-marketing reports of abuse, dependence, and withdrawal have been recorded. Unlike the benzodiazepines, zolpidem has little effect on the stages of sleep in normal human subjects. The drug is as effective as benzodiazepines in shortening sleep latency and prolonging total sleep time in patients with insomnia. After discontinuation of zolpidem, the beneficial effects on sleep reportedly persist for up to 1 week (Herrmann et al., 1993), but mild rebound insomnia on the first night also has occurred. Tolerance and physical dependence develop only rarely and under unusual circumstances (Cavallaro et al., 1993; Morselli, 1993). Indeed, zolpidem-induced improvement in sleep time of chronic insomniacs was sustained during as much as 6 months of treatment without signs of withdrawal or rebound after stopping the drug (Kummer et al., 1993). Nevertheless, zolpidem is approved only for the short-term treatment of insomnia. At therapeutic doses (5 to 10 mg), zolpidem infrequently produces residual daytime sedation or amnesia, and the incidence of other adverse effects (e.g., GI complaints or dizziness) is also low. As with the benzodiazepines, large overdoses of zolpidem do not produce severe respiratory depression unless other agents (e.g., ethanol) also are ingested (Garnier et al., 1994). Hypnotic doses increase the hypoxia and hypercapnia of patients with obstructive sleep apnea.

Zolpidem is absorbed readily from the GI tract; first-pass hepatic metabolism results in an oral bioavailability of ~70%, but this value is lower when the drug is ingested with food because of slowed absorption and increased hepatic blood flow. Zolpidem is eliminated almost entirely by conversion to inactive products in the liver, largely through oxidation of the methyl groups on the phenyl and imidazopyridine rings to the corresponding carboxylic acids. Its plasma t1/2 is ~2 hours in individuals with normal hepatic blood flow or function. This value may be increased 2-fold or more in those with cirrhosis and also tends to be greater in older patients; adjustment of dosage often is necessary in both categories of patients. Although little or no unchanged zolpidem is found in the urine, elimination of the drug is slower in patients with chronic renal insufficiency largely owing to an increase in its apparent volume of distribution.

Eszopiclone. Eszopiclone (LUNESTA) is the active S(+) enantiomer of zopiclone. Eszopiclone has no structural similarity to benzodiazepines, zolpidem, or zaleplon. Eszopiclone is used for the long-term treatment of insomnia and for sleep maintenance. It is prescribed to patients who have difficulty falling asleep as well as those who experience difficulty staying asleep, and is available in 1-, 2-, or 3-mg tablets.

Eszopiclone received FDA approval based on six randomized placebo-controlled clinical trials that showed it has efficacy in treating transient (Rosenberg et al., 2005) and chronic insomnia. In the transient insomnia study subjects receiving the drug showed a decreased latency to attain sleep, increased sleep efficiency, and fewer awakenings, as measured by both polysomnography and a morning questionnaire. There were no observed psychomotor aftereffects observed the next day. Eszopiclone also possesses efficacy as a sleep aid when taken chronically, for as long as 12 months (Melton et al., 2005). All chronic studies conducted to date found that eszopiclone decreased the latency to onset of sleep. No tolerance was observed, nor were signs of serious withdrawal, such as seizures or rebound insomnia, seen upon discontinuation of the drug. However, there are such reports for zopiclone, the racemate used outside the U.S. Mild withdrawal consisting of abnormal dreams, anxiety, nausea, and upset stomach can occur (rate ≤2%). A minor reported adverse effect of eszopiclone was a bitter taste. Eszopiclone is a schedule IV controlled substance in the U.S.

Eszopiclone is absorbed rapidly after oral administration, with a bioavailability of ~80%, and shows wide distribution throughout the body. It is 50-60% bound to plasma proteins and has a t1/2 of ~6 hours. It is metabolized by CYPs 3A4 and 2E1. Eszopiclone is believed to exert its sleep-promoting effects through its enhancement of GABA_A receptor function at the benzodiazepine binding site (Hanson et al., 2008; Jia et al., 2009).

