Other cardiovascular changes often noted when thiopental and other intravenous thiobarbiturates are administered after conventional preanesthetic medication include decreased renal and cerebral blood flow with a marked fall in CSF pressure. Although cardiac arrhythmias are observed only infrequently, intravenous anesthesia with barbiturates can increase the incidence of ventricular arrhythmias, especially when epinephrine and halothane also are present. Anesthetic concentrations of barbiturates have direct electrophysiological effects on the heart; in addition to depressing Na+ channels, they reduce the function of at least two types of K+ channels (Nattel et al., 1990; Pancrazio et al., 1993). However, direct depression of cardiac contractility occurs only when doses several times those required to cause anesthesia are administered, which probably contributes to the cardiovascular depression that accompanies acute barbiturate poisoning.

GI Tract. The oxybarbiturates tend to decrease the tone of the GI musculature and the amplitude of rhythmic contractions. The locus of action is partly peripheral and partly central, depending on the dose. A hypnotic dose does not significantly delay gastric emptying in humans. The relief of various GI symptoms by sedative doses is probably largely due to the central-depressant action.

Liver. The best-known effects of barbiturates on the liver are those on the microsomal drug-metabolizing system (Chapter 6), a site at which significant drug-drug interactions can occur. These effects vary with the duration of exposure to the barbiturate.

Acutely, the barbiturates combine with several CYPs and inhibit the biotransformation of a number of other drugs and endogenous substrates, such as steroids; other substrates may reciprocally inhibit barbiturate biotransformations. Drug interactions may result even when the other substances and barbiturates are oxidized by different microsomal enzyme systems.

Chronic administration of barbiturates markedly increases the protein and lipid content of the hepatic smooth endoplasmic reticulum, as well as the activities of glucuronofl transferase and CYPs 1A2, 2C9, 2C19, and 3A4. The induction of these enzymes increases the metabolism of a number of drugs and endogenous substances, including steroid hormones, cholesterol, bile salts, and vitamins K and D. This also results in an increased rate of barbiturate metabolism, which partly accounts for tolerance to barbiturates. Many sedative-hypnotics, various anesthetics, and ethanol also are metabolized by and/or induce the microsomal enzymes, and some degree of cross-tolerance therefore can occur. Not all microsomal biotransformations of drugs and endogenous substrates are affected equally, but a convenient rule of thumb is that at maximal induction in humans, the rates are approximately doubled. The inducing effect is not limited to the microsomal enzymes; for example, there are increases in δ-aminolevulinic acid (ALA) synthetase, a mitochondri al enzyme, and aldehyde dehydrogenase, a cytosolic enzyme. The effect of barbiturates on ALA synthetase can cause dangerous disease exacerbations in persons with intermittent porphyria.

Kidney. Severe oliguria or anuria may occur in acute barbiturate poisoning largely as a result of the marked hypotension.
Absorption, Fate, and Excretion. For sedative-hypnotic use, the barbiturates usually are administered orally (Table 17–4). Such doses are absorbed rapidly and probably completely; Na⁺ salts are absorbed more rapidly than the corresponding free acids, especially from liquid formulations. The onset of action varies from 10-60 minutes, depending on the agent and the formulation, and is delayed by the presence of food in the stomach. When necessary, intramuscular injections of solutions of the Na⁺ salts should be placed deeply into large muscles to avoid the pain and possible necrosis that can result at more superficial sites. The intravenous route usually is reserved for the management of status epilepticus (phenobarbital sodium) or for the induction and/or maintenance of general anesthesia (e.g., thiopental or methohexital).

Barbiturates are distributed widely, and they readily cross the placenta. The highly lipid-soluble barbiturates, led by those used to induce anesthesia, undergo redistribution after intravenous injection. Uptake into less vascular tissues, especially muscle and fat, leads to a decline in the concentration of barbiturate in the plasma and brain. With thiopental and methohexital, this results in the awakening of patients within 5-15 minutes of the injection of the usual anesthetic doses (Chapter 19).

Except for the less lipid-soluble aprobarbital and phenobarbital, nearly complete metabolism and/or conjugation of barbiturates in the liver precedes their renal excretion. The oxidation of radicals at C5 is the most important biotransformation that terminates biological activity. Oxidation results in the formation of alcohols, ketones, phenols, or carboxylic acids, which may appear in the urine as such or as glucuronic acid conjugates. In some instances (e.g., phenobarbital), N-glycosylation is an important metabolic pathway. Other biotransformations include N-hydroxylation, desulfuration of thiobarbiturates to oxobarbiturates, opening of the barbituric acid ring, and N-dealkylation of N-alkyl barbiturates to active metabolites (e.g., mephobarbital to phenobarbital). About 25% of phenobarbital and nearly all of aprobarbital are excreted unchanged in the urine. Their renal excretion can be increased greatly by osmotic diuresis and/or alkalization of the urine.

The metabolic elimination of barbiturates is more rapid in young people than in the elderly and infants, and t₁/₂ are increased during pregnancy partly because of the expanded volume of distribution. Chronic liver disease, especially cirrhosis, often increases the t₁/₂ of the biotransformable barbiturates. Repeated administration, especially of phenobarbital, shortens the t₁/₂ of barbiturates that are metabolized as a result of the induction of microsomal enzymes.

None of the barbiturates used for hypnosis in the U.S. appears to have an elimination t₁/₂ that is short enough for elimination to be virtually complete in 24 hours (Table 17–4). However, the relationship between duration of action and t₁/₂ of elimination is complicated by the fact that enantiomers of optically active barbiturates often differ in both biological potencies and rates of biotransformation. All of these barbiturates will accumulate during repetitive administration unless appropriate adjustments in dosage are made.

Furthermore, the persistence of the drug in plasma during the day favors the development of tolerance and abuse.

Therapeutic Uses

The major uses of individual barbiturates are listed in Table 17–4. As with the benzodiazepines, the selection of a particular barbiturate for a given therapeutic indication is based primarily on pharmacokinetic considerations.

CNS Uses. Benzodiazepines and other compounds for sedation have largely replaced barbiturates. Barbiturates, especially butabarbital and phenobarbital, are used sometimes to antagonize unwanted CNS-stimulant effects of various drugs, such as ephedrine, dextroamphetamine, and theophylline, although a preferred approach is adjustment of dosage or substitution of alternative therapy for the primary agents (see Chapter 24).

Untoward Effects

After-Effects. Drowsiness may last for only a few hours after a hypnotic dose of barbiturate, but residual CNS depression sometimes is evident the following day, and subtle distortions of mood and impairment of judgment and fine motor skills may be demonstrable. For example, a 200-mg dose of secobarbital has been shown to impair performance of driving or flying skills for 10-22 hours. Residual effects also may take the form of vertigo, nausea, vomiting, or diarrhea, or sometimes may be manifested as overt excitement. The user may awaken slightly intoxicated and feel euphoric and energetic; later, as the demands of daytime activities challenge possibly impaired faculties, the user may display irritability and temper.

Paradoxical Excitement. In some persons, barbiturates produce excitement rather than depression, and the patient may appear to be inebriated. This type of idiosyncrasy is relatively common among geriatric and debilitated patients and occurs most frequently with phenobarbital and N-methylbarbiturates. Barbiturates may cause restlessness, excitement, and even delirium when given in the presence of pain and may worsen a patient’s perception of pain.

Hypersensitivity. Allergic reactions occur, especially in persons with asthma, urticaria, angioedema, or similar conditions. Hypersensitivity reactions include localized swellings, particularly of the eyelids, cheeks, or lips, and erythematous dermatitis. Rarely, exfoliative dermatitis may be caused by phenobarbital and can prove fatal; the skin eruption may be associated with fever, delirium, and marked degenerative changes in the liver and other parenchymatous organs.

Drug Interactions. Barbiturates combine with other CNS depressants to cause severe depression; ethanol is the most frequent offender, and interactions with first-generation antihistamines also are common. Isoniazid, methylphenidate, and monoamine oxidase inhibitors also increase the CNS-depressant effects.

Barbiturates competitively inhibit the metabolism of certain other drugs; however, the greatest number of drug interactions results from induction of hepatic CYPs and the accelerated disappearance of many drugs and endogenous substances. The metabolism of vitamins D and K is accelerated, which may hamper bone mineralization and lower Ca²⁺ absorption in patients taking phenobarbital and may be responsible for the reported coagulation defects in neonates whose mothers had been taking phenobarbital. Hepatic
enzyme induction enhances metabolism of endogenous steroid hormones, which may cause endocrine disturbances, as well as of oral contraceptives, which may result in unwanted pregnancy. Barbiturates also induce the hepatic generation of toxic metabolites of chlorocarbons (chloroform, trichloroethylene, carbon tetrachloride) and consequently promote lipid peroxidation, which facilitates periportal necrosis of the liver caused by these agents.

**Other Untoward Effects.** Because barbiturates enhance porphyrin synthesis, they are absolutely contraindicated in patients with acute intermittent porphyrin or porphyria variegate. In hypnotic doses, the effects of barbiturates on the control of respiration are minor; however, in the presence of pulmonary insufficiency, serious respiratory depression may occur, and the drugs thus are contraindicated. Rapid intravenous injection of a barbiturate may cause cardiovascular collapse before anesthesia ensues, so the CNS signs of depth of anesthesia may fail to give an adequate warning of impending toxicity. Blood pressure can fall to shock levels; even slow intravenous injection of barbiturates often produces apnea and occasionally laryngospasm, coughing, and other respiratory difficulties.

**Barbiturate Poisoning.** The incidence of barbiturate poisoning has declined markedly, largely as a result of their decreased use as sedative-hypnotic agents. Nevertheless, poisoning with barbiturates is a significant clinical problem, and death occurs in a few percent of cases (Gary and Treszniewsky, 1983). Most of the cases are the result of deliberate attempts at suicide, but some are from accidental poisonings in children or in drug abusers. The lethal dose of barbiturate varies, but severe poisoning is likely to occur when >10 times the full hypnotic dose has been ingested at once. If alcohol or other depressant drugs also are present, the concentrations that can cause death are lower.

In severe intoxication, the patient is comatose; respiration is affected early. Breathing may be either slow or rapid and shallow. Eventually, blood pressure falls because the effect of the drug and of hypoxia on medullary vasomotor centers; depression of cardiac contractility and sympathetic ganglia also contributes. Pulmonary complications (e.g., atelectasis, edema, and bronchopneumonia) and renal failure are likely to be the fatal complications of severe barbiturate poisoning.

The treatment of acute barbiturate intoxication is based on general supportive measures, which are applicable in most respects to poisoning by any CNS depressant. Hemodialysis or hemoperfusion is necessary only rarely, and the use of CNS stimulants is contraindicated because they increase the mortality rate. If renal and cardiac functions are satisfactory, and the patient is hydrated, forced diuresis and alkalization of the urine will hasten the excretion of phenobarbital. Measures to prevent or treat atelectasis should be taken, and mechanical ventilation should be initiated when indicated. See Chapter 4, *Drug Toxicity and Poisoning.*

In severe acute barbiturate intoxication, circulatory collapse is a major threat. Often the patient is admitted to the hospital with severe hypotension or shock, and dehydration frequently is severe. Hypovolemia must be corrected, and if necessary, the blood pressure can be supported with dopamine. Acute renal failure consequent to shock and hypoxia accounts for perhaps one-sixth of the deaths. In the event of renal failure, hemodialysis should be instituted.

**MISCELLANEOUS SEDATIVE-HYPNOTIC DRUGS**

Many drugs with diverse structures have been used for their sedative-hypnotic properties, including ramelteon, paraldehyde, chloral hydrate, and meprobamate. With the exception of ramelteon and meprobamate, the pharmacological actions of these drugs generally resemble those of the barbiturates: they all are general CNS depressants that can produce profound hypnosis with little or no analgesia; their effects on the stages of sleep are similar to those of the barbiturates; their therapeutic index is limited, and acute intoxication, which produces respiratory depression and hypotension, is managed similarly to barbiturate poisoning; their chronic use can result in tolerance and physical dependence; and the syndrome after chronic use can be severe and life-threatening. The properties of meprobamate bear some resemblance to those of the benzodiazepines, but the drug has a distinctly higher potential for abuse and has less selective anti-anxiety effects.

The clinical use of these agents has decreased markedly, and deservedly so. Some of them may be useful in certain settings, particularly in hospitalized patients. The chemical structures and major pharmacological properties of paraldehyde, ethchlorvynol (PLACIDYL, others), chloral hydrate (NOCTEC, others), meprobamate, glutethimide, methyprylon, and etizolam can be found in previous editions of this book.

**Paraldehyde.** Paraldehyde is a polymer of acetaldehyde, basically a cyclic polyether. It has a strong odor and a disagreeable taste. Orally, it is irritating to the throat and stomach, and it is not administered parenterally because of its injurious effects on tissues. Use of paraldehyde has been discontinued in the U.S.

**Chloral Hydrate.** Chloral hydrate is formed by adding one molecule of water to the carbonyl group of chloral (2,2,2-trichloroacetaldehyde). Chloral hydrate may be used to treat patients with paradoxical reactions to benzodiazepines. Chloral hydrate is reduced rapidly to the active compound, trichloroethanol (CCI,CH₂OH), largely by hepatic alcohol dehydrogenase; significant amounts of chloral hydrate are not found in the blood after its oral administration. Therefore, its pharmacological effects probably are caused by trichloroethanol. Indeed, the latter compound can exert barbiturate-like effects on GABAₐ receptor channels *in vitro* (Lovingier et al., 1993).

Chloral hydrate is best known in the U.S. as a literary poison, the “knock-out drops” added to a strong alcoholic beverage to produce a “Mickey Finn” or “Mickey,” a cocktail given to an unwitting imbibner to render him malleable or unconscious, most famously Sam Spade in Dashiell Hammett’s 1930 novel, *The Maltese Falcon.* Now that detectives drink wine rather than whiskey, this off-label use of chloral hydrate has waned.
Meprobamate. Meprobamate a bis-carbamate ester, was introduced as an anti-anxiety agent and this remains its only approved use in the U.S. However, it also became popular as a sedative-hypnotic drug and is discussed here mainly because of its continued use for such purposes. The question of whether the sedative and anti-anxiety actions of meprobamate differ is unanswered, and clinical proof for the efficacy of meprobamate as a selective anti-anxiety agent in humans is lacking.

The pharmacological properties of meprobamate resemble those of the benzodiazepines in a number of ways. Meprobamate can release suppressed behaviors in experimental animals at doses that cause little impairment of locomotor activity, and although it can cause widespread depression of the CNS, it cannot produce anesthesia. However, ingestion of large doses of meprobamate alone can cause severe or even fatal respiratory depression, hypotension, shock, and heart failure. Meprobamate appears to have a mild analgesic effect in patients with musculoskeletal pain, and it enhances the analgesic effects of other drugs.

Meprobamate is well absorbed when administered orally. Nevertheless, an important aspect of intoxication with meprobamate is the formation of gastric bezoars consisting of undissolved meprobamate tablets; hence treatment may require endoscopy, with mechanical removal of the bezoar. Most of the drug is metabolized in the liver, mainly to a side-chain hydroxy derivative and a glucuronide; the kinetics of elimination may depend on the dose. The t1/2 of meprobamate may be prolonged during its chronic administration, even though the drug can induce some hepatic CYPs.

The major unwanted effects of the usual sedative doses of meprobamate are drowsiness and ataxia; larger doses produce considerable impairment of learning and motor coordination and prolongation of reaction time. Like the benzodiazepines, meprobamate enhances the CNS depression produced by other drugs.

The abuse of meprobamate has continued despite a substantial decrease in the clinical use of the drug. Carisoprodol (SOMA), a skeletal muscle relaxant whose active metabolite is meprobamate, also has abuse potential and has become a popular “street drug” (Reeves et al., 1999). Meprobamate is preferred to the benzodiazepines by subjects with a history of drug abuse. After long-term medication, abrupt discontinuation evokes a withdrawal syndrome usually characterized by anxiety, insomnia, tremors, and, frequently, hallucinations; generalized seizures occur in ~10% of cases. The intensity of symptoms depends on the dosage ingested.

Other Agents. Etomidate (AMIDATE, generic) is used in the U.S. and other countries as an intravenous anesthetic, often in combination with fentanyl. It is advantageous because it lacks pulmonary and vascular depressant activity, although it has a negative inotropic effect on the heart. Its pharmacology and anesthetic uses are described in Chapter 13. It also is used in some countries as a sedative-hypnotic drug in intensive care units, during intermittent positive-pressure breathing, in epidural anesthesia, and in other situations. Because it is administered only intravenously, its use is limited to hospital settings. The myoclonus commonly seen after anesthetic doses is not seen after sedative-hypnotic doses.

Clomethiazole has sedative, muscle relaxant, and anticonvulsant properties. It is used outside the U.S. for hypnosis in elderly and institutionalized patients, for preanesthetic sedation, and especially in the management of withdrawal from ethanol (Symposium, 1986b). Given alone, its effects on respiration are slight, and the therapeutic index is high. However, deaths from adverse interactions with ethanol are relatively frequent.

Propofol (DIPRIVAN) is a rapidly acting and highly lipophilic disopropylphenol used in the induction and maintenance of general anesthesia (Chapter 19), as well as in the maintenance of long-term sedation. Propofol sedation is of a similar quality to that produced by midazolam. Emergence from sedation occurs quickly owing to its rapid clearance (McKeage and Perry, 2003). Propofol has found use in intensive care sedation in adults (McKeage and Perry, 2003), as well as for sedation during gastrointestinal endoscopy procedures (Heuss and Inauen, 2004) and transvaginal oocyte retrieval (Dell and Cloote, 1998). Although its mechanism of action is not understood completely, propofol is believed to act primarily through enhancement of GABA_A receptor function. Effects on other ligand-gated channels and GPCRs also have been reported (Trapani et al., 2000).

Nonprescription Hypnotic Drugs. As part of the ongoing systematic review of over-the-counter (OTC) drug products, the FDA has ruled that diphenhydramine is the only antihistamine that is recognized as generally safe and effective for use in nonprescription sleep aids. Despite the prominent sedative side effects encountered during the use of doxylamine and pyrilamine, these agents subsequently were eliminated as ingredients in the OTC nighttime sleep aids marketed in the U.S. In 2004, doxylamine regained FDA approval as an OTC sleep aid and re-entered the market as Unisom Nighttime Sleep Aid (doxylamine 25-mg tablets). With elimination t1/2 of ~9 hours (diphenhydramine) and 10 hours (doxylamine), these antihistamines can be associated with prominent residual daytime sleepiness when taken the prior evening as a sleep aid.

MANAGEMENT OF INSOMNIA

Insomnia is one of the most common complaints in general medical practice, and its treatment is predicated on proper diagnosis. Although the precise function of sleep is not known, adequate sleep improves the quality of daytime wakefulness, and hypnotics should be used judiciously to avoid its impairment.

A number of pharmacological agents are available for the treatment of insomnia. The “perfect” hypnotic would allow sleep to occur with normal sleep architecture rather than produce a pharmacologically altered sleep pattern. It would not cause next-day effects, either of rebound anxiety or of continued sedation. It would not interact with other medications. It could be used chronically without causing dependence or rebound insomnia on discontinuation. Regular moderate exercise meets these criteria but often is not effective by itself, and many patients may not be able to exercise. However, even small amounts of exercise often are effective in promoting sleep.
Controversy in the management of insomnia revolves around two issues:

- Pharmacological versus nonpharmacological treatment
- Use of short-acting versus long-acting hypnotics

The side effects of hypnotic medications must be weighed against the sequelae of chronic insomnia, which include a 4-fold increase in serious accidents (Balter and Uhlenhuth, 1992). In addition to appropriate pharmacological treatment, the management of insomnia should correct identifiable causes, address inadequate sleep hygiene, eliminate performance anxiety related to falling asleep, provide entrainment of the biological clock so that maximum sleepiness occurs at the hour of attempted sleep, and suppress the use of alcohol and OTC sleep medications (Nino-Murcia, 1992).

Categories of Insomnia. The National Institute of Mental Health Consensus Development Conference (1984) divided insomnia into three categories:

- **Transient insomnia** lasts <3 days and usually is caused by a brief environmental or situational stressor. It may respond to attention to sleep hygiene rules. If hypnotics are prescribed, they should be used at the lowest dose and for only 2-3 nights. However, benzodiazepines given acutely before important life events, such as examinations, may result in impaired performance (James and Savage, 1984).

- **Short-term insomnia** lasts from 3 days to 3 weeks and usually is caused by a personal stressor such as illness, grief, or job problems. Again, sleep hygiene education is the first step. Hypnotics may be used adjunctively for 7-10 nights. Hypnotics are best used intermittently during this time, with the patient skipping a dose after 1-2 nights of good sleep.

- **Long-term insomnia** is insomnia that has lasted for >3 weeks; no specific stressor may be identifiable. A more complete medical evaluation is necessary in these patients, but most do not need an all-night sleep study.

Insomnia Accompanying Major Psychiatric Illnesses. The insomnia caused by major psychiatric illnesses often responds to specific pharmacological treatment for that illness. In major depressive episodes with insomnia, e.g., the selective serotonin reuptake inhibitors, which may cause insomnia as a side effect, usually will result in improved sleep because they treat the depressive syndrome. In patients whose depression is responding to the serotonin reuptake inhibitor but who have persistent insomnia as a side effect of the medication, judicious use of evening trazodone may improve sleep (Nierenberg et al., 1994), as well as augment the antidepressant effect of the reuptake inhibitor. However, the patient should be monitored for priapism, orthostatic hypotension, and arrhythmias.

Adequate control of anxiety in patients with anxiety disorders often produces adequate resolution of the accompanying insomnia. Sedative use in the anxiety disorders is decreasing because of a growing appreciation of the effectiveness of other agents, such as β-adrenergic receptor antagonists (Chapter 12) for performance anxiety and serotonin reuptake inhibitors for obsessive-compulsive disorder and perhaps generalized anxiety disorder. The profound insomnia of patients with acute psychosis owing to schizophrenia or mania usually responds to dopamine-receptor antagonists (Chapters 13 and 16). Benzodiazepines often are used adjunctively in this situation to reduce agitation; their use also will result in improved sleep.

Insomnia Accompanying Other Medical Illnesses. For long-term insomnia owing to other medical illnesses, adequate treatment of the underlying disorder, such as congestive heart failure, asthma, or COPD, may resolve the insomnia.

Adequate pain management in conditions of chronic pain, including terminal cancer pain, will treat both the pain and the insomnia and may make hypnotics unnecessary.

Many patients simply manage their sleep poorly. Adequate attention to sleep hygiene, including reduced caffeine intake, avoidance of alcohol, adequate exercise, and regular sleep and wake times, often will reduce the insomnia.

Conditioned (Learned) Insomnia. In those who have no major psychiatric or other medical illness and in whom attention to sleep hygiene is ineffective, attention should be directed to conditioned (learned) insomnia. These patients have associated the bedroom with activities consistent with wakefulness rather than sleep. In such patients, the bed should be used only for sex and sleep. All other activities associated with waking, even such quiescent activities as reading and watching television, should be done outside the bedroom.

Sleep-State Misperception. Some patients complain of poor sleep but have been shown to have no objective polysomnographic evidence of insomnia. They are difficult to treat.

Long-Term Insomnia. Nonpharmacological treatments are important for all patients with long-term insomnia. These include education about sleep hygiene, adequate exercise (where possible), relaxation training, and behavioral-modification approaches, such as sleep-restriction and stimulus-control therapies. In sleep-restriction therapy, the patient keeps a diary of the amount of time spent in bed and then chooses a time in bed of 30-60 minutes less than this time. This induces a mild sleep debt, which aids sleep onset. In stimulus-control therapy, the patient is instructed to go to bed only when sleepy, to use the bedroom only for sleep and sex, to get up and leave the bedroom if sleep does not occur within 15-20 minutes, to return to bed again only when sleepy, to arise at the same time each morning regardless of sleep quality the preceding night, and to avoid daytime naps. Nonpharmacological treatments for insomnia have been found to be particularly effective in reducing sleep-onset latency and time awake after sleep onset (Morin et al., 1994).
Side effects of hypnotic agents may limit their usefulness for insomnia management. The use of hypnotics for long-term insomnia is problematic for many reasons. Long-term hypnotic use leads to a decrease in effectiveness and may produce rebound insomnia on discontinuance. Almost all hypnotics change sleep architecture. The barbiturates reduce REM sleep; the benzodiazepines reduce slow-wave non-REM sleep and, to a lesser extent, REM sleep. While the significance of these findings is not clear, there is an emerging consensus that slow-wave sleep is particularly important for physical restorative processes. REM sleep may aid in the consolidation of learning. The blockade of slow-wave sleep by benzodiazepines may partly account for their diminishing effectiveness over the long term, and it also may explain their effectiveness in blocking sleep terrors, a disorder of arousal from slow-wave sleep.

Long-acting benzodiazepines can cause next-day confusion, with a concomitant increase in falls, whereas shorter-acting agents can produce rebound next-day anxiety. Paradoxically, the acute amnestic effects of benzodiazepines may be responsible for the patient’s subsequent report of restful sleep. Triazolam has been postulated to induce cognitive changes that blur the subjective distinction between waking and sleeping (Mendelson, 1993). Anterograde amnesia may be more common with triazolam. While the performance-disruptive effects of alcohol and diphenhydramine are reduced after napping, those of triazolam are not (Roehrs et al., 1993).

Benzodiazepines may worsen sleep apnea. Some hypersomnia patients do not feel refreshed after a night’s sleep and so may ask for sleeping pills to improve the quality of their sleep. The consensus is that hypnotics should not be given to patients with sleep apnea, especially of the obstructive type, because these agents decrease upper airway muscle tone while also decreasing the arousal response to hypoxia (Robinson and Zwillich, 1989). These individuals benefit from all-night sleep studies to guide treatment.

**Insomnia in Older Patients.** The elderly, like the very young, tend to sleep in a polyphasic (multiple sleep episodes per day) pattern rather than the monophasic pattern characteristic of younger adults. They may have single or multiple bedtime naps in addition to nighttime sleep. This pattern makes assessment of adequate sleep time difficult. Anyone who naps regularly will have shortened nighttime sleep without evidence of impaired daytime wakefulness, regardless of age. This pattern is exemplified in “siesta” cultures and probably is adaptive.

Changes in the pharmacokinetic profiles of hypnotic agents occur in the elderly because of reduced body water, reduced renal function, and increased body fat, leading to a longer t1/2 for benzodiazepines. A dose that produces pleasant sleep and adequate daytime wakefulness during week 1 of administration may produce daytime confusion and amnesia by week 3 as the level continues to rise, particularly with long-acting hypnotics. For example, the benzodiazepine diazepam is highly lipid soluble and is excreted by the kidney. Because of the increase in body fat and the decrease in renal excretion that typically occur from age 20-80, the t1/2 of the drug may increase 4-fold over this span.

Elderly people who are living full lives with relatively unimpaired daytime wakefulness may complain of insomnia because they are not sleeping as long as they did when they were younger. Injudicious use of hypnotics in these individuals can produce daytime cognitive impairment and so impair overall quality of life.

Once an older patient has been taking benzodiazepines for an extended period, whether for daytime anxiety or for nighttime sedation, terminating the drug can be a long, involved process. Since attempts at drug withdrawal may not be successful, it may be necessary to leave the patient on the medication, with adequate attention to daytime side effects.

**Management of Patients After Long-Term Treatment with Hypnotic Agents.** Patients who have been taking hypnotics for many months or even years pose a special problem (Fleming, 1993). If a benzodiazepine has been used regularly for >2 weeks, it should be tapered rather than discontinued abruptly. In some patients on hypnotics with a short t1/2, it is easier to switch first to a hypnotic with a long t1/2 and then to taper. The onset of withdrawal symptoms from medications with a long t1/2 may be delayed. Consequently, the patient should be warned about the symptoms associated with withdrawal effects.

**Prescribing Guidelines for the Management of Insomnia.** Hypnotics that act at GABA_A receptors, including the benzodiazepine hypnotics and the newer agents zolpidem, zopiclone, and zaleplon, are preferred to barbiturates because they have a greater therapeutic index, are less toxic in overdose, have smaller effects on sleep architecture, and have less abuse potential. Compounds with a shorter t1/2 are favored in patients with sleep-onset insomnia but without significant daytime anxiety who need to function at full effectiveness during the day. These compounds also are appropriate for the elderly because of a decreased risk of falls and respiratory depression. However, the patient and physician should be aware that early-morning awakening, rebound daytime anxiety, and amnestic episodes also may occur. These undesirable side effects are more common at higher doses of the benzodiazepines.

Benzodiazepines with longer t1/2 are favored for patients who have significant daytime anxiety and who may be able to tolerate next-day sedation but would be impaired further by rebound daytime anxiety. These benzodiazepines also are appropriate for patients receiving treatment for major depressive episodes because the short-acting agents can worsen early-morning awakening. However, longer-acting benzodiazepines can be associated with next-day cognitive impairment or delayed daytime cognitive impairment (after 2-4 weeks of treatment) as a result of drug accumulation with repeated administration.

Older agents such as barbiturates, chloral hydrate, and meprobamate should be avoided for the management of insomnia. They have high abuse potential and are dangerous in overdose.

well-versed in the uses of opium; Arab traders introduced the drug to the Orient, where it was employed mainly for the control of dysentery. By 1680, Sydenham was lauding opium: “Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium.”

Opium contains >20 distinct alkaloids. In 1806, Frederich Sertürner, a pharmacist’s assistant, reported the isolation by crystallization of a pure substance in opium that he named morphine, after Morpheus, the Greek god of dreams. By the middle of the 19th century, the use of pure alkaloids in place of crude opium preparations began to spread throughout the medical world, an event that coincided with the development of the hypodermic syringe and hollow needle, permitting direct delivery of such water-soluble formulations “under the skin” into the body.

In addition to the remarkable beneficial effects of opioids, the side effects and addictive potential of these drugs also have been known for centuries. In the civil war in the U.S., the administration of “soldier’s joy” often led to “soldier’s disease,” the opiate addiction brought about by medication of chronic pain states arising from war wounds. These problems stimulated a search for potent synthetic opioid analgesics free of addictive potential and other side effects. The early discovery of the synthetic product heroin by C.R. Alder Wright in 1874 was followed by its widespread utilization as a purportedly non-addictive cough suppressant and sedative. Unfortunately, heroin and all subsequent synthetic compounds that have been introduced into clinical use share the liabilities of classical opioids, including their addictive properties. However, this search for new opioid agonists led to the synthesis of opioid antagonists and compounds with mixed agonist–antagonist properties, which expanded therapeutic options and provided important tools for exploring mechanisms of opioid actions.

Until the early 1970s, the effects of morphine, heroin, and other opioids as anti-nociceptive and addictive agents, were well described, but mechanisms mediating the interaction of the opioid alkaloids with biological systems were unknown. In vivo and in vitro physiological studies investigating the pharmacology of opiate agonists, their antagonists, and cross-tolerance led to the hypothesis of three separate opioid receptors: mu (μ), kappa (κ), and delta (δ) (Martin et al., 1976). These results were paralleled by work showing multiple radioligand binding sites for opiates on brain cell membranes (Goldstein et al., 1971; Pert et al., 1973). The three-receptor hypothesis was confirmed by subsequent cloning, which indicated

Pain is a component of virtually all clinical pathologies, and management of pain is a primary clinical imperative. Opioids are a mainstay of pain treatment, but rational therapy may involve, depending upon the pain state, one or more drug classes, such as NSAIDs, anticonvulsants, and antidepressants. The properties of these non-opioid agents are presented in Chapters 34, 21, and 15. This chapter focuses first on the biochemical, pharmacological, and functional nature of the opioid system that defines the effects of opioids on pain processing, gastrointestinal-endocrine-autonomic functions, and reward-addiction circuits. Subsequently, the chapter presents principles that guide the use of opioid and non-opioid agents in the management of clinical pain states.

The term opiate refers to compounds structurally related to products found in opium, a word derived from opos, the Greek word for “juice,” natural opiates being derived from the resin of the opium poppy, Papaver somniferum. Opiates include the natural plant alkaloids, such as morphine, codeine, thebaine, and many semisynthetic derivatives. An opioid is any agent, regardless of structure, that has the functional and pharmacological properties of an opiate. Endogenous opioids, many of which are peptides, are naturally occurring ligands for opioid receptors found in animals. The term endorphin is used synonymously with endogenous opioid peptides but also refers to a specific endogenous opioid, β-endorphin. The term narcotic was derived from the Greek word narkotikos, for “benumbing” or “stupor.” Although narcotic originally referred to any drug that induced narcosis or sleep, the word has become associated with opioids and is often used in a legal context to refer to a variety of substances with abuse or addictive potential.

History. The first undisputed reference to opium is found in the writings of Theophrastus in the third century B.C. Arab physicians were
the existence of three main receptor types with an opioid pharmacology (Waldhoer et al., 2004). In 2000, the Committee on Receptor Nomenclature and Drug Classification of the International Union of Pharmacology adopted the terms MOP, DOP, and KOP receptors (mu opioid peptide receptor, etc.). In concert with identification of these opioid receptors, Kostelitz and associates (Hughes et al., 1975) identified an endogenous opiate-like factor that they called enkephalin (“from the head”). Soon afterward, two more classes of endogenous opioid peptides were isolated, the endorphins and dynorphins (Akil et al., 1984).

In the early work by Martin, a sigma (σ) receptor was identified and was thought to represent a site that accounted for the paradoxical excitatory effects of opiates; this site is now thought to be the phencyclidine binding site and is not strictly speaking an opiate receptor or an opiate site.

**ENDOGENOUS OPIOID SYSTEMS: AGONISTS AND RECEPTORS**

An agent found within the brain that acts through an opioid receptor is an endogenous opioid. Several distinct families of endogenous opioids peptides have been identified: principally the enkephalins, endorphins, and dynorphins. These families have several common properties:

- Each derives from a distinct large precursor protein, prepro-opiomelanocortin (POMC), preproenkephalin, and preprodynorphin, respectively, encoded by a corresponding gene.
- Each precursor is subject to complex cleavages by distinct trypsin-like enzymes, typically at sites designated by pairs of dibasic amino acids, and to a variety of post-translational modifications resulting in the synthesis of multiple peptides, some of which are active.
- Most opioid peptides with activity at a receptor share the common amino-terminal sequence of Tyr-Gly-Gly-Phe-(Met or Leu) followed by various C-terminal extensions yielding peptides ranging from a few (5) to many residues (Table 18–1; the endorphins, with different terminal sequences, are exceptions).

The POMC sequence contains a variety of non-opioid peptides including adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (αMSH), and β-lipotropin (β-LPH), all of which are generated by proteolytic cleavage of POMC. The major opioid peptide derived from further cleavage of β-lipotropin is the potent opioid agonist, β-endorphin. Although β-endorphin contains the sequence for met-enkephalin at its amino terminus, it is not converted to this peptide. The anatomical distribution of POMC-producing cells is relatively limited within the CNS, occurring mainly in the arcuate nucleus of the hypothalamus and the nucleus tractus solitarius. These neurons project widely to limbic and brainstem areas and to the spinal cord. POMC expression also occurs in the anterior and intermediate lobes of the pituitary and also are contained in pancreatic islet cells. Circulating β-endorphin derives primarily from the pituitary, from which it and other pituitary hormones are released (Chapter 38).

Proenkephalin contains multiple copies of met-enkephalin, as well as a single copy of leu-enkephalin. Proenkephalin peptides are present in areas of the CNS believed to be related to the processing of pain information (e.g., laminae I and II of the spinal cord, the spinal trigeminal nucleus, and the periaqueductal gray), to the modulation of affective behavior (e.g., amygdala, hippocampus, locus ceruleus, and the frontal cerebral cortex), to the modulation of motor control (e.g., caudate nucleus and globus pallidus), to the regulation of the autonomic nervous system (e.g., medulla oblongata), and to neuroendocrinological functions (e.g., median eminence). Although there are a few long enkephalergic fiber tracts, these peptides are contained primarily in interneurons with short axons. The peptides from proenkephalin also are found in chromaffin cells of the adrenal medulla and in nerve plexuses and exocrine glands of the stomach and intestine. Circulating proenkephalin products are considered to be largely derived from these sites.

Prodynorphin contains three peptides of differing lengths that all begin with the leu-enkephalin sequence: dynorphin A, dynorphin B, and neoendorphin (Figure 18–1). The peptides derived from prodynorphin are distributed widely in neurons and to a lesser extent in astrocytes throughout the brain and spinal cord and are frequently found co-expressed with other opioid peptide precursors. Nociceptin peptide is present in neurons widely distributed throughout brain (cortex, hippocampus, brainstem, and to a lesser degree, hypothalamus, thalamus, raphe nuclei, and periaqueductal gray matter) and spinal cord structures. It has been observed in neurons as well as astrocytes and neutrophils.

More recently, a family of peptides has been identified and named endomorphins, endomorphin-1 (Tyr–Pro–Trp–Phe–NH₂) and endomorphin-2 (Tyr–Pro–Phe–Phe–NH₂) (Zadina et al., 1997). By comparison with other opioid peptides, endomorphins have an atypical structure and display selectivity towards the μ opioid receptor (Fichna et al., 2007).

Several points should be stressed:

- Not all cells that make a given opioid pro-hormone precursor store and release the same mixture of opioid peptides; this results from differential processing secondary to variations in the cellular complement of peptidases that produce and degrade the active opioid fragments (Hook et al., 2008).
- Processing of these peptides is altered by physiological demands, leading to the release of a different mix of post-translationally derived peptides by a given cell under different conditions.
- Opioid peptides are found in plasma and reflect release from secretory systems such as the pituitary and the adrenals that do not reflect neuraxial release. Conversely, levels of these peptides in brain/spinal cord and in CSF arise from neuraxial systems and not from peripheral systems.

**OPIOID RECEPTORS**

**Principal Receptor Classes; Distribution**

The three opioid receptors—δ, μ, and κ—belong to the rhodopsin family of GPCRs (Chapter 3) and share

### Opiate Receptor Subtypes

The existence of three classes of opiate receptors (MOR, DOR, and KOR) is widely accepted. The opioid receptors appear early in vertebrate evolution, being already present with the appearance of jawed vertebrates. The human opiate receptors have been mapped to chromosome 1p355-33 (DOR), chromosome 8q11.23-21 (KOR), chromosome 6q25-26 (MOR), and chromosome 20q13.33 (NOR) (Dreborg et al., 2008). Low-stringency hybridization procedures have identified no opioid receptor types other than the cloned opioid receptors. Nevertheless, pharmacological studies have suggested the possible existence of at least two subtypes of each receptor. While cloning studies have not supported the existence of these subtypes as distinct classes, the modified specificity for opioid ligands may result from several underlying events.

#### Heterodimerization

In the membrane, opiate receptors can form both homo- and heterodimers. Dimerization can alter the pharmacological properties of the respective receptors. For example, DORs form heterodimers with both MORs and KORs. Thus, MOR-DOR and DOR-KOR heterodimers show less affinity for highly selective agonists, reduced agonist-induced receptor trafficking, and mutual synergy between receptor-selective agonists in binding to the

extensive sequence homologies (55-58%). The greatest diversity is found in their extracellular loops. In addition, all opioid receptors possess two conserved cysteine residues in the first and second extracellular loops forming a disulfide bridge.

μ, δ, and κ opioid receptors are widely distributed and this distribution has been examined in detail using immunohistochemistry, in situ hybridization, and more recently by noninvasive imaging techniques. The profound and diverse effects on CNS function are consistent with the density and diverse distribution of receptors in the brain and spinal cord (Henriksen et al., 2008). In addition, these receptors are expressed in a wide variety of peripheral tissues, including vascular, cardiac, airway/lung, gut, and many resident and circulating immune/inflammatory cells (discussed subsequently).

Following the cloning of the classical opioid receptors, the G-protein coupled opiate receptor-like protein (ORL1 or NOP) was cloned based on its structural homology (48-49% identity) to other members of the opioid receptor family; it has an endogenous ligand, nociceptin/orphanin (FQ: N/OFQ) (Stevens, 2009). See Figure 18–2. Since this system does not display an opioid pharmacology (Fioravanti et al., 2008), it will not be discussed in detail in this chapter.

N/OFQ binding sites have been found to be largely in the CNS and to be densely distributed in cortical regions, ventral forebrain, hippocampus, brainstem, and spinal cord, as well as in a number of peripheral cells including basophils, endothelial cells, and macrophages.
respective agonists and also in the agonist-induced intracellular signaling (Gupta et al., 2006).

**Alternative Splicing of Receptor RNA**

Alternative splicing of receptor heteronuclear RNA (e.g., exon skipping and intron retention) is thought to play an important role in producing in vivo diversity within many members of the GPCR superfamily (Chapter 3). Splice variants exist within each of the three opioid receptor families, and this alternative splicing of receptor transcripts may be crucial for the diversity of opioid receptors. As an example, the human 

**Receptor Subtype Agonists/Antagonists**

Studies on the presence and function of these receptors have depended upon the convergence between agonist/antagonist structure-activity studies and a variety of functional assays in biological and cloned receptor systems. Highly selective agonists have been developed that show specific affinity for the respective binding site and G-protein coupled reporter activation in cloned expression systems (e.g., DAMGO for MOR, DPDPE for DOR, and U-50,488, and U-69,593 for KOR) (Table 18–1). The study of the biological functions of opioid receptors in vivo has been aided by synthesis of selective antagonists. Among the most commonly used antagonists are cyclic analogs of somatostatin such as CTOP as a MOR antagonist, a derivative of naloxone called naltrindole as a DOR-receptor antagonist, and a bivalent derivative of naltrexone called nor-binaltorphimine (nor-BNI) as a KOR antagonist. These tools have made possible the characterization of the distribution of binding, in conjunction with immunohistochemistry using antibodies derived from cloned receptors, has served to define the anatomical distribution of the receptors and the roles of the respective receptors in biological functions. Positron emission tomography (PET) has been used to characterize in vivo binding in brain with selective isotopically labeled ligands (Henriksen and Willoch, 2008). In vivo delivery of selective antagonists and agonists into specific brain regions has established the receptor types and anatomical distribution involved in mediating various opioid effects (see below).

**Receptor Structure**

Each receptor consists of an extracellular N-terminus, seven transmembrane helices, three extra- and intracellular loops, and an intracellular C-terminus characteristic of the GPCRs. The opioid receptors...
Thus, for the KOR, a second basic hydrophobic group is implicated in forming a specific salt bridge; for the DOR, a hydrophobic group such as an indole forms the address. MOR ligands such as morphine lack a common chemical moiety and thus other elements are thought to contribute to ligand specificity at that receptor (Kane et al., 2006).

### Opiate Receptor Coupling to Membrane Function

Agonist binding results in conformational changes in the GPCR, initiating the G protein activation/inactivation cycle (Chapter 3). The μ, δ, and κ receptors largely couple through pertussis toxin-sensitive, G\(_i/G_o\) proteins (but occasionally to G\(_i\) or G\(_j\)). Upon receptor activation, the G\(_i/G_o\) coupling results in a large number of intracellular events, including:

- Inhibition of adenylyl cyclase activity
- Reduced opening of voltage-gated Ca\(^{2+}\) channels
- Stimulation of K\(^+\) current through several channels including G protein-activated inwardly rectifying K\(^+\) channels (GIRKs)
- Activation of PKC and PLC\(_{\beta}\)

As with other GPCRs, the second intracellular loop is involved in the efficacy of G-protein activation while the third loop defines the \(\alpha\) subunit that is activated (Gether, 2000).