### FLUMAZENIL: A BENZODIAZEPINE RECEPTOR ANTAGONIST

Flumazenil (ROMAZICON, generic), the only member of this class, is an imidazobenzodiazepine (Table 17–1) that behaves as a specific benzodiazepine receptor antagonist (Hoffman and Warren, 1993). Flumazenil binds with high affinity to specific sites on the GABA_A receptor, where it competitively antagonizes the binding and allosteric effects of benzodiazepines and other ligands. Flumazenil antagonizes both the electrophysiological and behavioral effects of agonist and inverse-agonist benzodiazepines and β-carbolines. The drug is given intravenously.

In animal models, the intrinsic pharmacological actions of flumazenil have been subtle; effects resembling those of inverse agonists sometimes have been detected at low doses, whereas slight benzodiazepine-like effects often have been evident at high doses. The evidence for intrinsic activity in human subjects is even more vague, except for modest anticonvulsant effects at high doses. However, anticonvulsant effects cannot be relied on for therapeutic utility because the administration of flumazenil may precipitate seizures under certain circumstances (discussed later).
Flumazenil is available only for intravenous administration. On intravenous administration, flumazenil is eliminated almost entirely by hepatic metabolism to inactive products with a half-life of ~1 hour; the duration of clinical effects usually is only 30-60 minutes. Although absorbed rapidly after oral administration, <25% of the drug reaches the systemic circulation owing to extensive first-pass hepatic metabolism; effective oral doses are apt to cause headache and dizziness.

The primary indications for the use of flumazenil are the management of suspected benzodiazepine overdose and the reversal of sedative effects produced by benzodiazepines administered during either general anesthesia or diagnostic and/or therapeutic procedures.

The administration of a series of small injections is preferred to a single bolus injection. A total of 1 mg flumazenil given over 1-3 minutes usually is sufficient to abolish the effects of therapeutic doses of benzodiazepines; patients with suspected benzodiazepine overdose should respond adequately to a cumulative dose of 1-5 mg given over 2-10 minutes; a lack of response to 5 mg flumazenil strongly suggests that a benzodiazepine is not the major cause of sedation. Additional courses of treatment with flumazenil may be needed within 20-30 minutes should sedation reappear.

Flumazenil is not effective in single-drug overdoses with either barbiturates or tricyclic antidepressants. To the contrary, the administration of flumazenil in these settings may be associated with the onset of seizures, especially in patients poisoned with tricyclic antidepressants (Spivey, 1992). Seizures or other withdrawal symptoms also may be precipitated in patients who had been taking benzodiazepines for protracted periods and in whom tolerance and/or dependence may have developed.

**MELATONIN CONGENERS**

Ramelteon. Ramelteon (ROZEREM) is a synthetic tricyclic analog of melatonin with the chemical name (S)-N-[2-(1,6,7,8-tetrahydro-2H-indeno[5,4-b] furan-8-y1)ethyl] propionamid. It was approved in the U.S. in 2005 for the treatment of insomnia, specifically sleep onset difficulties. Unlike other drugs licensed by the FDA for insomnia, ramelteon is not a controlled substance.

**Mechanism of Action.** Melatonin levels in the suprachiasmatic nucleus rise and fall in a circadian fashion, with concentrations increasing in the evening as an individual prepares for sleep, and then reaching a plateau and ultimately decreasing as the night progresses. Two GPCRs for melatonin, MT$_1$ and MT$_2$, are found in the suprachiasmatic nucleus, each playing a different role in sleep. Binding of agonists, such as melatonin, to MT$_1$ receptors promotes the onset of sleep while melatonin binding to MT$_2$ receptors shifts the timing of the circadian system (Liu et al., 1997). Ramelteon binds to both MT$_1$ and MT$_2$ receptors with high affinity but, unlike melatonin, it does not bind appreciably to quinone reductase 2, the structurally unrelated MT$_3$ receptor (Nosjean et al., 2000). Ramelteon is not known to bind to any other classes of receptors, such as nicotinic acetylcholine, neuropeptide, dopamine, or opiate receptors, or the benzodiazepine-binding site on GABA$_{	ext{A}}$ receptors.