### Regulation of Opiate Receptor Disposition

Like other GPCRs, MOR and DORs can undergo rapid agonist-mediated internalization via a classic endocytic, β-arrestin-mediated pathway, whereas KORs do not internalize after prolonged agonist exposure (Chu et al., 1997). Internalization of the MOR and DORs apparently occurs via partially distinct endocytic pathways, suggesting receptor-specific interactions with different mediators of intracellular trafficking. These processes may be induced differentially as a function of the structure of the ligand. For example, certain agonists, such as etorphine and enkephalins, cause rapid internalization of the receptor, whereas morphine does not cause MOR internalization, even though it decreases adenylyl cyclase activity equally well. In addition, a truncated receptor with normal G-protein coupling recycled constitutively from the membrane to the cytosol (Segredo et al., 1997), suggesting that activation of signal transduction and internalization are controlled by distinct molecular mechanisms. These studies also support the hypothesis that different ligands induce different conformational changes in the receptor that result in divergent intracellular events, and they may provide an explanation for differences in the spectrum of effects of various opioids.

### Functional Consequences of Acute and Chronic Opiate Receptor Activation

The loss of effect with exposure to opiates occurs over short- and long-term intervals.

#### Desensitization

Acute agonist occupancy of the opiate receptors results in activation of the intracellular signaling outlined previously. In the face of a transient activation (minutes to hours), a phenomenon called acute tolerance or desensitization can be observed that is specific for that receptor and disappears with a time course parallel to the clearance of the agonist. Short-term desensitization probably involves phosphorylation of the receptors resulting in an uncoupling of the receptor from its G-protein and/or internalization of the receptor.

#### Tolerance

Sustained administration of an opiate agonist (days to weeks) leads to progressive loss of drug effect. Here tolerance refers to a decrease in the apparent effectiveness of a drug with continuous administration.
or repeated agonist administration, and with the removal of the agonist disappears over several weeks. This tolerance is reflected by a reduction in the maximum achievable effect or a right shift in the dose-effect curve. This phenomenon can be manifested at the level of the intracellular cascade (e.g., reduced inhibition of adenylyl cyclase) and at the organ system level (e.g., loss of sedative and analgesic effects).

This loss of effect with persistent exposure to an opiate agonist has several key properties:

- Changes in response are time-dependent, with changes occurring over short-term (minutes to hours, as with desensitization) and long-term intervals (weeks to months).
- Tolerance to drug effect is surmountable with higher doses of the opioid.
- Tolerance is reversible over time after termination of the drug.
- Different physiological responses develop tolerance at different rates. Thus, at the organ system level, some end points show little or no tolerance development (pupillary miosis), some show moderate tolerance (constipation, emesis, analgesia, sedation), and some show rapid tolerance (euphorogenic).
- In general, opiate agonists of a given class will typically show a reduced response in a system rendered tolerant to another agent of that class (e.g., cross-tolerance between the μ agonists, such as morphine and fentanyl).

The completeness of this cross-tolerance is not consistent and forms the basis for the switching between opioid drugs used in clinical therapy. This incomplete cross-tolerance has been hypothesized to reflect small but important differences in the receptors with which the different opiates of the same class bind (Pasternak, 2005).

**Dependence.** During the state of tolerance, the phenomenon of dependence is observed. Dependence represents a state of adaptation manifested by receptor/drug class-specific withdrawal syndrome produced by cessation of drug exposure (e.g., by drug abstinence) or administration of an antagonist (e.g., naloxone). The withdrawal is manifested by the exaggerated appearance of enhanced signs of cellular activation. In the CNS, increased adenylyl cyclase, release of excitatory amino acids and cytokines, activation of microglia and astrocytes, and the initiation of apoptotic processes have been reported. Such indices of hyperexcitability are also noted in peripheral plexi such as are present in the GI tract and in autonomic ganglia (discussed later). At the organ system level, withdrawal is manifested by significant somatomotor and autonomic outflow (reflected by agitation, hyperalgesia, hypertension, diarrhea, pupillary dilation, and release of virtually all pituitary and adrenomedullary hormones) and by affective symptoms (dysphoria, anxiety, and depression) (Kreek et al., 1998). These phenomena are considered to be highly aversive and motivate the drug recipient to make robust efforts to avoid the withdrawal state. Consistent with...
the receptor selectivity of the effects, the withdrawal signs observed in an animal tolerant to a given opiate can be suppressed by application of another drug from the same class.

**Addiction.** Addiction is a behavioral pattern characterized by compulsive use of a drug and overwhelming involvement with its procurement and use. The positive, rewarding effects of opiates are considered to be the driving component for initiating the recreational use of opiates. This positive reward property in humans and animals is subject to the development of tolerance. Given the aversive nature of withdrawal symptoms, in the dependent organism, it is not surprising that avoidance and alleviation of withdrawal symptoms may become a primary motivation for compulsive drug taking (Kreek and Koob, 1998). When the drive to acquire the drug leads to drug-seeking behaviors that occur in spite of the physical, emotional, or societal damage suffered by the drug user, then the obsession or compulsion to acquire and use the drug is considered to reflect an addicted state. In animals, this may be manifest by willingness to tolerate very stressful conditions to acquire drug delivery. In humans, aberrant behaviors considered to be signs of addiction include prescription forgery, stealing drugs from others, and obtaining prescription drugs from nonmedical sources; these behaviors are considered indicators of an addiction disorder. Note that drug dependence is not synonymous with drug addiction. Any individual who is exposed for some period to opiates will display some degree of tolerance and should the drug be removed abruptly, there will be an expression of withdrawal signs, the severity of which will depend upon the dose and duration of drug exposure. Such a condition does not itself indicate an addicted state. Thus, tolerance and dependence are physiological responses seen in all patients but are not predictors of addiction (Chapter 24). For example, cancer pain often requires prolonged treatment with high doses of opioids, leading to tolerance and dependence. Yet abuse in this setting is considered to be unusual (Foley, 1993).

**Mechanisms of Tolerance/Dependence-Withdrawal**

The mechanisms underlying chronic tolerance and dependence/withdrawal are controversial. Several types of events are considered to contribute.

**Receptor Disposition.** With chronic opiate exposure, the general consensus is that the loss of effect is not related to the density of membrane receptors. As noted, acute desensitization or receptor internalization may play a role in the initiation of chronic tolerance but is not sufficient to explain persistent changes observed with chronic exposure. Thus, morphine, unlike other μ agonists, does not promote μ receptor internalization or receptor phosphorylation and desensitization (Koch et al., 2005; von Zastrow et al., 2003). These studies suggest that receptor desensitization and down-regulation are agonist specific. Other studies of GPCRs indicate that endocytosis and sequestration of receptors do not invariably lead to receptor degradation but can also result in receptor dephosphorylation and recycling to the surface of the cell (Krupnick and Benovic, 1998). Accordingly, opioid tolerance may not be related to receptor desensitization but rather to a lack of desensitization. Agonists that rapidly internalize opioid receptors also would rapidly desensitize signaling, but this desensitization would be at least partially reset by recycling of “reactivated” opioid receptors. The lack of desensitization caused by morphine may result in prolonged receptor signaling, which even though less efficient than that observed with other agonists, would lead to further downstream cellular adaptations that increase tolerance development. The measurement of relative agonist signaling versus endocytosis (RAVE) for opioid agonists could be predictive of the potential for tolerance development (Waldhoer et al., 2004).

**Adaptation of Intracellular Signaling Mechanisms in the Opioid Receptor-Bearing Neurons.** Coupling of MOR to cellular effectors, such as inhibition of adenylyl cyclase, activation of inwardly rectifying K⁺ channels, inhibition of Ca²⁺ currents, and inhibition of terminal release of transmitters demonstrates functional uncoupling of receptor occupancy from effector function (Williams et al., 2001). Importantly, the chronic opioid effect initiates adaptive counterregulatory change. The best example of such cellular counterregulatory processes is the rebound increase in cellular cyclic AMP levels produced by “superactivation” of adenylyl cyclase and up-regulation of the amount of enzyme. Such superactivation leads to an induction of an excitatory state mediated by an increased cation current through activation of PKA. Terminal transmitter release is thus commonly enhanced during opioid withdrawal (Bailey and Connor, 2005).

**System Level Counteradaptation.** In the face of chronic opiate exposure, an evident loss of drug effect is noted. An important line of speculation is that the apparent loss of inhibitory effect may reflect an enhanced excitability of the regulated link. Thus, tolerance to the analgesic action of chronically administered μ opiates may result in an activation of bulbospinal pathways that increases the excitability of spinal dorsal horn pain transmission linkages. Similarly, in the presence of chronic opiate exposure, opiate receptor occupancy will lead to the activation of PKC, which can phosphorylate and, accordingly, enhance the activation of local glutamate receptors of the N-methyl-D-aspartate (NMDA) type (Chapter 14). These receptors are known to mediate a facilitated state leading to enhanced spinal pain processing. Blocking of these receptors can at least partially attenuate the loss of analgesic efficacy with continued opiate exposure (Trujillo and Akil, 1991). These system level counteradaptation hypotheses may represent mechanisms that apply to specific systems (e.g., pain modulation) but not necessarily to others (e.g., sedation or miosis) (Christie, 2008).

**Differential Tolerance Development and Fractional Occupancy Requirements.** An interesting problem posed in explaining tolerance relates to the differential rates of tolerance development noted earlier. Why responses such as miosis show no tolerance over extended exposure (indeed, it is considered symptomatic in drug overdose of highly tolerant patients) while analgesia and sedation are more likely to show a reduction is not clear. One possibility is that tolerance represents a functional uncoupling of some fraction of the receptor population and that different physiological end points may require activation of different fractions of their coupled receptors to produce a given physiological effect. Accordingly, it would be consistent that receptors in the miosis pathways need to activate a small fraction of their receptors, relative to those systems mediating pain control to produce a significant physiological action (e.g., the systems mediating miosis have a greater functional receptor reserve).

**Effect Profile of Clinically Used Opioids**

Opiates, depending upon their receptor preferences, produce a variety of effects consistent with the role
played by the organ systems with which the receptors are associated. Whereas the primary clinical use of opioids is for their pain-relieving properties, opioids produce a host of other effects. This is not surprising in view of the wide distribution of opioid receptors in the brain and the periphery. Within the nervous systems, these effects range from analgesia to effects upon motivation and higher-order affect (euphoria), arousal, and a number of autonomic, hormonal, and motor processes. In the periphery, opiates can influence a variety of visceromotor systems, including those related to GI motility and smooth muscle tone. The next sections consider these class actions and their mechanisms.

**Analgesia.** In humans, morphine-like drugs produce analgesia, drowsiness, changes in mood, and mental clouding. When therapeutic doses of morphine are given to patients with pain, they report the pain to be less intense or entirely gone. Patients frequently report that the pain, though still present, is tolerable and that they feel more comfortable. In addition to relief of distress, some patients may experience euphoria. A significant feature of the analgesia is that it often occurs without loss of consciousness, though drowsiness commonly occurs (see “Respiration” later in the chapter). Morphine at these doses does not have anticonvulsant activity and usually does not cause slurred speech, emotional lability, or significant motor uncoordination.

When morphine in an analgesic dose is given to normal, pain-free individuals, the patients may report the drug experience to be frankly unpleasant. There may be drowsiness, difficulty in mentation, apathy, and lessened physical activity. As the dose is increased, the subjective, analgesic, and toxic effects, including respiratory depression, become more pronounced.

**Specificity of Analgesic Effects.** The relief of pain by morphine-like opioids is selective in that other somatosensory modalities, such as light touch, proprioception, and the sense of moderate temperatures, are unaffected. Systematic psychophysical studies have shown that low doses of morphine produce reductions in the affective but not the perceived intensity of pain whereas higher (clinically effective) doses reduced both reported perceived intensity and the affective response otherwise evoked by acute experimental pain stimuli (Price et al., 1985). In general, continuous dull pain (as generated by tissue injury and inflammation) is relieved more effectively than sharp intermittent (incident) pain, such as that associated with the movement of an inflamed joint, but with sufficient amounts of opioid it is possible to relieve even the severe piercing pain associated with acute renal or biliary colic.

**Pain States and Mechanisms Underlying Different Pain States.** Any meaningful discussion of the action of analgesic agents must include the appreciation that all pain is not the same and that a number of variables contribute to the patient’s pain report and therefore to the effect of the analgesic. Heuristically, one may think mechanistically of pain as several distinct sets of events, described in the next sections.

**Acute Nociception.** Acute activation of small high-threshold sensory afferents (Aδ and C fibers) generates transient input into the spinal cord, which in turn leads to activation of neurons that project contralaterally to the thalamus and thence to the somatosensory cortex. A parallel spinofugal projection is to the medial thalamus and from there to the anterior cingulate cortex, part of the limbic system. The output produced by acutely activating this ascending system is sufficient to evoke pain reports. Examples of such stimuli include a hot coffee cup, a needle stick, or an incision.

**Tissue Injury.** Following tissue injury or local inflammation (e.g., local skin burn, toothache, rheumatoid joint), an ongoing pain state arises that is characterized by burning, throbbing, or aching and an abnormal pain response (hyperalgesia) and can be evoked by otherwise innocuous or mildly aversive stimuli (tepid bathwater on a sunburn; moderate extension of an injured joint). This pain typically reflects the effects of active factors (such as prostaglandins, bradykinin, cytokines, and H⁺ ions, among many mediators) released into the injury site, which have the ability to activate the terminal of small high-threshold afferents (Aδ and C fibers) and to reduce the stimulus intensity required to activate these sensory afferents (peripheral sensitization). In addition, the ongoing afferent traffic initiated by the injury leads to the activation of spinal facilitatory cascades, yielding a greater output to the brain for any given input. This facilitation is thought to underlie the hyperalgesic states. Such tissue injury-evoked pain is often referred to as “nociceptive” pain (Figure 18–4).
Nerve Injury. Injury to the peripheral nerve yields complex anatomical and biochemical changes in the nerve and spinal cord that induce spontaneous dysesthesias (shooting, burning pain) and allodynia (light touch hurts). This nerve injury pain state may not depend upon the activation of small afferents, but may be initiated by low-threshold sensory afferents (e.g., Aβ fibers). Such nerve injuries result in the development of ectopic activity arising from neuromas formed by nerve injury and the dorsal root ganglia of the injured axons as well as a dorsal horn reorganization, such that low-threshold afferent input carried by Aβ fibers evokes a pain state. This dorsal horn reorganization reflects changes in ongoing inhibition and in the excitability of dorsal horn projection neurons (Latremoliere and Woolf, 2009). Examples of such nerve injury-inducing events include nerve trauma or compression (carpal tunnel syndrome), chemotherapy (as for cancer), diabetes, and in the post-herpetic state (shingles). These pain states are said to be neuropathic (Figure 18–5). Many clinical pain syndromes, such as found in cancer, typically represent a combination of these inflammatory and neuropathic mechanisms. Although nociceptive pain usually is responsive to opioid analgesics, neuropathic pain is typically considered to respond less well to opioid analgesics (McQuay, 1988).

Sensory Versus Affective Dimensions. Information generated by a high intensity peripheral stimulus initiates activity in defined pathways that activate higher-order systems that reflect the aversive magnitude of the stimulus. This reflects the sensory-discriminative dimension of the pain experience (such as the ability to accurately estimate and characterize the pain state). Painful stimuli have the certain ability to generate strong emotional components that reflect a distinction between pain as a specific sensation subserved by distinct neurophysiological structures, and pain such as suffering (the original sensation plus the reactions evoked by the sensation; the affective motivational dimension) (Melzack and Casey, 1968). When pain does not evoke its usual responses (anxiety, fear, panic, and suffering), a patient’s ability to tolerate the pain may be markedly increased, even when the capacity to perceive the sensation is relatively unaltered. It is clear, however, that alteration of the emotional reaction to painful stimuli is not the sole mechanism of analgesia. Thus, intrathecal administration of opioids can produce profound segmental analgesia without causing significant alteration of motor or sensory function or subjective effects (Yaksch, 1988).

Mechanisms of Opioid-Induced Analgesia. The analgesic actions of opiates after systemic delivery are believed to represent actions in the brain, spinal cord, and in some instances in the periphery.

Supraspinal Actions. The microinjection of opiates through chronically placed microinjection canulae targeted at specific brain sites has shown that opiate agonists will, in a manner consistent with their respective activity at a MOR, block pain behavior after delivery into a number of highly circumscribed brain regions and that these analgesic effects are naloxone reversible. The best characterized of these sites is the mesencephalic periaqueductal gray (PAG) matter. Microinjections of morphine into this region will block nociceptive responses in every species examined from rodents to primates; naloxone will reverse these effects.

Several mechanisms exist whereby opiates with an action limited to the PAG may act to alter nociceptive transmission. These are summarized in Figure 18–6. MOR agonists block release of the inhibitory transmitter GABA from tonically active PAG systems that regulate activity in projections to the medulla. PAG projections to the medulla activate medullospinal release of NE and 5-HT at the level of the spinal dorsal horn. This release can attenuate dorsal horn excitability (Yaksch, 1997). Interestingly, this PAG organization can also serve to increase excitability of dorsal raphe and locus coeruleus from which ascending serotonergic and noradrenergic projections to the limbic forebrain originate (the role of forebrain 5-HT and NE in mediating emotional tone is discussed in Chapter 15). In humans, it is not feasible to routinely access the site of action within the brain where opiates may act to alter nociceptive transmission as is done in preclinical models. However, intracerebroventricular opioids have been employed in humans for pain relief in cancer patients. Accordingly, it seems probable that the supraspinal site of opiate action in the human, as in other animal models, lies close to the ventricular lumen (Karavelis et al., 1996).

Spinal Opiate Action. A local action of opiates in the spinal cord will selectively depress the discharge of spinal dorsal horn neurons evoked by small (high-threshold) but not large (low-threshold) afferent nerve fibers. Intrathecal administration of opioids in animals ranging from mouse to human will reliably attenuate the response of the organism to a variety of somatic and visceral stimuli that otherwise evoke pain states. Specific opiate binding and receptor protein are limited for the most part to the substantia gelatinosa of the superficial dorsal horn, the region in which small, high-threshold sensory afferents show their principal termination. A significant proportion of these opiate receptors are associated with small peptidergic primary afferent C fibers and the remainder are on local dorsal horn neurons. This finding is consistent with the presence of opioid receptor protein being synthesized in and transported from small dorsal root ganglion cells.

Confirmation of the presynaptic action is provided by the observation that spinal opiates reduce the release of primary afferent...
The activation of dorsal horn projection neurons. The activation of K+ channels, thereby preventing transmitter release. A postsynaptic action of afferent-evoked excitation of the second order neuron. Opiate agonist acting at these sites jointly serves to attenuate the excitatory capacity of spinal opiates to reduce the release of excitatory neurotransmitters from C fibers and to decrease the excitability of dorsal horn neurons is believed to account for the powerful and selective effect of opiates on spinal nociceptive processing. In humans, there is extensive literature indicating that a variety of opiates delivered spinally (intrathecally or epidurally) can induce a powerful analgesia that is reversed by low doses of systemic naloxone (Yaksh, 1997).

**Peripheral Action.** It has been a principal tenet of opiate action that these agents act “centrally.” Direct application of opiates to a peripheral nerve can, in fact, produce a local anesthetic-like action at high concentrations, but this is not naloxone reversible and is believed to reflect a “nonspecific” action. Moreover, in studies examining normal animals, it can be demonstrated that the analgesic actions are limited if the agent does not readily penetrate the brain. Alternately, studies employing the direct injection of these agents into peripheral sites have demonstrated that under conditions of inflammation, where there is an increased terminal sensitivity leading to an exaggerated pain response (e.g., hyperalgesia), the local action of opiates can exert a normalizing effect upon the exaggerated thresholds. This has been demonstrated for the response to mechanical stimulation applied to inflamed paw or inflamed knee joints. In the absence of inflammation, there is no local peripheral effect. This action is believed to be mediated by opiate receptors on the peripheral terminals of small primary afferents. Local opiates in the knee joint and in the skin can reduce the firing of spontaneously active afferents observed when these tissues are inflamed. Whether the effects are uniquely on the afferent terminal, whether the opiate acts upon inflammatory cells that release products that sensitize the nerve terminal, or both, is not known (Stein and Lang, 2009).

**Mood Alterations and Rewarding Properties.** The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) are complex and not entirely clear. Neural systems thought to mediate opioid reinforcement overlap with, but are distinct from, those involved in physical dependence and analgesia (Koob et al., 1988). Behavioral and pharmacological data point to a pivotal role of the mesocorticolumbic (MCL) dopamine system, a basal forebrain circuit long implicated in reward and motivation (Figure 18–7).

The mesolimbic dopamine system originates in the ventral segmental area (VTA) and projects to the nucleus accumbens (NAc) in the forebrain. Dopamine and glutamate projections from the VTA and prefrontal cortex (PFC), respectively, synapse on NAc GABAergic neurons. These cells project to the ventral pallidum (VP). In the NAc, ionotropic glutamate receptors activate, while dopamine D2-like receptors inhibit GABAergic neurons. In general, interventions that suppress the NAc-VP GABA pathway leading to increased dopamine release are considered to be positively reinforcing, supporting, for example, self-administration. Thus, dopamine delivered directly into the NAc, mimicking increased extracellular release, is powerfully reinforcing. Opiates increase DA release in the NAc, and catheterized animals will activate administration of opiates directly into their VTA and into the NAc, emphasizing the importance of that system in opiate reward. In the NAc, MORs are present postsynaptically on GABAergic neurons. The reinforcing effects of opiates in the VTA are thought to be mediated through peptide transmitters such as substance P contained in small afferents (Yaksh et al., 1980). The presynaptic action corresponds to the ability of opiates to prevent the opening of voltage-sensitive Ca2+ channels, thereby preventing transmitter release. A postsynaptic action is demonstrated by the ability of opiates to block excitation of dorsal horn neurons directly evoked by glutamate, reflecting a direct activation of dorsal horn projection neurons. The activation of K+ channels in these postsynaptic neurons, leading to hyperpolarization, is consistent with a direct postsynaptic inhibition. The joint capacity of spinal opiates to reduce the release of excitatory neurotransmitters from C fibers and to decrease the excitability of dorsal horn neurons is believed to account for the powerful and selective analgesic actions of opiates in producing analgesia. Top left: Schematic of organization of opiate action in the periaqueductal gray. Top right: Opiate-sensitive pathways in PAG Mu opiate actions block the release of GABA from tonically active systems that otherwise regulate the projections to the medulla (1) leading to an activation of PAG outflow resulting and activation of forebrain (2) and spinal (3) monoamine receptors that regulate spinal cord projections (4) which provide sensory input to higher centers and mood.

Bottom left: Schematic of primary afferent synapse with second order dorsal horn spinal neuron, showing pre- and post-synaptic opiate receptors coupled to Ca2+ and K+ channels, respectively. Opiate receptor binding is highly expressed in the superficial spinal dorsal horn (substantia gelatinosa). These receptors are located presynaptically on the terminals of small primary afferents (C fibers) and postsynaptically on second order neurons. Presynaptically, activation of MOR blocks the opening of the voltage sensitive Ca2+ channel, which otherwise initiates transmitter release. Postsynaptically, MOR activation enhances opening of K+ channels, leading to hyperpolarization. Thus, an opiate agonist acting at these sites jointly serves to attenuate the afferent-evoked excitation of the second order neuron.
inhibition of local GABAergic neuronal activity, which otherwise acts to inhibit DA outflow (Xi and Stein, 2002).

**Respiration.** Although effects on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard analgesic doses in the absence of other contributing variables (discussed in the next sections). It should be stressed, however, that respiratory depression represents the primary cause of morbidity secondary to opiate therapy. In humans, death from opiate poisoning is nearly always due to respiratory arrest or obstruction (Pattinson, 2008). Opiates depress all phases of respiratory activity (rate, minute volume, and tidal exchange) and produce irregular and aperiodic breathing. The diminished respiratory volume is due primarily to a slower rate of breathing; with toxic amounts of opioids, the rate may fall to 3–4 breaths per minute. The respiratory depression is discernible even with doses too small to disturb consciousness and increases progressively as the dose is increased. After large doses of morphine or other agonists, patients will breathe if instructed to do so, but without such instruction, they may remain relatively apneic. Thus, opioids must be used with caution in patients with asthma, COPD, cor pulmonale, decreased respiratory reserve, preexisting respiratory depression, hypoxia, or hypercapnia to avoid apnea due to a decrease in respiratory drive coinciding with an increase airway resistance. While respiratory depression is not considered to be a favorable therapeutic effect of opiates, their ability to suppress respiratory drive is used to therapeutic advantage to treat dyspnea resulting, for example, in patients with chronic obstructive pulmonary disease (COPD), where air hunger leads to extreme agitation, discomfort, and gasping; similarly, opiates find use in patients who require artificial ventilation (Clemens and Klaschik, 2007).

**Mechanisms Underlying Respiratory Depression.** Respiratory rate and tidal volume depend upon intrinsic rhythm generators located in the ventrolateral medulla. These systems generate a “respiratory” rhythm that is driven by afferent input reflecting the partial pressure of arterial O2 as measured by chemosensors in the carotid and aortic bodies and CO2 as measured by chemosensors in the brainstem. Morphone-like opioids depress respiration through MOR and DOR receptors in part by a direct depressant effect on rhythm generation, with changes in respiratory pattern and rate observed at lower doses than changes in tidal volume. A key property of opiate effects on respiration is the depression of the ventilatory response to increased CO2. This effect is mediated by opiate depression of the excitability of brainstem chemosensory neurons. In addition to the effects on the CO2 response, opiates will depress ventilation otherwise driven by hypoxia though an effect upon carotid and aortic body chemosensors. Importantly, with opiates, hypoxic stimulation of chemoreceptors still may be effective when opioids have decreased the responsiveness to CO2, and inhalation of O2 may remove the residual drive resulting from the elevated PO2 and produce apnea (Pattinson, 2008). In addition to the effect upon respiratory rhythm and chemosensitivity, opiates can have mechanical effects on airway function by increasing chest wall rigidity and diminishing upper airway patency (Lalley, 2008).
**Factors Exacerbating Opiate-Induced Respiratory Depression.** A number of factors are recognized as increasing the risk of opiate-related respiratory depression even at therapeutic doses:

- **Other medications.** The combination of opiates with other depressant medications, such as general anesthetics, tranquilizers, alcohol, or sedative-hypnotics, produces additive depression of respiratory activity.
- **Sleep.** Natural sleep produces a decrease in the sensitivity of the medullary center to CO₂, and the depressant effects of morphine and sleep are at least additive. Obstructive sleep apnea is considered to be an important risk factor for increasing the likelihood of fatal respiratory depression.
- **Age.** Newborns can show significant respiratory depression and desaturation; and this may be evident in lower Apgar scores if opioids are administered parenterally to women within 2-4 hours of delivery because of transplacental passage of opioids. Elderly patients are at greater risk of depression because of reduced lung elasticity, chest wall stiffening, and decreased vital capacity.
- **Disease.** Opiates may cause a greater depressant action in patients with chronic cardiopulmonary or renal diseases because they can manifest a desensitization of their response to increased CO₂.
- **COPD.** Enhanced depression can also be noted in patients with chronic obstructive pulmonary disease (COPD) and sleep apnea secondary to diminished hypoxic drive.
- **Relief of Pain.** Because pain stimulates respiration, removal of the painful condition (as with the analgesia resulting from the therapeutic use of the opiate) will reduce the ventilatory drive and lead to apparent respiratory depression.

**Sedation.** Opiates can produce drowsiness and cognitive impairment. Such depression can augment respiratory impairment. These effects are most typically noted following initiation of opiate therapy or after dose incrementation. Importantly, these effects upon arousal resolve over a few days. As with respiratory depression, the degree of drug effect can be enhanced by a variety of predisposing patient factors including dementia, encephalopathies, or brain tumors as well as other depressant medications, including sleep aids, antihistamines, antidepressants, and anxiolytics (Cherny, 1996).

**Different Opiates.** Numerous studies have compared morphine and morphine-like opioids with respect to their ratios of analgesic to respiratory-depressant activities, and most have found that when equianalgesic doses are used, there is no significant difference. Maximal respiratory depression occurs within 5-10 minutes of intravenous administration of morphine or within 30-90 minutes of intramuscular or subcutaneous administration. Maximal respiratory depressant effects occur more rapidly with more lipid-soluble agents. After therapeutic doses, respiratory minute volume may be reduced for as long as 4-5 hours. Agents that have persistent kinetics, such as methadone, must be carefully monitored, particularly after dose incrementation.

**Management of Opiate Depression.** Life-threatening respiratory depression produced by any opiate agonist can be readily reversed by delivery of an opiate antagonist. Conversely, the ability to reverse the somnolent patient is considered to be indicative of an opiate-mediated effect. It is important to remember that most opiate antagonists have a relatively short duration of action as compared to an agonist such as morphine or methadone and fatal “re-narcotization” can occur if vigilance is not exercised.

**Neuroendocrine Effects.** The regulation of the release of hormones and factors from the pituitary is under complex regulation by opiate receptors in the hypothalamic-pituitary-adrenal (HPA) axis. Broadly considered, morphine-like opioids block the release of a large number of HPA hormones.

**Sex Hormones.** In males, acute opiate therapy reduces plasma cortisol, testosterone, and gonadotrophins. Inhibition of adrenal function is reflected by reduced cortisol production and reduced adrenal androgens (dehydroepiandrosterone, DHEA). In females, morphine will additionally result in lower LH and FSH release. In both males and females, chronic therapy can result in endocrinopathies, including hypogonadotropic hypogonadism. In men, this may result in decreased libido and, with extended exposure, reduced secondary sex characteristics. In women these exposures are associated with menstrual cycle irregularities. Importantly, these changes are reversible with removal of the opiate.

The mechanisms of the opiate regulation of gonadotrophin release may reflect a direct effect upon secreting pituicytes and an indirect action, through an effect on receptors present on hypothalamic neurons, to block release of gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH). This reduction of the releasing factors leads to reduced release of luteinizing hormone (LH), follicle-stimulating hormone (FSH), ACTH, and β-endorphin. This series of events leads to reduced circulating testosterone and cortisol. Secretion of thyrotropin is relatively unaffected.

**Prolactin.** Prolactin release from lactotrope cells in the anterior pituitary is under inhibitory control by dopamine released from tuberoinfundibulum neurons of the arcuate nucleus. MOR agonists act presynaptically on these dopamine-releasing terminals to inhibit DA release and thereby increase plasma prolactin.

**Growth Hormone.** Growth hormone (GH) is released in a pulsatile fashion from somatotrophs in the anterior pituitary. GH-releasing hormone (GHRH) neurons in the hypothalamic arcuate nucleus and inhibitory input from somatostatin (SST) cells in the periventricular nuclei regulate this. Although some opioids increase GH release, possibly by inhibiting SST release, acute morphine has little effect on plasma GH concentration (Bluet-Pajot et al., 2001).

**Antidiuretic Hormone and Oxytocin.** The effects of opiates on ADH and oxytocin release are complex. These hormones are synthesized in the perikarya of the magnocellular neurons in the parventricular and supraoptic nuclei of the hypothalamus and released from the posterior pituitary (Chapter 38). ADH (vasopressin) release can occur secondary to surgical stress, hypovolemia, hypotension, and low osmolality, while oxytocin release typically is released with afferent stimuli related to the milk ejection pathway. KOR agonists inhibit the release of oxytocin and antidiuretic hormone (and cause prominent diuresis). In humans, the administration of MOR agonists has little effect or tends to produce antidiuretic effects. Morphine reduces oxytocin secretion in nursing women (Lindow et al., 1999).

It should be noted that agents such as morphine may yield a hypotension secondary to histamine release and this would, by itself, promote ADH release. Based on electrophysiology and localization of opiate receptors, these effects upon vasopressin and oxytocin release may reflect both a direct effect upon terminal secretion as well as...
indirect effects upon dopaminergic and noradrenergic modulatory projections into the parventricular and supraoptic hypothalamus (Gimpl and Fahrenholz, 2001).

**Miosis.** Illumination of the pupil activates a reflex arc, which through local circuitry in the Edinger Westphal nucleus, activates parasympathetic outflow through the ciliary ganglion to the pupil, producing constriction. MOR opiates induce pupillary constriction (miosis) in the awake state and block pupillary reflex dilation during anesthesia. The parasympathetic outflow is locally regulated by GABAergic interneurons. Opiates are believed to block the GABAergic interneuron-mediated inhibition (Larson, 2008). At high doses of agonists, the miosis is marked, and pinpoint pupils are pathognomonic; however, marked mydriasis will occur with the onset of asphyxia. While some tolerance to the miotic effect develops, addicts with high circulating concentrations of opioids continue to have constricted pupils. Therapeutic doses of morphine increase accommodative power and lower intraocular tension in normal and glaucomatous eyes.

**Seizures and Convulsions.** In older children and adults, moderately higher doses of opiates produce EEG slowing. In the newborn, morphine has been shown to produce epileptiform activity (Young and da Silva, 2000) and occasionally seizure activity. While increased jaw and chest wall rigidity routinely occur at doses used for anesthesia induction, frank seizures and convulsions typically occur only at doses far in excess of those required to produce even profound analgesia. Myoclonus and seizures have been reported particularly in opioid tolerant patients on high doses of morphine-like opiates, including fentanyl, as encountered in hospice and terminal stages of pain therapy (Vella-Brincat and Macleod, 2007). However, seizures that are produced by some agents such as meperidine may occur at doses only moderately higher than those required for analgesia, especially in children, particularly with repeated delivery.

Several mechanisms are most certainly involved in these excitatory actions:

- **Inhibition of inhibitory interneurons.** Morphine-like drugs excite certain groups of neurons, especially hippocampal pyramidal cells, probably from inhibition of the release of GABA by interneurons (McGinty, 1988).
- **Direct stimulatory effects.** Opiates may interact with receptors coupled through both inhibitory and stimulatory G-protein, with the inhibitory coupling but not the excitatory coupling showing tolerance with continued exposure (King et al., 2005).
- **Actions mediated by non-opioid receptors.** The metabolites of some opiates have been implicated in seizure activity, notably morphine-3-glucuronide (from morphine) and normeperidine (from meperidine) (Seifert and Kenendy, 2004; Smith, 2000).

A special case is the withdrawal syndrome from an opiate-dependent state in the adult and in the infant born to an opiate-dependent mother. Withdrawal in these circumstances, either by antagonists or abstinence, can lead to prominent EEG activation, tremor, and rigidity. Approaches to the management of such activation are controversial. Re-narcotization with a tapering dose and management of symptoms with anticonvulsants and anesthetics has been suggested (Farid et al., 2008). Anticonvulsant agents may not always be effective in suppressing opioid-induced seizures (Chapter 21).

**Cough.** Morphine and related opioids depress the cough reflex at least in part by a direct effect on a cough center in the medulla and this can be achieved without altering the protective glottal function. There is no obligatory relationship between depression of respiration and depression of coughing, and effective antitusive agents are available that do not depress respiration (antitussives are discussed later in the chapter). Suppression of cough by such agents appears to involve receptors in the medulla that are less sensitive to naloxone (an opioid antagonist) than those responsible for analgesia (Chung and Pavord, 2008).

Cough is a protective reflex evoked by airway stimulation. It involves rapid expression of air against a transiently closed glottis. The reflex is complex, involving the central and peripheral nervous systems as well as the smooth muscle of the bronchial tree. Irritation of the bronchial mucosa causes bronchoconstriction, which in turn stimulates cough receptors (which probably represent a specialized type of stretch receptor) located in tracheobronchial passages. Afferent conduction from these receptors is via fibers in the vagus nerve; central components of the reflex probably include several mechanisms or centers that are distinct from the mechanisms involved in the regulation of respiration.

**Nauseant and Emetic Effects.** Nausea is the prodromal sensation that is a common feature of gastric upset that is associated with reduced gastric motility and increased secretions. Vomiting, the motor sequela of nausea, is a complex reflex characterized by simultaneous contractions of inspiratory-expiratory respiratory muscle, increased stomach pressure, relaxation of the esophageal sphincter, and retrograde reflex propulsion of gastric contents. Nausea and vomiting produced by morphine-like drugs are side-effects caused by direct stimulation of the chemoreceptor trigger zone for emesis in the area postrema of the medulla. Apomorphine is a structural analog of morphine that has no opioid action but has prominent emetogenic actions.

Nausea and vomiting are relatively uncommon in recumbent patients given therapeutic doses of morphine, but nausea occurs in ~40% and vomiting in 15% of ambulatory patients given 15 mg of the drug subcutaneously. This suggests that a vestibular component is also operative. Indeed, the nauseant and emetic effects of morphine are markedly enhanced by vestibular stimulation, and morphine and related synthetic analgesics produce an increase in vestibular sensitivity. A component of nausea is likely due to the gastric stasis that occurs postoperatively and that is exacerbated by analgesic doses of morphine (Greenwood-Van Meerveld, 2007). All clinically useful agonists produce some degree of nausea and vomiting. Careful, controlled clinical studies usually demonstrate that, in equianalgesic dosage, the incidence of such side effects is not significantly lower than that seen with morphine. Antagonists to the 5-HT3 receptor have supplanted phenothiazines and drugs used for motion sickness as the drugs of choice for the treatment of opioid-induced nausea and vomiting. Gastric prokinetic agents such as metoclopramide also are use-
ful anti-nausea and anti-emetic drugs (Cameron et al., 2003); however, caution is warranted due to the propensity of metoclopramide to cause tardive dyskinesia (Chapter 46).

Cardiovascular System. In the supine patient, therapeutic doses of morphine-like opioids have no major effect on blood pressure or cardiac rate and rhythm. Such doses can, however, produce peripheral vasodilation, reduced peripheral resistance, and an inhibition of baroreceptor reflexes. Thus, when supine patients assume the head-up position, orthostatic hypotension and fainting may occur. The peripheral arteriolar and venous dilation produced by morphine involves several mechanisms:

- morphine-induced release of histamine from mast cells, leading to vasodilation (reversed by naloxone only partially blocked by $H_1$ antagonists)
- blunting of the reflex vasoconstriction caused by increased $P_{CO_2}$

High doses of MOR agonists, such as fentanyl and sufentanil, used as anesthetic induction agents, have only modest effects upon hemodynamic stability, in part because they do not cause release of histamine (Monk et al., 1988).

Effects on the myocardium are not significant in normal individuals. In patients with coronary artery disease but no acute medical problems, 8-15 mg morphine administered intravenously produces a decrease in $O_2$ consumption, left ventricular end-diastolic pressure, and cardiac work; effects on cardiac index usually are slight. In patients with acute myocardial infarction, the cardiovascular responses to morphine may be more variable than in normal subjects, and the magnitude of changes (e.g., the decrease in blood pressure) may be more pronounced (Roth et al., 1988). Anesthetic induction doses (described later) of the MOR result in a centrally mediated increase in vagal outflow to the heart, leading to an atropine-sensitive bradycardia.

Morphine may exert its well-known therapeutic effect in the treatment of angina pectoris and acute myocardial infarction by decreasing preload, inotropy, and chronotropy, thus favorably altering determinants of myocardial $O_2$ consumption and helping to relieve ischemia. It is not clear whether the analgesic properties of morphine in this situation are due to the reversal of acidosis that may stimulate local acid-sensing ion channels (McCleskey and Gold, 1999) or to a direct analgesic effect on nociceptive afferents from the heart.

When administered before experimental ischemia, morphine has been shown to produce cardioprotective effects. Morphine can mimic the phenomenon of ischemic preconditioning, where a short ischemic episode paradoxically protects the heart against further ischemia. This effect appears to be mediated through receptors signaling through a mitochondrial ATP-sensitive K+ channel in cardiac myocytes; the effect also is produced by other GPCRs signaling through Gi (Fryer et al., 2000). Some researchers suggest that opioids can be anti-arrhythmic and anti-fibrillatory during and after periods of ischemia (Fryer et al., 2000), although other data suggest that opioids can be arrhythmogenic (McIntosh et al., 1992).

Morphine-like opioids should be used with caution in patients who have decreased blood volume because these agents can aggravate hypovolemic shock. Morphine should be used with great care in patients with cor pulmonale because deaths after ordinary therapeutic doses have been reported. The concurrent use of certain phenothiazines may increase the risk of morphine-induced hypotension.

Cerebral circulation is not affected directly by therapeutic doses of opiates. However, opioid-induced respiratory depression and $CO_2$ retention can result in cerebral vasodilation and an increase in cerebrospinal fluid pressure. This pressure increase does not occur when $PCO_2$ is maintained at normal levels by artificial ventilation. Nevertheless, opioids produce changes in arousal that can obscure the clinical course of patients with head injuries.

Motor Tone. At therapeutic doses required for analgesia, opiates have little effect upon motor tone or function. However, high doses of opioids, as used for anesthetic induction, produce muscular rigidity in humans. Thus, rigidity of the chest wall and masseter severe enough to compromise respiration and intubation is not uncommon during anesthesia and routinely requires the use muscle relaxants.

Myoclonus, ranging from mild twitching to generalized spasm, is an occasional side-effect, which has been reported with all clinical opiate agonists; while it may be observed at lower therapeutic doses, it is particularly prevalent in hospice patients receiving high doses (Lyss et al., 1997). The increased muscle tone is certainly mediated by a central effect although the mechanisms of its effects are not clear. High doses of spinal opiates can increase motor tone, possibly through an inhibition of inhibitory interneurons in the ventral horn of the spinal cord. Alternately, intracranial delivery can initiate rigidity in animal models possible reflecting on increased extrapyramidal activity. As already indicated, both actions are reversed by opiate antagonists.

GI Tract. Opiates have important effects upon all aspects of GI function. It is estimated that 40-95% of patients treated with opioids develop constipation and that changes in bowel function can be demonstrated even with acute dosing (Benyamin et al., 2008). Opioid receptors are densely distributed in enteric neurons between the myenteric and submucosal plexi and on a variety of secretory cells. The more prominent expression of the action mediated by these receptors will be reviewed in the next sections. Importantly, the presence of opioids can obscure recognition of the diagnosis or clinical course in patients with acute abdominal conditions.

Esophagus. The esophageal sphincter is under control by brainstem reflexes that activate cholinergic motor neurons originating in the esophageal myenteric plexus. This system regulates passage of material from the esophagus to the stomach and prevents regurgitation; conversely, it allows relaxation in the act of emesis. Morphine inhibits lower esophageal sphincter relaxation induced by swallowing and by esophageal distension. This effect is believed to be centrally mediated, as peripherally restricted opiates such as loperamide do not alter esophageal sphincter tone (Sidhu and Triadafilopoulos, 2008).

Stomach. Movement of a meal though the stomach reflects the coordinated contractions of the antrum and the resting tone of the gastric
The ability of peripherally limited opiate antagonists such as methylnaltrexone to reverse the constipatory actions of systemic opiate agonists usually decrease secretion of hydrochloric acid, although stimulation sometimes is evident. Activation of opioid receptors on parietal cells enhances secretion, but indirect effects, including increased secretion of somatostatin from the pancreas and reduced release of acetylcholine, appear to be dominant in most circumstances (Kromer, 1988).

**Intestine.** Morphine reduces propulsatile activity in the small and large intestine and diminishes intestinal secretions. Propulsatile Activity. Opiate agonists suppress local neurogenic networks that provide a rhythmic inhibition of muscle tone leading to concurrent increases in basal tone in the circular muscle of the small and large intestine. This results in enhanced high-amplitude phasic contractions, which are nonpropulsatile. The upper part of the small intestine, particularly the duodenum, is affected more than the ileum. A period of relative atony may follow the hypertonicity. The reduced rate of passage of the intestinal contents, along with reduced intestinal secretion, leads to increased water absorption, increasing viscosity of the bowel contents, and constipation. The tone of the anal sphincter is augmented greatly, and reflex relaxation in response to rectal distension is reduced. These actions, combined with inattention to the normal sensory stimuli for defecation reflex, owing to the central actions of the drug, contribute to morphine-induced constipation (Wood and Galligan, 2004).

The clinical relevance of the role of the peripheral opioid receptors in regulating GI motility after systemic opioids is supported by:

- The efficacy of peripherally limited opiate agonists such as loperamide as anti-diarrheals
- The ability of peripherally limited opiate antagonists such as methylnaltrexone to reverse the conspiratory actions of systemic opiate agonists

Direct delivery of opioids into the cerebral ventricles or into the spinal intrathecal space could also inhibit GI propulsive activity as long as the extrinsic innervation to the bowel is intact. Although some tolerance develops to the effects of opioids on GI motility, patients who take opioids chronically remain constipated.

**Intestinal Secretions.** In the presence of intestinal hypersecretion that may be associated with diarrhea, morphine-like drugs inhibit the transfer of fluid and electrolytes into the lumen by naloxone-sensitive actions on the intestinal mucosa and within the CNS (Kromer, 1988). Intestinal secretion arises from activation of enterocytes by local cholinergic submucosal plexus secretomotor neurons. Opioids act through μ/δ receptors on these secretomotor neurons to inhibit their excitatory output to the enterocytes and thereby reduce intestinal secretion.

**Biliary Tract.** Bile flow is regulated by the periodic contractions of the sphincter of Oddi, which is relaxed by inhibitory innervation. This inhibitory innervation is suppressed by opiates. After the subcutaneous injection of 10 mg morphine sulfate, the sphincter of Oddi constricts, and the pressure in the common bile duct may rise >10-fold within 15 minutes; this effect may persist for 2 hours or more. Fluid pressure also may increase in the gallbladder and produce symptoms that may vary from epigastric distress to typical biliary colic.

Some patients with biliary colic experience exacerbation rather than relief of pain when given opioids. Spasm of the sphincter of Oddi probably is responsible for elevations of plasma amylase and lipase that occur sometimes after morphine administration. All opioids can cause biliary spasm. Atropine only partially prevents morphine-induced biliary spasm, but opioid antagonists prevent or relieve it. Papaverine, another alkaloid of the poppy that lacks opioid activity, produces smooth muscle relaxation and is used therapeutically for GI, urethral, and biliary colic and for other nonvisceral conditions (e.g., embolism and angina pectoris) accompanied by smooth muscle spasm.

**Other Smooth Muscle**

**Ureter and Urinary Bladder.** Voiding is a highly organized response initiated by afferents activated by bladder filling and spinobulbospinal reflex arcs, which lead to contraction of the bladder and a reflex relaxation of the external urinary sphincter (Fowler et al., 2008). Morphine inhibits the urinary voiding reflex and increases the tone of the external sphincter with a resultant increase in the volume of the bladder. In animal models, this effect is mediated by MOR and DOR agonists. Stimulation of either receptor type in the brain or in the spinal cord exerts similar actions on bladder motility (Dray and Nunan, 1987). Tolerance develops to these effects of opioids on the bladder. Clinically, opiate-mediated inhibition of micturition can be of such clinical severity that catheterization sometimes is required after therapeutic doses of morphine, particularly with spinal drug administration. Importantly, in humans, the inhibition of systemic opiate effects on micturition is reversed by peripherally restricted antagonists (Rosow et al., 2007).

**Uterus.** If the uterus has been made hyperactive by oxytocics, morphine tends to restore the tone, frequency, and amplitude of contractions to normal.

**Skin.** Therapeutic doses of morphine cause dilation of cutaneous blood vessels. The skin of the face, neck, and upper thorax frequently becomes flushed. These changes may be due in part to the release of histamine and may be responsible for the sweating and some of the pruritus that commonly follow the systemic administration of morphine (described later). Histamine release probably accounts for the urticaria commonly seen at the site of injection. Though controversial, it is not blocked by naloxone and thought not to be mediated by opioid receptors. Itching is readily seen with morphine and meperidine but to a much lesser extent with oxymorphone, methadone, fentanyl, or sufentanil. This pruritus is a common and potentially disabling complication of opioid use. It can be caused by systemic as well as intraspinal injections of therapeutic doses of opioids, but it appears to be more intense after epidural or intrathecal administration (Ballantyne et al., 1988). The spinal effect, which is reversible by naloxone, may reflect a disinhibition of itch-specific neurons that have been identified in the spinal dorsal horn (Schmelz, 2002).

**Immune System.** The effects of opioids on the immune system are complex. Opioids modulate immune function by direct effects on...
cells of the immune system and indirectly through centrally mediated neuronal mechanisms (Sharp and Yaksh, 1997). The acute central immunomodulatory effects of opioids may be mediated by activation of the sympathetic nervous system; the chronic effects of opioids may involve modulation of the hypothalamic-pituitary-adrenal (HPA) axis (Mellon and Bayer, 1998).

Direct effects on immune cells may involve unique, incompletely characterized variants of the classical neuronal opioid receptors, with MOR variants being most prominent (Sharp and Yaksh, 1997). Atypical receptors could account for the fact that it has been very difficult to demonstrate significant opioid binding on immune cells despite the observance of robust functional effects. In contrast, morphine-induced immune suppression largely is abolished in knockout mice lacking the receptor gene, suggesting that the receptor is a major target of morphine’s actions on the immune system (Gaveriaux-Ruff et al., 1998). A proposed mechanism for the immune suppressive effects of morphine on neutrophils is through a nitric oxide-dependent inhibition of NF-kB activation (Welters et al., 2000). Others have proposed that the induction and activation of MAP kinase also may play a role (Chuang et al., 1997).

Overall, the effects of opioids appear to be modestly immunosuppressive, and increased susceptibility to infection and tumor spread have been observed. In some situations, immune effects appear more prominent with acute administration than with chronic administration, which could have important implications for the care of the critically ill (Sharp and Yaksh, 1997). In contrast, opioids have been shown to reverse pain-induced immunosuppression and increase tumor metastatic potential in animal models (Page and Ben-Eliyahu, 1997). Therefore, opioids may either inhibit or augment immune function depending on the context in which they are used. These studies also indicate that withholding opioids in the presence of pain in immunocompromised patients actually could worsen immune function. Taken together, these studies indicate that opioid-induced immune suppression may be clinically relevant both to the treatment of severe pain and in the susceptibility of opioid addicts to infection (e.g., human immunodeficiency virus (HIV) infection and tuberculosis). Different opioid agonists also may have unique immunomodulatory properties. Better understanding of these properties eventually should help to guide the rational use of opioids in patients with cancer or at risk for infection or immune compromise.

**Temperature Regulation.** Opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms such that body temperature usually falls slightly. Systematic studies have shown that MOR agonists such as alfentanil and meperidine, acting in the CNS, will result in slightly increased thresholds for sweating and significantly lower the threshold temperatures for evoking vasoconstriction and shivering (Sessler, 2008). In precipitated withdrawal, elevated body temperatures are observed, an observation consistent with the report that chronic high dosage may increase body temperature (Martin, 1983).

**FUNCTIONAL OPIOID DRUG TYPES**

Most of the clinically used opioid agonists presented below are relatively selective for MOR. They produce analgesia, affect mood and rewarding behavior, and alter respiratory, cardiovascular, GI, and neuroendocrine function. KOR agonists, with few exceptions (e.g., butorphanol), are not typically employed for long-term therapy since they may produce dysphoric and psychotomimetic effects. DOR agonists, while analgesic in animal models, have not found clinical utility, and NOR agonists have largely proven to lack analgesic effects. Opiates that are relatively receptor selective at lower doses will interact with additional receptor types when given at high doses. This is especially true as doses are escalated to overcome tolerance.

The mixed agonist–antagonist agents frequently interact with more than one receptor class at usual clinical doses. The actions of these drugs are particularly interesting because they may act as an agonist at one receptor and as an antagonist at another. Mixed agonist–antagonist compounds were developed with the hope that they would have less addictive potential and less respiratory depression than morphine and related drugs. In practice, however, for the same degree of analgesia, the same intensity of side effects occurs. A “ceiling effect” limiting the amount of analgesia attainable often is seen with these drugs, such as buprenorphine, which is approved for the treatment of opioid dependence. Some mixed agonist–antagonist drugs, such as pentazocine and nalorphine (not available in the U.S.), can precipitate withdrawal in opioid-tolerant patients. For these reasons, except for the sanctioned use of buprenorphine to manage opioid addiction, the clinical use of these mixed agonist–antagonist drugs is generally limited.

The dosing guidelines and duration of action for the numerous drugs that are part of opioid therapy are summarized in Table 18–2.

**MORPHINE AND STRUCTURALLY RELATED AGONISTS**

Even though there are many compounds with pharmacological properties similar to those of morphine, morphine remains the standard against which new analgesics are measured.

**Source and Composition of Opium**

Because the synthesis of morphine is difficult, the drug still is obtained from opium or extracted from poppy straw. Opium is obtained from the unripe seed capsules of the poppy plant, *Papaver somniferum*. The milky juice is dried and powdered to make powdered opium, which contains a number of alkaloids. Only a few—morphine, codeine, and papaverine—have clinical utility. These alkaloids can be divided into two distinct chemical classes, phenanthrenes and benzylisoquinolines. The principal phenanthrenes are morphine (10% of opium), codeine (0.5%), and thebaine (0.2%).

Published tables vary in the suggested doses that are equi-analgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical response is necessary. Because there is not complete cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose when changing drugs and to retitrate to response. **Caution:** Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics. **Caution:** Doses listed for patients with body weight less than 50 kg cannot be used as initial starting doses in babies less than 6 months of age. Consult the Clinical Practice Guideline for Acute Pain Management: Operative or Medical Procedures and Trauma section on management of pain in neonates for recommendations. **Caution:** For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences. **Caution:** Codeine doses above 65 mg often are not appropriate due to diminishing incremental analgesia with increasing doses but continually increasing constipation and other side effects. **Caution:** Doses of aspirin and acetaminophen in combination opioid/NSAID preparations must also be adjusted to the patient’s body weight. Maximum acetaminophen dose: 4 g/day in adults, 90 mg/kg/day in children. **Caution:** Doses for moderate pain not necessarily equivalent to 30 mg oral or 10 mg parenteral morphine. **Risk of seizures:** Parenteral formulation not available in the U.S. **Oxycontin** is an extended-release preparation containing up to 160 mg of oxycodone per tablet and recommended for use every 12 hours. It has been subject to substantial abuse. Modified from Agency for Healthcare Policy and Research, 1992.
The principal benzylisoquinolines are papaverine (1%) (a smooth muscle relaxant) and noscapine (6%).

**Chemistry of Morphiine and Its Congeners**

The structure of morphine is shown in Figure 18–8. Many semisynthetic derivatives are made by relatively simple modifications of morphine or thebaine. Codeine is methylmorphine, the methyl substitution being on the phenolic hydroxyl group. Thebaine differs from morphine only in that both hydroxyl groups are methylated and that the ring has two double bonds (6,7; 8,14). Thebaine has little analgesic action but is a precursor of several important 14-OH compounds, such as oxycodone and naloxone. Certain derivatives of thebaine are >1000 times as potent as morphine (e.g., etorphine). Diacetylmorphine, or heroin, is made from morphine by acetylation at the 3 and 6 positions. Apomorphine, which also can be prepared from morphine, is a potent emetic and dopaminergic D1 and D2 agonist, has no opiate receptor interactions, and displays no analgesic actions (Chapters 22 and 46). Hydromorphone, oxymorphone, hydrocodone, and oxycodone are also made by modifying the morphine molecule. The structural relationships between morphine and some of its surrogates and antagonists are shown in Figure 18–8.

**Structure-Activity Relationship of the Morphine-Like Opioids.**

In addition to morphine, codeine, and the semisynthetic derivatives of the natural opium alkaloids, a number of other structurally distinct chemical classes of drugs have pharmacological actions similar to those of morphine. Clinically useful compounds include the morphinans, benzomorphans, methadones, phenylpiperidines, and propionanilides. Although the two-dimensional representations of these chemically diverse compounds appear to be quite different, molecular models show certain common characteristics, as indicated by the heavy lines in the structure of morphine shown in Figure 18–8. Among the important properties of the opioids that can be altered by structural modification are their affinities for various types of opioid receptors, their activities as agonists versus antagonists, their lipid solubilities, and their resistance to metabolic breakdown. For example, blockade of the phenolic hydroxyl at position 3, as in codeine and heroin, drastically reduces binding to receptors; these compounds are converted in vivo to the potent analgesics morphine and 6-acetyl morphine, respectively.

**Absorption, Distribution, Metabolism, and Excretion**

**Absorption.** In general, the opioids are modestly absorbed from the GI tract; absorption through the rectal mucosa is adequate and a few agents (e.g., morphine, hydromorphone) are available in suppositories. The more lipophilic opioids are absorbed readily through the nasal or buccal mucosa. Those with the greatest lipid solubility also can be absorbed transdermally. Opioids, particularly morphine, have been widely used for spinal delivery to produce analgesia though a spinal action. These agents display useful transdural movement adequate to permit their use epidurally.

With most opioids, including morphine, the effect of a given dose is less after oral than after parenteral administration because of variable but significant first-pass metabolism in the liver. For example, the bioavailability of oral preparations of morphine is only ~25%. The shape of the time-effect curve also varies with the route of administration, so the duration of action often is somewhat longer with the oral route. If adjustment is made for variability of first-pass metabolism and clearance, adequate relief of pain can be achieved with oral administration of morphine. Satisfactory analgesia in cancer patients is associated with a very broad range of steady-state concentrations of morphine in plasma (16-364 ng/mL) (Neumann et al., 1982).

When morphine and most opioids are given intravenously, they act promptly. However, the more lipid-soluble compounds (e.g., fentanyl) act more rapidly than morphine after subcutaneous administration because of differences in the rates of absorption and entry into the CNS. Compared with more lipid-soluble opioids such as codeine, heroin, and methadone, morphine crosses the blood-brain barrier at a considerably lower rate.

**Distribution and Metabolism.** About one-third of morphine in the plasma is protein-bound after a therapeutic dose. Morphine itself does not persist in tissues, and 24 hours after the last dose, tissue concentrations are low.

The major pathway for the metabolism of morphine is conjugation with glucuronic acid. The two major metabolites formed are morphine-6-glucuronide and morphine-3-glucuronide. Small amounts of morphine-3,6-diglucuronide also may be formed. Although the 3- and 6-glucuronides are quite polar, both still can cross the blood-brain barrier to exert significant clinical effects (Christrup, 1997).

Morphine-6-glucuronide has pharmacological actions indistinguishable from those of morphine. Morphine-6-glucuronide given systemically is approximately twice as potent as morphine in animal models (Paul et al., 1989) and in humans (Osborne et al., 1988). With chronic administration, the 6-glucuronide accounts for a significant portion of morphine’s analgesic actions (Osborne et al., 1988). Indeed, with chronic oral dosing, the blood levels of morphine-6-glucuronide typically exceed those of morphine. Given its greater MOR potency and its higher concentration, morphine-6-glucuronide may be responsible for most of morphine’s analgesic activity in patients receiving chronic oral morphine. Morphine-6-glucuronide is excreted by the kidney. In renal failure, the levels of morphine-6-glucuronide can accumulate, perhaps explaining morphine’s potency and long duration in patients with compromised renal function. In adults, the \( t_{1/2} \) of morphine is ~2 hours; the \( t_{1/2} \) of morphine-6-glucuronide is somewhat longer. Children achieve adult renal function values by 6 months of age. In elderly patients, lower doses of morphine are recommended based on a smaller volume of distribution (Owen et al., 1983) and the general decline in renal function in the elderly.

Morphine-3-glucuronide, another important metabolite, has little affinity for opioid receptors but may contribute to excitatory effects of morphine (Smith, 2000). N-Demethylation of morphine to normorphine is a minor metabolic pathway in humans but is more prominent in rodents (Yeh et al., 1977). N-Dealkylation also is important in the metabolism of some congeners of morphine.

**Excretion.** Morphine is eliminated by glomerular filtration, primarily as morphine-3-glucuronide; 90% of the total excretion takes place during the first day. Very little morphine is excreted unchanged. Enterohepatic circulation of morphine and its glucuronides occurs,
which accounts for the presence of small amounts of morphine in feces and urine for several days after the last dose.

In contrast to morphine, codeine is ~60% as effective orally as parenterally as an analgesic and as a respiratory depressant. Codeine analogs such as levorphanol, oxycodone, and methadone have a high ratio of oral-to-parenteral potency. The greater oral efficacy of these drugs reflects lower first-pass metabolism in the liver. Once absorbed, codeine is metabolized by the liver, and its metabolites are excreted chiefly as inactive forms in the urine. A small fraction (~10%) of administered codeine is O-demethylated to morphine, and free and

\(\d\)The numbers 3, 6, and 17 refer to positions in the morphine molecule, as shown above. 1 Other changes in the morphine molecule are:
(1) Single instead of double bond between C7 and C8; (2) OH added to C14; (3) No oxygen between C4 and C5; (4) Endoetheno bridge between C6 and C14; 1-hydroxy-1,2,3-trimethylpropyl substitution on C7.

Figure 18-8. Structures of morphine-related opiate agonists and antagonists.
Conjugated morphine can be found in the urine after therapeutic doses of codeine. Codeine has an exceptionally low affinity for opioid receptors, and the analgesic effect of codeine is due to its conversion to morphine. However, codeine’s antitussive actions may involve distinct receptors that bind codeine itself, and codeine is commonly employed for the management of cough. The t½ of codeine in plasma is 2-4 hours.

CYP2D6 catalyzes the conversion of codeine to morphine. Well-characterized genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as an analgesic for ~10% of the Caucasian population (Eichelbaum and Evert, 1996). Other polymorphisms (e.g., the CYP2D6*2x2 genotype) can lead to ultra-rapid metabolism and thus increased sensitivity to codeine’s effects due to higher than expected serum morphine levels in 4-5% of the US population and 16-28% of North Africans, Ethiopians, and Arabs (Eichelbaum and Evert, 1996). Other variations in metabolic efficiency among ethnic groups are apparent. For example, Chinese produce less morphine from codeine than do Caucasians and also are less sensitive to morphine’s effects. The reduced sensitivity to morphine may be due to decreased production of morphine-6-glucuronide (Caraco et al., 1999). Thus, it is important to consider the possibility of metabolic enzyme polymorphism in any patient who experiences toxicity or does not receive adequate analgesia from codeine or other opioid prodrugs (e.g., hydrocodone and oxycodone).

Heroin (diacetylmorphine) is rapidly hydrolyzed to 6-monoacetylmorphine (6-MAM), which in turn is hydrolyzed to morphine. Heroin and 6-MAM are more lipid soluble than morphine and enter the brain more readily. Evidence suggests that morphine and 6-MAM are responsible for the pharmacological actions of heroin. Heroin is excreted mainly in the urine largely as free and conjugated morphine.

**Therapeutic Actions and Precautions**

Morphine and related opioids produce a wide spectrum of unwanted effects, including respiratory depression, nausea, vomiting, dizziness, mental clouding, dysphoria, pruritus, constipation, increased pressure in the biliary tract, urinary retention, and hypotension. The bases of these effects were described earlier. Rarely, a patient may develop delirium. Increased sensitivity to pain after analgesia has worn off and between-dose withdrawal also may occur.

A number of factors may alter a patient’s sensitivity to opioid analgesics, including the integrity of the blood-brain barrier. For example, when morphine is administered to a newborn infant in weight-appropriate doses extrapolated from adults, unexpectedly profound effects (analgesia and respiratory depression) may be observed. This is due to the immaturity of the blood-brain barrier in neonates. As mentioned previously, morphine is hydrophilic, so proportionately less morphine normally crosses into the CNS than with more lipophilic opioids. In neonates or when the blood-brain barrier is compromised, lipophilic opioids may give more predictable clinical results than morphine. In adults, the duration of the analgesia produced by morphine increases progressively with age; however, the degree of analgesia that is obtained with a given dose changes little. Changes in pharmacokinetic parameters only partially explain these observations. The patient with severe pain may tolerate larger doses of morphine. However, as the pain subsides, the patient may exhibit sedation and even respiratory depression as the stimulatory effects of pain are diminished.

All opioid analgesics are metabolized by the liver and should be used with caution in patients with hepatic disease because increased bioavailability after oral administration or cumulative effects may occur. Renal disease also significantly alters the pharmacokinetics of morphine, codeine, dihydrocodeine, meperidine, and propoxyphene. Although single doses of morphine are well tolerated, the active metabolite, morphine-6-glucuronide, may accumulate with continued dosing, and symptoms of opioid overdose may result (Cham and Matzke, 1987). This metabolite also may accumulate during repeated administration of codeine to patients with impaired renal function. When repeated doses of meperidine are given to such patients, the accumulation of normeperidine may cause tremor and seizures. Similarly, the repeated administration of propoxyphene may lead to naloxone-insensitive cardiac toxicity caused by the accumulation of norpropoxyphene (Cham and Matzke, 1987).

Morphine and related opioids must be used cautiously in patients with compromised respiratory function (e.g., emphysema, kyphoscoliosis, severe obesity). In patients with cor pulmonale, death has occurred after therapeutic doses of morphine. Although many patients with such conditions seem to be functioning within normal limits, they are already using compensatory mechanisms, such as increased respiratory rate. Many have chronically elevated levels of plasma CO₂ and may be less sensitive to the stimulating actions of CO₂. The further imposition of the depressant effects of opioids can be disastrous. The respiratory-depressant effects of opioids and the related capacity to elevate intracranial pressure must be considered in the presence of head injury or an already elevated intracranial pressure. While head injury per se does not constitute an absolute contraindication to the use of opioids, the possibility of exaggerated depression of respiration and the potential need to control ventilation of the patient must be considered. Finally, since opioids may produce mental clouding and side effects such as miosis and vomiting, which are important signs in following the clinical course of patients with head injuries, the advisability of their use must be weighed carefully against these risks.

Patients with reduced blood volume are considerably more susceptible to the vasodilating effects of morphine and related drugs, and these agents must be used cautiously in patients with hypotension from any cause.

Morphine causes histamine release, which can cause bronchoconstriction and vasodilation. Morphine has the potential to precipitate or exacerbate asthmatic attacks and should be avoided in patients with a history of asthma. Other receptor agonists associated with a lower incidence of histamine release, such as the fentanyl derivatives, may be better choices for such patients.

Aside from their ability to release histamine, opioid analgesics may evoke allergic phenomena, but a true allergic response is uncommon. The effects usually are manifested as urticaria and other types of skin rashes such as fixed eruptions; contact dermatitis in nurses and pharmaceutical workers also occurs. Wheals at the site of injection of morphine, codeine, and related drugs are likely secondary to histamine release. Anaphylactoid reactions have been reported after intravenous administration of codeine and morphine, but such
Morphine and has a t₁/₂ of 12-16 hours; repeated administration at short intervals may thus lead to accumulation of the drug in plasma. Other agents in this class closely parallel those of morphine. However, clinical reports suggest that it may produce less nausea and vomiting.

Levorphanol is metabolized less rapidly than morphine and has a t₁/₂ of 12-16 hours; repeated administration at short intervals may thus lead to accumulation of the drug in plasma. Other agents in this class include nalbuphine (NUBAIN, others) and butorphanol (STADOL, others), which are discussed in the section “Opioid Agonists/Antagonists and Partial Agonists” later in the chapter.

MEPERIDINE, DIPHENOXYLATE, LOPERAMIDE

The structural formulas of meperidine, a phenylpiperidine, and some of its congeners, are shown in Figure 18–9. Two important congeners are diphenoxylate and loperamide. These agents are MOR agonists with principal pharmacological effects on the CNS and neural elements in the bowel.

Meperidine

Meperidine is predominantly a MOR agonist that produces a pattern of effects similar but not identical to those already described for morphine.

Effects on Organ Systems

CNS Actions. Meperidine is a potent MOR agonist yielding strong analgesic actions. Peak respiratory depression is observed within 1 hour of intramuscular administration, and there is a return toward normal starting at ~2 hours. Like other opioids, meperidine causes pupillary constriction, increases the sensitivity of the labyrinthine apparatus, and has effects on the secretion of pituitary hormones similar to those of morphine. Meperidine sometimes causes CNS excitation, characterized by tremors, muscle twitches, and seizures; these effects are due largely to accumulation of a metabolite, normeperidine. Meperidine has well known local anesthetic properties, particularly noted after epidural administration. As with morphine, respiratory depression is responsible for an accumulation of CO₂, which in turn leads to cerebrovascular dilation, increased cerebral blood flow, and elevation of cerebrospinal fluid pressure.

Cardiovascular System. The effects of meperidine on the cardiovascular system generally resemble those of morphine, including the ability to release histamine following parenteral administration. Intramuscular administration of meperidine does not affect heart rate significantly, but intravenous administration frequently produces a marked increase in heart rate.

Smooth Muscle. Meperidine has effects on certain smooth muscles qualitatively similar to those observed with other opioids. Meperidine does not cause as much constipation as does morphine, even when given over prolonged periods of time; this may be related to its greater ability to enter the CNS, thereby producing analgesia at lower systemic concentrations. As with other opioids, clinical doses of meperidine slow gastric emptying sufficiently to delay absorption of other drugs significantly.

The uterus of a nonpregnant woman usually is mildly stimulated by meperidine. Administered before an oxytocic, meperidine does not exert any antagonistic effect. Therapeutic doses given during active labor do not delay the birth process; in fact, the frequency, duration, and amplitude of uterine contraction sometimes may be increased (Zimmer et al., 1988). The drug does not interfere with normal postpartum contraction or involution of the uterus, and it does not increase the incidence of postpartum hemorrhage. See also “Therapeutic Uses” later in the chapter.

Absorption, Distribution, Metabolism, and Excretion. Meperidine is absorbed by all routes of administration, but the rate of absorption may be erratic after intramuscular injection. The peak plasma concentration usually occurs at ~45 minutes, but the range is wide. After oral administration, only ~50% of the drug escapes first-pass metabolism to enter the circulation, and peak concentrations in plasma usually are observed within 1-2 hours.

In humans, meperidine is hydrolyzed to meperidinic acid, which in turn is partially conjugated. Meperidine also is N-demethylated to normeperidine, which then may be hydrolyzed to normeperidinic acid and subsequently conjugated. The clinical significance of the formation of normeperidine is discussed later. Meperidine is metabolized chiefly in the liver, with a t₁/₂ of ~3 hours. In patients with cirrhosis, the bioavailability of meperidine is increased to as much as 80%, and the t₁/₂ of both meperidine and normeperidine are prolonged. Approximately 60% of meperidine in plasma is protein bound. Only a small amount of meperidine is excreted unchanged.

Untoward Effects, Precautions, and Contraindications. The pattern and overall incidence of untoward effects that follow the use of meperidine are similar to those observed after equianalgesic doses of morphine, except that constipation and urinary retention may be less common. Patients who experience nausea and vomiting with morphine

Figure 18–9. Chemical structures of piperidine and phenylpiperidine analgesics.
may not do so with meperidine; the converse also may be true. As with other opioids, tolerance develops to some of these effects. The contraindications generally are the same as for other opioids. In patients or addicts who are tolerant to the depressant effects of meperidine, large doses repeated at short intervals may produce an excitatory syndrome including hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are due to the accumulation of normeperidine, which has a t1/2 of 15-20 hours, compared to 3 hours for meperidine. Since normeperidine is eliminated by the kidney and the liver, decreased renal or hepatic function increases the likelihood of toxicity. As a result of these properties, meperidine is not recommended for the treatment of chronic pain because of concerns over metabolite toxicity. It should not be used for longer than 48 hours or in doses >600 mg/day (see www.ahrq.gov).

**Interactions with Other Drugs.** Severe reactions may follow the administration of meperidine to patients being treated with MAO inhibitors. Two basic types of interactions can be observed. The most prominent is an excitatory reaction (“serotonin syndrome”) with delirium, hyperthermia, headache, hyper- or hypotension, rigidity, convulsions, coma, and death. This reaction may be due to the ability of meperidine to block neuronal reuptake of 5-HT, resulting in serotoninergic overactivity (Stack et al., 1988). Conversely, the MAO inhibitor interaction with meperidine may resemble acute narcotic overdose owing to the inhibition of hepatic CYPs. Therefore, meperidine and its congeners are contraindicated in patients taking MAO inhibitors or within 14 days after discontinuation of an MAO inhibitor. Similarly, dextromethorphan (an analog of levorphanol used as a non-narcotic cough suppressant) also inhibits neuronal 5-HT uptake and must be avoided in these patients. In addition, tramadol and tapentadol (centrally acting synthetic opioid analgesics, described later) inhibit the uptake of norepinephrine and 5-HT and should not be used concomitantly with MAO inhibitors or selective serotonin reuptake inhibitors (SSRIs).

Chlorpromazine increases the respiratory-depressant effects of meperidine, as do tricyclic antidepressants; this is not true of diazepam. Concurrent administration of drugs such as promethazine or chlorpromazine also may greatly enhance meperidine-induced sedation without slowing clearance of the drug. Treatment with phenobarbital or phenytoin increases systemic clearance and decreases oral bioavailability of meperidine; this is associated with an elevation of the concentration of normeperidine in plasma (Edwards et al., 1982). As with morphine, concomitant administration of amphetamine has been reported to enhance the analgesic effects of meperidine and its congeners while counteracting sedation.

**Therapeutic Uses.** The major use of meperidine is for analgesia. Unlike morphine and its congeners, meperidine is not used for the treatment of cough or diarrhea. The analgesic effects of meperidine are detectable ~15 minutes after oral administration, peak in 1-2 hours, and subside gradually. The onset of analgesic effect is faster (within 10 minutes) after subcutaneous or intramuscular administration, and the effect reaches a peak in ~1 hour, corresponding closely to peak concentrations in plasma. In clinical use, the duration of effective analgesia is ~1.5-3 hours. In general, 75-100 mg meperidine hydrochloride (pethidine, DEMEROL, others) given parenterally is approximately equivalent to 10 mg morphine, and in equianalgesic doses, meperidine produces as much sedation, respiratory depression, and euphoria as does morphine. In terms of total analgesic effect, meperidine is about one-third as effective when given orally as when administered parenterally. A few patients may experience dysphoria.

Single doses of meperidine also appear to be effective in the treatment of postanesthetic shivering. Meperidine, 25-50 mg, is used frequently with antihistamines, corticosteroids, acetaminophen, or nonsteroidal anti-inflammatory drugs (NSAIDs) to prevent or ameliorate infusion-related rigors and shaking chills that accompany the intravenous administration of agents such as amphotericin B, aldesleukin (interleukin-2), trastuzumab, and alemtuzumab.

Meperidine crosses the placental barrier and even in reasonable analgesic doses causes a significant increase in the percentage of babies who show delayed respiration, decreased respiratory minute volume, or decreased O2 saturation or who require resuscitation. Fetal and maternal respiratory depression induced by meperidine can be treated with naloxone. The fraction of drug that is bound to protein is lower in the fetus; concentrations of free drug thus may be considerably higher than in the mother. Nevertheless, meperidine produces less respiratory depression in the newborn than does an equianalgesic dose of morphine or methadone (Fishburne, 1982).

### Diphenoxylate

Diphenoxylate is a meperidine congener that has a definite constipating effect in humans. Its only approved use is in the treatment of diarrhea (Chapter 46). Although single doses in the therapeutic range (see below) produce little or no morphine-like subjective effects, at high doses (40-60 mg) the drug shows typical opioid activity, including euphoria, suppression of morphine abstinence syndrome, and a morphine-like physical dependence after chronic administration. Diphenoxylate is unusual in that even its salts are virtually insoluble in aqueous solution, thus obviating the possibility of abuse by the parenteral route.

Diphenoxylate hydrochloride is available only in combination with atropine sulfate (LOMOTIL, others). The recommended daily dosage of diphenoxylate for the treatment of diarrhea in adults is 20 mg in divided doses. Diarrhea refractory to maximal doses of diphenoxylate for 10 days is unlikely to be controlled by further therapy. Difenoxin, a metabolite of diphenoxylate, has actions similar to those of the parent compound. Like diphenoxylate, difenoxin is marketed in a fixed dose with atropine (MOTOFEN) for the management of diarrhea.

### Loperamide

Loperamide (IMODIUM, others), like diphenoxylate, is a piperidine derivative (Figure 18–3). It slows GI motility
by effects on the circular and longitudinal muscles of the intestine, presumably as a result of its interactions with opioid receptors in the intestine. Some part of its antiarrhythmic effect may be due to a reduction of gastrointestinal secretion (described earlier) (Kromer, 1988). In controlling chronic diarrhea, loperamide is as effective as diphenoxylate. In clinical studies, the most common side effect was abdominal cramps. Little tolerance develops to its constipating effect.

In human volunteers taking large doses of loperamide, concentrations of drug in plasma peak ~4 hours after ingestion; this long latency may be due to inhibition of GI motility and to enterohepatic circulation of the drug. The apparent elimination t½ is 7-14 hours. Loperamide is poorly absorbed after oral administration and, in addition, apparently does not penetrate well into the brain due to the exporting activity of P-glycoprotein, which is widely expressed in the brain endothelium (Sadeque et al., 2000). Mice with deletions of one of the genes encoding the P-glycoprotein transporter have much higher brain levels and significant central effects after administration of loperamide (Schinkel et al., 1996). Inhibition of P-glycoprotein by many clinically used drugs, such as quinidine and verapamil, possibly could lead to enhanced central effects of loperamide.

In general, loperamide is unlikely to be abused parenterally because of its low solubility; large doses of loperamide given to human volunteers do not elicit pleasurable effects typical of opioids. The usual dosage is 4-8 mg/day; the daily dose should not exceed 16 mg.

**FENTANYL AND CONGENERS**

**Fentanyl**

Fentanyl is a synthetic opioid related to the phenylpiperidines (Figure 18–9). The actions of fentanyl and its congeners, sufentanil, remifentanil, and alfentanil, are similar to those of other MOR agonists. Alfentanil (ALFENTA, others) is seldom used. Fentanyl and sufentanil are very important drugs in anesthetic practice because of their relatively short time to peak analgesic effect, rapid termination of effect after small bolus doses, minimal direct depressant effects on the myocardium, and their ability to significantly reduce the dosing requirement for the volatile agents (“MAC-sparing”; see Chapter 19). In addition to a role in anesthesia, fentanyl also is used in the management of severe pain states.

**Pharmacological Properties**

**CNS Effects.** Fentanyl and its congeners are all extremely potent analgesics and typically exhibit a very short duration of action when given parenterally. As with other opioids, nausea, vomiting, and itching can be observed. Muscle rigidity, while possible after all narcotics, appears to be more common after the high doses used in anesthetic induction. Rigidity can be treated with depolarizing or non-depolarizing neuromuscular blocking agents while controlling the patient’s ventilation. Care must be taken to make sure that the patient is not simply immobilized but aware. Respiratory depression is similar to that observed with other receptor agonists, but the onset is more rapid. As with analgesia, respiratory depression after small doses is of shorter duration than with morphine but of similar duration after large doses or long infusions. As with morphine and meperidine, delayed respiratory depression also can be seen after the use of fentanyl or sufentanil, possibly owing to enterohepatic circulation. High doses of fentanyl can cause neuroexcitation and, rarely, seizure-like activity in humans (Bailey and Stanley, 1994). Fentanyl has minimal effects on intracranial pressure when ventilation is controlled and the arterial CO2 concentration is not allowed to rise.

**Cardiovascular System.** Fentanyl and its derivatives decrease heart rate and mildly decrease blood pressure. However, these drugs do not release histamine and direct depressant effects on the myocardium are minimal. For this reason, high doses of fentanyl or sufentanil are commonly used as the primary anesthetic for patients undergoing cardiovascular surgery or for patients with poor cardiac function.

**Absorption, Distribution, Metabolism, and Excretion.** These agents are highly lipid soluble and rapidly cross the blood-brain barrier. This is reflected in the t½ for equilibration between the plasma and cerebrospinal fluid of ~5 minutes for fentanyl and sufentanil. The levels in plasma and cerebrospinal fluid decline rapidly owing to redistribution of fentanyl from highly perfused tissue groups to other tissues, such as muscle and fat. As saturation of less well-perfused tissue occurs, the duration of effect of fentanyl and sufentanil approaches the length of their elimination t½ (~3-4 hours). Fentanyl and sufentanil undergo hepatic metabolism and renal excretion. With the use of higher doses or prolonged infusions, the drugs accumulate, these clearance mechanisms become progressively saturated, and fentanyl and sufentanil become longer acting.

**Therapeutic Uses.** Fentanyl citrate (SUBLIMAZE, others) and sufentanil citrate (SUFENTA, others) have widespread popularity as anesthetic adjuncts (Chapter 19). They are used commonly either intravenously, epidurally, or intrathecally. The analgesic effects of fentanyl and sufentanil are similar to those of morphine and other opioids. Fentanyl is ~100 times more potent than morphine, and sufentanil is ~1000 times more potent than morphine. The time to peak analgesic effect after intravenous administration of fentanyl and sufentanil (~5 minutes) is notably less than that for morphine and meperidine (~15 minutes). Recovery from analgesic effects also occurs more quickly. However, with larger doses or prolonged infusions, the effects of these drugs become more lasting, with durations of action becoming similar to those of longer-acting opioids (described later). Intravenous use of fentanyl and sufentanil for postoperative pain has been popular.

Epidural use of fentanyl and sufentanil for postoperative or labor analgesia has significant popularity. A combination of epidural opioids with local anesthetics permits reduction in the dosage of both components, minimizing the side effects of the local anesthetic (i.e., motor blockade) and the opioid (i.e., urinary retention, itching, and delayed respiratory depression in the case of morphine). An important caveat to their spinal use is that because of their rapid clearance, these agents at analgesic spinal doses can produce blood levels that are similar to those producing effects after systemic administration (Bernards, 2004).
The use of fentanyl and sufentanil in chronic pain treatment has become more widespread. The development of novel, minimally invasive routes of administration for fentanyl has facilitated the use of these compounds in chronic pain management. Transdermal patches (DURAGESIC, others) that provide sustained release of fentanyl for 48-72 hours are available. However, factors promoting increased absorption (e.g., fever) can lead to relative overdosage and increased side effects (see “Routes of Analgesic Drug Administration” later in the chapter). Transbuccal absorption by the use of buccal tablets, soluble buccal film, and lollypop-like lozenges permits rapid absorption and has found use in the management of acute incident pain (FENTORA, ACTIQ, ONSOLIS, others) and for the relief of breakthrough cancer pain. As fentanyl is poorly absorbed in the GI tract, the optimal absorption is through buccal absorption. Accordingly, there is little opportunity for overdosing by that route.

Remifentanil

This compound was developed in an effort to create an analgesic with a more rapid onset and predictable termination of effect. The potency of remifentanil is approximately equal to that of fentanyl. The pharmacological properties of remifentanil are similar to those of fentanyl and sufentanil. They produce similar incidences of nausea, vomiting, and dose-dependent muscle rigidity. Nausea, vomiting, itching, and headaches have been reported when remifentanil has been used for conscious analgesia for painful procedures. Intracranial pressure changes are minimal when ventilation is controlled. Seizures after remifentanil administration have been reported (Beers and Camporesi, 2004).

Absorption, Fate, and Excretion. Remifentanil has a more rapid onset of analgesic action than fentanyl or sufentanil. Analgesic effects occur within 1-1.5 minutes following intravenous administration. Peak respiratory depression after bolus doses of remifentanil occurs after 5 minutes (Patel and Spencer, 1996). Remifentanil is metabolized by plasma esterases, with a t1/2 of 8-20 minutes (Burkle et al., 1996); thus, elimination is independent of hepatic metabolism or renal excretion. There is no prolongation of effect with repeated dosing or prolonged infusion. Age and weight can affect clearance of remifentanil, requiring that dosage be reduced in the elderly and based on lean body mass. However, neither of these conditions causes major changes in duration of effect. After 3- to 5-hour infusions of remifentanil, recovery of respiratory function can be seen within 3-5 minutes; full recovery from all effects of remifentanil is observed within 15 minutes (Glass et al., 1999). The primary metabolite, remifentanil acid, has 0.05-0.025% of the potency of the parent compound, and is excreted renally.

Therapeutic Uses. Remifentanil hydrochloride (ULTIVA) is useful for short, painful procedures that require intense analgesia and blunting of stress responses; the drug is routinely given by continuous intravenous infusion because its short duration of action makes bolus administration impractical. The titratability of remifentanil and its consistent, rapid offset make it ideally suited for short surgical procedures where rapid recovery is desirable. Remifentanil also has been used successfully for longer neurosurgical procedures, where rapid emergence from anesthesia may be important. However, in cases where postprocedural analgesia is required, remifentanil alone is a poor choice. In this situation, either a longer-acting opioid or another analgesic modality should be combined with remifentanil for prolonged analgesia, or another opioid should be used. Remifentanil is not used intraspinally because of its formulation with glycine, an inhibitory transmitter in the spinal dorsal horn.

METHADONE AND PROPOXYPHENE

Methadone

Methadone (Figure 18–9) is a long-acting MOR agonist with pharmacological properties qualitatively similar to those of morphine. The analgesic activity of methadone, a racemate, is almost entirely the result of its content of L-methadone, which is 8-50 times more potent than the D isomer. D-methadone also lacks significant respiratory depressant action and addiction liability but possesses antitussive activity.

CNS Effects. The outstanding properties of methadone are its analgesic activity, its efficacy by the oral route, its extended duration of action in suppressing withdrawal symptoms in physically dependent individuals, and its tendency to show persistent effects with repeated administration. Miotic and respiratory-depressant effects can be detected for >24 hours after a single dose; on repeated administration, marked sedation is seen in some patients. Effects on cough, bowel motility, biliary tone, and the secretion of pituitary hormones are qualitatively similar to those of morphine.

Absorption, Distribution, Metabolism, and Excretion. Methadone is absorbed well from the GI tract and can be detected in plasma within 30 minutes of oral ingestion; it reaches peak concentrations at ~4 hours. After therapeutic doses, ~90% of methadone is bound to plasma proteins. Peak concentrations occur in brain within 1-2 hours of subcutaneous or intramuscular administration, and this correlates well with the intensity and duration of analgesia. Methadone also can be absorbed from the buccal mucosa.

Methadone undergoes extensive biotransformation in the liver. The major metabolites, the results of N-demethylation and cyclization to form pyrrolidines and pyrrolone, are excreted in the urine and the bile along with small amounts of unchanged drug. The amount of methadone excreted in the urine is increased when the urine is acidified. The t1/2 of methadone is long, 15-40 hours.

Methadone appears to be firmly bound to protein in various tissues, including brain. After repeated administration, there is gradual accumulation in tissues. When administration is discontinued, low concentrations are maintained in plasma by slow release from extravascular binding sites; this process probably accounts for the relatively mild but protracted withdrawal syndrome.

Side Effects, Toxicity, Drug Interactions, and Precautions. Side effects, toxicity, and conditions that alter sensitivity, as well as the
treatment of acute intoxication, are similar to those described for morphine. During long-term administration, there may be excessive sweating, lymphocytosis, and increased concentrations of prolactin, albumin, and globulins in the plasma. Rifampin and phenytoin accelerate the metabolism of methadone and can precipitate withdrawal symptoms. Unlike other opioids, methadone is associated with the prolonged QT syndrome and is additive with agents known to prolong the QT interval. Serious cardiac arrhythmias, including torsades de pointes, have been observed during treatment with methadone.