**Clinical Pharmacology.** Prescribing guidelines suggest that an 8-mg tablet be taken ~30 minutes before bedtime. Ramelteon is rapidly absorbed from the GI tract and a peak serum concentration is obtained within an hour (Hibberd and Stevenson 2004). Because of the significant first-pass metabolism that occurs after oral administration, ramelteon bioavailability is <2% (Amakye et al., 2004). In the bloodstream, ~80% of ramelteon is protein bound (Takeda Pharmaceuticals North America, 2006). The drug is largely metabolized by the hepatic CYPs 1A2, 2C, and 3A4, with t$_{1/2}$ of ~2 hours in humans. Of the four metabolites, one, M-II, acts as an agonist at MT$_1$ and MT$_2$ receptors and may contribute to the sleep-promoting effects of ramelteon.

Ramelteon is efficacious in combating both transient and chronic insomnia. Subjects given 16 or 64 mg of ramelteon in a clinical trial showed a significantly shorter latency to sleep onset, as well as increased total sleep time, compared to placebo controls (Roth et al., 2005); the drug was generally well tolerated by patients and did not impair next-day cognitive function. Ramelteon is also useful in the treatment of chronic insomnia, with no tolerance occurring in its reduction of sleep onset latency even after 6 months of drug administration (Mayer et al., 2009). Sleep latency, evaluated by polysomnography as well as by subject questionnaires, was consistently found to be shorter in patients given ramelteon compared to placebo controls (Erman et al., 2006; Zammit et al., 2007). No evidence of rebound insomnia or withdrawal effects were noted upon ramelteon withdrawal. Ramelteon appears to act by producing a phase advance of the endogenous circadian rhythm (Richardson et al., 2008).

In animals, ramelteon does not produce discriminative stimulus effects similar to those of benzodiazepine receptor agonists, and long-term administration has no effects on spontaneous or operant behaviors, motor activity or posture (France et al., 2006). In addition, ramelteon has no demonstrated positive reinforcing effects in intravenous self-administration experiments performed in rhesus monkeys and there is no indication of abuse liability in humans (Griffiths and Johnson, 2005).

**BARBITURATES**

The barbiturates were once used extensively as sedative-hypnotic drugs. Except for a few specialized uses, they have been largely replaced by the much safer benzodiazepines.

**Chemistry.** Barbituric acid is 2,4,6-trioxohexahydropyrimidine. This compound lacks central depressant activity, but the presence of alkyl or aryl groups at position 5 confers sedative-hypnotic and sometimes other activities. The general structural formula for the barbiturates and the structures of selected compounds are included in Table 17–4.

<sup>a</sup>O except in thiopental, where it is replaced by S.<sup>b</sup>IM, intramuscular injection; IV, intravenous administration. <sup>c</sup>Value represents terminal t<sub>1/2</sub> due to metabolism by the liver; redistribution following parenteral administration produces effects lasting only a few minutes.

![Diagram of the structures of barbiturates](image)
The carbonyl group at position 2 takes on acidic character because of lactam–lactim ("keto"–"enol") tautomerization, which is favored by its location between the two electronegative amido nitrogens. The lactim form is favored in alkaline solution, and salts result. Barbiturates in which the oxygen at C2 is replaced by sulfur sometimes are called thiobarbiturates. These compounds are more lipidsoluble than the corresponding oxybarbiturates. In general, structural changes that increase lipid solubility decrease duration of action, decrease latency to onset of activity, accelerate metabolic degradation, and increase hypnotic potency.

**Pharmacological Properties**

The barbiturates reversibly depress the activity of all excitable tissues. The CNS is exquisitely sensitive, and even when barbiturates are given in anesthetic concentrations, direct effects on peripheral excitable tissues are weak. However, serious deficits in cardiovascular and other peripheral functions occur in acute barbiturate intoxication.