Therapeutic Uses. The primary uses of methadone hydrochloride (DOLOPHINE, others) are relief of chronic pain, treatment of opioid abstinence syndromes, and treatment of heroin users. In the U.S., prescribing methadone for abstinence syndrome and maintenance of heroin users is regulated by Federal Opioid Treatment Standards (42 CFR 8.12). The onset of analgesia occurs 10-20 minutes after parenteral administration and 30-60 minutes after oral medication. The average minimal effective analgesic concentration in blood is ~30 ng/mL (Gourlay et al., 1986). The typical oral dose is 2.5-10 mg repeated every 8-12 hours as needed depending on the severity of the pain and the response of the patient. Care must be taken when escalating the dosage because of the prolonged t1/2 of the drug and its tendency to accumulate over a period of several days with repeated dosing. Iatrogenic overdoses have occurred during initiation of therapy and dosing titration with methadone because of too-rapid titration or the concomitant use of depressant drugs. The peak respiratory depressant effects of methadone typically occur later and persist longer than the peak analgesic effects so it is necessary to exercise vigilance and strongly caution patients against self-medicating with CNS depressants, particularly during treatment initiation and dose titration. Methadone is not used widely as an antiperistaltic agent and should not be used in labor.

Despite its longer plasma t1/2, the duration of the analgesic action of single doses is essentially the same as that of morphine. With repeated use, cumulative effects are seen, so either lower dosages or longer intervals between doses become possible. In contrast to morphine, methadone and many of its congeners retain a considerable degree of their effectiveness when given orally. In terms of total analgesic effects, methadone given orally is ~50% as effective as the same dose administered intramuscularly; however, the oral-parenteral potency ratio is considerably lower when peak analgesic effect is considered. In equianalgesic doses, the pattern and incidence of untoward effects caused by methadone and morphine are similar.

Because of its oral bioavailability and long t1/2, methadone has been widely implemented as a replacement modality to treat heroin dependence. Methadone, like other opiates, will produce tolerance and dependence. Thus, addicts who receive daily subcutaneous or oral therapy develop partial tolerance to the nausea, anorectic, miotic, sedative, respiratory-depressant, and cardiovascular effects of methadone. Many former heroin users treated with oral methadone show virtually no overt behavioral effects (Mattick et al., 2009). Development of physical dependence during the long-term administration of methadone can be demonstrated following abrupt drug withdrawal or by administration of an opioid antagonist. Likewise, subcutaneous administration of methadone to former opioid addicts produces euphoria equal in duration to that caused by morphine, and its overall abuse potential is comparable with that of morphine.

Propoxyphene

Propoxyphene is structurally related to methadone (Figure 18–9). Its analgesic effect resides in the D-isomer. However, L-propxyphene seems to have some antitussive activity. D-propxyphene may be combined with a number of adjuvants including acetaminophen or acetylsalicylic acid. A variant on propoxyphene is formulation as the napsylate salt, which slows absorption and reduces solubility (to diminish diversion for IV delivery).

Pharmacological Actions. Although slightly less selective than morphine, propoxyphene binds primarily to μ opioid receptors and produces analgesia and other CNS effects that are similar to those seen with morphine-like opioids. It is likely that at equianalgesic doses the incidence of side effects such as nausea, anorexia, constipation, abdominal pain, and drowsiness are similar to those of codeine.

As an analgesic, propoxyphene is about one-half to two-thirds as potent as codeine given orally. A dose of 90-120 mg of propoxyphene hydrochloride administered orally would equal the analgesic effects of 60 mg of codeine, a dose that usually produces about as much analgesia as 600 mg aspirin. Combinations of propoxyphene and aspirin, like combinations of codeine and aspirin, afford a higher level of analgesia than does either agent given alone (Beaver, 1988).

Absorption, Distribution, Metabolism, and Excretion. After oral administration, concentrations of propoxyphene in plasma reach their highest values at 1-2 hours. There is great variability between subjects in the rate of clearance and the plasma concentrations that are achieved. The average t1/2 of propoxyphene in plasma after a single dose is 6-12 hours, which is longer than that of codeine. In humans, the major route of metabolism is N-demethylation to yield nortorpropoxyphene. The t1/2 of nortorpropoxyphene is ~30 hours, and its accumulation with repeated doses may be responsible for some of the observed toxicity (Chan and Matzke, 1987).

Toxicity. Given orally, propoxyphene is approximately one-third as potent as orally administered codeine in depressing respiration. Moderately toxic doses usually produce CNS and respiratory depression, but with still larger doses the clinical picture may be complicated by convulsions in addition to respiratory depression. Delusions, hallucinations, confusion, cardiotoxicity, and pulmonary edema also have been noted. Respiratory-depressant effects are significantly enhanced when ethanol or sedative-hypnotics are ingested concurrently. Naloxone antagonizes the respiratory-depressant, convulsant, and some of the cardiotoxic effects of propoxyphene. A second aspect of propoxyphene toxicity is liver or renal toxicity that arises when the combination medication containing acetaminophen or acetylsalicylate, respectively, is employed in conjunction with intake of those medications separately, leading to a frank overdose of these adjuvants.

Tolerance and Dependence. Very large doses (800 mg propoxyphene hydrochloride [DARVON, others] or 1200 mg of the napsylate [DARVON-N]) per day) reduce the intensity of the morphine withdrawal syndrome somewhat less effectively than do 1500 mg doses of codeine. Maximal tolerated doses are equivalent to daily
doses of 20-25 mg morphine given subcutaneously. The use of higher doses of propoxyphene is accompanied by untoward effects including toxic psychoses. Very large doses produce some respiratory depression in morphine-tolerant addicts, suggesting that cross-tolerance between propoxyphene and morphine is incomplete. Abrupt discontinuation of chronically administered propoxyphene hydrochloride (up to 800 mg/day given for almost 2 months) results in mild abstinence phenomena, and large oral doses (300-600 mg) produce subjective effects that are considered pleasurable by postaddicts. The drug is quite irritating when administered either intravenously or subcutaneously, so abuse by these routes results in severe damage to veins and soft tissues.

Therapeutic Uses. In 2009, the European Medicines Agency completed a review of the safety and effectiveness of dextropropoxyphene-containing medicines and concluded that the benefits do not outweigh the risks and recommended a gradual withdrawal of marketing authorization throughout the EU (European Medicines Agency, 2009). The conclusion reached by the agency included an assessment that dextropropoxyphene-containing medicines are weak painkillers with a limited effectiveness in the treatment of pain and a narrow therapeutic index. Furthermore, the agency judged acetaminophen (paracetamol) containing combinations with dextropropoxyphene to be no more effective than acetaminophen alone. In the U.S., propoxyphene has been approved for mild to moderate pain since 1957. Recently the drug has been labeled with additional warnings related to the risk of rapidly fatal effects in the event of an overdose (FDA, 2009). Thus, in the U.S., propoxyphene should not be prescribed to patients who are suicidal or have a history of suicidal ideation. In addition, higher than expected serum levels of propoxyphene should be anticipated from the concomitant administration of strong CYP3A4 inhibitors such as ritonavir, ketoconazole, itraconazole, clarithromycin, nelfinavir, nefazadone, amiodarone, amphenavir, aprepitant, diltiazem, erythromycin, fluconazole, fosamprenavir, grapefruit juice, and verapamil. Propoxyphene alternatives should be considered for patients receiving a strong CYP3A4 inhibitor and others at risk for overdose, particularly those with pre-existing heart disease.

Other Opioid Agonists

Tramadol. Tramadol (ULTRAM) is a synthetic codeine analog that is a weak MOR agonist. Part of its analgesic effect is produced by inhibition of uptake of norepinephrine and serotonin. In the treatment of mild to moderate pain, tramadol is as effective as morphine or meperidine. However, for the treatment of severe or chronic pain, tramadol is less effective. Tramadol is as effective as meperidine in the treatment of labor pain and may cause less neonatal respiratory depression.

Pharmacokinetics. Tramadol is 68% bioavailable after a single oral dose and 100% available when administered intramuscularly. Its affinity for the μ opioid receptor is only 1/6000 that of morphine. However, the primary O-demethylated metabolite of tramadol is two to four times as potent as the parent drug and may account for part of the analgesic effect. Tramadol is supplied as a racemic mixture, which is more effective than either enantiomer alone. The (+)-enantiomer binds to the receptor and inhibits serotonin uptake. The (−)-enantiomer inhibits norepinephrine uptake and stimulates α₂ adrenergic receptors (Lewis and Han, 1997). Tramadol undergoes extensive hepatic metabolism by a number of pathways, including CYP2D6 and CYP3A4, as well as by conjugation with subsequent renal excretion. The rate of formation of the active metabolite is dependent on CYP2D6 and therefore is subject to both metabolic induction and inhibition. The elimination t1/2 is 6 hours for tramadol and 7.5 hours for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2-3 hours. The duration of analgesia is ~6 hours. The maximum recommended daily dose is 400 mg.

Side Effects and Adverse Effects. Common side effects of tramadol include nausea, vomiting, dizziness, dry mouth, sedation, and headache. Respiratory depression appears to be less than with equianalgesic doses of morphine, and the degree of constipation is less than that seen after equivalent doses of codeine (Duthie, 1998). Tramadol can cause seizures and possibly exacerbate seizures in patients with predisposing factors. While tramadol-induced analgesia is not entirely reversible by naltrexone, tramadol-induced respiratory depression is reversed by naltrexone. However, the use of naltrexone increases the risk of seizure in patients exposed to tramadol. Misuse, diversion, physical dependence, abuse, addiction, and withdrawal have been reported in conjunction with the use of tramadol. Tramadol has been shown to reinitiate physical dependence in some patients who have previously been dependent on other opioids, thus it should be avoided in patients with a history of addiction. Precipitation of withdrawal necessitates that tramadol be tapered prior to discontinuation. Tramadol should not be used in patients taking MAO inhibitors (Lewis and Han, 1997), SSRIs, or other drugs that lower the seizure threshold (described earlier).

Tapentadol. Tapentadol (NUCYNTA) is structurally and mechanistically similar to tramadol. It displays a mild opioid activity and possesses monoamine reuptake inhibitor activity. It is considered similar to tramadol in activity, efficacy, and side-effect profile. Like tramadol, it should not be used concurrently with agents that enhance monoamine activity or lower the seizure threshold, such as MAO inhibitors and SSRIs. The major pathway of tapentadol metabolism is conjugation with glucuronic acid; ~70% of the dose is excreted in urine in the conjugated form.

OPIOID AGONISTS/ANTAGONISTS AND PARTIAL AGONISTS

The drugs described in this section differ from clinically used μ opioid receptor agonists. Drugs such as nalbuphine and butorphanol are competitive MOR antagonists but exert their analgesic actions by acting as agonists at KOR receptors. Pentazocine qualitatively resembles these drugs, but it may be a weaker MOR receptor antagonist or partial agonist while retaining its KOR agonist activity. Buprenorphine, on the other hand, is a partial agonist at MOR. The stimulus for the development of mixed agonist–antagonist drugs was a desire for analgesics with less respiratory depression and addictive potential. However, the clinical use of these compounds is limited by undesirable side-effects and limited analgesic effects.
**Pentazocine**

Pentazocine was synthesized as part of a deliberate effort to develop an effective analgesic with little or no abuse potential. It has agonistic actions and weak opioid antagonistic activity.

**Pharmacological Actions and Side Effects.** The pattern of CNS effects produced by pentazocine generally is similar to that of the morphine-like opioids, including analgesia, sedation, and respiratory depression. The analgesic effects of pentazocine are due to agonistic actions at opioid receptors. Higher doses of pentazocine (60-90 mg) elicit dysphoric and psychotomimetic effects. The mechanisms responsible for these side effects are not known but might involve activation of supraspinal receptors because it has been suggested that these untoward effects may be reversible by naloxone.

The cardiovascular responses to pentazocine differ from those seen with typical receptor agonists, in that high doses cause an increase in blood pressure and heart rate. Pentazocine acts as a weak antagonist or partial agonist at opioid receptors. Pentazocine does not antagonize the respiratory depression produced by morphine. However, when given to patients dependent on morphine or other MOR agonists, pentazocine may precipitate withdrawal. Ceiling effects for analgesia and respiratory depression are observed at doses above 50-100 mg of pentazocine (Bailey and Stanley, 1994).

**Therapeutic Uses.** Pentazocine lactate (TALWIN) injection is indicated for the relief of moderate to severe pain and is also used as a preoperative medication and as a supplement to anesthesia. Pentazocine tablets for oral use are only available in fixed-dose combinations with acetaminophen (TALACEN, others) or naloxone (TALWIN NX). Combination of pentazocine with naloxone reduces the potential misuse of tablets as a source of injectable pentazocine by producing undesirable effects in subjects dependent on opioids. After oral ingestion, naloxone is destroyed rapidly by the liver. An oral dose of ~50 mg pentazocine results in analgesia equivalent to that produced by 60 mg of orally administered codeine.

**Nalbuphine**

Nalbuphine is related structurally to naloxone and oxymorphone (Figure 18–8). It is generally considered to be a KOR agonist-MOR antagonist opioid with a spectrum of effects that qualitatively resembles that of pentazocine; however, nalbuphine is considered to be less likely to produce dysphoric side effects than is pentazocine.

**Pharmacological Actions and Side Effects.** An intramuscular dose of 10 mg nalbuphine is equianalgesic to 10 mg morphine, with similar onset and duration of analgesic and subjective effects. Nalbuphine depresses respiration as much as do equianalgesic doses of morphine; however, nalbuphine exhibits a ceiling effect such that increases in dosage beyond 30 mg produce no further respiratory depression as well as no further analgesia. In contrast to pentazocine and butorphanol, 10 mg nalbuphine given to patients with stable coronary artery disease does not produce an increase in cardiac index, pulmonary arterial pressure, or cardiac work, and systemic blood pressure is not significantly altered; these indices also are relatively stable when nalbuphine is given to patients with acute myocardial infarction (Roth et al., 1988); nevertheless, morphine is generally considered a first-line agent for use during acute cardiac events to relieve chest pain and anxiety. The GI effects of nalbuphine probably are similar to those of pentazocine. Nalbuphine produces few side effects at doses of 10 mg or less; sedation, sweating, and headache are the most common. At much higher doses (70 mg), psychotomimetic side effects (e.g., dysphoria, racing thoughts, and distortions of body image) can occur. Nalbuphine is metabolized in the liver and has a plasma t1/2 of 2-3 hours. Nalbuphine is 20-25% as potent when administered orally as when given intramuscularly. No oral dosage forms are commercially available in the U.S.

**Tolerance and Physical Dependence.** In subjects dependent on low doses of morphine (60 mg/day), nalbuphine precipitates an abstinence syndrome. Prolonged administration of nalbuphine can produce physical dependence. The withdrawal syndrome is similar in intensity to that seen with pentazocine. The potential for abuse of parenteral nalbuphine in subjects not dependent on receptor agonists probably is similar to that for parenteral pentazocine.

**Therapeutic Use.** Nalbuphine hydrochloride (NUBAIN, others) is used to produce analgesia. Because it is an agonist–antagonist, administration to patients who have been receiving morphine-like opioids may create difficulties unless a brief drug-free interval is interposed. The usual adult dose is 10 mg parenterally every 3-6 hours; this may be increased to 20 mg in nontolerant individuals. A caveat: agents that act through the KOR have been reported to be relatively more effective in women than in men (Gear et al., 1999).

**Butorphanol**

Butorphanol is a morphinan congener with a profile of actions similar to those of pentazocine and nalbuphine: KOR agonist-MOR antagonist opioid. The structural formula of butorphanol is shown in Figure 18–8.

**Therapeutic Use.** In general, butorphanol tartrate (STADOL, others) is considered to be best suited for the relief of acute pain (e.g., postoperative), and because of its potential for antagonizing MOR agonists should not be used in combination. Because of its side effects on the heart, it is less useful than morphine or meperidine in patients with congestive heart failure or myocardial infarction. The usual dose is 1-4 mg of the tartrate given intramuscularly, or 0.5-2 mg given intravenously, every 3-4 hours. A nasal formulation is available and has proven to be effective in pain relief, including migraine pain. This formulation may be particularly useful for patients with severe headaches who are unresponsive to other forms of treatment.

**Pharmacological Actions and Side Effects.** In postoperative patients, a parenteral dose of 2-3 mg butorphanol produces analgesia and respiratory depression approximately equal to that produced by 10 mg morphine or 80-100 mg meperidine; the onset, peak, and duration of action are similar to those that follow the administration of morphine. The plasma t1/2 of butorphanol is ~3 hours. Like pentazocine, analgesic doses of butorphanol produce an increase in pulmonary arterial pressure and in the work of the heart; systemic arterial pressure is slightly decreased (Popio et al., 1978).

The major side effects of butorphanol are drowsiness, weakness, sweating, feelings of floating, and nausea. While the incidence
of psychotomimetic side effects is lower than that with equianalgesic doses of pentazocine, they are qualitatively similar. Nasal administration is associated with drowsiness and dizziness. Physical dependence can occur.

**Buprenorphine**

Buprenorphine is a highly lipophilic MOR agonist derived from thebaine (Figure 18–8). It is 25-50 times more potent than morphine, though it is considered to be a partial MOR agonist (e.g., has limited intrinsic activity) and accordingly can display antagonism when used in conjunction with a full agonist (see below).

**Pharmacological Actions and Side Effects.** Buprenorphine produces analgesia and other CNS effects that are qualitatively similar to those of morphine. About 0.4 mg buprenorphine is equianalgesic with 10 mg morphine given intramuscularly (Wallenstein et al., 1986). Although variable, the duration of analgesia usually is longer than that of morphine. Some of the subjective and respiratory-depressant effects are unequivocally slower in onset and last longer than those of morphine. For example, peak miosis occurs ~6 hours after intramuscular injection, whereas maximal respiratory depression is observed at ~3 hours.

Because buprenorphine is a partial MOR agonist, it may cause symptoms of abstinence in patients who have been receiving receptor agonists for several weeks. It antagonizes the respiratory depression produced by anesthetic doses of fentanyl about as well as naloxone without completely reversing opioid pain relief (Boysen and Hertel, 1988). Although respiratory depression has not been a major problem, it is not clear whether there is a ceiling for this effect (as seen with nalbuphine and pentazocine). The respiratory depression and other effects of buprenorphine can be prevented by prior administration of naloxone, but they are not readily reversed by high doses of naloxone once the effects have been produced. This suggests that buprenorphine dissociates very slowly from opioid receptors.

The t_{1/2} for dissociation from the receptor is 166 minutes for buprenorphine, as opposed to 7 minutes for fentanyl (Boas and Villiger, 1985). Therefore, plasma levels of buprenorphine may not parallel clinical effects. Cardiovascular and other side effects (e.g., sedation, nausea, vomiting, dizziness, sweating, and headache) appear to be similar to those of morphine-like opioids.

Buprenorphine is relatively well absorbed by most routes. Administered sublingually, the drug (0.4-0.8 mg) produces satisfactory analgesia in postoperative patients. Concentrations in blood peak within 5 minutes of intramuscular injection and within 1-2 hours of oral or sublingual administration. While the plasma t_{1/2} in plasma is ~3 hours, this value bears little relationship to the rate of disappearance of effects (discussed earlier). Both N-dealkylated and conjugated metabolites are detected in the urine, but most of the drug is excreted unchanged in the feces. About 96% of the circulating drug is bound to protein.

**Physical Dependence.** When buprenorphine is discontinued, a withdrawal syndrome develops that is delayed in onset for 2-14 days; this consists of typical but generally not very severe morphine-like withdrawal signs and symptoms, and it persists for 1-2 weeks (Fudala et al., 1989).

**Therapeutic Uses.** Buprenorphine (BUPRENEX) injection is indicated for use as an analgesic. In the U.S., use of the oral formulations of buprenorphine (SUBUTEX) and buprenorphine in fixed-dose combination with naloxone (SUBOXONE) is limited to the treatment of opioid dependence by the Drug Addiction Treatment Act (DATA) of 2000 [21 U.S.C. 823(g)]. This act created an opportunity for clinicians with special training to be exempted from the requirement to obtain a special DEA license when using buprenorphine to treat opioid addicts. The usual intramuscular or intravenous dose for analgesia is 0.3 mg given every 6 hours. Buprenorphine is metabolized to norbuprenorphine by CYP3A4. Thus, care should be taken in treating patients who also are taking known inhibitors of CYP3A4 (e.g., azole antifungals, macrolide antibiotics, and HIV protease inhibitors), as well as drugs that induce CYP3A4 activity (e.g., certain anticonvulsants and rifampin).

Buprenorphine for the treatment of opioid addiction is initiated with sublingual drug, followed by maintenance therapy with a fixed-dose combination formulation of buprenorphine and naloxone. The partial agonist properties of buprenorphine limit its utility in the treatment of addicts who require high maintenance doses of opioids (Kreek et al., 2002).

**OPIOID ANTAGONISTS**

A variety of agents bind competitively to one or more of the opioid receptors, display little or no intrinsic activity, and robustly antagonize the effects of receptor agonists. These agents have obvious therapeutic utility in the treatment of opioid overdose. Under ordinary circumstances, these opioid antagonists produce few effects in the absence of an exogenous agonist. However, under certain conditions (e.g., shock), when the endogenous opioid systems are activated, the administration of an opioid antagonist alone may have visible consequences.

**Chemistry.** Relatively minor changes in the structure of an opioid can convert a drug that is primarily an agonist into one with antagonistic actions at one or more types of opioid receptors. The most common such substitution is that of a larger moiety (e.g., an allyl or methylcyclopropy group) for the N-methyl group that is typical of the MOR agonists. Such substitutions transform morphine to nalorphine, levorphanol to levallorphan, and oxymorphone to naloxone (NARCAN, others) or naltrexone (REVIA, VIVITROL, others) (Figure 18–8). In some cases, congeners are produced that are competitive antagonists at MOR but that also have agonistic actions at KORs. Nalorphine and levallorphan have such properties. Other congeners, especially naloxone and naltrexone, appear to be devoid of agonistic actions and interact with all types of opioid receptors, albeit with somewhat different affinities (Martin, 1983). Nalmefene (no longer marketed in the U.S.) is a relatively pure MOR antagonist that is more potent than naloxone (Dixon et al., 1986). A number of other non-peptide antagonists have been developed that are relatively selective for individual types of opioid receptors. These include cypriodine and β-funaltrexamine, for MOR; naltrindole for DOR; and norbinaltorphimine for KOR (Portoghese, 1989), though these agents are not in clinical use.

The majority of the agents noted above are relatively lipid soluble and have excellent CNS bioavailability after systemic delivery. A recognition that there was a need for antagonism limited to
Peripheral sites led to the development of agents that have poor CNS bioavailability such as methylnaltrexone (RELISTOR).

**Pharmacological Properties**

If endogenous opioid systems have not been activated, the profile of opioid antagonist effects depend on the presence or absence of the exogenous opioid agonist and on the degree to which physical dependence on an opioid has developed.

**Effects in the Absence of Opioid Agonists.** Subcutaneous doses of naloxone up to 12 mg produce no discernible subjective effects in humans, and 24 mg causes only slight drowsiness. Naltrexone also appears to be a relatively pure antagonist but with higher oral efficacy and a longer duration of action.

The effects of opiate receptor antagonists are usually both subtle and limited. Most likely this reflects the low levels of tonic activity and organizational complexity of the opioid systems in various physiologic systems (Drolet et al., 2001). In the face of a variety of physical (pain) or psychological stressors, an increased release of a variety of opioid peptides occurs. Many stressors will activate central circuits. Changes in circulating levels of endorphins in plasma are often cited in events such as runner’s high, yet such peripheral changes have little significance to central systems, given the minimal ability of these peptides to penetrate the blood-brain barrier.

**Pain.** Opiate antagonism in humans is associated with variable effects ranging from no effect to a mild hyperalgesia and even hypoalgesia as measured in a variety of well-controlled experimental pain paradigms (France et al., 2007). A number of studies have, however, suggested that agents such as naloxone appear to attenuate the analgesic effects of placebo medications and acupuncture (Benedetti and Amanzio, 1997).

**Stress.** Even at high doses of different antagonists, normal subjects typically show modest changes in blood pressure or heart rate. In laboratory animals, the administration of naloxone will reverse or attenuate the hypotension associated with shock of diverse origins, including that caused by anaphylaxis, endotoxin, hypovolemia, and injury to the spinal cord; opioid agonists aggravate these conditions (Amir, 1988; Faden, 1988).

**Affect.** High doses of naltrexone appeared to cause mild dysphoria in one study but little or no subjective effects in others (Gonzalez and Brogden, 1988).

**Endocrine Effects.** Endogenous opioid peptides participate in the regulation of pituitary secretion apparently by exerting tonic inhibitory effects on the release of certain hypothalamic hormones (Chapter 38). Thus, the administration of naloxone or naltrexone increases the secretion of gonadotropin-releasing hormone and corticotropin-releasing hormone and elevates the plasma concentrations of LH, FSH, and ACTH, as well as the steroid hormones produced by their target organs. Antagonists do not consistently alter basal or stress-induced concentrations of prolactin in plasma in men; paradoxically, naloxone stimulates the release of prolactin in women. Opioid antagonists augment the increases in plasma concentrations of cortisol and catecholamines that normally accompany stress or exercise.

Endogenous opioid peptides probably have some role in the regulation of feeding or energy metabolism: in laboratory models, opioid antagonists increase energy expenditure, interrupt hibernation in appropriate species, induce weight loss, and prevent stress-induced overeating and obesity. These observations have led to the experimental use of opioid antagonists in the treatment of human obesity, especially that associated with stress-induced eating disorders. However, naltrexone does not accelerate weight loss in very obese subjects, even though short-term administration of opioid antagonists reduces food intake in lean and obese individuals (Atkinson, 1987).

Even after prolonged administration of high doses of the antagonist alone, discontinuation of naloxone is not followed by any recognizable withdrawal syndrome, and the withdrawal of naltrexone, another relatively pure antagonist, produces very few signs and symptoms. However, long-term administration of antagonists increases the density of opioid receptors in the brain and causes a temporary exaggeration of responses to the subsequent administration of opioid agonists (Yoburn et al., 1988). Naltrexone and naloxone have no known potential for abuse.

**Effects in the Presence of Opioid Agonists**

**Actions on Acute Opioid Effects.** Small doses (0.4-0.8 mg) of naloxone given intramuscularly or intravenously prevent or promptly reverse the effects of receptor agonists. In patients with respiratory depression, an increase in respiratory rate is seen within 1-2 minutes. Sedative effects are reversed, and blood pressure, if depressed, returns to normal. Higher doses of naloxone are required to antagonize the respiratory-depressant effects of buprenorphine; 1 mg naloxone intravenously completely blocks the effects of 25 mg heroin. Naloxone reverses the psychotomimetic and dysphoric effects of agonist–antagonist agents such as pentazocine, but much higher doses (10-15 mg) are required. The duration of antagonistic effects depends on the dose but usually is 1-4 hours. Antagonism of opioid effects by naloxone often is accompanied by an “overdose but usually is 1-4 hours. Antagonism of opioid effects by naloxone often is accompanied by an “overdose” phenomenon. For example, respiratory rate depressed by opioids transiently becomes higher than that before the period of depression. Rebound release of catecholamines may cause hypertension, tachycardia, and ventricular arrhythmias. Pulmonary edema also has been reported after naloxone administration.

**Effects in Opioid-Dependent Patients.** In subjects who are dependent on morphine-like opioids, small subcutaneous doses of naloxone (0.5 mg) precipitate a moderate to severe withdrawal syndrome that is very similar to that seen after abrupt withdrawal of opioids, except that the syndrome appears within minutes of administration and subsides in ~2 hours. The severity and duration of the syndrome are related to the dose of the antagonist and to the degree and type of dependence. Higher doses of naloxone will precipitate a withdrawal...
syndrome in patients dependent on pentazocine, butorphanol, or nalbuphine. Naloxone produces overshoot phenomena suggestive of early acute physical dependence 6-24 hours after a single dose of an μ agonist (Heishman et al., 1989). In dependent patients, peripheral side-effects, notably reduced GI motility and constipation, can be reversed by methylnaltrexone with doses of 0.15 mg/kg subcutaneously, producing reliable bowel movements and no evidence of centrally mediated withdrawal signs (Thomas et al., 2008).

Absorption, Distribution, Metabolism, and Excretion

Although absorbed readily from the GI tract, naloxone is almost completely metabolized by the liver before reaching the systemic circulation and thus must be administered parenterally. The drug is absorbed rapidly from parenteral sites of injection and is metabolized in the liver primarily by conjugation with glucuronic acid; other metabolites are produced in small amounts. The t_{1/2} of naloxone is ~1 hour, but its clinically effective duration of action can be even less.

Compared with naloxone, naltrexone retains much more of its efficacy by the oral route, and its duration of action approaches 24 hours after moderate oral doses. Peak concentrations in plasma are reached within 1-2 hours and then decline with an apparent t_{1/2} of ~3 hours; this value does not change with long-term use. Naltrexone is metabolized to 6-naltrexol, which is a weaker antagonist but has a longer t_{1/2}, ~13 hours. Naltrexone is much more potent than naloxone, and 100 mg oral doses given to patients addicted to opioids produce concentrations in tissues sufficient to block the euphorogenic effects of 25-mg intravenous doses of heroin for 48 hours (Gonzalez and Brogden, 1988). Methylnaltrexone is handled similarly to naltrexone. It is converted to methyl-6-naltrexol isomers and is largely eliminated primarily as the unchanged drug with significant active renal secretion. The terminal disposition t_{1/2} of methylnaltrexone is ~8 hours.

Therapeutic Uses

Treatment of Opioid Overdosage. Opioid antagonists, particularly naloxone, have an established use in the treatment of opioid-induced toxicity, especially respiratory depression. Its specificity is such that reversal by this agent is virtually diagnostic for the contribution of an opiate to the depression. Naloxone acts rapidly to reverse the respiratory depression associated with high doses of opioids. It should be used cautiously because it also can precipitate withdrawal in dependent subjects and cause undesirable cardiovascular side effects. By carefully titrating the dose of naloxone, it usually is possible to rapidly antagonize the respiratory-depressant actions without eliciting a fully expressed withdrawal syndrome. The duration of action of naloxone is relatively short, and it often must be given repeatedly or by continuous infusion. Opioid antagonists also have been employed effectively to decrease neonatal respiratory depression secondary to the intravenous or intramuscular administration of opioids to the mother. In the neonate, the initial dose is 10 μg/kg given intravenously, intramuscularly, or subcutaneously.

Management of Constipation. The peripherally limited antagonists such as methylnaltrexone have a very important role in the management of the constipation and the reduced GI motility present in the patient undergoing chronic opioid therapy (as for chronic pain or methadone maintenance) and have been approved by the FDA for that use. With distribution restricted to the periphery, these agents do not alter central opioid agonist actions. Worrisome reports of GI perforation in this setting are under review by FDA. Other strategies for the management of opioid-induced constipation are described in Chapter 46.

Management of Abuse Syndromes. There is considerable interest in the use of opiate antagonists such as naltrexone as an adjuvant in treating a variety of non-opioid dependency syndromes such as alcoholism (Chapters 23 and 24), where an opiate antagonist decreases the chance of relapse (Anton, 2008). Interestingly, patients with a single nucleotide polymorphism (SNP) in the MOR gene have significantly lower relapse rates to alcoholism when treated with naltrexone (Haile et al., 2008). Naltrexone is FDA-approved for treatment of alcoholism.

Trauma. The potential utility of opiate antagonists in the treatment of shock, stroke, spinal cord and brain trauma, and other disorders that may involve mobilization of endogenous opioid peptides has been reported; but opioid antagonists have failed to demonstrate neuroprotective benefits and their study in trauma has been largely abandoned (Hawryluk et al., 2008).

CENTRALLY ACTIVE ANTITUSSIVES

Cough is a useful physiological mechanism that serves to clear the respiratory passages of foreign material and excess secretions. It should not be suppressed indiscriminately. There are, however, many situations in which cough does not serve any useful purpose but may, instead, annoy the patient, prevent rest and sleep, or hinder adherence to otherwise beneficial medication regimens (e.g., angiotension-converting enzyme (ACE) inhibitor-induced cough). Chronic cough can contribute to fatigue, especially in elderly patients. In such situations, the physician should try to substitute a drug with a different side effect profile (e.g., an AT1 antagonist in place of an ACE inhibitor) or add an antitusive agent that will reduce the frequency or intensity of the coughing (Chapters 12 and 36).

A number of drugs reduce cough as a result of their central actions, including opioid analgesics (codeine, hydrocodone, and dihydrocodeine are the opioids most commonly used to suppress cough). Cough suppression often occurs with lower doses of opioids than those needed for analgesia. A 10- or 20-mg oral dose of codeine, although ineffective for analgesia,
produces a demonstrable antitussive effect, and higher doses produce even more suppression of chronic cough. A few other antitussive agents are noted below.

**Dextromethorphan**

Dextromethorphan (D-3-methoxy-N-methylmorphinan) is the D-isomer of the codeine analog methorphan; however, unlike the L-isomer, it has no analgesic or addictive properties and does not act through opioid receptors. The drug acts centrally to elevate the threshold for coughing. Its effectiveness in patients with pathological cough has been demonstrated in controlled studies; its potency is nearly equal to that of codeine. Compared with codeine, dextromethorphan has fewer subjective and GI side effects (Matthys et al., 1983). In therapeutic dosages, the drug does not inhibit ciliary activity, and its antitussive effects persist for 5-6 hours. Its toxicity is low, but extremely high doses may produce CNS depression.

Sites that bind dextromethorphan with high affinity have been identified in membranes from various regions of the brain (Craviso et al., 1983). Although dextromethorphan is known to function as an NMDA-receptor antagonist, the dextromethorphan binding sites are not limited to the known distribution of NMDA receptors (Elliott et al., 1994). Thus, the mechanism by which dextromethorphan exerts its antitussive effect still is not clear.

The average adult dosage of dextromethorphan hydrobromide is 10-30 mg three to six times daily, not to exceed 120 mg daily. The drug is marketed for over-the-counter sale in liquids, syrups, capsules, soluble strips, lozenges, and freezer pops or in combinations with antihistamines, bronchodilators, expectorants, and decongestants. An extended-release dextromethorphan suspension (DELSYM) is approved for twice daily administration.

Two other antitussives not currently recognized as generally safe and effective (GRAS/E) by the FDA, carbetapentane (pentoxyverine) and caramiphen, are known to bind avidly to the dextromethorphan binding sites; codeine, levopropoxyphene, and other antitussive opioids (as well as naloxone) do not bind. Although noscapine (discussed later) enhances the affinity of dextromethorphan, it appears to interact with distinct binding sites (Karlsson et al., 1988). The relationship of these binding sites to antitussive actions is not known; however, these observations, coupled with the ability of naloxone to antagonize the antitussive effects of codeine but not those of dextromethorphan, indicate that cough suppression can be achieved by a number of different mechanisms.

**Other Antitussives**

Pholcodine [3-O-(2-morpholinoethyl) morphine] is used clinically in many countries outside the U.S. Although structurally related to the opioids, pholcodine has no opioid-like actions because the substitution at the 3-position is not removed by metabolism. Pholcodine is at least as effective as codeine as an antitussive; it has a long t½ and can be given once or twice daily.

Benzonatate (TESSALON, others) is a long-chain polyglycol derivative chemically related to procaine and believed to exert its antitussive action on stretch or cough receptors in the lung, as well as by a central mechanism. It is available in oral capsules and the dosage is 100 mg three times daily; doses as high as 600 mg daily have been used safely.

**Patient-Controlled Analgesia (PCA)**

With this modality, the patient has limited control of the dosing of opioid from an infusion pump programmed within tightly mandated parameters. PCA can be used for intravenous, epidural, or intrathecal administration of opioids. This technique avoids delays inherent in administration by a caregiver and generally permits better alignment between pain control and individual differences in pain perception and responsiveness to opioids. The PCA technique also gives the patient a greater sense of control over the pain. With shorter-acting opioids, serious toxicity or excessive use rarely occurs; however, caution is warranted due to the potential for serious medication errors associated with this delivery method. PCA is suitable for adults and children capable of understanding the principles involved. It is generally conceded that PCA is preferred over intramuscular injections for postoperative pain control.

**Spinal Delivery**

Administration of opioids into the epidural or intrathecal space provides more direct access to the first pain-processing synapse in the dorsal horn of the spinal cord. This permits the use of doses substantially lower than those required for oral or parenteral administration (Table 18–3). Systemic side effects of opioid administration thus are decreased. In postoperative pain management sustained release epidural injections are accomplished through the incorporation of morphine into a liposomal formulation (DEPODUR), providing up to 48 hours of pain relief (Hartrick and Hartrick, 2008). The management of chronic pain with spinal opiates has been addressed by the use of chronically implanted intrathecal catheters connected to subcutaneously implanted refillable pumps (Wallace and Yaksh, 2000).

Though they have important therapeutic uses, epidural and intrathecal opioids have their own dose-dependent side effects, such as pruritis, nausea, vomiting, respiratory depression, and urinary retention. Hydrophilic opioids such as morphine (DURAMORPH, others)
have a longer residence times in the cerebrospinal fluid; as a consequence, after intrathecal or epidural morphine, delayed respiratory depression can be observed for as long as 24 hours after a bolus dose. While the risk of delayed respiratory depression is reduced with more lipophilic opioids, it is not eliminated. Extreme vigilance and appropriate monitoring are required for all opioid-naïve patients receiving intraspinal narcotics. Use of intraspinal opioids in the opioid-naïve patient is reserved for postoperative pain control in an inpatient monitored setting. Epidural administration of opioids has become popular in the management of postoperative pain and for providing analgesia during labor and delivery. Lower systemic opioid levels are achieved with epidural opioids, leading to less placental transfer and less potential for respiratory depression of the newborn (Shnider and Levinson, 1987). Many opioids and other adjuvants are commonly used for neuraxial administration in adults and children; however, the majority of agents employed have not undergone appropriate preclinical safety evaluation and approval for these clinical indications; thus, such uses are “off-label”. Thus, at this time, those agents approved for spinal delivery represent a novel environment wherein the neuraxis may be exposed to exceedingly high concentrations of an agent for an extended period of time and safety by another route (e.g., PO, IV) may not translate to safety after spinal delivery (Yaksh and Allen, 2004).

Patients on chronic spinal opioid therapy are less likely to experience respiratory depression. Selected patients who fail conservative therapies for chronic pain may receive intraspinal opioids chronically through an implanted programmable pump.

Analogous to the relationship between systemic opioids and NSAIDs, intraspinal narcotics often are combined with other agents that include local anesthetics, N-type Ca²⁺ channel blockers (e.g., ziconotide), α₂ adrenergic agonists, and GABA₉ agonists. This permits synergy between drugs with different mechanisms allowing the use of lower concentrations of both agents, minimizing side-effects and the opioid-induced complications (Wallace and Yaksh, 2000).

### Local Drug Action

Opioid receptors on peripheral sensory nerves respond to locally applied opioids during inflammation (Stein, 1993). Peripheral analgesia permits the use of lower doses, applied locally, than those necessary to achieve a systemic effect. The pain relief generated by this route of delivery is limited but the technique has been demonstrated to have some efficacy in postoperative pain (Stein, 1993). Development of such compounds and expansion of clinical applications of this technique are active areas of research.

### Rectal Administration

This route is an alternative for patients with difficulty swallowing or other oral pathology and who prefer a less invasive route than parenteral administration. This route is not well tolerated by most children. Onset of action is within 10 minutes. In the U.S., only morphine and hydromorphone are available in rectal suppository formulations.

### Inhalation

Opioids can be delivered by nebulizer. However, this delivery method is rarely used due to erratic absorption from the lung and highly variable therapeutic effect.

### Oral Transmucosal Administration

Opioids can be absorbed through the oral mucosa more rapidly than through the stomach. Bioavailability is greater owing to avoidance of first-pass metabolism, and lipophilic opioids are absorbed better by this route than are hydrophilic compounds such as morphine. A transmucosal delivery system that suspends fentanyl in a dissolvable sugar-based lollipop (ACTIQ, others) or rapidly dissolving buccal tablet (FENTORA) have been approved for the treatment of cancer pain; in this setting, transmucosal fentanyl relieves pain within 15 minutes, and patients easily can titrate the appropriate dose.

ᵃLow doses may be effective when administered to the elderly or when injected in the thoracic region.
ᵇIf combining with a local anesthetic, consider using 0.0625% bupivacaine. ᶜDuration of analgesia varies widely; higher doses produce longer duration. With the exception of epidural/intrathecal morphine or epidural sufentanil, all other spinal opioid use is considered to be off label.

Adapted from International Association for the Study of Pain, 1992.
A buccal fentanyl “film” is FDA-approved for the treatment of cancer pain (ONSOLIS). The film is applied to the buccal mucosa and slowly dissolves releasing the fentanyl to cross the mucosa into the bloodstream. A New Drug Application has been filed with the FDA for a sublingual tablet (ABSTRAL, formerly RAPINYL). Transmucosal fentanyl also has been studied as a premedicant for children; however, this technique has been largely abandoned owing to undesirable side effects such as respiratory depression, sedation, nausea, vomiting, and pruritus.

**Transnasal Administration**

Butorphanol, a KOR agonist/MOR antagonist has been employed intranasally. A transnasal pectin-based fentanyl spray is currently in clinical trials for the treatment of cancer related pain. Administration is well tolerated and pain relief occurs within 10 minutes of delivery (Kress et al., 2009).

**Transdermal and Iontophoretic Administration**

Transdermal fentanyl patches are approved for use in sustained pain. The opioid permeates the skin, and a “depot” is established in the stratum corneum layer. Unlike other transdermal systems (i.e., transdermal scopolamine), anatomic position of the patch does not affect absorption. However, fever and external heat sources (heating pads, hot baths) can increase absorption of fentanyl and potentially lead to an overdose (Rose et al., 1993). This modality is well suited for cancer pain treatment because of its ease of use, prolonged duration of action, and stable blood levels (Portenoy et al., 1993). It may take up to 12 hours to develop analgesia and up to 16 hours to observe full clinical effect. Plasma levels stabilize after two sequential patch applications, and the kinetics do not appear to change with repeated applications (Portenoy et al., 1993). However, there may be a great deal of variability in plasma levels after a given dose. The plasma t1/2 after patch removal is ~17 hours. Thus, if excessive sedation or respiratory depression is experienced, antagonist infusions may need to be maintained for an extended period. Dermatological side effects from the patches, such as rash and itching, usually are mild.

Iontophoresis is the transport of soluble ions through the skin by using a mild electric current. This technique has been employed with morphine (Ashburn et al., 1992). Unlike transdermal opioids, a drug reservoir does not build up in the skin, thus limiting the duration of both desired and undesired effects. Patient-controlled iontophoretic transdermal fentanyl systems have been developed, but none is currently marketed.

**THERAPEUTIC USE OF OPIATES IN PAIN CONTROL**

Management of pain is an important element in any therapeutic intervention. Failure to adequately manage pain can have important negative consequences on physiological function such as autonomic hyper-reactivity (increased blood pressure, heart rate, suppression of gastrointestinal motility, reduced secretions), reduced mobility leading to deconditioning, muscle wasting, joint stiffening, and decalcification, and can contribute to deleterious changes in the psychological state (depression, helplessness syndromes, anxiety). By many hospital accrediting organizations, and by law in many states, appropriate pain assessment and adequate pain management are considered to be standard of care, with pain being considered the “fifth vital sign.”