**Central Nervous System**

*Sites and Mechanisms of Action on the CNS.* Barbiturates act throughout the CNS; non-anesthetic doses preferentially suppress polysynaptic responses. Facilitation is diminished, and inhibition usually is enhanced. The site of inhibition is either postsynaptic, as at cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamic relay neurons, or pre-synaptic, as in the spinal cord. Enhancement of inhibition occurs primarily at synapses where neurotransmission is mediated by GABA acting at GABA<sub>Α</sub> receptors.

The barbiturates exert several distinct effects on excitatory and inhibitory synaptic transmission. For example, (–)-pentobarbital potentiates GABA-induced increases in chloride conductance and depresses voltage-activated Ca<sup>2+</sup> currents at similar concentrations (below 10 μM) in isolated hippocampal neurons; above 100 μM, chloride conductance is increased in the absence of GABA (French-Mullen et al., 1993). Phenobarbital is less efficacious and much less potent in producing these effects, whereas (+)-pentobarbital has only weak activity. Thus, the more selective anticonvulsant properties of phenobarbital and its higher therapeutic index may be explained by its lower capacity to depress neuronal function as compared with the anesthetic barbiturates.

The mechanisms underlying the actions of barbiturates on GABA<sub>Α</sub> receptors appear to be distinct from those of either GABA or the benzodiazepines for reasons that include the following:

- Like benzodiazepines, barbiturates enhance the binding of GABA to GABA<sub>Α</sub> receptors in a Cl<sup>-</sup>-dependent and picrotoxin-sensitive fashion; however, barbiturates promote (rather than reduce) the binding of benzodiazepines.
- Barbiturates potentiate GABA-induced Cl<sup>-</sup> currents by prolonging periods during which bursts of channel opening occur rather than by increasing the frequency of these bursts, as benzodiazepines do.
- Only α and β (not γ) subunits are required for barbiturate action.
- Barbiturate-induced increases in Cl<sup>-</sup> conductance are not affected by the deletion of the tyrosine and threonine residues in the β subunit that govern the sensitivity of GABA<sub>Α</sub> receptors to activation by agonists (Amin and Weiss, 1993).

Sub-anesthetic concentrations of barbiturates also can reduce glutamate-induced depolarizations (Macdonald and McLean, 1982) (Chapter 12); only the AMPA subtypes of glutamate receptors sensitive to kainic acid (Figure 14–10) or quisqualic acid appear to be affected (Marszalec and Narahashi, 1993). At higher concentrations that produce anesthesia, pentobarbital suppresses high-frequency repetitive firing of neurons, apparently as a result of inhibiting the function of voltage-dependent, tetrodotoxin-sensitive Na<sup>+</sup> channels (Figure 11–4); in this case, however, both stereoisomers are about equally effective (Frenkel et al., 1990). At still higher concentrations, voltage-dependent K<sup>+</sup> conductances are reduced. Taken together, the findings that barbiturates activate inhibitory GABA<sub>Α</sub> receptors and inhibit excitatory AMPA receptors can explain their CNS-depressant effects (Saunders and Ho, 1990).

Barbiturates can produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia. The use of barbiturates for general anesthesia is discussed in Chapter 19. Certain barbiturates, particularly those containing a 5-phenyl substituent (e.g., phenobarbital and mephobarbital), have selective anticonvulsant activity (Chapter 21). The anti-anxiety properties of the barbiturates are inferior to those exerted by the benzodiazepines.

Except for the anticonvulsant activities of phenobarbital and its congeners, the barbiturates possess a low degree of selectivity and a narrow therapeutic index. Thus, it is not possible to achieve a desired effect without evidence of general depression of the CNS. Pain perception and reaction are relatively unimpaired until the moment of unconsciousness, and in small doses, barbiturates increase reactions to painful stimuli. Hence, they cannot be relied on to produce sedation or sleep in the presence of even moderate pain.