The comments included here are only a general orientation to the principles in pain management. Extensive efforts by many individuals and organizations have resulted in the publication of many useful guidelines for the management of pain states including acute pain, cancer pain, and neuropathic pain (Table 18–4). In the case of cancer pain, adherence to standardized protocols has been shown to improve pain management.

significantly (Du Pen et al., 1999). The next sections provide guidelines for rational drug selection, discuss routes of administration other than the standard oral and parenteral methods, and outline general principles for the use of opioids in acute and chronic pain states.

Guidelines for Opiate Dosing

Whereas the World Health Organization three-step ladder was initially targeted at the treatment of cancer pain, it is accepted practice to use this three-step ladder to treat chronic noncancer pain (Table 18–5). The three-step ladder encourages the use of more conservative therapies before initiating opioid therapy. However, in the presence of severe pain, the opioids should be considered sooner rather than later.

Numerous societies and agencies have published guidelines for the use of strong opioids in treating pain, including the American Academy of Pain Medicine, the American Pain Society, the Federation of State Medical Boards (FSMB), and the Drug Enforcement Agency. While slightly different in particulars, all guidelines to date share the criteria established by the FSMB (Table 18–6).

Guidelines for the oral and parenteral dosing of commonly used opioids are presented in Table 18–2. Tables such as those presented here are only guidelines. They are typically constructed with the use of these agents in the management of acute (e.g., postoperative) pain in opioid-naive patients. A number of factors will contribute to the dosing requirement (described in subsequent sections).

Methadone is considered separately in Table 18–7 as updated safety information has emerged more recently. In 2006, the FDA notified health care professionals of reports of death and life-threatening adverse events, such as respiratory depression and cardiac arrhythmias in patients receiving methadone. Methadone is thought to be involved in about one-third of all prescription opioid-related deaths, exceeding hydrocodone and oxycodone, despite being prescribed one-tenth as often. This has led to revisions in the labeled dosing recommendations.

### Variables Modifying the Therapeutic Response to Opiates

There is substantial individual variability in responses to opioids. A standard intramuscular dose of 10 mg morphine sulfate will relieve severe pain adequately in only 2 of 3 patients. The minimal effective analgesic concentration for opioids, such as morphine, meperidine (pethidine), alfentanil, and sufentanil, varies among patients by factors of 5–10 (Woodhouse and Mather, 2000). Adjustments will have to be made based on clinical response. Appropriate therapeutics typically involve undertaking a treatment strategy that most efficiently addresses the pain state, minimizes the potential for undesired drug effects, and accounts for the variables that can influence an individual patient’s response to opiate analgesia.

**Pain Intensity.** Increased pain intensity may require titrating doses to produce acceptable analgesia with tolerable side effects.

**Type of Pain State.** Systems underlying a pain state may be broadly categorized as being mediated by events secondary to injury and inflammation and by injury to the sensory afferent or nervous system. Neuropathic conditions may be less efficaciously managed by opioids than pain secondary to tissue injury and inflammation. Such pain states are more efficiently managed by combination treatment modalities.

**Acuity and Chronicity of Pain.** The pain state in any given clinical condition is not typically constant and will vary over time. In chronic pain states, the daily course of the pain may fluctuate, e.g., being greater in the morning hours or upon awakening. Arthritic states display flares that are associated with an exacerbated pain condition. Changes in the magnitude of pain occur during the daily routine resulting in “breakthrough pain” during episodic events such as

### Table 18–5

<table>
<thead>
<tr>
<th>Step</th>
<th>Description</th>
</tr>
</thead>
</table>
| **Step 1** Mild to Moderate Pain | Non-opioid ± adjuvant agent  
  • Acetaminophen or an NSAID should be used, unless contraindicated. Adjuvant agents are those that enhance analgesic efficacy, treat concurrent symptoms that exacerbate pain, and/or provide independent analgesic activity for specific types of pain. |
| **Step 2** Mild to Moderate Pain or Pain Uncontrolled after Step 1 | Short-acting opioid as required ± non-opioid around the clock (ATC) ± adjuvant agent  
  • Morphine, oxycodone, or hydromorphone should be added to acetaminophen or an NSAID for maximum flexibility of opioid dose. |
| **Step 3** Moderate to Severe Pain or Pain Uncontrolled after Step 2 | Sustained release/long-acting opioid ATC or continuous infusion + short-acting opioid as required ± non-opioid ± adjuvant agent  
  • Sustained release oxycodone, morphine, oxymorphone or transdermal fentanyl is indicated. |

*ahttp://www.who.int/cancer/palliative/painladder/en/*
dressing changes (incident pain). These examples emphasize the need for individualized management of increased or decreased pain levels with baseline analgesic dosing supplemented with the use of short-acting “rescue” medications as required. In the face of ongoing severe pain, analgesics should be dosed in continuous or “around-the-clock” fashion rather than on an as-needed basis. This provides more consistent analgesic levels and avoids unnecessary suffering (Vashi et al., 2005).

Opioid Tolerance. Chronic exposure to one opiate agonist typically leads to a reduction in the efficacy of other opiate agonists. The degree of tolerance can be remarkable. For example, 10 mg of an oral opioid (such as morphine) is considered a high dose for a treatment-naïve individual whereas 100 mg IV may produce only minor sedation in severely tolerant individual.

Patient Physical State and Genetic Variables. Codeine, hydrocodone, and oxycodone are weak analgesic prodrugs that are metabolized into the much more effective analgesic drugs morphine, hydromorphone, and oxymorphone, respectively, by CYP2D6 (Supernaw, 2001). The analgesic properties of morphine, hydromorphone, oxymorphone, propoxyphene, and fentanyl are largely due to their direct influence on opioid receptors and do not require additional metabolism, although the first metabolite of propoxyphene, norpropoxyphene, is also an effective analgesic with a very long t1/2.

The activity of CYP2D6 is inhibited by selective serotonin reuptake inhibitors, including fluoxetine, fluvoxamine, paroxetine, sertraline, and bupropion, medications that are commonly administered to pain patients. The CYP2D6 inhibition resulting from these interacting medications may render opioids less effective as analgesics in some patients. Whereas diminished activity of the CYP2D6 isozyme will lead to less efficacy of prodrug opioids, the opposite occurs with methadone. Although methadone is primarily metabolized through the CYP3A4 isozyme, genetic polymorphisms involving deficiencies in the CYP2C9, CYP2C19, and CYP2D6 isoenzymes may lead to surprisingly high methadone plasma concentrations resulting in overdose.

Opioids are highly protein bound and factors such as plasma pH may dramatically change binding. In addition, α1-acid glycoprotein (AAG) is an acute-phase reactant protein that is elevated in cancer patients and has a high affinity for basic drugs such as methadone and meperidine. Morphine and meperidine should be avoided in patients with renal impairment since morphine-6-glucuronide (a metabolite of morphine) and normeperidine (a metabolite of meperidine) are excreted by the kidney and will accumulate and lead to toxicity. Other states that may increase the risk of adverse effects of the opioids include chronic obstructive pulmonary disease, sleep apnea, dementia, benign prostatic hypertrophy, unstable gait, and pretreatment constipation.

</table>
Routes of Administration Available. The aim in chronic pain states is to prefer to employ the least invasive routes of drug administration, which include oral, buccal, or transdermal delivery. IV routes are more useful in perioperative in-hospital pain management and during end-of-life care. Patients with chronic pain states where side effects from systemic drug exposure are intolerable and are candidates for spinal drug delivery; however, this may require surgery for indwelling catheterization and pump placement.

Dose Selection/Titration. The conservative approach to the initiation of chronic opioid therapy suggests starting with low doses that may be incremented on the basis of the pharmacokinetics of the drug. In chronic pain states, the aim would be the use of long-acting medications to permit once or twice daily dosing (e.g., controlled release formulations or methadone). Such agents reach steady-state slowly. Rapid incrementation is to be avoided and rescue medication should be made available for breakthrough pain during initial dosing titration.

Opiate Rotation. Opioid rotation is the practice of changing to a different opioid when the patient either fails to achieve benefit or side effects are reached before analgesia is sufficient. In a retrospective review, it was found that the first opioid prescribed was effective for 36% of patients, was stopped because of side effects in 30%, and was stopped for ineffectiveness in 34% (Quang-Cantagrel et al., 2000). Of the remaining patients, the second opioid prescribed after the failure of the first was effective in 31%, the third in 40%, the fourth in 56%, and the fifth in 14%. Thus, if it is necessary to change the opioid prescription because of intolerable side effects or ineffectiveness, the cumulative percentage of efficacy increases with each new opioid tested. Failure or intolerance of one opioid cannot necessarily predict the patient’s response or acceptance to another. Practically, opioid rotation involves incrementing the dose of a given opioid, e.g., morphine, to one limited by side-effect and insufficient analgesia. At this point an alternate opioid medication at an equipotent dose may be substituted for the first medication. Agents typically involved in such rotation sequences are various oral opioids such as morphine, methadone, dilaudid, and oxycodone and the fentanyl patch systems. Care must be taken to titrate the doses and monitor the patient closely during such drug transitions.

Combination Therapy. In general, the use of combinations of drugs with the same pharmacological kinetic profile is not warranted (e.g., morphine plus methadone). Nor if the drugs have overlapping targets and opposing effects (e.g., combining a MOR agonist with an agent having mixed agonist/antagonist properties). On the other hand, certain opiate combinations are useful. For example, in a chronic pain state with periodic incident or breakthrough pain, the patient might receive a slow-release formulation of morphine for baseline pain relief and the acute incident pain may be managed with a rapid-onset/short-lasting formulation such as buccal fentanyl.

For inflammatory or nociceptive pain, it is routinely recommended that opioids be combined with other analgesic agents, such as NSAIDs or acetaminophen. In this way, one can take advantage of the analgesic effects produced by the adjuvant and minimize the dose requirement of the opioid. In some situations, NSAIDs can provide analgesia equal to that produced by 60 mg codeine. The analgesic synergism between opioids and aspirin-like drugs is discussed below and in Chapter 34. In the case of neuropathic pain, other drug classes may be useful in combination with the opiate. For example, antidepressants that block amine reuptake, such as amitriptyline or duloxetine, and anticonvulsants such as gabapentin, may enhance the analgesic effect and may be synergistic in some pain states. Different classes of drug may have distinguishable efficacy in different models of pain processing (Table 18–8).

The “opioid-sparing” strategy is the backbone of the “analgesic ladder” for pain management proposed by the World Health Organization. Weaker opioids can be supplanted by stronger opioids in cases of moderate and severe pain. Antidepressants such as duloxetine and amitriptyline are used in the treatment of chronic neuropathic pain but have limited intrinsic analgesic actions in acute pain. However, antidepressants may enhance morphine-induced analgesia (Levine et al., 1986).

NON-ANALGESIC THERAPEUTIC USES OF OPIOIDS

Dyspnea

Morphine is used to alleviate the dyspnea of acute left ventricular failure and pulmonary edema, and the response to intravenous morphine may be dramatic. The mechanism underlying this relief is not clear. It may involve an alteration of the patient’s reaction to impaired respiratory function and an indirect reduction of the work of the heart owing to reduced fear and apprehension. However, it is more probable that the major benefit is due to cardiovascular effects, such as decreased peripheral resistance and an increased capacity of the peripheral and splanchnic vascular compartments. Nitroglycerin, which also causes vasodilation, may be superior to morphine in this condition (Hoffman and Reynolds, 1987). In patients with normal blood gases but severe breathlessness owing to chronic obstruction of airflow (“pink puffers”), dihydrocodeine, 15 mg orally before exercise, reduces the feeling of breathlessness and increases exercise tolerance (Johnson et al., 1983). Nonetheless, opioids generally are contraindicated in pulmonary edema unless severe pain also is present.

Anesthetic Adjuvants

High doses of opioids, notably fentanyl and sufentanil, are widely used as the primary anesthetic agents in many surgical procedures. They have powerful “MAC-sparing” effects, e.g., they reduce the concentrations of volatile anesthetic otherwise required to produce an adequate anesthetic depth. Although respiration is so depressed that physical assistance is required, patients can retain consciousness. Therefore, when using opioids as the primary anesthetic agent, it is important to use in conjunction with an agent that results in unconsciousness and produces amnesia such as the benzodiazepines or low concentrations of volatile anesthetics. High doses of opiate also result in prominent rigidity of the chest wall and masseters requiring concurrent treatment with muscle relaxants to permit intubations and ventilation.

TREATMENT OF ACUTE OPIOID TOXICITY

Acute opioid toxicity may result from clinical overdosage, accidental overdosage, or attempts at suicide. Occasionally, a delayed type of toxicity may occur from
the injection of an opioid into chilled skin areas or in patients with low blood pressure and shock. The drug is not fully absorbed, and therefore, a subsequent dose may be given. When normal circulation is restored, an excessive amount may be absorbed suddenly. It is difficult to define the exact amount of any opioid that is toxic or lethal to humans. Recent experiences with methadone indicate that in nontolerant individuals, serious toxicity may follow the oral ingestion of 40-60 mg. Older literature suggests that in the case of morphine, a normal, opiate-naïve, pain-free adult is not likely to die after oral doses <120 mg or to have serious toxicity with <30 mg parenterally.

**Symptoms and Diagnosis**

The patient who has taken an overdose of an opioid usually is stuporous or, if a large overdose has been taken, may be in a profound coma. The respiratory rate will be very low, or the patient may be apneic, and cyanosis may be present. As respiratory exchange decreases, blood pressure, at first likely to be near normal, will fall progressively. If adequate oxygenation is restored early, the blood pressure will improve; if hypoxia persists untreated, there may be capillary damage, and measures to combat shock may be required. The pupils will be symmetrical and pinpoint in size; however, if hypoxia is severe, they may be dilated. Urine formation is depressed. Body temperature falls, and the skin becomes cold and clammy. The skeletal muscles are flaccid, the jaw is relaxed, and the tongue may fall back and block the airway. Frank convulsions occasionally may be noted in infants and children. When death occurs, it is nearly always from respiratory failure. Even if respiration is restored, death still may occur as a result of complications that develop during the period of coma, such as pneumonia or shock. Noncardiogenic pulmonary edema is seen commonly with opioid poisoning. It probably is not due to contaminants or to anaphylactic reactions, and it has been observed after toxic doses of morphine, methadone, propoxyphene, and pure heroin.

The triad of coma, pinpoint pupils, and depressed respiration strongly suggests opioid poisoning. The finding of needle marks suggestive of addiction further supports the diagnosis. Mixed poisonings, however, are not uncommon. Examination of the urine and gastric contents for drugs may aid in diagnosis, but the results usually become available too late to influence treatment.

**Treatment**

The first step is to establish a patent airway and ventilate the patient. Opioid antagonists can produce dramatic reversal of the severe respiratory depression, and the antagonist naloxone is the treatment of choice. However, care should be taken to avoid precipitating withdrawal in dependent patients, who may be extremely sensitive to antagonists. The safest approach is to dilute the standard naloxone dose (0.4 mg) and slowly administer it intravenously, monitoring arousal and respiratory function. With care, it usually is possible to reverse the respiratory depression without precipitating a major withdrawal syndrome. If no response is seen with the first dose, additional doses can be given. Patients should be observed for rebound increases in sympathetic nervous system activity, which may result in cardiac arrhythmias and pulmonary edema. For reversing opioid poisoning in children, the initial dose of naloxone is 0.01 mg/kg. If no effect is seen after a total dose of 10 mg, one can reasonably
question the accuracy of the diagnosis. Pulmonary edema sometimes associated with opioid overdosage may be countered by positive-pressure respiration. Tonic-clonic seizures, occasionally seen as part of the toxic syndrome with meperidine, propoxyphene, and tramadol, are ameliorated by treatment with naloxone.

The presence of general CNS depressants does not prevent the salutary effect of naloxone, and in cases of mixed intoxications, the situation will be improved largely owing to antagonism of the respiratory-depressant effects of the opioid. However, some evidence indicates that naloxone and naltrexone also may antagonize some of the depressant actions of sedative-hypnotics. One need not attempt to restore the patient to full consciousness. The duration of action of the available antagonists is shorter than that of many opioids; hence patients can slip back into coma. This is particularly important when the overdosage is due to methadone. The depressant effects of these drugs may persist for 24-72 hours, and fatalities have occurred as a result of premature discontinuation of naloxone. In cases of overdoses of these drugs, a continuous infusion of naloxone should be considered. Toxicity owing to overdose of pentazocine and other opioids with mixed actions may require higher doses of naloxone.

**CLINICAL SUMMARY**

Opioid analgesics provide symptomatic relief of pain, but the underlying disease remains. The clinician must weigh the benefits of this relief against any potential risk to the patient, which may be quite different in an acute compared with a chronic disease.

In acute problems, opioids will reduce the intensity of pain. However, physical signs (such as abdominal rigidity with an acute abdomen) generally will remain. Relief of pain can facilitate history taking and examination in the emergency room, and the patient’s ability to tolerate diagnostic procedures. In most cases analgesics should not be withheld for fear of obscuring the progression of underlying disease.

The problems that arise in the relief of pain associated with chronic conditions are more complex. Repeated daily administration of opioid analgesics eventually will produce tolerance and some degree of physical dependence. The degree will depend on the particular drug, the frequency of administration, the quantity administered, the genetic predisposition, and the psychosocial status of the patient. The decision to control any chronic symptom, especially pain, by the repeated administration of an opioid must be made carefully. When pain is due to chronic nonmalignant disease, conservative measures using non-opioid drugs should be tried before resorting to the opioids. Such measures include the use of NSAIDs, local nerve blocks, antidepressant drugs, electrical stimulation, acupuncture, hypnosis, and behavioral modification.

Selected subpopulations of chronic nonmalignant pain patients can clearly be maintained adequately on opioids for extended periods of time. Careful patient selection is important before starting chronic opioid therapy. All patients should have a risk assessment for drug abuse, diversion, and noncompliance using a validated assessment questionnaire. Chronic pain patients at a higher risk of abuse should not necessarily be denied opioids; however, these patients will require a higher level of monitoring (i.e., random urine drug testing, limited supplies, pill counting) and perhaps referral to a specialist in pain or addiction to assist with therapy.

In the usual doses, morphine-like drugs relieve suffering by altering the emotional component of the painful experience, as well as by producing analgesia. Control of pain, especially chronic pain, must include attention to both psychological factors and the social impact of the illness that sometimes play dominant roles in determining the suffering experienced by the patient. The physician must consider the substantial variabilities in patients’ capacities to tolerate pain and in their responses to opioids. Some clinicians, out of an exaggerated concern for the possibility of inducing addiction, tend to prescribe initial doses of opioids that are too small or given too infrequently to alleviate pain and then respond to the patient’s continued complaints with an even more exaggerated concern about drug dependence despite the high probability that the request for more drug is only the expected consequence of the inadequate dosage initially prescribed. Infants and children probably are more apt to receive inadequate treatment for pain than are adults owing to communication challenges, physician’s lack of familiarity with appropriate pain assessment methodologies in this population, and inexperience with the use of strong opioids in children. If an illness or procedure causes pain for an adult, there is no reason to assume that it will produce less pain for a child (Yaster and Deshpande, 1988).

**Pain of Terminal Illness and Cancer Pain**

Opioids are not indicated in all cases of terminal illness, but the analgesia, tranquility, and even euphoria afforded by the use of opioids can make the final days of life far less distressing for the patient and family. Although physical dependence and tolerance may develop, this possibility should not prevent physicians from fulfilling their primary obligation to ease the patient’s discomfort. The physician should not wait until the patient becomes agonizing; no patient should ever wish for death because of a physician’s reluctance to use adequate amounts of effective opioids. This sometimes may entail the regular use of opioid analgesics in substantial doses. Such patients,
while they may be physically dependent, are not “addicts” even though they may need large doses on a regular basis. Physical dependence is not equivalent to addiction (Chapter 24).

Most clinicians who are experienced in the management of chronic pain associated with malignant disease or terminal illness recommend that a baseline long-acting opioid be administered around the clock so that pain is continually under control and patients do not dread its return (Foley, 1993). For breakthrough pain episodes, a fast-onset, short-acting opioid can be administered. Less drug is needed to prevent the recurrence of pain than to relieve it initially. Morphine remains the opioid of choice in most of these situations, and the route and dose should be adjusted to the needs of the individual patient. Oral morphine is adequate in most situations. Sustained-release preparations of oral morphine and oxycodone are available that can be administered at 8-, 12-, or 24-hour intervals (morphine) or 8- to 12-hour intervals (oxycodone); thus, superior control of pain often can be achieved with fewer side effects using the same daily dose; a decrease in the fluctuation of plasma concentrations of morphine may be partially responsible.

Constipation is an exceedingly common problem when opioids are used, and the use of stool softeners and laxatives should be initiated early; newer modalities include the use of peripheral opiate antagonists such as methylnaltrexone. Amphetamines have demonstrable mood-elevating and analgesic effects, enhance opioid-induced analgesia, and can reverse opioid induced sedation. However, not all terminal patients require the euphoriant effects of amphetamine, and some experience side effects, such as anorexia. Controlled studies demonstrate no superiority of oral heroin over oral morphine. Similarly, after adjustment is made for potency, parenteral heroin is not superior to morphine in terms of analgesia, effects on mood, or side effects (Sawynok, 1986). Although tolerance does develop to oral opioids, many patients obtain relief from the same dosage for weeks or months. In cases where one opioid loses effectiveness, switching to another may provide better pain relief. “Cross-tolerance” among opioids exists, but clinically and experimentally, cross-tolerance among related receptor agonists is not complete. The reasons for this are not clear but may relate to differences between agonists in receptor-binding characteristics and subsequent cellular signaling interactions.

When oral opioids and other analgesics are no longer satisfactory, subcutaneous or intravenous opioids, nerve blocks, or neurolysis may be required if the nature of the disease permits. Epidural or intrathecal administration of opioids may be useful when administration of opioids by usual routes no longer yields adequate relief of pain.

General Anesthetics

General anesthetics depress the central nervous system to a sufficient degree to permit the performance of surgery and other noxious or unpleasant procedures. Inevitably, anesthetics also suppress normal homeostatic reflexes. Not surprisingly, general anesthetics have low therapeutic indices and thus require great care in administration. While all general anesthetics produce a relatively similar anesthetic state, they are quite dissimilar in their secondary actions (side effects) on other organ systems. The selection of specific drugs and routes of administration to produce general anesthesia is based on their pharmacokinetic properties and on the secondary effects of the various drugs, in the context of the proposed diagnostic or surgical procedure and with the consideration of the individual patient’s age, associated medical condition, and medication use. Anesthesiologists also employ sedatives (Chapter 17), neuromuscular blocking agents (Chapter 11), and local anesthetics (Chapter 20) as the situation requires.

Historical Perspectives. Crawford Long, a physician in rural Georgia, first used ether anesthesia in 1842. William T.G. Morton, a Boston dentist and medical student, performed the first public demonstration of general anesthesia using diethyl ether in 1846 when Gilbert Abbott underwent surgical excision of a neck tumor at the Massachusetts General Hospital in the operating room now known as “the ether dome.” The era of modern anesthesia and a revolution in the medical care of the surgical patient had begun.

Ether was the ideal “first” anesthetic. A liquid at room temperature, it readily vaporized, and was easy to administer. Ether, unlike nitrous oxide, was potent and could produce anesthesia without diluting room air to hypoxic levels. It was relatively nontoxic and produced limited respiratory or circulatory compromise. Ether maintained a role in clinical anesthesia until the 1950s.

Horace Wells, a dentist, noted at a stage show that an injured participant under the influence of nitrous oxide felt no pain. The next day Wells had a tooth extracted while breathing nitrous oxide. An attempt in 1845 by Wells to demonstrate his discovery at the Massachusetts General Hospital in Boston ended in failure when the patient cried out and nitrous oxide fell into disuse. In 1868, Edmond Andrews, a Chicago surgeon, described the co-administration of nitrous oxide and oxygen, a practice that continues to this day.

The Scottish obstetrician James Simpson introduced chloroform in 1847. Chloroform had a more pleasant odor than ether and was nonflammable. It was, however, a hepatotoxin and a severe cardiovascular depressant, which limited its ultimate utility. Despite incidents of intraoperative and postoperative deaths associated with chloroform, its use continued, especially in Great Britain, for nearly 100 years.

The anesthetic properties of cyclopropane were discovered accidentally in 1929 by chemists analyzing impurities in propylene. Cyclopropane is a pleasant-smelling gas that produces rapid anesthetic induction and recovery, and was widely used as a general anesthetic for over 30 years. However, cyclopropane is explosive when mixed with air, oxygen, or nitrous oxide. In 1956 came the introduction of halothane, a nonflammable volatile halogenated alkane that quickly became the dominant anesthetic.

In 1935, Lundy demonstrated the clinical usefulness of thiopental, a rapidly acting agent that could be administered intravenously; however, anesthetic doses of thiopental resulted in serious depression of the circulatory, respiratory, and nervous systems. The further development of intravenous anesthetic agents such as propofol, combined with other intravenous anesthetic adjuncts such as midazolam, dexmedetomidine, and remifentanil, has led to the use of total intravenous anesthesia (TIVA) as a clinically useful tool in modern anesthetic practice.

General Anesthetics and Therapeutic Gases

Piyush M. Patel, Hemal H. Patel, and David M. Roth

GENERAL PRINCIPLES OF SURGICAL ANESTHESIA

Unlike the practice of every other branch of medicine, anesthesia is usually neither therapeutic nor diagnostic. The exceptions to this, such as treatment of status
asthmaticus with halothane and intractable angina with epidual local anesthetics, should not obscure this critical point that permeates the training and practice of the specialty. Hence, administration of general anesthesia, as well as the development of new anesthetic agents and physiologic monitoring technology, has been driven by three general objectives:

1. **Minimizing the potentially deleterious direct and indirect effects of anesthetic agents and techniques.**

2. **Sustaining physiologic homeostasis during surgical procedures** that may involve major blood loss, tissue ischemia, reperfusion of ischemic tissue, fluid shifts, exposure to a cold environment, and impaired coagulation.

3. **Improving postoperative outcomes** by choosing techniques that block or treat components of the surgical stress response, which may lead to short- or long-term sequelae.

### Hemodynamic Effects of General Anesthesia.

The most prominent physiological effect of anesthesia induction, associated with the majority of both intravenous and inhalational agents, is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression, or both; a blunting of baroreceptor control; and a generalized decrease in central sympathetic tone. Agents vary in the magnitude of their specific effects (described later in the chapter), but in all cases the hypotensive response is enhanced by underlying volume depletion or preexisting myocardial dysfunction. Even anesthetics that show minimal hypotensive tendencies under normal conditions (e.g., etomidate and ketamine) must be used with caution in trauma victims, in whom intravascular volume depletion is being compensated by intense sympathetic discharge. Smaller-than-normal anesthetic dosages are employed in patients presumed to be sensitive to hemodynamic effects of anesthetics.

### Respiratory Effects of General Anesthesia.

Airway maintenance is essential following induction of anesthesia, as nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation, introduced by Kuhn in the early 1900s, has been a major reason for a decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neurumuscular blocking agents commonly are used to effect such relaxation (Chapter 11), reducing the risk of coughing or gagging during laryngoscopic-assisted instrumentation of the airway, and thus reducing the risk of aspiration prior to secure placement of an endotracheal tube. Alternatives to an endotracheal tube include a facemask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis. The choice of airway management is based on the type of procedure and characteristics of the patient.

### Hypothermia.

Patients commonly develop hypothermia (body temperature < 36°C) during surgery. The reasons for the hypothermia include low ambient temperature, exposed body cavities, cold intravenous fluids, altered thermoregulatory control, and reduced metabolic rate. General anesthetics lower the core temperature set point at which thermoregulatory vasoconstriction is activated to defend against heat loss. Furthermore, vasodilation produced by both general and regional anesthesia offsets cold-induced peripheral vasoconstriction, thereby redistributing heat from central to peripheral body compartments, leading to a decline in core temperature (Sessler, 2000). Metabolic rate and total body oxygen consumption decrease with general anesthesia by ~30%, reducing heat generation.

Even small drops in body temperatures may lead to an increase in perioperative morbidity, including cardiac complications, wound infections, and impaired coagulation. Prevention of hypothermia has emerged as a major goal of anesthetic care. Modalities to maintain normothermia include using warm intravenous fluids, heat exchangers in the anesthesia circuit, forced-warm-air covers, and new technology involving water-filled garments with microprocessor feedback control to a core temperature set point.

### Nausea and Vomiting.

Nausea and vomiting in the postoperative period continue to be significant problems following general anesthesia and are caused by an action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by serotonin (5-HT), histamine, acetylcholine (ACh), and dopamine (DA). The 5-HT3-receptor antagonists, ondansetron and dolasetron (Chapters 13 and 46), are very effective in suppressing nausea and vomiting. Common treatments also include droperidol, metoclopramide, dexamethasone, and avoidance of N2O. The use of propofol as an induction agent and the
nonsteroidal anti-inflammatory drug ketorolac as a substitute for opioids may decrease the incidence and severity of postoperative nausea and vomiting.

Other Emergence and Postoperative Phenomena. Hypertension and tachycardia are common as the sympathetic nervous system regains its tone and is enhanced by pain. Myocardial ischemia can appear or markedly worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5-30% of patients and is characterized by tachycardia, restlessness, crying, moaning, and thrashing. A variety of neurologic signs, including delirium, spasticity, hyperreflexia, and Babinski sign, are often manifest in the patient emerging from anesthesia. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of meperidine (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of all of these emergence phenomena is greatly reduced when opioids and α2 agonists (dexametomidine) are employed as part of the intraoperative regimen.

Airway obstruction may occur during the postoperative period because residual anesthetic effects continue to partially obtund consciousness and reflexes (especially in patients who normally snore or who have sleep apnea). Strong inspiratory efforts against a closed glottis can lead to negative-pressure pulmonary edema. Pulmonary function is reduced postoperatively following all types of anesthesia and surgery, and hypoxemia may occur. Hypertension can be prodigious, often requiring aggressive treatment.

Pain control can be complicated in the immediate postoperative period. The respiratory suppression associated with opioids can be problematic among postoperative patients who still have a substantial residual anesthetic effect. Patients can alternate between states of excruciating pain to somnolence with airway obstruction, all in a matter of moments. The nonsteroidal anti-inflammatory agent ketorolac (30-60 mg intravenously) frequently is effective, and the development of injectable cyclooxygenase-2 inhibitors (Chapter 34) holds promise for analgesia without respiratory depression. In addition, regional anesthetic techniques are an important part of a perioperative multimodal approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal anti-inflammatory drugs, opioids, α2 adrenergic receptor agonists, and NMDA-receptor antagonists. Patient-controlled administration of intravenous and epidural analgesics makes use of small, computerized pumps activated on demand but programmed with safety limits to prevent overdose. The agents used are opioids (frequently morphine) by the intravenous route, and an opioid, local anesthetic, or both by the epidural route. These techniques have revolutionized postoperative pain management, can be continued for hours or days, and promote ambulation and improved bowel function until oral pain medications are initiated.

**ACTIONS AND MECHANISMS OF GENERAL ANESTHETICS**

**The Anesthetic State**

General anesthetics are a structurally diverse class of drugs that produce a common end point—a behavioral state referred to as *general anesthesia*. In the broadest sense, general anesthesia can be defined as a global but reversible depression of CNS function resulting in the loss of response to and perception of all external stimuli. While this definition is appealing in its simplicity, it is not useful for two reasons: First, it is inadequate because anesthesia is not simply a deafferented state; e.g., amnesia is an important aspect of the anesthetic state. Second, not all general anesthetics produce identical patterns of deafferentation. Barbiturates, e.g., are very effective at producing amnesia and loss of consciousness, but are not effective as analgesics.

An alternative way of defining the anesthetic state is to consider it as a collection of “component” changes in behavior or perception. The components of the anesthetic state include:

- amnesia
- immobility in response to noxious stimulation
- attenuation of autonomic responses to noxious stimulation
- analgesia
- unconsciousness

It is important to remember that general anesthesia is useful only insofar as it facilitates the performance of surgery or other noxious procedures. The performance of surgery usually requires an immobilized patient who does not have an excessive autonomic response to surgery (blood pressure and heart rate) and who has amnesia for the procedure. Indeed, if an anesthetic produces profound amnesia, it can be difficult in principle to determine if it also produces either analgesia or unconsciousness.

**Measurement of Anesthetic Potency**

The potency of general anesthetic agents usually is measured by determining the concentration of general anesthetic that prevents movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in MAC units, with 1 MAC defined as the minimum alveolar concentration that prevents movement in response to surgical stimulation in 50% of subjects.

The strengths of MAC as a measurement are that:

- alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry
- it provides a direct correlate of the free concentration of the anesthetic at its site(s) of action in the CNS
- it is a simple-to-measure end point that reflects an important clinical goal

End points other than immobilization also can be used to measure anesthetic potency. For example, the ability to respond to verbal commands (MACawake) and the ability to form memories also have been correlated with alveolar anesthetic concentration. Interestingly, verbal response and memory formation both are suppressed at a fraction
of MAC. Furthermore, the ratio of the anesthetic concentrations required to produce amnesia and immobility vary significantly among different inhalational anesthetic agents (nitrous oxide versus isoflurane) (Table 19–1), suggesting that anesthetic agents may produce these behavioral end points through different cellular and molecular mechanisms. The potency of intravenous anesthetic agents is somewhat more difficult to measure; we lack methods to measure blood or plasma anesthetic concentration continuously, and we cannot determine the free concentration of the drug at its site of action. Generally, the potency of intravenous agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

Mechanisms of Anesthesia

The molecular and cellular mechanisms by which general anesthetics produce their effects have remained one of the great mysteries of pharmacology. For most of the 20th century, it was theorized that all anesthetics act by a common mechanism (the unitary theory of anesthesia). The leading unitary theory was that anesthesia is produced by perturbation of the physical properties of cell membranes. This thinking was based largely on the observation that the anesthetic potency of a gas correlated with its solubility in olive oil. This correlation, referred to as the Meyer-Overton rule, was interpreted as implicating the lipid bilayer as the likely target of anesthetic action. Clear exceptions to the Meyer-Overton rule have now been noted (Franks, 2006). For example, inhalational and intravenous anesthetics can be enantioselective in their action as anesthetics (etomidate, steroids, isoflurane). The fact that enantiomers with identical physical properties have unique actions indicates that properties other than bulk solubility are important in determining anesthetic action. Consequently, the lipid theory of anesthesia has largely been discarded (Franks, 2006). This realization has focused thinking on identification of specific protein binding sites for anesthetics.

A substantial body of work indicates that an anesthetic agent produces different components of the anesthetic state by means of actions at different anatomic loci in the nervous system and may produce these component effects through different cellular and molecular actions. Moreover, increasing evidence supports the hypothesis that different anesthetic agents produce specific components of anesthesia by actions at different molecular targets. Given these insights, the unitary theory of anesthesia has been largely discarded.

<sup>a</sup>MAC (minimum alveolar concentration) values are expressed as vol %, the percentage of the atmosphere that is anesthetic. A value of MAC greater than 100% means that hyperbaric conditions would be required.

<sup>b</sup>MAC<sub>AWAKE</sub> is the concentration at which appropriate responses to commands are lost.

<sup>c</sup>EC<sub>50</sub> is the concentration that produces memory suppression in 50% of patients. —, Not available.
The inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses in various preparations. These effects likely are produced by both pre- and postsynaptic actions of the inhalational anesthetics. The inhalational anesthetic isoflurane clearly can inhibit neurotransmitter release, while the small reduction in presynaptic action potential amplitude produced by isoflurane (3% reduction at MAC concentration) substantially inhibits neurotransmitter release (Wu et al., 2004b). The latter effect occurs because the reduction in the presynaptic action potential is amplified into a much larger reduction in presynaptic Ca\(^{2+}\) influx, which in turn is amplified into an even greater reduction in transmitter release. This effect may account for the majority of the reduction in transmitter release by inhalational anesthetics at some excitatory synapses.

Inhalational anesthetics also can act postsynaptically, altering the response to released neurotransmitter. These actions are thought to be due to specific interactions of anesthetic agents with neurotransmitter receptors.

The intravenous anesthetics produce a narrower range of physiological effects. Their predominant actions are at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the intravenous agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

**Molecular Actions of General Anesthetics.** A variety of ligand-gated ion channels, receptors and signal transduction proteins are modulated by general anesthetics. Of these, the strongest evidence for a direct effect of anesthetics exists for the GABA\(_\alpha\) and NMDA receptors and the two-pore K\(^+\) channels, as described later in this section.

Chloride channels gated by the inhibitory GABA\(_\alpha\) receptors (Chapters 14 and 17) are sensitive to clinical concentrations of a wide variety of anesthetics, including the halogenated inhalational agents and many intravenous agents (propofol, barbiturates, etomidate, and neurosteroids). At clinical concentrations, general anesthetics increase the sensitivity of the GABA\(_\alpha\) receptor to GABA, thus enhancing inhibitory neurotransmission and depressing nervous system activity. The action of anesthetics on the GABA\(_\alpha\) receptor probably is mediated by binding of the anesthetics to specific sites on the GABA\(_\alpha\)-receptor protein, since point mutations of the receptor can eliminate the effects of the anesthetic on ion channel function (Rudolph and Antkowiak, 2004). Judging from the capacity of mutations in various regions (and subunits) of the GABA\(_\alpha\) receptor to selectively affect the actions of various anesthetics, there likely are specific binding sites for at least several classes of anesthetics (Belelli et al., 1997). Notably, none of the general anesthetics competes with GABA for its binding site on the receptor. The capacity of propofol and etomidate to inhibit the response to noxious stimuli is mediated by a specific site on the \(\beta_3\) subunit of the GABA\(_\alpha\) receptor, whereas the sedative effects of these anesthetics are mediated by the same site on the \(\beta_2\) subunit (Reynolds et al., 2003). These results indicate that two components of anesthesia can be mediated by GABA\(_\alpha\) receptors. For anesthetics other than propofol and etomidate, which components of anesthesia are produced by actions on GABA\(_\alpha\) receptors remains a matter of conjecture.

Structurally related to the GABA\(_\alpha\) receptors are other ligand-gated ion channels including glycine receptors and neuronal nicotinic acetylcholine receptors. Glycine receptors may play a role in mediating inhibition by anesthetics of responses to noxious stimuli. Clinical concentrations of inhalational anesthetics enhance the capacity of glycine to activate glycine-gated chloride channels (glycine receptors), which play an important role in inhibitory neurotransmission in the spinal cord and brainstem. Propofol, neurosteroids, and barbiturates also potentiate glycine-activated currents, whereas etomidate and ketamine do not. Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal nicotinic acetylcholine receptors (Violet et al., 1997). However, these actions do not appear to mediate anesthetic immobilization (Eger et al., 2002); rather, neuronal nicotinic receptors could mediate other components of anesthesia such as analgesia or amnesia.

The only general anesthetics that do not have significant effects on GABA\(_\alpha\) or glycine receptors are ketamine, nitrous oxide, cyclopropane, and xenon. These agents inhibit a different type of ligand-gated ion channel, the N-methyl-D-aspartate (NMDA) receptor (Chapter 14). NMDA receptors are glutamate-gated cation channels that are somewhat selective for calcium and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity. Ketamine inhibits NMDA receptors by binding to the phencyclidine site on the NMDA-receptor protein, and the NMDA receptor is thought to be the principal molecular target for ketamine’s anesthetic actions. Nitrous oxide (Jevtovic-Todorovic et al., 1998), cyclopropane (Raines et al., 2001), and xenon (de Sousa et al., 2000) are potent and selective inhibitors of NMDA-activated currents, suggesting that these agents also may produce unconsciousness by means of actions on NMDA receptors.

Inhalational anesthetics have two other known molecular targets that may mediate some of their actions. Halogenated inhalational anesthetics activate some members of a class of K\(^+\) channels known as...
two-pore domain channels (Patel et al., 1999); other two-pore domain channel family members are activated by xenon, nitrous oxide, and cyclopropane (Franks, 2006). These channels are located in both pre-synaptic and post-synaptic sites. The post-synaptic channels are important in setting the resting membrane potential of neurons and may be the molecular locus through which these agents hyperpolarize neurons. Activation of pre-synaptic channels can lead to hyperpolarization of the pre-synaptic terminal, thereby reducing neurotransmitter release. Modulation of neurotransmitter release can also be modulated by interaction of anesthetics with the molecular machinery involved in neurotransmitter release. The action of inhalational anesthetics requires a protein complex (syntaxin, SNAP-25, synaptobrevin) involved in synaptic neurotransmitter release (van Swinderen et al., 1999). These molecular interactions may explain, in part, the capacity of inhalational anesthetics to cause presynaptic inhibition in the hippocampus and could contribute to the amnesic effect of inhalational anesthetics.

**Anatomic Sites of Anesthetic Action.** In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Delineation of the precise anatomic sites of action is difficult because many anesthetics diffuse in the CNS. For example, isoflurane at 2 MAC can cause electrical silence in the brain. However, in vitro studies show that specific cortical pathways exhibit markedly different sensitivities to both inhalational and intravenous anesthetics (MacIver and Roth, 1988), suggesting that anesthetics produce specific components of the anesthetic state through actions at specific sites in the CNS. Consistent with this possibility, inhalational anesthetics produce immobilization in response to a surgical incision (the end point used in determining MAC) by action on the spinal cord (Rampil, 1994). Given that amnesia or unconsciousness cannot result from anesthetic actions in the spinal cord, one concludes that different components of anesthesia are produced at different sites in the CNS. Indeed, recent studies show that the sedative effects of pentobarbital and propofol (GABA-ergic anesthetics) are mediated by GABA_\text{A}_\text{A} receptors in the tuberomammillary nucleus (Nelson et al., 2002), and the sedative effects of the intravenous anesthetic dexmedetomidine (an \(\alpha_2\) adrenergic receptor agonist) are produced by actions in the locus ceruleus (Mizobe et al., 1996). These findings suggest that the sedative actions of some anesthetics share the neuronal pathways involved in endogenous sleep.

Functional imaging studies of the awake and anesthetized brain have revealed that most anesthetics cause, with some exceptions, a global reduction in cerebral metabolic rate (CMR) and in cerebral blood flow (CBF); agent-specific effects on CMR and CBF will be described later in the chapter. A consistent feature of general anesthesia is a suppression of metabolism in the thalamus (Alkire et al., 2008). This is not surprising given the demonstration that inhalational anesthetics depress the excitability of thalamic neurons. The thalamus serves as a major relay by which sensory input from the periphery ascends to the cortex. Suppression of thalamic activity might isolate the cortex from ascending input. Thus, the thalamus may serve as a switch between the awake and anesthetized states (Franks, 2008). In addition, general anesthesia results in the suppression of activity in specific regions of the cortex, including the mesial parietal cortex, posterior cingulate cortex, precuneous, and inferior parietal cortex. Of interest is the recent observation that electrical activity in the cortex is suppressed before that in the thalamus. This suggests that it is cortical suppression that, via the corticothalamic fibers, leads to thalamic suppression, thereby making the cortex the primary target of anesthetics (Alkire et al., 2008). However, the temporal relationships between thalamus and cortical activity (and deactivation) under general anesthesia need further clarification before the relative importance of each site to anesthetic induced loss of consciousness is known (Franks, 2008).

The similarities between natural sleep and the anesthetized state suggest that anesthetics might also modulate endogenous sleep regulating pathways, which include ventrolateral preoptic (VLPO) and tuberomammillary nuclei. VLPO projects inhibitory GABA-ergic fibers to ascending arousal nuclei, which in turn project to the cortex, forebrain, and subcortical areas; release of histamine, 5-HT, orexin, NE, and ACh mediate wakefulness (Sanders and Maze, 2007). Intravenous and inhalational agents with activity at GABA_A receptors can increase the inhibitory effects of VLPO, thereby suppressing consciousness. Dexmedetomidine, an \(\alpha_2\) agonist, also increases VLPO-mediated inhibition by suppressing the inhibitory effect of locus ceruleus neurons on VLPO (Sanders et al., 2007). Finally, both intravenous and inhalational anesthetics depress hippocampal neurotransmission (Kendig et al., 1991), a probable locus for their amnesic effects.

**Summary.** Current evidence supports the view that most intravenous general anesthetics act predominantly through GABA_A receptors and perhaps through some interactions with other ligand-gated ion channels such as NMDA receptors and two-pore K^+ channels. The halogenated inhalational agents have a variety of molecular targets, consistent with their status as complete (all components) anesthetics. Nitrous oxide, ketamine, and xenon constitute a third category of general anesthetics that are likely to produce unconsciousness by inhibition of the NMDA receptor and/or activation of two-pore-domain K^+ channels.

**PARENTERAL ANESTHETICS**

**Pharmacokinetic Principles**

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 19-1). Hydrophobicity is the key factor governing their pharmacokinetics. After a single intravenous bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord where they produce anesthesia within a single circulation
time. Subsequently blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less perfused tissues such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism (Figure 19–2). After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments. Thus, parenteral anesthetic half-life are “context-sensitive,” and the degree to which a $t_{1/2}$ is contextual varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Table 19–2 and Figure 19–3). For example, after a single bolus of thiopental, patients usually emerge from anesthesia within 10 minutes; however, a patient may require more than a day to awaken from a prolonged thiopental infusion.

Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors. For example, in patients with lower cardiac output, the relative perfusion of the brain and the fraction of anesthetic dose delivered to the brain are higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of anesthetic. The elderly also typically require a smaller anesthetic dose, primarily because of a smaller initial volume of distribution. As described later in the chapter, similar principles govern the pharmacokinetics of the hydrophobic inhalational anesthetics, with the added complexity of drug uptake by inhalation.

**SPECIFIC PARENTERAL AGENTS**

**Barbiturates**

**Chemistry and Formulations.** Barbiturates are derivatives of barbituric acid (2,4,6-trioxohexahydropyrimidine), with either an oxygen or a sulfur at the 2-position (Figure 19–1). The three barbiturates most commonly used in clinical anesthesia are sodium thiopental, thiamylal, and methohexital. Sodium thiopental (PENTOTHAL, others) has been used most frequently for inducing anesthesia. Thiamylal (SURITAL) is licensed in the U.S. only for veterinary use. Barbiturates are supplied as racemic mixtures despite enantioselectivity in their anesthetic potency. Barbiturates are formulated as the sodium salts with 6% sodium carbonate and

reconstituted in water or isotonic saline to produce 2.5% (thiopental), 2% (thiamylal), or 1% (methohexital) alkaline solutions (10 ≤ pH ≤ 11). Mixing barbiturates with drugs in acidic solutions during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the intravenous tubing.

Dosages and Clinical Use. Recommended intravenous dosing for parenteral anesthetics in a healthy young adult is given in Table 19–2.

The typical induction dose (3-4 mg/kg) of thiopental produces unconsciousness in 10-30 seconds with a peak effect in 1 minute and duration of anesthesia of 5-8 minutes. Neonates and infants usually require a higher induction dose (5-8 mg/kg), whereas elderly and pregnant patients require less (1-3 mg/kg) (Gin et al., 1997). Dosage calculation based on lean body mass reduces individual variation in dosage requirements. Doses can be reduced by 10-50% after premedication with benzodiazepines, opiates, or α₂ adrenergic agonists, because of their additive hypnotic effect (Nishina et al., 1994; Short et al., 1991; Wang et al., 1996). Thiamylal is approximately equipotent with and in all aspects similar to thiopental. Methohexital (BREVITAL) is 3-fold more potent but otherwise similar to thiopental in onset and duration of action. Thiopental and thiamylal produce little to no pain on injection; methohexital elicits mild pain. Veno-irritation can be reduced by injection into larger non-hand veins and by prior intravenous injection of lidocaine (0.5-1 mg/kg). For induction of pediatric patients without IV access, any of the three drugs can be given off-label per rectum at ~10-fold the IV dose.

**Pharmacokinetics and Metabolism.** Pharmacokinetic parameters for parenteral anesthetics are given in Table 19–2. As already discussed, the principal mechanism limiting anesthetic duration after single doses is redistribution of these hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances.

Methohexital differs from the other two intravenous barbiturates in its much more rapid clearance; thus, it accumulates less during prolonged infusions. Because of their slow elimination and large volumes of distribution, prolonged infusions or very large doses of thiopental and thiamylal can produce unconsciousness lasting several days. Even single induction doses of thiopental and to a lesser degree methohexital can produce psychomotor impairment lasting up to 8 hours (Beskow et al., 1995). Propofol has largely supplanted methohexital for outpatient procedures that require a rapid return to an alert state (see “Propofol” later in the chapter).

All three barbiturates are primarily eliminated by hepatic metabolism and renal excretion of inactive metabolites; a small fraction of thiopental undergoes desulfuration to the longer-acting hypnotic pentobarbital. In patients with cirrhosis, a larger volume of distribution combined with a reduction in clearance can result in prolongation of the clinical action of barbiturates. These drugs are highly protein bound (Table 19–2). Hepatic disease or other conditions that reduce serum protein concentration will increase the initial free concentration and hypnotic effect of an induction dose; this is noted in patients with advanced cirrhosis in whom the protein synthesis capacity of the liver is greatly compromised.

**Side Effects**

**Nervous System.** Barbiturates suppress the EEG and can produce burst suppression of the EEG. They reduce the cerebral metabolic rate, as measured by cerebral O₂ consumption (CMRO₂), in a dose-dependent manner. Induction doses of thiopental reduce CMRO₂ by 25-30%, with a maximal decrease of 55% occurring at two to five times that dose (Stullken et al., 1977). As a consequence of the decrease in CMRO₂, cerebral blood flow and intracranial pressure are similarly reduced.

Because it markedly lowers cerebral metabolism, thiopental has been used as a protectant against cerebral ischemia; however, the large doses required and the subsequent prolonged sedation have precluded its use clinically for this purpose. Thiopental also reduces intraocular pressure. Presumably in part due to their CNS depressant activity, barbiturates are effective anticonvulsants. Thiopental in particular is a proven medication in the treatment of status epilepticus. Methohexital can increase ictal activity, and seizures have been described in patients who received doses sufficient to produce burst

---

**Figure 19–3. Context-sensitive half-time of general anesthetics.** The duration of action of single intravenous doses of anesthetic/hypnotic drugs is similarly short for all and is determined by redistribution of the drugs away from their active sites (see Figure 19–2). However, after prolonged infusions, drug half-lives and durations of action are dependent on a complex interaction between the rate of redistribution of the drug, the amount of drug accumulated in fat, and the drug’s metabolic rate. This phenomenon has been termed the context-sensitive half-time; that is, the t₁/₂ of a drug can be estimated only if one knows the context—the total dose and over what time period it has been given. Note that the half-times of some drugs such as etomidate, propofol, and ketamine increase only modestly with prolonged infusions; others (e.g., diazepam and thiopental) increase dramatically. (Reproduced with permission from Reves JG, Glass PSA, Lubarsky DA, et al: Intravenous anesthetics, in Miller RD et al, (eds): *Miller’s Anesthesia*, 7th ed. Philadelphia: Churchill Livingstone, 2010, p 718. Copyright © Elsevier.)
suppression of the EEG (Todd et al., 1984). This property makes methohexital a good choice for anesthesia in patients who undergo electroconvulsive therapy.

**Cardiovascular System.** The anesthetic barbiturates produce dose-dependent decreases in blood pressure. The effect is due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex. Thiopental maintains the ratio of myocardial O₂ supply to demand in patients with coronary artery disease within a normal blood pressure range.

Hypotension can be severe in patients with an impaired ability to compensate for venodilation such as those with hypovolemia, cardiomyopathy, valvular heart disease, coronary artery disease, cardiac tamponade, or β-adrenergic blockade. None of the barbiturates has been shown to be arrhythmogenic.

**Respiratory System.** Barbiturates are respiratory depressants. Induction doses of thiopental decrease minute ventilation and tidal volume, with a smaller and inconsistent decrease in respiratory rate (Grounds et al., 1987). Reflex responses to hypercarbia and hypoxia are diminished by anesthetic barbiturates (Hirshman et al., 1975); and at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. With the exception of uncommon anaphylactoid reactions, these drugs have little effect on bronchomotor tone (Kingston and Hirshman, 1984). Compared to propofol, barbiturates produce a higher incidence of wheezing in asthmatics, attributed to histamine release from mast cells, during induction of anesthesia (Pizov et al., 1995).

**Other Side Effects.** Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. A single induction dose of thiopental does not alter tone of the gravid uterus, but may produce mild transient depression of newborn activity. True allergies to barbiturates are rare; however, direct drug-induced histamine release is occasionally seen (Sprung et al., 1997).

Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegate porphyria and are contraindicated in such patients. The abnormal synthesis of protoporphyrin (important in hemoglobin production) results in excess porphobilinogen. Barbiturates induce aminolevulinic acid synthase, an enzyme responsible for phophobilinogen synthesis. This leads to excessive porphobilinogen levels and can precipitate acute porphyrnic crises that are manifested by severe abdominal pain, nausea, vomiting, psychiatric disorders, and neurologic abnormalities.

Methohexital can produce pain on injection to a greater degree than thiopental. Inadvertent intra-arterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction that can threaten limb survival. Methohexital and to a lesser degree other barbiturates can produce excitatory symptoms on induction such as cough, hiccup, muscle tremors, twitching, and hypertonus.

Unlike inhalational anesthetics and succinylcholine, barbiturates and all other parenteral anesthetics apparently do not trigger malignant hyperthermia (Rosenberg et al., 1997).

**Propofol**

Propofol is the most commonly used parenteral anesthetic in the U.S. Fospropofol is a prodrug form that is converted to propofol in vivo. The clinical pharmacological properties of propofol are summarized in Table 19–2.

![Propofol](image)

**Chemistry and Formulations.** The active ingredient in propofol, 2,6-diisopropylphenol, is an oil at room temperature and insoluble in aqueous solutions. Propofol is formulated for IV administration as a 1% (10 mg/mL) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatidylcholine. In the U.S., disodium EDTA (0.05 mg/mL) or sodium metabisulfite (0.25 mg/mL) is added to inhibit bacterial growth. Nevertheless, significant bacterial contamination of open containers has been associated with serious patient infections; propofol should be administered within 4 hours of its removal from sterile packaging; unused drug should be discarded.

The lipid emulsion formulation of propofol is associated with significant pain on injection and hyperlipidemia. A new aqueous formulation of propofol, fospropofol, which is not associated with these adverse effects, has recently been approved for use for sedation in patients undergoing diagnostic procedures. Fospropofol, which itself is inactive, is a phosphate ester prodrug of propofol that is hydrolyzed by endothelial alkaline phosphatases to yield propofol, phosphate, and formaldehyde. The formaldehyde is rapidly converted to formic acid, which then is metabolized by tetrahydrofolate dehydrogenase to CO₂ and water (Fechner et al., 2008).

**Dosage and Clinical Use.** The induction dose of propofol (100 mg, others) in a healthy adult is 2-2.5 mg/kg and it has an onset and duration of anesthesia similar to thiopental (Table 19–2). As with barbiturates, dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination t₁/₂, propofol often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10-50% of the induction dose) every 5 minutes or as needed are effective. An infusion of propofol produces a more stable drug level (100-300 μg/kg per minute) and is better suited for longer-term anesthetic maintenance. Infusion rates should be tailored to patient response and the levels of other hypnotics. Sedating doses of propofol are 20-50% of those required for general anesthesia. However, even at these lower doses, caregivers should be vigilant and prepared for all of the side effects of propofol discussed below, particularly airway obstruction and apnea.

Fospropofol produces dose-dependent sedation and can be administered in otherwise healthy individuals at 2-8 mg/kg intravenously (delivered either as a bolus or by a short infusion over 5-10 min). The optimum dose for sedation is ~6.5 mg/kg. This results in a loss of consciousness in ~10 minutes. The duration of the sedative effect is ~45 min.
Pharmacokinetics and Metabolism. The pharmacokinetics of propofol are governed by the same principles that apply to barbiturates. Onset and duration of anesthesia after a single bolus are similar to thiopental. Recovery after multiple doses or continuous infusions has been shown to be much faster after propofol than after thiopental or even methohexital. Propofol has a context-sensitive t1/2 of ~10 min with an infusion lasting 3 hours and ~40 minutes for infusions lasting up to 8 hours (Figure 19–3). Propofol’s shorter duration of action after infusion can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment (Figure 19–3). The rapid clearance of propofol explains the more rapid emergence from anesthesia in comparison to barbiturates; this facilitates a more rapid discharge from the recovery room.

Propofol is metabolized in the liver by conjugation to sulfate and glucuronic acid to less active metabolites that are renally excreted; however, its clearance exceeds hepatic blood flow, and anhepatic metabolism, particularly in the lungs and kidneys, has been demonstrated (Veroli et al., 1992). In patients with moderate cirrhosis, the volume of distribution of propofol is increased significantly. However, terminal elimination t1/2 and emergence from propofol anesthesia is not substantially different from healthy patients (Servin et al., 1990). Propofol is highly protein bound, and its pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels.

Clearance of propofol is reduced in the elderly; given that the central volume of distribution of propofol is also reduced, the required dose of propofol for both induction and maintenance of anesthesia may be decreased. In neonates, propofol clearance is also reduced (Allegaert et al., 2007). Infusion of propofol in neonates therefore has the potential for substantial accumulation and a consequent delay in emergence from anesthesia or sedation. By contrast, in young children, a more rapid clearance in combination with a larger central volume may necessitate larger doses of propofol for induction and maintenance of anesthesia (Kataria et al., 1994).

The t1/2 for hydrolysis of fospropofol is 8 min. Fospropofol has a small volume of distribution and a terminal t1/2 ~46 min. The currently published pharmacokinetic data on fospropofol were derived using an analytical method that has now been shown to be inaccurate; correct pharmacokinetic data are not yet available (Fechner et al., 2008).

Pharmacology and Side Effects

Nervous System. The sedation and hypnotic actions of propofol are mediated by its action on GABA_A receptors; agonism at these receptors results in an increased chloride conduction and hyperpolarization of neurons. Propofol suppresses the EEG, and in sufficient doses, can produce burst suppression of the EEG. Propofol decreases CMRO_2, cerebral blood flow, and intracranial and intracerebral pressures by about the same amount as thiopental. Like thiopental, propofol has been used in patients at risk for cerebral ischemia; however, no human outcome studies have been performed to determine its efficacy as a neuroprotectant. Excitatory phenomena, such as choreiform movements and opisthotonus, have been observed after propofol injection with the same frequency as that seen with thiopental but less than with methohexital. These movements, which are transient, are not associated with seizure activity. Results from studies on the anticonvulsant effects of propofol have been mixed; some data even suggest it has proconvulsant activity when combined with other drugs. However, propofol has been shown to suppress seizure activity in experimental models and has been used for the treatment of status epilepticus in humans (Parviainen et al., 2007).

Cardiovascular System. Propofol produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by thiopental. The fall in blood pressure can be explained by both vasodilation and possibly mild depression of myocardial contractility. Propofol appears to blunt the baroreceptor reflex and reduce sympathetic nerve activity (Ebert and Muzi, 1994). As with thiopental, propofol should be used with caution in patients at risk for or intolerant of decreases in blood pressure; these include patients with significant blood loss and hypovolemia.

Respiratory System. At equipotent doses, propofol produces a slightly greater degree of respiratory depression than thiopental (Blouin et al., 1991). Patients given propofol should be monitored to ensure adequate oxygenation and ventilation. Propofol appears to be less likely than barbiturates to provoke bronchospasm and may be the induction agent of choice in asthmatics (Pizov et al., 1995). The bronchodilator properties of propofol may be attenuated by the metabisulfite preservative in some propofol formulations (Brown et al., 2001).

Other Side Effects. Propofol has no clinically significant effects on hepatic, renal, or endocrine organ systems. Unlike thiopental, propofol does not have an anti-analgesic effect. It has a significant anti-emetic action. Propofol elicits pain on injection that can be reduced with lidocaine and the use of larger arm and antecubital veins. Propofol provokes anaphylactoid reactions at about the same low frequency as thiopental; the histamine release (in the absence of anaphylactic or anaphylactoid reactions) that occurs with thiopental administration is greater than that with propofol. Although propofol does cross placental membranes, it is considered safe for use in pregnant women; like thiopental, propofol only transiently depresses activity in the newborn (Abboud et al., 1995). Propofol does not trigger malignant hyperthermia.

A rare but potentially fatal complication, termed propofol infusion syndrome (PRIS), has been described primarily in prolonged, higher-dose infusions of propofol in young or head-injured patients. The syndrome is characterized by metabolic acidosis, hyperlipidemia, rhabdomyolysis, and an enlarged liver. While the precise mechanisms by which PRIS occurs are not clear, alterations in mitochondrial metabolism and electron transport chain function have been described (Kam and Cardone, 2007).

The side-effect profile of fospropofol is similar to that of propofol. Fospropofol’s slower onset of sedation (due to the need for hydrolysis of the prodrug) results in a lower incidence of hypotension, respiratory depression, apnea, and loss of airway patency. Nonetheless, unintended deep levels of sedation can occur with fospropofol, and the drug should therefore be used only by individuals who can maintain an adequate airway and support cardiorespiratory function.

Whether fospropofol can also cause PRIS is not currently known (Fechner et al., 2008). A metabolic byproduct of fospropofol is formic acid. This is degraded to CO_2 and water by tetrahydrofolate dehydrogenase, an enzyme that requires folate as a co-factor. In patients who have a folate deficiency, there is a theoretical risk of formic acid accumulation; to date, such an adverse event has not been reported.
Etomidate

Etomidate is a substituted imidazole that is supplied as the active d-isomer (Figure 19–1). Etomidate is poorly soluble in water and is formulated as a 2 mg/mL solution in 35% propylene glycol. An aqueous solution of etomidate using sulfobutyl ether-7β-cyclodextrin as a solubilizing agent has been developed; this formulation is not currently available for clinical use in the U.S. Unlike thiopental, etomidate does not induce precipitation of neuromuscular blockers or other drugs frequently given during anesthetic induction.

Etomidate's clinical pharmacological properties are listed in Table 19–2.

Dosage and Clinical Use. Etomidate (AMIDATE, others) is primarily used for anesthetic induction of patients at risk for hypotension.

Induction doses of etomidate (0.2-0.6 mg/kg) have a rapid onset and short duration of action (Table 19–2) and are accompanied by a high incidence of pain on injection and myoclonic movements. Lidocaine effectively reduces the pain of injection, while myoclonic movements can be reduced by premedication with either benzodiazepines or opiates. These myoclonic movements, which are similar to seizures, are not associated with convulsive activity on the EEG. Etomidate is pharmacokinetically suitable for off-label infusion for anesthetic maintenance (10 μg/kg per minute) or sedation (5 μg/kg per minute); however, long-term infusions are not recommended (see below, under “Respiratory and Other Side Effects”). Etomidate also may be given rectally (6.5 mg/kg) with an onset of ~5 minutes.

Pharmacokinetics and Metabolism. An induction dose of etomidate has a rapid onset; redistribution limits the duration of action (Table 19–2). Metabolism occurs in the liver, primarily to inactive compounds. Elimination is both renal (78%) and biliary (22%). Compared to thiopental, the duration of action of etomidate increases less with repeated doses (Figure 19–3). The plasma protein binding of etomidate is high but less than that of barbiturates and propofol (Table 19–2).

Side Effects

Nervous System. Etomidate produces hypnosis and has no analgesic effects. The effects of etomidate on cerebral blood flow, metabolism, and intracranial and intraocular pressures are similar to those of thiopental (without dropping mean arterial blood pressure) (Modica and Tempelhoff, 1992). Etomidate has been used as a protectant against cerebral ischemia; however, animal studies have failed to show a consistent beneficial effect (Drummond et al., 1995), and no controlled human trials have been performed. Etomidate produces increased EEG activity in epileptogenic foci and has been associated with seizures (Ebrahimi et al., 1986).

Cardiovascular System. Cardiovascular stability after induction is a major advantage of etomidate over either barbiturates or propofol. Induction doses of etomidate typically produce a small increase in heart rate and little or no decrease in blood pressure or cardiac output. Etomidate has little effect on coronary perfusion pressure while reducing myocardial O2 consumption (Kettler et al., 1974). Thus, of all induction agents, etomidate is best suited to maintain cardiovascular stability in patients with coronary artery disease, cardiomyopathy, cerebral vascular disease, or hypovolemia.

Respiratory and Other Side Effects. The degree of respiratory depression due to etomidate appears to be less than that due to thiopental. Like methohexital, etomidate may induce hiccups but does not significantly stimulate histamine release. Despite minimal cardiac and respiratory effects, etomidate does have two major drawbacks. Etomidate has been associated with nausea and vomiting. The drug also inhibits adrenal biosynthetic enzymes required for the production of cortisol and some other steroids. Single induction doses of etomidate may mildly and transiently reduce cortisol levels but no significant differences in outcome after short-term administration have been found, even for variables specifically known to be associated with adrenocortical suppression (Wagner et al., 1984). Thus, while etomidate is not recommended for long-term infusion, it appears safe for anesthetic induction and has some unique advantages in patients prone to hemodynamic instability. A rapidly metabolized and ultra-short-acting analog, methoxycarbonyl-etomidate, has been developed that retains the favorable pharmacological properties of etomidate but does not produce adrenocortical suppression after bolus dosing (Cotton and Clauging, 2009).

Ketamine

Ketamine is an arylcyclohexylamine, a congener of phencyclidine (Figure 19–1). Clinical pharmacokinetic data for ketamine appear in Table 19–2.

Ketamine is supplied as a mixture of the R+ and S- isomers even though the S- isomer is more potent with fewer side effects. Although more lipophilic than thiopental, ketamine is water soluble and available as 10-, 50-, and 100-mg/mL solutions in sodium chloride plus the preservative benzethonium chloride.

Dosage and Clinical Use. Ketamine (KETALAR, others) has unique properties that make it useful for anesthetizing patients at risk for hypotension and bronchospasm and for certain pediatric procedures. However, significant side effects limit its routine use. Ketamine rapidly produces a hypnotic state quite distinct from that of other anesthetics. Patients have profound analgesia, unresponsiveness to commands, and amnesia, but may have their eyes open, move their limbs involuntarily, and breathe spontaneously. This cataleptic state has been termed dissociative anesthesia. The administration of ketamine has been shown to reduce the development of tolerance to long-term opioid use. Low-dose ketamine infusion for this purpose has been advocated in patients who have developed significant tolerance to opioids (Himmelshefer and Durieux, 2005).

Ketamine typically is administered intravenously but also is effective by intramuscular, oral, and rectal routes. The induction doses are 0.5-1.5 mg/kg IV, 4-6 mg/kg IM, and 8-10 mg/kg PR. Onset of action after an intravenous dose is similar to that of the other parenteral anesthetics, but the duration of anesthesia of a single dose is longer (Table 19–2). For anesthetic maintenance, ketamine occasionally is continued as an infusion (25-100 μg/kg per minute). Ketamine does not elicit pain on injection or true excitatory behavior as described for methohexital, although involuntary movements produced by ketamine can be mistaken for anesthetic excitement.
Pharmacokinetics and Metabolism. The onset and duration of an induction dose of ketamine are determined by the same distribution/redistribution mechanisms operant for all the other parenteral anesthetics.

Ketamine is hepatically metabolized to norketamine, which has reduced CNS activity; norketamine is further metabolized and excreted in urine and bile. Ketamine has a large volume of distribution and rapid clearance that make it suitable for continuous infusion without the lengthening in duration of action seen with thiopental (Table 19–2 and Figure 19–3). Protein binding is much lower with ketamine than with the other parenteral anesthetics (Table 19–2).

Side Effects

Nervous System. Ketamine has indirect sympathomimetic activity and can support blood pressure on anesthetic induction in patients who are at risk of developing significant hypotension. Ketamine’s behavioral effects are distinct from those of other anesthetics. The ketamine-induced cataleptic state is accompanied by nystagmus with pupillary dilation, salivation, lacrimation, and spontaneous limb movements with increased overall muscle tone. Although ketamine does not produce the classic anesthetic state, patients are amnestic and unresponsive to painful stimuli. Ketamine produces profound analgesia, a distinct advantage over other parenteral anesthetics.

Unlike other parenteral anesthetics, ketamine increases cerebral blood flow and intracranial pressure (ICP) with minimal alteration of cerebral metabolism. The racemic mixture of ketamine can increase cerebral metabolic rate (CMR) and cerebral blood flow (CBF), particularly in the anterior cingulate and frontal cortex, thalamus, and putamen (Langsjo et al., 2004). S ketamine produces similar changes in CBF and CMR whereas R+ ketamine reduces both CMR and CBF (Vollenweider et al., 1997). These properties of ketamine have raised a concern that ICP can increase in patients with compromised intracranial compliance. However, ketamine does not increase ICP in patients with intracranial hypertension (Bourgojn et al., 2005). Moreover, the effects of ketamine on CBF can be readily attenuated by the simultaneous administration of sedative hypnotics (propofol, midazolam, barbiturates). In aggregate, the available data suggest that the contraindication of ketamine in patients with intracranial pathology or cerebral ischemia needs re-evaluation (Himmelscher et al., 2005).

In some studies, ketamine increased intraocular pressure, and its use for induction of patients with open eye injuries is controversial (Whitacre and Ellis, 1984). The effects of ketamine on seizure activity appear mixed, without either strong pro- or anticonvulsant activity. Emergence delirium, characterized by hallucinations, vivid dreams, and delusions, is a frequent complication of ketamine that can result in serious patient dissatisfaction and can complicate postoperative management. Delirium symptoms are most frequent in the first hour after emergence and appear to occur less frequently in children. Benzodiazepines reduce the incidence of emergence delirium (Dundee and Lilburn, 1978).

Cardiovascular System. Unlike other anesthetics, induction doses of ketamine typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most likely mediated by inhibition of both central and peripheral catecholamine reuptake. Ketamine has direct negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect sympathomimetic action (Pagel et al., 1992). Thus, ketamine is a useful drug, along with etomidate, for patients at risk for hypotension during anesthesia. While not arrhythmogenic, ketamine increases myocardial O2 consumption and is not an ideal drug for patients at risk for myocardial ischemia.

Respiratory System. The respiratory effects of ketamine are perhaps the best indication for its use. Induction doses of ketamine produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other general anesthetics. Ketamine is a potent bronchodilator due to its indirect sympathomimetic activity and perhaps some direct bronchodilating activity. Thus, ketamine is particularly well-suited for anesthetizing patients at high risk for bronchospasm. Increased salivation that attends ketamine administration can be effectively prevented by anticholinergic agents such as glycopyrrolate.

Summary of Parenteral Anesthetics

Parenteral anesthetics are the most common drugs used for anesthetic induction of adults. Their lipophilicity, coupled with the relatively high perfusion of the brain and spinal cord, results in rapid onset and short duration after a single bolus dose. However, these drugs ultimately accumulate in fatty tissue, prolonging recovery if multiple doses are given, particularly for drugs with lower rates of clearance. Each anesthetic has its own unique set of properties and side effects (Table 19–3). Propofol and thiopental are the two most commonly used parenteral agents. Propofol is advantageous for procedures where rapid return to a preoperative mental status is desirable. Thiopental has a long-established track record of safety. Etomidate usually is reserved for patients at risk for hypotension and/or myocardial ischemia. Ketamine is best suited for patients with asthma or for children undergoing short, painful procedures.

INHALATIONAL ANESTHETICS

Introduction

A wide variety of gases and volatile liquids can produce anesthesia. The structures of the currently used inhalational anesthetics are shown in Figure 19–4. One of the troublesome properties of the inhalational anesthetics is their low safety margin. The inhalational anesthetics have therapeutic indices (LD50/ED50) that range from 2 to 4, making these among the most dangerous drugs in clinical use.

The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side-effect profile. Hence, the selection of an inhalational anesthetic often is based on matching a patient’s pathophysiology with drug side-effect profiles. The specific adverse effects of each of
the inhalational anesthetics are emphasized in the following sections.

Table 19–1 lists the widely varying physical properties of the inhalational agents in clinical use. These properties are important because they govern the pharmacokinetics of the inhalational agents. Ideally, an inhalational agent would produce a rapid induction of anesthesia and a rapid recovery following discontinuation.

**Pharmacokinetic Principles**

The inhalational agents are some of the very few pharmacological agents administered as gases. The fact that these agents behave as gases rather than as liquids requires that different pharmacokinetic constructs be used in analyzing their uptake and distribution.

It is essential to understand that inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the two tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. Note, however, that while the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different. Indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentration in two tissues when the partial pressures of anesthetic are equal in the two tissues. Blood:gas, brain:blood, and fat:blood partition coefficients for the various inhalational agents are listed in Table 19–1. These partition coefficients show that inhalational anesthetics are more soluble in some tissues (e.g., fat) than they are in others (e.g., blood), and that there is significant range in the solubility of the various inhalational agents in such tissues.

In clinical practice, one can monitor the equilibration of a patient with anesthetic gas. Equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. In other words, equilibrium is the point at which there is no net uptake of anesthetic from the alveoli into the blood. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly, as illustrated for nitrous oxide in Figure 19–5. If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs

**Figure 19–4.** Structures of inhalational general anesthetics. Note that all inhalational general anesthetic agents except nitrous oxide and halothane are ethers, and that fluorine progressively replaces other halogens in the development of the halogenated agents. All structural differences are associated with important differences in pharmacological properties.
because fat represents a huge anesthetic reservoir that will be filled only slowly because of the modest blood flow to fat. This is illustrated by the slow approach of halothane alveolar partial pressure to inspired partial pressure in Figure 19–5.

In considering the pharmacokinetics of anesthetics, one important parameter is the speed of anesthetic induction. Anesthesia is produced when anesthetic partial pressure in brain is equal to or greater than MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC. While the rate of rise of alveolar partial pressure will be slower for anesthetics that are highly soluble in blood and other tissues, this limitation on speed of induction can be overcome largely by delivering higher inspired partial pressures of the anesthetic.

Elimination of inhalational anesthetics is largely the reverse process of uptake. For agents with low blood and tissue solubility, recovery from anesthesia should mirror anesthetic induction, regardless of the duration of anesthetic administration. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of anesthetic administration. This occurs because the accumulated amounts of anesthetic in the fat reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MACawake, a partial pressure somewhat lower than MAC (Table 19–1).

Halothane

Halothane is 2-bromo-2-chloro-1,1,1-trifluoroethane (Figure 19–4). Halothane is a volatile liquid at room temperature and must be stored in a sealed container. Because halothane is a light-sensitive compound that also is subject to spontaneous breakdown, it is marketed in amber bottles with thymol added as a preservative. Mixtures of halothane with O2 or air are neither flammable nor explosive.

Pharmacokinetics. Halothane has a relatively high blood:gas partition coefficient and high fat:blood partition coefficient (Table 19–1). Induction with halothane therefore is relatively slow, and the alveolar halothane concentration remains substantially lower than the inspired halothane concentration for many hours of administration. Because halothane is soluble in fat and other body tissues, it will accumulate during prolonged administration. Therefore, the speed of recovery from halothane is lengthened as a function of duration of administration.

Approximately 60-80% of halothane taken up by the body is eliminated unchanged by the lungs in the first 24 hours after its administration. A substantial amount of the halothane not eliminated in exhaled gas is biotransformed by hepatic CYPs. The major metabolite of halothane is trifluoroacetic acid, which is formed by removal of bromine and chlorine ions. Trifluoroacetic acid, bromine, and chlorine all can be detected in the urine. Trifluoroacetylchloride, an intermediate in oxidative metabolism of halothane, can trifluoroacetylate several proteins in the liver. An immune reaction to these altered proteins may be responsible for the rare cases of fulminant halothane-induced hepatic necrosis. A minor reductive pathway accounts for ~1% of halothane metabolism that generally is observed only under hypoxic conditions.

Clinical Use. Halothane, introduced in 1956, was the first modern, halogenated inhalational anesthetic used in clinical practice. It is a potent agent that usually is used for maintenance of anesthesia. It is not pungent and is therefore well tolerated for inhalation induction of anesthesia. This is most commonly done in children, in whom preoperative placement of an intravenous catheter can be difficult. Anesthesia is produced by halothane at end-tidal concentrations of 0.7-1%. The use of halothane in the U.S. has diminished substantially in the past decade because of the introduction of newer inhalational agents with better pharmacokinetic...
and side-effect profiles. Halothane continues to be extensively used in children because it is well tolerated for inhalation induction and because the serious side effects appear to be diminished in children. Halothane has a low cost and therefore is still widely used in developing countries.

Side Effects

**Cardiovascular System.** The most predictable side effect of halothane is a dose-dependent reduction in arterial blood pressure. Mean arterial pressure typically decreases ~20-25% at MAC concentrations of halothane. This reduction in blood pressure is primarily the result of direct myocardial depression leading to reduced cardiac output (Figure 19–6). Myocardial depression is thought to result from attenuation of depolarization-induced intracellular calcium transients. Halothane-induced hypotension usually is accompanied by either bradycardia or a normal heart rate. Attenuation of baroreceptor reflex function decreases the chronotropic and inotropic responses to a reduction in blood pressure (Constant et al., 2004). Heart rate can be increased during halothane anesthesia by exogenous catecholamine or by sympathoadrenal stimulation. Halothane-induced reductions in blood pressure and heart rate generally disappear after several hours of constant halothane administration, presumably because of progressive sympathetic stimulation.

Halothane does not cause a significant change in systemic vascular resistance. Nonetheless, it does alter the resistance and autoregulation of specific vascular beds, leading to redistribution of blood flow. The vascular beds of the skin and brain are dilated directly by halothane, leading to increased cerebral blood flow and skin perfusion. Conversely, autoregulation of renal, splanchic, and cerebral blood flow is inhibited by halothane, leading to reduced perfusion of these organs in the face of reduced blood pressure. Coronary autoregulation is largely preserved during halothane anesthesia. Finally, halothane inhibits hypoxic pulmonary vasoconstriction, leading to increased perfusion to poorly ventilated regions of the lung and an increased alveolar:arterial O2 gradient.

Halothane also has significant effects on cardiac rhythm. Sinus bradycardia and atrioventricular rhythms occur frequently during halothane anesthesia but usually are benign. These rhythms result mainly from a direct depressive effect of halothane on sinoatrial node discharge. Halothane also can sensitize the myocardium to the arrhythmogenic effects of epinephrine (Sumikawa et al., 1983). Premature ventricular contractions and sustained ventricular tachycardia can be observed during halothane anesthesia when exogenous administration or endogenous adrenal production elevates plasma epinephrine levels.

**Respiratory System.** Spontaneous respiration is rapid and shallow during halothane anesthesia. The decreased alveolar ventilation results in an elevation in arterial CO2 tension from 40 mm Hg to >50 mm Hg at 1 MAC (Figure 19–7). The elevated CO2 does not provoke a compensatory increase in ventilation, because halothane causes a concentration-dependent inhibition of the ventilatory response to CO2. This action of halothane is thought to be mediated by depression of central chemoreceptor mechanisms. Halothane also inhibits peripheral chemoreceptor responses to arterial hypoxemia. Thus, neither hemodynamic (tachycardia and hypertension) nor ventilatory responses to hypoxemia are observed during halothane anesthesia, making it prudent to monitor arterial O2 directly. Halothane also is an effective bronchodilator (Yamakage, 1992) and has been effectively used as a treatment of last resort in patients with status asthmaticus (Gold and Helrich, 1970).

**Nervous System.** Halothane dilates the cerebral vasculature, increasing cerebral blood flow and cerebral blood volume. This can result in an increase in intracranial pressure, especially in patients with space-occupying intracranial masses, brain edema, or preexisting intracranial hypertension. Halothane attenuates autoregulation of cerebral blood flow in a dose-dependent manner. Hence, cerebral blood flow can increase even with a modest reduction in arterial pressure. With a reduction of arterial pressure that is below the lower limit of autoregulation, cerebral blood flow can decrease significantly. Halothane suppresses cerebral metabolism and cerebral metabolic rate is decreased.

**Muscle.** Halothane causes some relaxation of skeletal muscle by its central depressant effects. Halothane also potentiates the actions of non-depolarizing muscle relaxants (curariform drugs; Chapter 11), increasing both their duration of action and the magnitude of their effect. Halothane and the other halogenated inhalational anesthetics can trigger malignant hyperthermia, a syndrome characterized by
Severe muscle contraction, rapid development of hyperthermia, and a massive increase in metabolic rate in genetically susceptible patients. This syndrome frequently is fatal and is treated by immediate discontinuation of the anesthetic and administration of dantrolene.

Uterine smooth muscle is relaxed by halothane. This is a useful property for manipulation of the fetus (version) in the prenatal period and for delivery of retained placenta postnatally. However, halothane inhibits uterine contractions during parturition, prolonging labor and increasing blood loss, and therefore is not used as an analgesic or anesthetic for labor and vaginal delivery.

Kidney. Patients anesthetized with halothane usually produce a small volume of concentrated urine. This is the consequence of halothane-induced reduction of renal blood flow and glomerular filtration rate, which may be reduced by 40-50% at 1 MAC. Halothane-induced changes in renal function are fully reversible and are not associated with long-term nephrotoxicity.

Liver and GI Tract. Halothane reduces splanchnic and hepatic blood flow as a consequence of reduced perfusion pressure, as discussed above. This reduced blood flow has not been shown to produce detrimental effects on hepatic or GI function.

Halothane can produce fulminant hepatic necrosis in a small number of patients. This syndrome generally is characterized by fever, anorexia, nausea, and vomiting, developing several days after anesthesia and can be accompanied by a rash and peripheral eosinophilia. There is a rapid progression to hepatic failure, with a fatality rate of ~50%. This syndrome occurs in ~1 in 10,000 patients receiving halothane and is referred to as halothane hepatitis (Study, 1966). Current thinking is that halothane hepatitis is the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of halothane metabolism (see the “Pharmacokinetics” section for halothane earlier in the chapter).

Isoflurane

Isoflurane (FORANE, others) is 1-chloro-2,2,2-trifluoroethyl difluoromethyl ether (Figure 19–4). It is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or oxygen.

Pharmacokinetics. Isoflurane has a blood:gas partition coefficient substantially lower than that of halothane or enflurane (Table 19–1). Consequently, induction with isoflurane and recovery from isoflurane are faster than with halothane. Changes in anesthetic depth also can be achieved more rapidly with isoflurane than with halothane or enflurane.

More than 99% of inhaled isoflurane is excreted unchanged by the lungs. Approximately 0.2% of absorbed isoflurane is metabolized by CYP2E1. This small amount of isoflurane degradation products produced is insufficient to produce any renal, hepatic, or other organ toxicity. Isoflurane does not appear to be a mutagen, teratogen, or carcinogen.

Clinical Use. Isoflurane is a commonly used inhalational anesthetic worldwide.

It is typically used for maintenance of anesthesia after induction with other agents because of its pungent odor, but induction of anesthesia can be achieved in < 10 minutes with an inhaled concentration of 3% isoflurane in O₂; this concentration is reduced to 1-2% (~1-2 MAC) for maintenance of anesthesia. The use of other drugs such as opioids or nitrous oxide reduces the concentration of isoflurane required for surgical anesthesia.

Side Effects

Cardiovascular System. Isoflurane produces a concentration-dependent decrease in arterial blood pressure. Unlike halothane, cardiac output is well maintained with isoflurane, and hypotension is the result of decreased systemic vascular resistance (Figure 19–6). Isoflurane produces vasodilation in most vascular beds, with particularly pronounced effects in skin and muscle. Isoflurane is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O₂ consumption. In theory, this makes isoflurane a particularly safe anesthetic to use for patients with ischemic heart disease. Concern that isoflurane might produce myocardial ischemia by inducing “coronary steal” has not been substantiated in animal and human studies. Isoflurane significantly attenuates baroreceptor function. Patients anesthetized with isoflurane generally have mildly elevated heart rates as a compensatory...
response to reduced blood pressure; however, rapid changes in isoflurane concentration can produce both transient tachycardia and hypertension due to isoflurane-induced sympathetic stimulation.

**Respiratory System.** Isoflurane produces concentration-dependent depression of ventilation. Patients spontaneously breathing isoflurane have a normal respiration rate but a reduced tidal volume, resulting in a marked reduction in alveolar ventilation and an increase in arterial CO₂ tension (Figure 19–7). Isoflurane is particularly effective at depressing the ventilatory response to hypercapnia and hypoxia (Hirshman et al., 1977). While isoflurane is an effective bronchodilator, it also is an airway irritant and can stimulate airway reflexes during induction of anesthesia, producing coughing and laryngospasm.

**Nervous System.** Isoflurane dilates the cerebral vasculature, producing increased cerebral blood flow; this vasodilating activity is less than that of either halothane or enflurane (Drummond et al., 1983). There is a modest risk of an increase in intracranial pressure in patients with preexisting intracranial hypertension. Isoflurane reduces cerebral metabolic O₂ consumption in a dose dependent manner. At 1.5-2.0 MAC, isoflurane produces burst suppression of the EEG and reduces cerebral metabolic rate by ~50%. The modest effects of isoflurane on cerebral blood flow can be reversed readily by hyperventilation (McPherson et al., 1989).

**Muscle.** Isoflurane produces some relaxation of skeletal muscle by its central effects. It also enhances the effects of both depolarizing and non-depolarizing muscle relaxants. Isoflurane is more potent than halothane in its potentiation of neuromuscular blocking agents. Like other halogenated inhalational anesthetics, isoflurane relaxes uterine smooth muscle and is not recommended for analgesia or anesthesia for labor and vaginal delivery.

**Kidney.** Isoflurane reduces renal blood flow and glomerular filtration rate, resulting in a small volume of concentrated urine. Changes in renal function observed during isoflurane anesthesia are rapidly reversed, with no long-term renal sequelae or toxicities.

**Liver and Gastrointestinal Tract.** Splanchnic and hepatic blood flows are reduced with increasing doses of isoflurane as systemic arterial pressure decreases. Liver function tests are minimally affected by isoflurane, with no reported incidence of hepatic toxicity.

**Enflurane**

Enflurane (ETHRANE, others) is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether (Figure 19–4).

> It is a clear, colorless liquid at room temperature with a mild, sweet odor. Like other inhalational anesthetics, it is volatile and must be stored in a sealed bottle. It is nonflammable and non-explosive in mixtures of air or oxygen.

**Pharmacokinetics.** Because of its relatively high blood-gas partition coefficient, induction of anesthesia and recovery from enflurane are relatively slow (Table 19–1).

Enflurane is metabolized to a modest extent, with 2-8% of absorbed enflurane undergoing oxidative metabolism in the liver by CYP2E1. Fluoride ions are a by-product of enflurane metabolism, but plasma fluoride levels are low and nontoxic. Patients taking isoniazid exhibit enhanced metabolism of enflurane with significantly elevated serum fluoride concentrations (Mazze et al., 1982).

**Clinical Use.** As with isoflurane, enflurane is primarily utilized for maintenance rather than induction of anesthesia.

Surgical anesthesia can be induced with enflurane in < 10 minutes with an inhaled concentration of 4% in oxygen. Anesthesia can be maintained with concentrations from 1.5-3%. As with other anesthetics, the enflurane concentrations required to produce anesthesia are reduced when it is co-administered with nitrous oxide or opioids. With the advent of new inhalational agents, enflurane is rarely used for clinical anesthesia in developed countries.