**Effects on Stages of Sleep.** Hypnotic doses of barbiturates increase the total sleep time and alter the stages of sleep in a dose-dependent manner. Like the benzodiazepines, these drugs decrease sleep latency, the number of awakenings, and the durations of REM and slow-wave sleep. During repetitive nightly administration, some tolerance to the effects on sleep occurs within a few days, and the effect on total sleep time may be reduced by as much as 50% after 2 weeks of use. Discontinuation leads to rebound increases in all the parameters reported to be decreased by barbiturates.

**Tolerance.** Pharmacodynamic (functional) and pharmacokinetic tolerance to barbiturates can occur. The former contributes more to the decreased effect than does the latter. With chronic administration of gradually increasing doses, pharmacodynamic tolerance continues to develop over a period of weeks to months, depending on the dosage schedule, whereas pharmacokinetic tolerance reaches its peak in a few days to a week. Tolerance to the effects on mood, sedation, and hypnosis occurs more readily and is greater than that to the anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases. Pharmacodynamic tolerance to barbiturates confers cross-tolerance to all general CNS-depressant drugs, including ethanol.
Abuse and Dependence. Like other CNS depressant drugs, barbiturates are abused, and some individuals develop a dependence on them (Chapter 24). Moreover, the barbiturates may have euphoriant effects.

Peripheral Nervous Structures. Barbiturates selectively depress transmission in autonomic ganglia and reduce nicotinic excitation by choline esters. This effect may account, at least in part, for the fall in blood pressure produced by intravenous oxybarbiturates and by severe barbiturate intoxication. At skeletal neuromuscular junctions, the blocking effects of both tubocurarine and decamethonium are enhanced during barbiturate anesthesia. These actions probably result from the capacity of barbiturates at hypnotic or anesthetic concentrations to inhibit the passage of current through nicotinic cholinergic receptors. Several distinct mechanisms appear to be involved, and little stereoselectivity is evident.

Respiration. Barbiturates depress both the respiratory drive and the mechanisms responsible for the rhythmic character of respiration. The neurogenic drive is diminished by hypnotic doses but usually no more so than during natural sleep. However, neurogenic drive is essentially eliminated by a dose three times greater than that used normally to induce sleep. Such doses also suppress the hypoxic drive and, to a lesser extent, the chemoreceptor drive. At still higher doses, the powerful hypoxic drive fails. However, the margin between the lighter planes of surgical anesthesia and dangerous respiratory depression is sufficient to permit the ultra-short-acting barbiturates to be used, with suitable precautions, as anesthetic agents.

The barbiturates only slightly depress protective reflexes until the degree of intoxication is sufficient to produce severe respiratory depression. Coughing, sneezing, hiccupping, and laryngospasm may occur when barbiturates are employed as intravenous anesthetic agents. Indeed, laryngospasm is one of the chief complications of barbiturate anesthesia.

Cardiovascular System. When given orally in sedative or hypnotic doses, barbiturates do not produce significant overt cardiovascular effects except for a slight decrease in blood pressure and heart rate such as occurs in normal sleep. In general, the effects of thiopental anesthesia on the cardiovascular system are benign in comparison with those of the volatile anesthetic agents; there usually is either no change or a fall in mean arterial pressure (Chapter 19).

Apparently, a decrease in cardiac output usually is sufficient to offset an increase in peripheral resistance, which sometimes is accompanied by an increase in heart rate. Cardiovascular reflexes are obtunded by partial inhibition of ganglionic transmission. This is most evident in patients with congestive heart failure or hypovolemic shock, whose reflexes already are operating maximally and in whom barbiturates can cause an exaggerated fall in blood pressure. Because barbiturates also impair reflex cardiovascular adjustments to inflation of the lung, positive-pressure respiration should be used cautiously and only when necessary to maintain adequate pulmonary ventilation in patients who are anesthetized or intoxicated with a barbiturate.