**Side Effects**

**Cardiovascular System.** Enflurane causes a concentration-dependent decrease in arterial blood pressure. Hypotension is due in part to depression of myocardial contractility, with some contribution from peripheral vasodilation (Figure 19–6). Enflurane has minimal effects on heart rate and produces neither the bradycardia seen with halothane nor the tachycardia seen with isoflurane.

**Respiratory System.** The respiratory effects of enflurane are similar to those of halothane. Spontaneous ventilation with enflurane produces a pattern of rapid, shallow breathing. Minute ventilation is markedly decreased, and a Pa CO₂ of 60 mm Hg can be seen with 1 MAC of enflurane (Figure 19–7). Enflurane produces a greater depression of the ventilatory responses to hypoxia and hypercarbia than do either halothane or isoflurane (Hirshman et al., 1977). Enflurane, like other inhalational anesthetics, is an effective bronchodilator.

**Nervous System.** Enflurane is a cerebral vasodilator and thus can increase intracranial pressure in some patients. Like other inhalational anesthetics, enflurane reduces cerebral metabolic O₂ consumption. Enflurane has an unusual property of producing electrical seizure activity. High concentrations of enflurane or profound hypocarbia during enflurane anesthesia result in a characteristic high-voltage, high-frequency electroencephalographic (EEG) pattern that progresses to spike-and-dome complexes. The spike-and-dome pattern can be punctuated by frank seizure activity that may or may not be accompanied by peripheral motor manifestations of seizure activity. The seizures are self-limited and are not thought to produce permanent damage. Epileptic patients are not particularly susceptible to enflurane-induced seizures. Nonetheless, enflurane generally is not used in patients with seizure disorders.

**Muscle.** Enflurane produces significant skeletal muscle relaxation in the absence of muscle relaxants. It also significantly enhances the effects of non-depolarizing muscle relaxants. As with other inhalational agents, enflurane relaxes uterine smooth muscle. It is not widely used for obstetric anesthesia.

**Kidney.** Like other inhalational anesthetics, enflurane reduces renal blood flow, glomerular filtration rate, and urinary output. These effects are rapidly reversed upon drug discontinuation. Enflurane metabolism produces significant plasma levels of fluoride ions (20-40 μmol) and can produce transient urinary-concentrating defects following prolonged administration (Mazze et al., 1977). There is scant evidence of...
long-term nephrotoxicity following enflurane use, and it is safe to use in patients with renal impairment, provided that the depth of enflurane anesthesia and the duration of administration are not excessive.

**Liver and GI Tract.** Enflurane reduces splanchnic and hepatic blood flow in proportion to reduced arterial blood pressure. Enflurane does not appear to alter liver function or to be hepatotoxic.

---

**Desflurane**

Desflurane (SUPRANE) is difluoromethyl 1-fluoro-2,2,2-trifluoromethyl ether (Figure 19–4). It is a highly volatile liquid at room temperature (vapor pressure = 681 mm Hg) and thus must be stored in tightly sealed bottles.

Delivery of a precise concentration of desflurane requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with other gases (O₂, air, or N₂O). Desflurane is nonflammable and non-explosive in mixtures of air or oxygen.

**Pharmacokinetics.** Desflurane has a very low blood:gas partition coefficient (0.42) and also is not very soluble in fat or other peripheral tissues (Table 19–1). For this reason, the alveolar (and blood) concentration rapidly rises to the level of inspired concentration.

Indeed, within 5 minutes of administration, the alveolar concentration reaches 80% of the inspired concentration. This provides for a very rapid induction of anesthesia and for rapid changes in depth of anesthesia following changes in the inspired concentration. Emergence from anesthesia also is very rapid with desflurane. The time to awakening following desflurane is shorter than with halothane or sevoflurane and usually does not exceed 5-10 minutes in the absence of other sedative agents (La Colla et al., 2007).

Desflurane is metabolized to a minimal extent, and > 99% of absorbed desflurane is eliminated unchanged through the lungs. A small amount of absorbed desflurane is oxidatively metabolized by hepatic CYPs. Virtually no fluoride ions are detectable in serum after desflurane administration, but low concentrations of trifluoroacetic acid are found in serum and urine (Koblin et al., 1988).

**Clinical Use.** Desflurane is a widely used anesthetic for outpatient surgery because of its rapid onset of action and rapid recovery. The drug irritates the tracheobronchial tree and can provoke coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an intravenous agent, with desflurane subsequently administered for maintenance of anesthesia. Maintenance of anesthesia usually requires inhaled concentrations of 6-8% (~1 MAC). Lower concentrations of desflurane are required if it is co-administered with nitrous oxide or opioids.

**Side Effects**

**Cardiovascular System.** Desflurane, like all inhalational anesthetics, causes a concentration-dependent decrease in blood pressure. Desflurane has a very modest negative inotropic effect and produces hypotension primarily by decreasing systemic vascular resistance (Eger, 1994) (Figure 19–6). Thus, cardiac output is well preserved during desflurane anesthesia, as is blood flow to the major organ beds (splanchnic, renal, cerebral, and coronary). Marked increases in heart rate often are noted during induction of desflurane anesthesia and during abrupt increases in the delivered concentration of desflurane. This transient tachycardia results from desflurane-induced stimulation of the sympathetic nervous system (Ebert and Muzi, 1993). Unlike some inhalational anesthetics, the hypotensive effects of desflurane do not wane with increasing duration of administration.

**Respiratory System.** Similarly to halothane and enflurane, desflurane causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At low concentrations (< 1 MAC) the net effect is to preserve minute ventilation. At desflurane concentrations > 1 MAC, minute ventilation is markedly depressed, resulting in elevated arterial CO₂ tension (Paco₂) (Figure 19–7). Patients spontaneously breathing desflurane at concentrations > 1.5 MAC will have extreme elevations of Paco₂ and may become apneic. Desflurane, like other inhalational agents, is a bronchodilator. However, it also is a strong airway irritant, and can cause coughing, breath-holding, laryngospasm, and excessive respiratory secretions. Because of its irritant properties, desflurane is not used for induction of anesthesia.

**Nervous System.** Desflurane decreases cerebral vascular resistance and cerebral metabolic O₂ consumption. Burst suppression of the EEG is achieved with ~ 2 MAC desflurane; at this level, CMRO₂ is reduced by ~ 50%. Under conditions of normocapnia and normotension, desflurane produces an increase in cerebral blood flow and can increase intracranial pressure in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during desflurane anesthesia, and increases in intracranial pressure thus can be prevented by hyperventilation.

**Muscle.** Desflurane produces direct skeletal muscle relaxation as well as enhancing the effects of non-depolarizing and depolarizing neuromuscular blocking agents (Caldwell et al., 1991).

**Kidney.** Consistent with its minimal metabolic degradation, desflurane has no reported nephrotoxicity.

**Liver and GI Tract.** Desflurane is not known to affect liver function tests or to cause hepatotoxicity.

**Desflurane and Carbon Monoxide.** Inhaled anesthetics are administered via a circle system circuit that permits unidirectional flow of gas. This system permits rebreathing of exhaled gases that contain CO₂. To prevent rebreathing of CO₂ (which can lead to hypercarbia), CO₂ absorbers are incorporated into the anesthesia delivery circuits. These CO₂ absorbers contain either Ca(OH)₂ or Ba(OH)₂, and smaller quantities of more potent alcalis, NaOH and KOH. Interaction of inhaled anesthetics with these strong alcalis results in the formation of CO. The amount of CO produced is insignificant as long as the CO₂ absorbent is sufficiently hydrated. With almost complete desiccation of the CO₂ absorbents, substantial quantities of CO can be produced. This effect is greatest with desflurane and can be prevented by the use of well-hydrated, fresh CO₂ absorbent.

---

**Sevoflurane**

Sevoflurane (ULTANE, others) is fluoromethyl 2,2,2-trifluoro-1-[trifluoromethyl]ethoxy (Figure 19–4).

It is a clear, colorless, volatile liquid at room temperature and must be stored in a sealed bottle. It is
nonflammable and non-explosive in mixtures of air or oxygen. However, sevoflurane can undergo an exothermic reaction with desiccated CO₂ absorbent (BARALyme) to produce airway burns (Fatheree and Leighton, 2004) or spontaneous ignition, explosion, and fire (Wu et al., 2004a). Care must be taken to ensure that sevoflurane is not used with an anesthesia machine in which the CO₂ absorbent has been dried by prolonged gas flow through the absorbent. The reaction of sevoflurane with desiccated CO₂ absorbent also can produce CO, which can result in serious patient injury; this effect is less than that with desflurane.

**Pharmacokinetics.** The low solubility of sevoflurane in blood and other tissues provides for rapid induction of anesthesia, rapid changes in anesthetic depth following changes in delivered concentration, and rapid emergence following discontinuation of administration (Table 19–1).

Approximately 3% of absorbed sevoflurane is biotransformed. Sevoflurane is metabolized in the liver by CYP2E1, with the predominant product being hexafluoroisopropanol (Kharasch et al., 1995). Hepatic metabolism of sevoflurane also produces inorganic fluoride. Serum fluoride concentrations peak shortly after surgery and decline rapidly. Interaction of sevoflurane with soda lime also produces decomposition products. The major product of interest is referred to as compound A, pentafluoroisopropenyfluoromethyl ether (see “Kidney” under “Side Effects”) (Hanaki et al., 1987).

**Clinical Use.** Sevoflurane is widely used, particularly for outpatient anesthesia, because of its rapid recovery profile. It is well-suited for inhalation induction of anesthesia (particularly in children) because it is not irritating to the airway. Induction of anesthesia is rapidly achieved using inhaled concentrations of 2-4% sevoflurane.

**Side Effects**

**Cardiovascular System.** Sevoflurane, like all other halogenated inhalational anesthetics, produces a concentration-dependent decrease in arterial blood pressure. This hypotensive effect primarily is due to systemic vasodilation, although sevoflurane also produces a concentration-dependent decrease in cardiac output (Figure 19–6). Unlike isoflurane or desflurane, sevoflurane does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

**Respiratory System.** Sevoflurane produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in Pa₄CO₂ (Doi and Ikeda, 1987) (Figure 19–7). Sevoflurane is not irritating to the airway and is a potent bronchodilator. Because of this combination of properties, sevoflurane is the most effective clinical bronchodilator of the inhalational anesthetics (Rooke et al., 1997).

**Nervous System.** Sevoflurane produces effects on cerebral vascular resistance, cerebral metabolic O₂ consumption, and cerebral blood flow that are very similar to those produced by isoflurane and desflurane. Its cerebral vasodilating capacity is less than that of isoflurane, and particularly desflurane. At ~2 MAC anesthesia, sevoflurane produces burst suppression of the EEG, and at this level, CMRO₂ is reduced by ~50%. While sevoflurane can increase intracranial pressure in patients with poor intracranial compliance, the response to hypocapnia is preserved during sevoflurane anesthesia, and increases in intracranial pressure can be prevented by hyperventilation. In children, sevoflurane is associated with delirium upon emergence from anesthesia. This delirium, the causes of which are not clear, is short lived and without any reported adverse long-term sequelae.

**Muscle.** Sevoflurane produces skeletal muscle relaxation and enhances the effects of non-depolarizing and depolarizing neuromuscular blocking agents. Its effects are similar to those of other halogenated inhalational anesthetics.

**Kidney.** Controversy has surrounded the potential nephrotoxicity of compound A, the degradation product produced by interaction of sevoflurane with the CO₂ absorbent soda lime. Biochemical evidence of transient renal injury has been reported in human volunteers (Eger et al., 1997). Large clinical studies have shown no evidence of increased serum creatinine, blood urea nitrogen, or any other evidence of renal impairment following sevoflurane administration (Mazze et al., 2000). The FDA recommends that sevoflurane be administered with fresh gas flows of at least 2 L/min to minimize accumulation of compound A.

**Liver and GI Tract.** Sevoflurane is not known to cause hepatotoxicity or alterations of hepatic function tests.

**Nitrous Oxide**

Nitrous oxide (dinitrogen monoxide; N₂O) is a colorless, odorless gas at room temperature (Figure 19–4).

N₂O is sold in steel cylinders and must be delivered through calibrated flow meters provided on all anesthesia machines. Nitrous oxide is neither flammable nor explosive, but it does support combustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

**Pharmacokinetics.** Nitrous oxide is very insoluble in blood and other tissues (Table 19–1). This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration.

The rapid uptake of N₂O from alveolar gas serves to concentrate co-administered halogenated anesthetics; this effect (the “second gas effect”) speeds induction of anesthesia. On discontinuation of N₂O administration, nitrous oxide gas can diffuse from blood to the alveoli, diluting O₂ in the lung. This can produce an effect called diffusional hypoxia. To avoid hypoxia, 100% O₂ rather than air should be administered when N₂O is discontinued.

Nitrous oxide is almost completely eliminated by the lungs, with some minimal diffusion through the skin. Nitrous oxide is not biotransformed by enzymatic action in human tissue, and 99.9% of absorbed nitrous oxide is eliminated unchanged. N₂O can oxidize...
the cobalt I (Co\(^{+}\)) form of vitamin B\(_{12}\) to Co\(^{3+}\) (Sanders et al., 2007), thereby preventing vitamin B\(_{12}\) from acting as a co-factor for methionine synthetase. The latter is important in the synthesis of a number of products including DNA, RNA, and myelin. Indeed, methionine synthetase activity is dramatically reduced after 3-4 hours of N\(_{2}\)O exposure; activity of the enzyme is restored in 3-4 days. Inactivation of methionine synthetase can produce signs of vitamin B\(_{12}\) deficiency, including megaloblastic anemia and peripheral neuropathy. This is of particular concern in patients with malnutrition, vitamin B\(_{12}\) deficiency, or alcoholism. For this reason, N\(_{2}\)O is not used as a chronic analgesic or as a sedative in critical care settings.

**Clinical Use.** N\(_{2}\)O is a weak anesthetic agent that has significant analgesic effects. Noncompetitive antagonist activity at the NMDA receptor contributes to its anesthetic mechanism. However, surgical anesthetic depth is only achieved under hyperbaric conditions. By contrast, analgesia is produced at concentrations as low as 20%.

The analgesic property of N\(_{2}\)O is a function of the activation of opioidergic neurons in the periaqueductal gray matter (Fang et al., 1997) and the adrenergic neurons in the locus ceruleus (Sawamura et al., 2000). At least part of the activation of the locus ceruleus is due to release of corticotropin-releasing factor from the hypothalamus as a result of antagonism of the NMDA receptor.

In doses approaching 70-80%, significant sedation is produced. Therefore, N\(_{2}\)O is frequently used in concentrations of ~50% to provide analgesia and mild sedation in outpatient dentistry. Nitrous oxide cannot be used at concentrations > 80% because this limits the delivery of adequate O\(_{2}\). Because of this limitation, nitrous oxide is used primarily as an adjunct to other inhalational or intravenous anesthetics. Nitrous oxide substantially reduces the requirement for inhalational anesthetics. For example, at 70% nitrous oxide, the MAC for other inhalational agents is reduced by ~60%, allowing for lower concentrations of halogenated anesthetics and a lesser degree of side effects.

One major problem with N\(_{2}\)O is that it will exchange with N\(_{2}\) in any air-containing cavity in the body. Moreover, because of their differential blood:gas partition coefficients, nitrous oxide will enter the cavity faster than nitrogen escapes, thereby increasing the volume and/or pressure in this cavity. Examples of air collections that can be expanded by nitrous oxide include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intraocular air bubble, a pulmonary bulla, and intracranial air. Nitrous oxide should be avoided in these clinical settings.

**Side Effects**

**Cardiovascular System.** Although N\(_{2}\)O produces a negative inotropic effect on heart muscle in vitro, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of nitrous oxide on the sympathetic nervous system. The cardiovascular effects of nitrous oxide also are heavily influenced by the concomitant administration of other anesthetic agents. When nitrous oxide is co-administered with halogenated inhalational anesthetics, it generally produces an increase in heart rate, arterial blood pressure, and cardiac output. In contrast, when nitrous oxide is co-administered with an opioid, it generally decreases arterial blood pressure and cardiac output. Nitrous oxide also increases venous tone in both the peripheral and pulmonary vasculature. The effects of N\(_{2}\)O on pulmonary vascular resistance can be exaggerated in patients with pre-existing pulmonary hypertension; thus, the drug generally is not used in these patients.

**Respiratory System.** N\(_{2}\)O causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. The net effect is that minute ventilation is not significantly changed and PaCO\(_{2}\) remains normal. However, even modest concentrations of nitrous oxide markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O\(_{2}\) saturation directly in patients receiving or recovering from nitrous oxide.

**Nervous System.** When administered alone, nitrous oxide can significantly increase cerebral blood flow and intracranial pressure. This cerebral vasodilatory capacity of N\(_{2}\)O is significantly attenuated by the simultaneous administration of intravenous agents such as opiates and propofol. By contrast, the combination of N\(_{2}\)O and inhaled agents results in greater vasodilation than the administration of the inhaled agent alone at equivalent anesthetic depth.

**Muscle.** Nitrous oxide does not relax skeletal muscle and does not enhance the effects of neuromuscular blocking drugs. Unlike the halogenated anesthetics, nitrous oxide does not trigger malignant hyperthermia.

**Kidney, Liver, and GI Tract.** Nitrous oxide is not known to produce any changes in renal or hepatic function and is neither nephrotoxic nor hepatotoxic.

**Xenon**

Xenon is an inert gas that first was identified as an anesthetic agent in 1951. It is not approved for use in the U.S. and is unlikely to enjoy widespread use because it is a rare gas that cannot be manufactured and must be extracted from air. This limits the quantities of available xenon gas and renders xenon very expensive. Recent advances in the manufacturing technology, coupled with development of low-flow circuit systems that permit recycling of xenon, have led to a resurgence in the interest in xenon as an anesthetic agent. Much of this enthusiasm is based on the observation that xenon, unlike other anesthetic agents, has minimal cardiorespiratory side effects (Lynch et al., 2000).

Xenon exerts its analgesic and anesthetic effects at a number of receptor systems in the CNS. Of these, non-competitive antagonism of the NMDA receptor and agonism at the TREK channel (a member of the two-pore K+ channel family) are thought to be the central mechanisms of xenon action (Franks and Honore, 2004).

Xenon is extremely insoluble in blood and other tissues, providing for rapid induction and emergence from anesthesia (Table 19–1). It is sufficiently potent to produce surgical anesthesia when administered with 30% oxygen. However, supplementation with an intravenous agent such as propofol appears to be required for clinical
anesthesia (Rasmussen et al., 2006). Xenon is well tolerated in patients of advanced age. No long-term side effects from xenon anesthesia have been reported.

Effects on Organ Systems

**Cardiovascular System.** Xenon has minimal effects on cardiovascular function. Arterial pressure, unlike the situation with other anesthetic agents, is well maintained. Left ventricular contractility is not affected and heart rate and systemic vascular resistance are essentially unchanged. Autonomic function is better maintained under xenon anesthesia than under anesthesia with propofol and inhaled anesthetics (Hanss et al., 2006). Even in patients with significant cardiac disease, xenon maintains a favorable profile (Lockwood et al., 2006).

**Respiratory System.** Under xenon anesthesia, respiratory rate is reduced slightly. However, an increase in tidal volume maintains minute ventilation, indicating that there is minimal respiratory depression. An increase in airway pressure does occur; this has been attributed to the greater density and viscosity of xenon (compared to oxygen) and not due to changes in bronchomotor tone (Baumert et al., 2002).

**Central Nervous System.** Like other anesthetic agents, xenon reduces cerebral metabolism by 25-30%. This reduction in metabolism is accompanied by a corresponding reduction in cerebral blood flow. Consequently, xenon is not expected to increase intracranial pressure.

**Liver, Kidney, and GI Tract.** Xenon is an inert agent and does not undergo metabolism. Hepatic or renal toxicity with its use have not been reported.

### ANESTHETIC ADJUNCTS

A general anesthetic is rarely given as the sole agent. Anesthetic adjuncts usually are used to augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects. Because they are such an integral part of general anesthetic drug regimens, their use as anesthetic adjuncts is described briefly here. The detailed pharmacology of each drug is covered in other chapters.

### Benzodiazepines

While benzodiazepines (Chapter 17) can produce anesthesia similar to that of barbiturates, they are more commonly used for sedation rather than general anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is midazolam followed distantly by diazepam (VALIUM, others), and lorazepam (ATIVAN, others).

Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral midazolam is particularly useful for sedation of young children. Midazolam produces minimal venous irritation as opposed to diazepam and lorazepam, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis. Midazolam has the pharmacokinetic advantage, particularly over lorazepam, of being more rapid in onset and shorter in duration of effect. Sedative doses of midazolam (0.01-0.05 mg/kg intravenously) reach peak effect in ~2 minutes and provide sedation for ~30 minutes. Elderly patients tend to be more sensitive to and have a slower recovery from benzodiazepines (Jacobs et al., 1995); thus, titration to the desired effect of smaller doses in this age group is prudent. Midazolam is hepatically metabolized with a clearance (6-11 mL/min per kg), similar to that of methohexital and ~20 and 7 times higher than those of diazepam and lorazepam, respectively. Either for prolonged sedation or for general anesthetic maintenance, midazolam is more suitable for infusion than are other benzodiazepines, although its duration of action does significantly increase with prolonged infusions (Figure 19–3). Benzodiazepines reduce both cerebral blood flow and metabolism but at equi-anesthetic doses are less potent in this respect than are barbiturates. They are effective anticonvulsants and sometimes are given to treat status epilepticus. Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea. Thus, blood pressure and respiratory rate should be monitored in patients sedated with intravenous benzodiazepines.

**α₂ Adrenergic Agonists.** Dexmedetomidine (PRECEDEX) is an imidazole derivative that is a highly selective α₂ adrenergic receptor agonist (Kamibayashi and Maze, 2000). Dexmedetomidine is FDA-approved for short-term (< 24 hours) sedation of critically ill adults and sedation prior to and/or during surgical or other medical procedures in non-intubated patients. Activation of the α₁₉ adrenergic receptor by dexmedetomidine produces both sedation and analgesia, but does not reliably provide general anesthesia, even at maximal doses (Lakhiani et al., 1997).

Dexmedetomidine is a sedative-hypnotic that provides analgesia with little respiratory depression and, in most patients, a tolerable decrease in blood pressure and heart rate. The drug is likely to be increasingly used for sedation and as an anesthetic adjunct.

The most common side effects of dexmedetomidine include hypotension and bradycardia, both of which are attributed to decreased catecholamine release by activation peripherally and in the CNS of the α₁₉ receptor (Lakhiani et al., 1997). Nausea and dry mouth also are common untoward reactions. At higher drug concentrations, the α₂B subtype is activated, resulting in hypertension and a further decrease in heart rate and cardiac output. Dexmedetomidine has the very useful property of producing sedation and analgesia with minimal respiratory depression (Belleville et al., 1992); thus, it is particularly valuable in sedation of patients who are not endotracheally
intubated and mechanically ventilated. The sedation produced by dexmedetomidine has been noted to be more akin to natural sleep, with patients relatively easy to arouse (Hall et al., 2000). However, dexmedetomidine does not appear to provide reliable amnesia and additional agents may need to be employed if lack of recall is desirable.

Dexmedetomidine is supplied as an aqueous solution of the hydrochloride salt and should be diluted in normal saline to a final concentration of 4 μg/mL for intravenous delivery, the only approved route of administration. The recommended loading dose is 1 μg/kg given over 10 minutes, followed by infusion at a rate of 0.2-0.7 μg/kg per hour. Reduced doses should be considered in patients with risk factors for severe hypotension. The distribution and terminal half-lives are 6 minutes and 2 hours, respectively. Dexmedetomidine is highly protein bound and is primarily hepatically metabolized; the glucuronide and methyl conjugates are excreted in the urine.

Analgesics

With the exception of ketamine, neither parenteral nor currently available inhalational anesthetics are effective analgesics. Thus, analgesics typically are administered with general anesthetics to reduce anesthetic requirement and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal anti-inflammatory drugs, COX-2 inhibitors, and acetaminophen (Chapter 34) sometimes provide adequate analgesia for minor surgical procedures. However, opioids are the primary analgesics used during the perioperative period because of the rapid and profound analgesia they produce.

Fentanyl (SUBLIMAZE, others), sufentanil (SUFEENTA, others), alfentanil (ALFENTA, others), remifentanil (ULTIVA), meperidine (DEMEROL, others), and morphine are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ-opioid receptors. Their order of potency (relative to morphine) is: sufentanil (1000 ×), remifentanil (300 ×), fentanyl (100 ×), alfentanil (15 ×), morphine (1 ×), and meperidine (0.1 ×). These agents are discussed in more detail in Chapter 18.

The choice of a perioperative opioid is based primarily on duration of action, since, at appropriate doses, all produce similar analgesia and side effects. Remifentanil has an ultrashort duration of action (~10 minutes) and accumulates minimally with repeated doses or infusion; it is particularly well suited for procedures that are briefly painful, but for which little analgesia is required postoperatively. Single doses of fentanyl, alfentanil, and sufentanil all have similar intermediate durations of action (30, 20, and 15 minutes, respectively), but recovery after prolonged administration varies considerably. Fentanyl’s duration of action lengthens the most with infusion, sufentanil’s much less so, and alfentanil’s the least. Except for remifentanil, all of the above-mentioned opioids are metabolized in the liver, followed by renal and biliary excretion of the metabolites. Remifentanil is hydrolyzed by tissue and plasma esterases. Given its rapid elimination, termination of the effects of remifentanil can result in significant pain in the surgical patient. Consequently, longer-acting opiates are often given prior to discontinuation of remifentanil.

During the perioperative period, opioids often are given at induction to preempt responses to predictable painful stimuli (e.g., endotracheal intubation and surgical incision). Subsequent doses either by bolus or infusion are titrated to the surgical stimulus and the patient’s hemodynamic response. Marked decreases in respiratory rate and heart rate with much smaller reductions in blood pressure are seen to varying degrees with all opioids. Muscle rigidity that can impair ventilation sometimes accompanies larger doses of opioids. The incidence of spincter of Oddi spasm is increased with all opioids, although morphine appears to be more potent in this regard (Hahn et al., 1988). The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree. A useful side effect of meperidine is its capacity to reduce shivering, a common problem during emergence from anesthesia (Pauca et al., 1984); other opioids are not as efficacious against shivering, perhaps due to less κ receptor agonism. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain (Chapter 18). Neuraxial opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

Neuromuscular Blocking Agents

The practical aspects of the use of neuromuscular blockers as anesthetic adjuncts are briefly described here. The detailed pharmacology of this drug class is presented in Chapter 11.

Depolarizing (e.g., succinylcholine) and non-depolarizing muscle relaxants (e.g., vecuronium) often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the intravenous line prior to injection of a muscle relaxant. Following induction, continued muscle relaxation is desirable for many procedures to aid surgical exposure and to provide additional insurance of immobility. Of course, muscle relaxants are not by themselves anesthetics and should not be used in lieu of adequate anesthetic depth. The action of non-depolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor such as neostigmine or edrophonium (Chapter 10) combined with a muscarinic receptor antagonist (e.g., glycopyrrolate or atropine; Chapter 9) to offset the muscarinic activation resulting from esterase inhibition. Other than histamine release by some agents, non-depolarizing muscle relaxants used in this manner have
few side effects. However, succinylcholine has multiple serious side effects (bradycardia, hyperkalemia, and severe myalgia) including induction of malignant hyperthermia in susceptible individuals.

ANESTHETIC CYTOPROTECTION AND TOXICITY

The conventional view of general anesthesia is that anesthetics produce a reversible loss of consciousness and that CNS function returns to basal levels upon termination of anesthesia and recovery of consciousness. Recent data, however, have cast doubt upon this notion. Exposure of rodents to anesthetic agents during the period of synaptogenesis (within the first 10 days post birth) results in widespread neurodegeneration in the developing brain (Jevtovic-Todorovic et al., 2003). This neuronal injury, which is apoptotic in nature, results in disturbed electrophysiologic function and cognitive dysfunction in adolescent and adult rodents that were exposed to anesthetics during the neonatal period. A variety of agents, including isoflurane, propofol, midazolam, nitrous oxide, and thiopental, manifest this toxicity (Patel and Sun, 2009).

Although the etiology is not clear, GABA_A agonism and NMDA receptor antagonism play a role. In particular, the combination of a GABA_A agonist and NMDA receptor antagonist produce the greatest toxicity. Until the occurrence of this neurotoxicity during brain development has been established in pre-clinical studies, its relevance to the use of anesthetics in humans will not be clear. To date, there are no data to suggest that the provision of anesthesia to neonates and infants undergoing surgery produces any neurotoxicity. Ongoing clinical trials in humans should clarify this within the next few years.

By contrast, anesthetics reduce ischemic injury to a variety of tissues, including the brain and heart. This protective effect is robust and results in better functional outcomes in comparison to ischemic injury that occurs in unanesthetized awake subjects. With respect to ischemic injury of the brain, anesthetics (inhalational agents, propofol, barbiturates, ketamine, lidocaine, midazolam) suppress excitotoxic injury produced by excessive glutamate release, reduce inflammation, and promote pro-survival signaling (Head et al., 2007). In addition, exposure to anesthesia results in the activation of plasmalemmal and mitochondrial ATP-dependent K+ channels, activation of signal transduction pathways (NO synthase, MAP kinases), and protein synthesis that render the brain less vulnerable to subsequent ischemic injury. In a similar fashion, volatile anesthetics and, under some conditions, propofol and barbiturates, reduce myocardial ischemia-reperfusion injury (Frassdorf et al., 2009). The molecular mechanisms leading to cardiac protection by volatile anesthetics involve activation of “classical” preconditioning signaling pathways (e.g., GPCRs, endothelial NO synthase, survival protein kinases, PKC, reactive oxygen species, ATP-dependent K+ channels, and the mitochondrial permeability transition pore) (Hausenloy and Scorrano, 2007). Propofol and barbiturates may induce specific components of the “classical” pathways involved in cardiac protection; however, there is debate as to whether these agents are truly protective or injurious to the ischemic myocardium (Frassdorf et al., 2009).

OXYGEN

Oxygen (O_2) is essential to life. Hypoxia is a life-threatening condition in which oxygen delivery is inadequate to meet the metabolic demands of the tissues. Since oxygen delivery is the product of blood flow and oxygen content, hypoxia may result from alterations in tissue perfusion, decreased oxygen tension in the blood, or decreased oxygen-carrying capacity. In addition, hypoxia may result from restricted oxygen transport from the microvasculature to cells or impaired utilization within the cell. An inadequate supply of oxygen ultimately results in the cessation of aerobic metabolism and oxidative phosphorylation, depletion of high-energy compounds, cellular dysfunction, and death.

Normal Oxygenation

Oxygen makes up 21% of air, which at sea level represents a partial pressure of 21 kPa (158 mm Hg). While the fraction (percentage) of O_2 remains constant regardless of atmospheric pressure, the partial pressure of O_2 (P_O2) decreases with lower atmospheric pressure. Since the partial pressure drives the diffusion of O_2, ascent to elevated altitude reduces the uptake and delivery of oxygen to the tissues. Conversely, increases in atmospheric pressure (e.g., hyperbaric therapy or breathing at depth) raise the P_O2 in inspired air and increase gas uptake. As the air is delivered to the distal airways and alveoli, the P_O2 decreases by dilution with CO_2 and water vapor and by uptake into the blood.

Under ideal conditions, when ventilation and perfusion are well matched, the alveolar P_O2 will be ~14.6 kPa (110 mm Hg). The corresponding alveolar partial pressures of water and CO_2 are 6.2 kPa (47 mm Hg) and 5.3 kPa (40 mm Hg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and capillary blood, and the P_O2 in end-capillary blood is typically within a fraction of a kPa of that in the alveoli. In some diseases, the diffusion barrier...
for gas transport may be increased, or, during exercise, when high cardiac output reduces capillary transit time, full equilibration may not occur, and the alveolar–end-capillary PO2 gradient may be increased.

The PO2 in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a PO2 of ~5.3 kPa (40 mm Hg). Together, the diffusional barrier, ventilation–perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial oxygen gradient, which is normally 1.3-1.6 kPa (10-12 mm Hg) when air is breathed and 4.0-6.6 kPa (30-50 mm Hg) when 100% oxygen is breathed.

Oxygen is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of oxygen typically reduces the PO2 of venous blood by an additional 7.3 kPa (55 mm Hg). Although the PO2 at the site of cellular oxygen utilization—the mitochondria—is not known, oxidative phosphorylation can continue at a PO2 of only a few mm Hg.

In the blood, oxygen is carried primarily in chemical combination with hemoglobin and is to a small extent dissolved in solution. The quantity of oxygen combined with hemoglobin depends on the PO2, as illustrated by the sigmoidal oxyhemoglobin dissociation curve (Figure 19–8). Hemoglobin is ~98% saturated with oxygen when air is breathed under normal circumstances, and it binds 1.3 mL of oxygen per gram when fully saturated. The steep slope of this curve with falling PO2 facilitates unloading of oxygen from hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing PCO2, and decreasing pH, as is found in metabolically active tissues, lowers the oxygen saturation for the same PO2 and thus delivers additional oxygen where and when it is most needed. However, the flattening of the curve with higher PO2 indicates that increasing blood PO2 by inspiring oxygen-enriched mixtures can increase the amount of oxygen carried by hemoglobin only minimally. Further increases in blood oxygen content can occur only by increasing the amount of oxygen dissolved in plasma. Because of the low solubility of oxygen (0.226 mL/L per kPa or 0.03 mL/L per mm Hg at 37°C), breathing 100% oxygen can increase the amount of oxygen dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired PO2 is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved oxygen is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 19–4).

**Oxygen Deprivation**

An understanding of the causes and effects of oxygen deficiency is necessary for the rational therapeutic use of the gas. *Hypoxia* is the term used to denote insufficient oxygenation of the tissues. *Hypoxemia* generally implies a failure of the respiratory system to oxygenate arterial blood.

**Pulmonary Mechanisms of Hypoxemia.** Classically, there are five causes of hypoxemia: low inspired oxygen fraction (FIO2), increased diffusion barrier, hypoventilation, ventilation–perfusion mismatch, and shunt or venous admixture.

Low FIO2 is a cause of hypoxemia only at high altitude or in the event of equipment failure, such as a gas blender malfunction or a mislabeled compressed-gas tank. An increase in the barrier to diffusion of oxygen within the lung is rarely a cause of hypoxemia in a resting subject, except in end-stage parenchymal lung disease. Both these problems may be alleviated with administration of supplemental oxygen, the former by definition and the latter by increasing the gradient driving diffusion.

Hypoventilation causes hypoxemia by reducing the alveolar PO2 in proportion to the buildup of CO2 in the alveoli. During hypoventilation, there is decreased delivery of oxygen to the alveoli, whereas its removal by the blood remains the same, causing its alveolar concentration to fall. The opposite occurs with carbon dioxide. This is described by the alveolar gas equation:

$$PAO_2 = PI_{O2} - (PACO_2/R)$$

where PAO2 and PACO2 are the alveolar partial pressures of oxygen and carbon dioxide, PI_{O2} is the partial pressure of oxygen in the inspired gas, and R the respiratory quotient.

Under normal conditions, breathing room air at sea level (corrected for the partial pressure of water vapor), the PI_{O2} is ~20 kPa (150 mm Hg), the PACO2 ~5.3 kPa (40 mm Hg), R is 0.8, and thus the PAO2 is normally around 13.3 kPa (100 mm Hg). It would require

*This table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial O₂ tension increases, the amount of dissolved O₂ increases in direct proportion to the PO₂, but the amount of oxygen bound to hemoglobin reaches a maximum of 196 mL O₂/liter (100% saturation of hemoglobin at 15 g/dL). Further increases in O₂ content require increases in dissolved oxygen. At 100% inspired O₂, dissolved O₂ still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the hemoglobin in the mixed venous blood remains fully saturated with O₂. The figures in this table are approximate and are based on the assumptions of 15 g/dL hemoglobin, 50 mL O₂/liter whole-body oxygen extraction, and constant cardiac output. When severe anemia is present, arterial PO₂ remains the same, but arterial content is lower; oxygen extraction continues, resulting in lower O₂ content and tension in mixed venous blood. Similarly, as cardiac output falls significantly, the same oxygen extraction occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.*
substantial hypoventilation, with the $P_{A\text{CO}_2}$ rising to over 9.8 kPa (72 mm Hg), to cause the $P_{A\text{O}_2}$ to fall below 7.8 kPa (60 mm Hg). This cause of hypoxemia is readily prevented by administration of even small amounts of supplemental $O_2$.

Shunt and V/Q mismatch are related causes of hypoxemia but with an important distinction in their responses to supplemental oxygen. Optimal gas exchange occurs when blood flow (Q) and ventilation (V) are matched quantitatively. However, regional variations in V/Q matching typically exist within the lung, particularly in the presence of lung disease. As ventilation increases relative to blood flow, the alveolar $P_{O_2}$ ($P_{A\text{O}_2}$) increases; because of the flat shape of the oxyhemoglobin dissociation curve at high $P_{O_2}$ (Figure 19–8), this increased $P_{A\text{O}_2}$ does not contribute much to the oxygen content of the blood. Conversely, as the V/Q ratio falls and perfusion increases relative to ventilation, the $P_{A\text{O}_2}$ of the blood leaving these regions falls relative to regions with better matched ventilation and perfusion. Since the oxyhemoglobin dissociation curve is steep at these lower $P_{O_2}$ values, the oxygen saturation and content of the pulmonary venous blood falls significantly. At the extreme of low V/Q ratios, there is no ventilation to a perfused region, and a pure shunt results; thus the blood leaving the region has the same low $P_{O_2}$ and high $P_{A\text{CO}_2}$ as mixed venous blood.

The deleterious effect of V/Q mismatch on arterial oxygenation is a direct result of the asymmetry of the oxyhemoglobin dissociation curve. Adding supplemental oxygen generally will make up for the fall in $P_{A\text{O}_2}$ in low V/Q units and thereby improve arterial oxygenation. However, since there is no ventilation to units with pure shunt, supplemental oxygen will not be effective in reversing hypoxemia from this cause. Because of the steep oxyhemoglobin dissociation curve at low $P_{O_2}$, even moderate amounts of pure shunt will cause significant hypoxemia despite oxygen therapy (Figure 19–9). For the same reason, factors that decrease mixed venous $P_{O_2}$, such as decreased cardiac output or increased $O_2$ consumption, enhance the hypoxemic effects of mismatch and shunt.

Nonpulmonary Causes of Hypoxia. In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to hypoxia at the tissue level. These may be divided into categories of $O_2$ delivery and $O_2$ utilization. Oxygen delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (e.g., stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (e.g., compartment syndrome, venous stasis, or venous hypertension). Decreased $O_2$-carrying capacity of the blood likewise will reduce oxygen delivery, such as occurs with anemia, CO poisoning, or hemoglobinopathy. Finally, hypoxia may occur when transport of $O_2$ from the capillaries to the tissues is decreased (edema) or utilization of the $O_2$ by the cells is impaired (CN$^-$ toxicity).

Effects of Hypoxia. There has been a considerable increase in our understanding of the cellular and biochemical changes that occur after acute and chronic hypoxia. Regardless of the cause, hypoxia produces a marked alteration in gene expression, mediated in part by hypoxia inducible factor-1$\alpha$ (Brahimi-Horn and Pouyssegur, 2009). Ultimately, hypoxia results in the cessation of aerobic metabolism, exhaustion of high-energy intracellular stores, cellular dysfunction, and death. The time course of cellular demise depends on the tissue’s relative metabolic requirements, $O_2$ and energy stores, and anaerobic capacity. Survival times (the time from the onset of circulatory arrest to significant organ dysfunction) range from 1-2 minutes in the cerebral cortex to around 5 minutes in the heart and 10 minutes in the kidneys and liver, with the potential for some degree of recovery if reperfused. Revival times (the duration of hypoxia beyond which recovery is no longer possible) are ~4 to 5 times longer. Less severe degrees of hypoxia have progressive physiological
effects on different organ systems (Nunn, 2005b). Responses of individual organ systems to hypoxia are summarized next.

**Respiratory System.** Hypoxia stimulates the carotid and aortic baroreceptors to cause increases in both the rate and depth of ventilation. Minute volume almost doubles when normal individuals inspire gas with a PO₂ of 6.6 kPa (50 mm Hg). Dyspnea is not always associated with simple hypoxia but occurs when the respiratory minute volume approaches half the maximal breathing capacity; this may occur with minimum exertion in patients in whom maximal breathing capacity is reduced by lung disease. In general, little warning precedes the loss of consciousness resulting from hypoxia.

**Cardiovascular System.** Hypoxia causes reflex activation of the sympathetic nervous system by both autonomic and humoral mechanisms, resulting in tachycardia and increased cardiac output. Peripheral vascular resistance, however, decreases primarily through local autoregulatory mechanisms, with the net result that blood pressure generally is maintained unless hypoxia is prolonged or severe. In contrast to the systemic circulation, hypoxia causes pulmonary vasoconstriction and hypertension, an extension of the normal regional vascular response that matches perfusion with ventilation to optimize gas exchange in the lung (hypoxic pulmonary vasoconstriction).

**CNS.** The CNS is least able to tolerate hypoxia. Hypoxia is manifest initially by decreased intellectual capacity and impaired judgment and psychomotor ability. This state progresses to confusion and restlessness and ultimately to stupor, coma, and death as the arterial PO₂ decreases below 4.5 kPa (30-40 mm Hg). Victims often are unaware of this progression.

**Cellular and Metabolic Effects.** When the mitochondrial PO₂ falls below ~0.13 kPa (1 mm Hg), aerobic metabolism stops, and the less efficient anaerobic pathways of glycolysis become responsible for the production of cellular energy. End products of anaerobic metabolism, such as lactic acid, are released into the circulation in measurable quantities. Energy-dependent ion pumps slow, and transmembrane ion gradients dissipate. Intracellular concentrations of Na⁺, Ca²⁺, and H⁺ increase, finally leading to cell death. The time course of cellular demise depends on the relative metabolic demands, oxygen storage capacity, and anaerobic capacity of the individual organs. Restoration of perfusion and oxygenation prior to hypoxic cell death paradoxically can result in an accelerated form of cell injury (ischemia–reperfusion syndrome), which is thought to result from the generation of highly reactive oxygen free radicals.

**Adaptation to Hypoxia.** Long-term hypoxia results in adaptive physiological changes; these have been studied most thoroughly in persons exposed to high altitude. Adaptations include increased numbers of pulmonary alveoli, increased concentrations of hemoglobin in blood and myoglobin in muscle, and a decreased ventilatory response to hypoxia. Short-term exposure to high altitude produces similar adaptive changes. In susceptible individuals, however, acute exposure to high altitude may produce acute mountain sickness, a syndrome characterized by headache, nausea, dyspnea, sleep disturbances, and impaired judgment progressing to pulmonary and cerebral edema. Mountain sickness is treated with rest and analgesics when mild or supplemental oxygen, descent to lower altitude, or an increase in ambient pressure when more severe. Acetazolamide (a carbonic anhydrase inhibitor) and dexamethasone also may be helpful. The syndrome usually can be avoided by a slow ascent to altitude, adequate hydration, and prophylactic use of acetazolamide or dexamethasone.

Certain aspects of fetal and newborn physiology are strongly reminiscent of adaptation mechanisms found in hypoxia-tolerant animals (Mortola, 1999), including shifts in the oxyhemoglobin dissociation curve (fetal hemoglobin), reductions in metabolic rate and body temperature (hibernation-like mode), reductions in heart rate and circulatory redistribution (as in diving mammals), and redirection of energy utilization from growth to maintenance metabolism. These adaptations probably account for the relative tolerance of the fetus and neonate to both chronic (uterine insufficiency) and short-term hypoxia.

**Oxygen Inhalation**

**Physiological Effects of Oxygen Inhalation.** Oxygen inhalation is used primarily to reverse or prevent the development of hypoxia; other consequences usually are minor. However, when O₂ is breathed in excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

**Respiratory System.** Inhalation of O₂ at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of O₂ inhalation because of a paradoxical increase in the tension of CO₂ in tissues. This increase results from the increased concentration of oxyhemoglobin in venous blood, which causes less efficient removal of carbon dioxide from the tissues.

In a small number of patients whose respiratory center is depressed by long-term retention of CO₂, injury, or drugs, ventilation is maintained largely by stimulation of carotid and aortic chemoreceptors, commonly referred to as the hypoxic drive. The provision of too much oxygen can depress this drive, resulting in respiratory acidosis. In these cases, supplemental oxygen should be titrated carefully to ensure adequate arterial saturation. If hyperventilation results, then mechanical ventilatory support with or without tracheal intubation should be provided.

Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the airspaces while oxygen is absorbed. High oxygen concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis, occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of oxygen administration.

**Cardiovascular System.** Aside from reversing the effects of hypoxia, the physiological consequences of oxygen inhalation on the cardiovascular system are of little significance. Heart rate and cardiac output are slightly reduced when 100% O₂ is breathed; blood pressure changes little. While pulmonary arterial pressure changes little in normal subjects with oxygen inhalation, elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with oxygen therapy or return to sea level. In particular, in neonates with congenital heart disease
and left-to-right shunting of cardiac output, oxygen supplementation must be regulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

**Metabolism.** Inhalation of 100% O₂ does not produce detectable changes in O₂ consumption, CO₂ production, respiratory quotient, or glucose utilization.

**Oxygen Administration**

Oxygen is supplied as a compressed gas in steel cylinders, and a purity of 99% is referred to as *medical grade*. Most hospitals have oxygen piped from insulated liquid oxygen containers to areas of frequent use. For safety, oxygen cylinders and piping are color-coded (green in the U.S.), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to oxygen systems. Oxygen concentrators, which employ molecular sieve, membrane, or electrochemical technologies, are available for low-flow home use. Such systems produce 30-95% oxygen depending on the flow rate.

Oxygen is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. Only a closed delivery system with an airtight seal to the patient’s airway and complete separation of inspired from expired gases can precisely control FIO₂. In all other systems, the actual delivered FIO₂ will depend on the ventilatory pattern (i.e., rate, tidal volume, inspiratory–expiratory time ratio, and inspiratory–expiratory flow) and delivery system characteristics.

**Low-Flow Systems.** Low-flow systems, in which the oxygen flow is lower than the inspiratory flow rate, have a limited ability to raise the FIO₂ because they depend on entrained room air to make up the balance of the inspired gas. The FIO₂ of these systems is extremely sensitive to small changes in the ventilatory pattern. Nasal cannulae—small, flexible prongs that sit just inside each naris—deliver oxygen at 1-6 L/min. The nasopharynx acts as a reservoir for storing the oxygen, and patients may breathe through either the mouth or nose as long as the nasal passages remain patent. These devices typically deliver 24-28% FIO₂ at 2-3 L/min. Up to 40% FIO₂ is possible at higher flow rates, although this is poorly tolerated for more than brief periods because of mucosal drying. The simple face mask, a clear plastic mask with side holes for clearance of expiratory gas and inspiratory air entrainment, is used when higher concentrations of oxygen delivered without tight control are desired. The maximum FIO₂ of a face mask can be increased from around 60% at 6-15 L/min to > 85% by adding a 600- to 1000-mL reservoir bag. With this partial rebreathing mask, most of the inspired volume is drawn from the reservoir, avoiding dilution by entrainment of room air.

**High-Flow Systems.** The most commonly used high-flow oxygen delivery device is the Venturi-style mask, which uses a specially designed mask insert to entrain room air reliably in a fixed ratio and thus provides a relatively constant FIO₂ at relatively high flow rates. Typically, each insert is designed to operate at a specific oxygen flow rate, and different inserts are required to change the FIO₂. Lower delivered FIO₂ values use greater entrainment ratios, resulting in higher total (oxygen plus entrained air) flows to the patient, ranging from 80 L/min for 24% FIO₂ to 40 L/min at 50% FIO₂. While these flow rates are much higher than those obtained with low-flow devices, they still may be lower than the peak inspiratory flows for patients in respiratory distress, and thus the actual delivered O₂ concentration may be lower than the nominal value. Oxygen nebulizers, another type of Venturi-style device, provide patients with humidified oxygen at 35-100% FIO₂ at high flow rates. Finally, oxygen blenders provide high inspired oxygen concentrations at very high flow rates. These devices mix high-pressure compressed air and oxygen to achieve any concentration of O₂ from 21-100% at flow rates of up to 100 L/min. These same blenders are used to provide control of FIO₂ for ventilators, CPAP/BiPAP machines, oxygenators, and other devices with similar requirements. Again, despite the high flows, the delivery of high FIO₂ to an individual patient also depends on maintaining a tight-fitting seal to the airway and/or the use of reservoirs to minimize entrainment of diluting room air.

**Monitoring of Oxygenation.** Monitoring and titration are required to meet the therapeutic goal of oxygen therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Cyanosis appears when ~5 g/dL of deoxyhemoglobin is present in arterial blood, representing an oxygen saturation of ~67% when a normal amount of hemoglobin (15 g/dL) is present. However, when anemia lowers the hemoglobin to 10 g/dL, then cyanosis does not appear until the arterial blood saturation has decreased to 50%. Invasive approaches for monitoring oxygenation include intermittent laboratory analysis of arterial or mixed venous blood gases and placement of intravascular cannulae capable of continuous measurement of oxygen tension. The latter method, which relies on fiber-optic oximetry, is used frequently for the continuous measurement of mixed venous hemoglobin saturation as an index of tissue extraction of oxygen, usually in critically ill patients.

Noninvasive monitoring of arterial oxygen saturation can be achieved using transcutaneous pulse oximetry, in which oxygen saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the pulsatile component of this signal. Application is simple, and calibration is not required. Pulse oximetry measures hemoglobin saturation and not PO₂. It is not sensitive to increases in PO₂ that exceed levels required to saturate the blood fully. Pulse oximetry is very useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating oxygen therapy in situations where toxicity from oxygen or side effects of excess oxygen are of concern. Near infrared spectroscopy (NIRS) is a noninvasive technique being used to monitor oxygen content in the cerebral cortex. Unlike pulse oximetry NIRS measures all reflected light in both pulsatile arterial blood and nonpulsatile venous blood, the primary compartment in the cerebral vascular bed. NIRS is useful to monitor cerebral oxygenation in surgical procedures involving cardiopulmonary bypass and circulatory arrest (Guarracino, 2008).

**Complications of Oxygen Therapy.** Administration of supplemental oxygen is not without potential complications. In addition to the
potential to promote absorption atelectasis and depress ventilation (discussed earlier), high flows of dry oxygen can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified oxygen thus should be used when prolonged therapy (>1 hour) is required. Finally, any oxygen-enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken both in the operating room and for patients on oxygen at home.

It is important to realize that hypoxemia still can occur despite the administration of supplemental oxygen. Furthermore, when supplemental oxygen is administered, desaturation occurs at a later time after airway obstruction or hypoventilation, potentially delaying the detection of these critical events. Therefore, whether or not oxygen is administered to a patient at risk for these problems, it is essential that both O₂ saturation and adequacy of ventilation be assessed frequently.

Therapeutic Uses of Oxygen

Correction of Hypoxia. The primary therapeutic use of oxygen is to correct hypoxia. Hypoxia is most commonly a manifestation of an underlying disease, and administration of oxygen thus should be viewed as temporizing therapy. Efforts must be directed at correcting the cause of the hypoxia. For example, airway obstruction is unlikely to respond to an increase in inspired oxygen tension without relief of the obstruction. More important, while hypoxemia owing to hypoventilation after a narcotic overdose can be improved with supplemental oxygen administration, the patient remains at risk for respiratory failure if ventilation is not increased through stimulation, narcotic reversal, or mechanical ventilation. Hypoxia resulting from most pulmonary diseases can be alleviated at least partially by administration of oxygen, allowing time for definitive therapy to reverse the primary process. Thus, administration of oxygen is basic and important treatment for all forms of hypoxia.

Reduction of Partial Pressure of an Inert Gas. Since nitrogen constitutes some 79% of ambient air, it also is the predominant gas in most gas-filled spaces in the body. In situations such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of air-filled spaces. Since nitrogen is relatively insoluble, inhalation of high concentrations of oxygen (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of oxygen for air embolism is additionally beneficial because it helps to relieve localized hypoxia distal to the vascular obstruction. In the case of decompression sickness, or bends, lowering the inert gas tension in blood and tissues by oxygen inhalation prior to or during a barometric decompression reduces the supersaturation that occurs after decompression so that bubbles do not form. If bubbles do form in either tissues or the vasculature, administration of oxygen is based on the same rationale as that described for gas embolism.

Hyperbaric Oxygen Therapy. Oxygen can be administered at greater than atmospheric pressure in hyperbaric chambers (Thom, 2009). Clinical uses of hyperbaric oxygen therapy include the treatment of trauma, burns, radiation damage, infections, non-healing ulcers, skin grafts, spasticity, and other neurological conditions. Hyperbaric chambers can withstand pressures that range from 200 to 600 kPa (2-6 atm), although inhaled oxygen tension that exceeds 300 kPa (3 atm) rarely is used. Chambers range from single-person units to multiroom establishments housing complex medical equipment.

Hyperbaric oxygen therapy has two components: increased hydrostatic pressure and increased O₂ pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased oxygen pressure at the tissue is the primary therapeutic goal for other indications for hyperbaric O₂. A small increase in Po₂ in ischemic areas enhances the bactericidal activity of leukocytes and increases angiogenesis. Repetitive brief exposures to hyperbaric oxygen may enhance therapy for chronic refractory osteomyelitis, osteoradionecrosis, crush injury, or the recovery of compromised skin and tissue grafts. Increased O₂ tension can be bacteriostatic and useful in the treatment for the spread of infection with Clostridium perfringens and clostridial myonecrosis (gas gangrene).

Hyperbaric oxygen may be useful in generalized hypoxia. In CO poisoning, hemoglobin (Hb) and myoglobin become unavailable for O₂ binding because of the high affinity of these proteins for CO. Affinity for CO is ~250 times greater than the affinity for O₂; thus, an alveolar concentration of CO = 0.4 mm Hg (1/250th that of alveolar O₂, which is ~100 mm Hg), will compete equally with O₂ for binding sites on Hb. High Po₂ facilitates competition of O₂ for Hb binding sites as CO is exchanged in the alveoli. In addition, hyperbaric O₂ increases the availability of dissolved O₂ in the blood (Table 19–4). In a randomized clinical trial (Weaver et al., 2002), hyperbaric O₂ decreased the incidence of long- and short-term neurological sequelae after CO intoxication. The occasional use of hyperbaric oxygen in cyanide poisoning has a similar rationale. Hyperbaric oxygen may be useful in severe short-term anemia since sufficient oxygen can be dissolved in the plasma at 3 atm to meet metabolic demand. Such treatment must be limited because oxygen toxicity depends on increased Po₂, not on the oxygen content of the blood.

Adverse effects of hyperbaric oxygen therapy include middle ear barotrauma, CNS toxicity, seizures, lung toxicity, and aspiration pneumonia. Contraindications to hyperbaric oxygen therapy include pneumothorax and concurrent doxorubicin, bleomycin, or disulfiram therapy. Relative contraindications include respiratory tract infections, severe obstructive lung disease, fever, seizure disorders, optic neuritis, pregnancy, concurrent steroid use, and claustrophobia.

Oxygen Toxicity

Oxygen is used in cellular energy production and is crucial for cellular metabolism. However, oxygen also has deleterious actions at the cellular level. Oxygen toxicity may result from increased production of hydrogen peroxide and reactive agents such as superoxide anion, singlet oxygen, and hydroxyl radicals that attack and damage lipids, proteins, and other macromolecules, especially those in biological membranes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These
factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms.

Respiratory Tract. The pulmonary system is usually the first to exhibit toxicity, a function of its continuous exposure to the highest oxygen tensions in the body. Subtle changes in pulmonary function can occur within 8–12 hours of exposure to 100% O₂. Increases in capillary permeability, which will increase the alveolararterial oxygen gradient and ultimately lead to further hypoxemia, and decreased pulmonary function can be seen after only 18 hours of exposure (Clark, 1988). Serious injury and death, however, require much longer exposures. Pulmonary damage is directly related to the inspired oxygen tension, and concentrations of < 0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung. Endothelial injury results in loss of surface area from interstitial edema and leaks into the alveoli.

Decreases of inspired oxygen concentrations remain the cornerstone of therapy for oxygen toxicity. Tolerance also may play a role in protection from oxygen toxicity; animals exposed briefly to high O₂ tensions are subsequently more resistant to toxicity. Sensitivity in humans also can be altered by preexposure to both high and low O₂ concentrations (Clark, 1988). These studies strongly suggest that changes in alveolar surfactant and cellular levels of antioxidant enzymes play a role in protection from oxygen toxicity.

Nervous System. Retinopathy of prematurity (ROP) is an eye disease in premature infants involving abnormal vascularization of the developing retina that can result from oxygen toxicity or relative hypoxia (Lutty et al., 2006). Retinal changes can progress to blindness and are likely caused by fibrovascular proliferation. Central nervous system problems are rare, and toxicity occurs only under hyperbaric conditions where exposure exceeds 200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when oxygen tension is returned to normal. Increased inspired oxygen concentrations are often administered to patients who have sustained acute ischemic central nervous system injury. In premature neonates and those who have sustained in utero asphyxia, hyperoxia and hypocapnia are associated with worse neurologic outcomes (Klinger et al., 2005). Similarly, in preclinical studies, resuscitation from cardiac arrest with high inspired oxygen concentrations leads to worse outcomes (Balan et al., 2006). These data indicate that oxygen therapy should be titrated to maintain an acceptable P₀₂ and that hyperoxemia should be avoided (Sola, 2008).

CARBON DIOXIDE

Transfer and Elimination of CO₂
Carbon dioxide is produced by metabolism at approximately the same rate as O₂ is consumed. At rest, this value is ~3 mL/kg per minute, but it may increase dramatically with exercise. CO₂ diffuses readily from the cells into the blood, where it is carried partly as bicarbonate ion (HCO₃⁻), partly in chemical combination with hemoglobin and plasma proteins, and partly in solution at a partial pressure of ~6 kPa (46 mm Hg) in mixed venous blood. CO₃ is transported to the lung, where it is normally exhaled at the rate it is produced, leaving a partial pressure of ~5.2 kPa (40 mm Hg) in the alveoli and in arterial blood. An increase in Pco₂ results in a respiratory acidosis and may be due to decreased ventilation or the inhalation of CO₂, whereas an increase in ventilation results in decreased Pco₂ and a respiratory alkalosis. Since CO₂ is freely diffusible, the changes in blood Pco₂ and pH soon are reflected by intracellular changes in Pco₂ and pH.

Effects of Carbon Dioxide
Alterations in Pco₂ and pH have widespread effects in the body, particularly on respiration, circulation, and the CNS. Complete discussions of these and other effects are found in textbooks of respiratory physiology (Nunn, 2005a).

Respiration. CO₂ is a rapid, potent stimulus to ventilation in direct proportion to the inspired CO₂. Inhalation of 10% carbon dioxide can produce minute volumes of 75 L/min in normal individuals. CO₂ stimulates breathing by acidifying central chemoreceptors and the peripheral carotid bodies (Guenet, 2008). Elevated Pco₂ causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion (Duane et al., 1979).

Circulation. The circulatory effects of CO₂ result from the combination of its direct local effects and its centrally mediated effects on the autonomic nervous system. The direct effect of CO₂ on the heart, diminished contractility, results from pH changes and a decreased myofilament Ca²⁺ responsiveness (van den Bos et al., 1979). The direct effect on systemic blood vessels results in vasodilation. CO₂ causes widespread activation of the sympathetic nervous system and an increase in the plasma concentrations of epinephrine, norepinephrine, angiotensin, and other vasoactive peptides. The results of sympathetic nervous system activation generally are opposite to the local effects of carbon dioxide. The sympathetic effects consist of increases in cardiac contractility, heart rate, and vasoconstriction (Chapter 12).

The balance of opposing local and sympathetic effects, therefore, determines the total circulatory response to CO₂. The net effect of CO₂ inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of CO₂ appear more important, and total peripheral resistance decreases when the Pco₂ is increased. CO₂ also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased Pco₂ are due to the release of catecholamines.

Hypocarbia results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.
CNS. Hypercapnia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. This central depression has therapeutic importance. For example, in patients who are hypoventilating from narcotics or anesthetics, increasing Pco₂ may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can have lethal consequences. The inhalation of high concentrations of carbon dioxide (~50%) produces marked cortical and subcortical depression of a type similar to that produced by anesthetic agents.

Methods of Administration. CO₂ is marketed in gray metal cylinders as the pure gas or as CO₂ mixed with oxygen. It usually is administered at a concentration of 5-10% in combination with O₂ by means of a face mask. Another method for the temporary administration of CO₂ is by rebreathing, such as from an anesthesia breathing circuit when the soda lime canister is bypassed or from something as simple as a paper bag. A potential safety issue exists in that tanks containing carbon dioxide plus oxygen are the same color as those containing 100% CO₂. When tanks containing CO₂ and O₂ have been used inadvertently where a fire hazard exists (e.g., in the presence of electrocautery during laparoscopic surgery), explosions and fires have resulted.

Therapeutic Uses. CO₂ is used for insufflation during endoscopic procedures (e.g., laparoscopic surgery) because it is highly soluble and does not support combustion. Inadvertent gas emboli thus are dissolved and eliminated more easily by the respiratory system. CO₂ can be used to flood the surgical field during cardiac surgery. Because of its density, carbon dioxide displaces the air surrounding the open heart so that any gas bubbles trapped in the heart are carbon dioxide rather than insoluble nitrogen (Nadolny and Svensson, 2000). Similarly, CO₂ is used to de-bubble cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO) circuits. It is used to adjust pH during cardiopulmonary bypass procedures when a patient is cooled.

Hypocapnia, with its attendant respiratory alkalosis, still has some uses in anesthesia. It constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. While short-term hypocapnia is effective for this purpose, sustained hypocapnia has been associated with worse outcomes in patients with head injury (Muizelaar et al., 1991). Consequently, hypocapria should be instituted with a clearly defined indication and normocapria should be re-established as soon the indication for hypocapria no longer applies.

NITRIC OXIDE

Nitric oxide (NO) is a free-radical gas long known as an air pollutant and a potential toxin. NO is now known as a critical endogenous cell-signaling molecule with an increasing number of potential therapeutic applications.

Endogenous NO is produced from L-arginine by a family of enzymes called NO synthases (neural, inducible and endothelial). NO is both an intra-cellular and a cell-cell messenger implicated in a wide range of physiological and pathophysiological events in numerous cell types, including the cardiovascular, immune, and nervous systems. NO activates the soluble guanylyl cyclase, increasing cellular cyclic GMP (Chapter 3). In the vasculature, basal release of NO produced by endothelial cells is a primary determinant of resting vascular tone; NO causes vasodilation when synthesized in response to shear stress or a variety of vasodilating agents (Chapter 27). It also inhibits platelet aggregation and adhesion. Impaired NO production has been implicated in diseases such as atherosclerosis, hypertension, cerebral and coronary vasospasm, and ischemia–reperfusion injury. In the immune system, NO serves as an effector of macrophage-induced cytotoxicity, and overproduction of NO is a mediator of inflammation. In neurons, NO acts as a mediator of long-term potentiation. Cytotoxicity resulting from N-methyl-D-aspartate (NMDA), and non-adrenergic non-cholinergic neurotransmission; NO has been implicated in mediating central nociceptive pathways (Chapters 8 and 18).

NO is rapidly inactivated in the circulation by oxyhemoglobin and by the reaction with NO with the heme iron, leading to the formation of nitrosyl-hemoglobin. Small quantities of methemoglobin are also produced and these are converted to the ferrous form of heme iron by cytochrome b₅ reductase. The majority of inhaled NO is excreted in the urine in the form of nitrate. Rapid withdrawal of NO can result in a rebound increase in pulmonary pressure; gradual withdrawal should minimize rebound phenomena (Griffiths and Evans, 2005).

Therapeutic Uses. NO when inhaled selectively dilates the pulmonary vasculature with minimal systemic cardiovascular effects due to its rapid inactivation by oxyhemoglobin in the pulmonary circulation (Cooper, 1999). Ventilation–perfusion matching is preserved or improved by NO because inhaled NO is distributed only to ventilated areas of the lung and dilates only those vessels directly adjacent to the ventilated alveoli. Thus, inhaled NO decreases elevated pulmonary artery pressure and pulmonary vascular resistance and often improves oxygenation. The dose of NO that is required for an improvement in oxygenation is lower than that required for a reduction in pulmonary pressure (Griffiths and Evans, 2005).

Inhaled NO (iNO) has potential as a therapy for numerous diseases associated with increased pulmonary vascular resistance. In patients with adult respiratory distress syndrome (ARDS), iNO is more often used to improve oxygenation rather than reducing pulmonary pressure. NO does improve oxygenation but this effect is transient. Moreover, the use of iNO therapy is not associated with either a reduction in the duration of mechanical ventilation or in morbidity or mortality (Taylor et al., 2004). iNO-mediated reductions in pulmonary pressure have prompted its use in patients with pulmonary hypertension in other clinical settings. Transient reduction in pulmonary pressure have been reported in patients undergoing cardiac surgery (Winterhalter et al., 2008) and pulmonary transplantation (Ardehali et al., 2001). Although transient physiologic improvements do occur, long-term outcome is essentially unchanged (Meade et al., 2003). Several small studies and case reports have suggested potential benefits of inhaled NO in a variety of conditions, including pulmonary hypertension and right heart
failure associated with orthotopic heart transplantation, weaning from cardiopulmonary bypass in adult and congenital heart disease patients, ventricular assist device placement, primary pulmonary hypertension, pulmonary embolism, acute chest syndrome in sickle-cell patients, congenital diaphragmatic hernia, high-altitude pulmonary edema, and lung transplantation (Haddad et al., 2000). Larger prospective, randomized studies for these disease conditions either have not yet been performed or have failed to confirm any changes in outcome.

Inhaled NO is FDA-approved for only one indication, persistent pulmonary hypertension of the newborn (Mourani et al., 2004). A recent systematic review of the available data in neonates has shown that in very sick neonates with poor oxygenation, iNO does improve oxygenation but it does not improve mortality, reduce the incidence of bronchopulmonary dysplasia that is common in this population, or reduce the incidence of brain injury (Hintz et al., 2007, Su and Chen, 2008). Whether there are subsets of patients who may have a favorable response to iNO remains to be determined.

**Diagnostic Uses.** Inhaled NO also is used in several diagnostic applications. Inhaled NO can be used during cardiac catheterization to safely and selectively evaluate the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (DL) across the alveolar–capillary unit. NO is more effective than carbon dioxide in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature (Haddad et al., 2000).

NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. The measurement of fractional exhaled NO (FeNO) is a noninvasive marker for airway inflammation with utility in the assessment of respiratory tract diseases including asthma, respiratory tract infection and chronic lung diseases (Taylor et al., 2006).

**Toxicity.** Administered at low concentrations (0.1-50 ppm), inhaled NO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50-100 ppm. In the context of NO as an atmospheric pollutant, the Occupational Safety and Health Administration places the 7-hour exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to nitrogen dioxide (NO₂) in the presence of high concentrations of O₂. Even low concentrations of NO₂ (2 ppm) have been shown to be highly toxic in animal models, with observed changes in lung histopathology, including loss of cilia, hypertrophy, and focal hyperplasia in the epithelium of terminal bronchioles. It is important, therefore, to keep NO₂ formation during NO therapy at a low level. This can be achieved by the administration of NO at a site in the respiratory circuit as close to the patient as possible and timing the delivery of NO to inspiration. Laboratory studies have suggested potential additional toxic effects of chronic low doses of inhaled NO, including surfactant inactivation and the formation of peroxynitrite by interaction with superoxide. Nitric oxide and peroxynitrite have been implicated in cellular mechanisms of oxygen toxicity in the lung and central nervous system (Allen et al., 2009). The ability of NO to inhibit or alter the function of a number of iron- and heme-containing proteins, including cyclooxygenase, lipoxygenases, and oxidative cytochromes, as well as its interactions with ADP-ribosylation, suggests a need for further investigation of the toxic potential of NO under therapeutic conditions (Haddad et al., 2000).

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. The blood content of methemoglobin, however, generally will not increase to toxic levels with appropriate use of inhaled NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation (Haddad et al., 2000).

Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding complications have not been reported.

In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema formation. Careful monitoring of cardiac output, left atrial pressure, or pulmonary capillary wedge pressure is important in this situation.

Despite these concerns, there are limited reports of inhaled NO-related toxicity in humans. The most important requirements for safe NO inhalation therapy include:

- continuous measurement of NO and NO₂ concentrations using either chemiluminescence or electrochemical analyzers
- frequent calibration of monitoring equipment
- intermittent analysis of blood methemoglobin levels
- the use of certified tanks of NO
- administration of the lowest NO concentration required for therapeutic effect

**Methods of Administration.** Courses of treatment of patients with inhaled NO are highly varied, extending from 0.1 to 40 ppm in dose and for periods of a few hours to several weeks in duration. The minimum effective inhaled NO concentration should be determined for each patient to minimize the chance for toxicity. Given that sensitivity to NO can vary in the patient during the course of administration, the determination of dose response relationship on a frequent basis should assist in the titration of the optimum dose of NO. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO₂ concentrations. A constant inspired concentration of NO is obtained by administering NO in nitrogen to the inspiratory limb of the ventilator circuit in either a pulse or continuous mode. While inhaled NO may be administered to spontaneously breathing patients by a closely fitting mask, it usually is delivered during mechanical ventilation. Nasal prong administration is being employed in therapeutic trials of home administration for treatment of primary pulmonary hypertension (Griffiths et al., 2005).

**HELLEUM**

Helium (He) is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses. Helium is produced by separation from liquefied natural gas and is supplied in brown cylinders. Helium can be mixed with oxygen and administered by mask or endotracheal tube. Under hyperbaric conditions, it can be substituted for the bulk.
of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, laser airway surgery, as a label in imaging studies, and for diving at depth. The determinations of residual lung volume, functional residual capacity, and related lung volumes require a highly diffusible non-toxic gas that is insoluble and does not leave the lung by the bloodstream so that, by dilution, the lung volume can be measured. Helium is well suited to these needs. A breath of a known concentration of helium is given, and the concentration of helium is measured in the mixed expired gas, allowing calculation of the other pulmonary volumes.

Pulmonary gas flow normally is laminar. With increased flow rates or a narrowed flow pathway, a component of pulmonary gas flow becomes turbulent. Helium can be added to oxygen to reduce turbulence due to airway obstruction since the density of helium is less than that of air and the viscosity of helium is greater than that of air. Addition of helium reduces the Reynolds number of the mixture (the Reynolds number is proportional to density and inversely proportional to viscosity), thereby reducing turbulence. Mixtures of helium and oxygen reduce the work of breathing. The utility of helium/oxygen mixtures is limited by the fact that oxygenation often accompanies airway obstruction. The need for increased inspired O₂ concentration limits the fraction of helium that can be used. Furthermore, even though helium reduces the Reynolds number of the gas mixture, the viscosity of helium is greater than that of air, and the increased viscosity increases the resistance to flow according to Poiseuille’s law, whereby flow is inversely proportional to viscosity.

Helium has high thermal conductivity, making it useful during laser surgery on the airway. This more rapid conduction of heat away from the point of contact of the laser beam reduces the spread of tissue damage and the likelihood that the ignition point of flammable materials in the airway will be reached. Its low density improves the flow through the small endotracheal tubes typically used in such procedures. However, its use for this purpose is rare.

Laser-polarized helium is used as an inhalational contrast agent for pulmonary magnetic resonance imaging. Optical pumping of hyperpolarized helium increases the signal from the gas in the lung to permit detailed imaging of the airways and inspired airflow patterns (Hopkins et al., 2007).

**Hyperbaric Applications.** The depth and duration of diving activity are limited by oxygen toxicity, inert gas (nitrogen) narcosis, and nitrogen supersaturation when decompressing. Oxygen toxicity is a problem with prolonged exposure to compressed air at 500 kPa (5 atm) or more. This problem can be minimized by dilution of oxygen with helium, which lacks narcotic potential even at very high pressures and is quite insoluble in body tissues. This low solubility reduces the likelihood of bubble formation after decompression, which therefore can be achieved more rapidly. The low density of helium also reduces the work of breathing in the otherwise dense hyperbaric atmosphere. The lower heat capacity of helium also decreases respiratory heat loss, which can be significant when diving at depth.

**HYDROGEN SULFIDE**

Hydrogen sulfide (H₂S), which has a characteristic rotten egg smell, is a colorless, flammable, water-soluble gas that is primarily considered a toxic agent due to its ability to inhibit mitochondrial respiration through blockade of cytochrome c oxidase. Recent research has demonstrated that H₂S in low quantities may have the potential to limit cell death (Lefer, 2007). Inhibition of respiration is potentially toxic; however, if depression of respiration occurs in a controlled manner, it may allow non-hibernating species exposed to inhaled H₂S to enter a state akin to suspended animation (i.e., a slowing of cellular activity to a point where metabolic processes are inhibited but not terminal) and thereby increase tolerance to stress. H₂S also may cause activation of ATP-dependent K⁺ channels, cause vasodilation properties, and serve as a free radical scavenger. H₂S has been shown to protect against whole-body hypoxia, lethal hemorrhage, and ischemia-reperfusion injury in various organs including the kidney, lung, liver, and heart. Currently, effort is underway for development of gas-releasing molecules that could deliver H₂S and other therapeutic gases to diseased tissue (Bannenberg and Vieira, 2009). Though H₂S has clinical potential, further verification in preclinical models is necessary as is more information regarding the route of delivery, timing, formulation, and concentration of H₂S.

**BIBLIOGRAPHY**

Pagel PS, Kampine JP, Schmeling WT, Wartlter DC. Ketamine depresses myocardial contractility as evaluated by the preload recruitable stroke work relationship in chronically instrumented dogs with autonomic nervous system blockade. Anesthesiology, 1992, 76:564–572.

Local anesthetics bind reversibly to a specific receptor site within the pore of the Na⁺ channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction. Thus, a local anesthetic in contact with a nerve trunk can cause both sensory and motor paralysis in the area innervated. These effects of clinically relevant concentrations of local anesthetics are reversible with recovery of nerve function and no evidence of damage to nerve fibers or cells in most clinical applications.

**History.** The first local anesthetic, cocaine, was serendipitously discovered to have anesthetic properties in the late 19th century. Cocaine occurs in abundance in the leaves of the coca shrub (*Erythroxylon coca*). For centuries, Andean natives have chewed an alkali extract of these leaves for its stimulatory and euphoric actions. Cocaine was first isolated in 1860 by Albert Niemann. He, like many chemists of that era, tasted his newly isolated compound and noted that it caused a numbing of the tongue. Sigmund Freud studied cocaine's physiological actions, and Carl Koller introduced cocaine into clinical practice in 1884 as a topical anesthetic for ophthalmological surgery. Shortly thereafter, Halstead popularized its use in infiltration and conduction block anesthesia.

**Chemistry and Structure-Activity Relationship.** Cocaine is an ester of benzoic acid and the complex alcohol 2-carbomethoxy, 3-hydroxy-tropane (Figure 20–1). Because of its toxicity and addictive properties (Chapter 24), a search for synthetic substitutes for cocaine began in 1892 with the work of Einhorn and colleagues, resulting in the synthesis of procaine, which became the prototype for local anesthetics for nearly half a century. The most widely used agents today are procaine, lidocaine, bupivacaine, and tetracaine.

The typical local anesthetics contain hydrophilic and hydrophobic moieties that are separated by an intermediate ester or amide linkage (Figure 20–1). A broad range of compounds containing these minimal structural features can satisfy the requirements for action as local anesthetics. The hydrophilic group usually is a tertiary amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, local anesthetics with an ester link are hydrolyzed readily by plasma esterases.

The structure-activity relationship and the physicochemical properties of local anesthetics have been reviewed by Courtney and Strichartz (1987). Hydrophobicity increases both the potency and the duration of action of the local anesthetics; association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na⁺ channels is thought to be hydrophobic (see *Mechanism of Action*), so that receptor affinity for anesthetic agents is greater for more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.

Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency- and voltage-dependence of their action.

**Mechanism of Action.** Local anesthetics act at the cell membrane to prevent the generation and the conduction of nerve impulses. Conduction block can be demonstrated in squid giant axons from which the axoplasm has been removed.

Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na⁺ that normally is produced by a slight depolarization of the membrane (Chapters 8, 11, and 14) (Strichartz and Ritchie, 1987). This action of local anesthetics is due to their direct interaction with voltage-gated Na⁺ channels. As the anesthetic action progresses in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action potential declines, impulse
Figure 20–1. Structural formulas of selected local anesthetics. Most local anesthetics consist of a hydrophobic (aromatic) moiety (black), a linker region (orange), and a substituted amine (hydrophilic region, in red). The structures above are grouped by the nature of the linker region. Procaine is a prototypic ester-type local anesthetic; esters generally are well hydrolyzed by plasma esterases, contributing to the relatively short duration of action of drugs in this group. Lidocaine is a prototypic amide-type local anesthetic; these structures generally are more resistant to clearance and have longer durations of action. There are exceptions, including benzocaine (poorly water soluble; used only topically) and the structures with a ketone, an amidine, and an ether linkage. Chloroprocaine has a chlorine atom on C2 of the aromatic ring of procaine.

Conduction slows, and the safety factor for conduction decreases. These factors decrease the probability of propagation of the action potential, and nerve conduction eventually fails.

Local anesthetics can bind to other membrane proteins (Butterworth and Strichartz, 1990). In particular, they can block K⁺ channels (Strichartz and Ritchie, 1987). However, since the interaction of local anesthetics
with K+ channels requires higher concentrations of drug, blockade of conduction is not accompanied by any large or consistent change in resting membrane potential.

Quaternary analogs of local anesthetics block conduction when applied internally to perfused giant axons of squid but are relatively ineffective when applied externally. These observations suggest that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the membrane (Narahashi and Frazier, 1971; Strichartz and Ritchie, 1987). Therefore, local anesthetics applied externally first must cross the membrane before they can exert a blocking action.

Although a variety of physicochemical models have been proposed to explain how local anesthetics achieve conduction block (Courtney and Strichartz, 1987), it now is generally accepted that the major mechanism of action of these drugs involves their interaction with one or more specific binding sites within the Na+ channel (Butterworth and Strichartz, 1990). The Na+ channels of the mammalian brain are complexes of glycosylated proteins with an aggregate molecular size in excess of 300,000 Da; the individual subunits are designated α (260,000 Da) and β1 to β4 (33,000-38,000 Da). The large α subunit of the Na+ channel contains four homologous domains (I-IV); each domain is thought to consist of six transmembrane segments in α-helical conformation (S1-S6; Figure 20–2) and an additional, membrane-reentrant pore (P) loop. The Na+-selective transmembrane pore of the channel presumably resides in the center of a nearly symmetrical structure formed by the four homologous domains. The voltage dependence of channel opening is hypothesized to reflect conformational changes that result from the movement of “gating charges” within the voltage-sensor module of the sodium channel in response to changes in the transmembrane potential. The gating charges are located in the S4 transmembrane helix; the S4 helices are both hydrophobic and positively charged, containing lysine or arginine residues at every third position. It is postulated that these residues move perpendicular to the plane of the membrane under the influence of the transmembrane potential, initiating a series of conformational changes in all four domains, which leads to the open state of the channel (Figure 20–2) (Catterall, 2000; Yu et al., 2005).

The transmembrane pore of the Na+ channel is thought to be surrounded by the S5 and S6 transmembrane helices and the short membrane-associated segments between them that form the P loop. Amino acid residues in these short segments are the most critical determinants of the ion conductance and selectivity of the channel.

After it opens, the Na+ channel inactivates within a few milliseconds due to closure of an inactivation gate. This functional gate is formed by the short intracellular loop of protein that connects homologous domains III and IV (Figure 20–2). This loop folds over the intracellular mouth of the transmembrane pore during the process of inactivation and binds to an inactivation gate “receptor” formed by the intracellular mouth of the pore.

Amino acid residues important for local anesthetic binding are found in the S6 segments in domains I, III, and IV (Ragsdale et al., 1994; Yarov-Yarovoy et al., 2002). Hydrophobic amino acid residues near the center and the intracellular end of the S6 segment may interact directly with bound local anesthetics (Figure 20–3).

Experimental mutation of a large hydrophobic amino acid residue (isoleucine) to a smaller one (alanine) near the extracellular end of this segment creates a pathway for access of charged local anesthetic drugs from the extracellular solution to the receptor site. These findings place the local anesthetic receptor site within the intracellular half of the transmembrane pore of the Na+ channel, with part of its structure contributed by amino acids in the S6 segments of domains I, III, and IV.

**Frequency- and Voltage-Dependence of Local Anesthetic Action.** The degree of block produced by a given concentration of local anesthetic depends on how the nerve has been stimulated and on its resting membrane potential. Thus, a resting nerve is much less sensitive to a local anesthetic than one that is repetitively stimulated; higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the local anesthetic molecule in its charged form gains access to its binding site within the pore only when the Na+ channel is in an open state and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na+ channel (Butterworth and Strichartz, 1990; Courtney and Strichartz, 1987). Local anesthetics exhibit these properties to different extents depending on their pKₐ, lipid solubility, and molecular size. In general, the frequency dependence of local anesthetic action depends critically on the rate of dissociation from the receptor site in the pore of the Na+ channel. A high frequency of stimulation is required for rapidly dissociating drugs so that drug binding during the action potential exceeds drug dissociation between action potentials. Dissociation of smaller and more hydrophobic drugs is more rapid, so a higher frequency of stimulation is required to yield frequency-dependent block. Frequency-dependent block of ion channels is most important for the actions of antiarrhythmic drugs (Chapter 29).

**Differential Sensitivity of Nerve Fibers to Local Anesthetics.** Although there is great individual variation, for most patients treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 20–1). Classical experiments with intact nerves showed that the δ wave in the compound action potential, which represents slowly conducting, small-diameter myelinated fibers, was reduced more rapidly and at lower concentrations of cocaine than was the α wave, which represents rapidly conducting, large-diameter fibers (Gasser and Erlanger, 1929). In general, autonomic fibers, small
Figure 20–2. Structure and function of voltage-gated Na+ channels. **A.** A two-dimensional representation of the α (center), β₁ (left), and β₂ (right) subunits of the voltage-gated Na⁺ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. ψ indicates sites of demonstrated N-linked glycosylation. Note the repeated structure of the four homologous domains (I-IV) of the α subunit. **Voltage Sensing.** The S4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) represents the positively charged amino acid residues at every third position within these segments. Electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane; depolarization allows them to move outward. **Pore.** The S5 and S6 transmembrane segments and the short membrane-associated loop between them (P loop) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see panel **B**). The amino acid residues indicated by circles in the P loop are critical for determining the conductance and ion selectivity of the Na⁺ channel and its ability to bind the extracellular pore-blocking toxins tetrodotoxin and saxitoxin. **Inactivation.** The short intracellular loop connecting homologous domains III and IV serves as the inactivation gate of the Na⁺ channel. It is thought to fold into the intracellular mouth of the pore and occlude it within a few milliseconds after the channel opens. Three hydrophobic residues (isoleucine–phenylalanine–methionine; IFM) at the position marked h appear to serve as an inactivation particle, entering the intracellular mouth of the pore and binding therein to an inactivation gate receptor there. **Modulation.** The gating of the Na⁺ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by PKC slows inactivation. Phosphorylation of sites in the intracellular loop between homologous domains I and II by either PKC or PKA reduces Na⁺ channel activation. (Adapted from Catterall, 2000, with permission. Copyright © Elsevier.). **B.** The four homologous domains of the Na⁺ channel α subunit are illustrated as a square array, as viewed looking down on the membrane. The sequence of conformational changes that the Na⁺ channel undergoes during activation and inactivation is diagrammed. Upon depolarization, each of the four homologous domains sequentially undergoes a conformational change to an activated state. After all four domains have activated, the Na⁺ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes over the intracellular mouth of the channel and occludes it, preventing further ion conductance (see Catterall, 2000).
unmyelinated C fibers (mediating pain sensations), and small myelinated Aδ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated Aγ, Aβ, and Aα fibers (mediating postural, touch, pressure, and motor information) (Raymond and Gissen, 1987). The differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics.

The precise mechanisms responsible for this apparent specificity of local anesthetic action on pain fibers are not known, but several factors may contribute. The initial hypothesis from the classical work on intact nerves was that sensitivity to local anesthetic block increases with decreasing fiber size, consistent with high sensitivity for pain sensation mediated by small fibers and low sensitivity for motor function mediated by large fibers (Gasser and Erlanger, 1929). However, when nerve fibers are dissected from nerves to allow direct measurement of action potential generation, no clear correlation of the concentration dependence of local anesthetic block with fiber diameter is observed (Fink and Cairns, 1984; Franz and Perry, 1974; Huang et al., 1997). Therefore, it is unlikely that the fiber size per se determines the sensitivity to local anesthetic block under steady-state conditions. However, the spacing of nodes of Ranvier increases with the size of nerve fibers. Because a fixed number of nodes must be blocked to prevent conduction, small fibers with closely spaced nodes of Ranvier may be blocked more rapidly during treatment of intact nerves, because the local anesthetic reaches a critical length of nerve more rapidly (Franz and Perry, 1974). Differences in tissue barriers and location of smaller C fibers and Aδ fibers in nerves also may influence the rate of local anesthetic action.

Effect of pH. Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Inasmuch as the local anesthetics are weak bases (typical pKₐ values range from 8-9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and the catecholamines added as vasoconstrictors. Under usual conditions of administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

Although the unprotonated species of the local anesthetic is necessary for diffusion across cellular membranes, it is the cationic

---

**Figure 20–3. The local anesthetic receptor site.** A. A drawing of the pore structure of a bacterial K⁺ channel (KcsA), which is related to the sodium channel. The KcsA channel has two transmembrane segments, analogous to the S5 and S6 segments of sodium channels. The S6-like segment forms the walls of the inner pore while the P loop forms the narrow ion selectivity filter at its extracellular (top) end. Four separate KcsA subunits form the pore in their center; only two of the subunits are shown here. B. A structural model of the local anesthetic receptor site. The S6 segments from domains I, III, and IV of the sodium channel α subunit are illustrated, based on the structure of the KcsA channel (panel A). The amino acid residues in these three transmembrane segments that contribute to the local anesthetic receptor site are indicated in single letter code and are presented in space-filling representation (light blue). An etidocaine molecule (black) is illustrated bound in the receptor site. Substitutions of the light blue residues with alanine reduce the affinity for local anesthetic block of sodium channels. It therefore is likely that the side chains of these amino acid residues contact bound local anesthetics in their receptor site. I1760 and I409 likely form the outer boundary of the local anesthetic receptor site. Mutations of I1760 allow drug access to the receptor site from the extracellular side. (This figure was originally published in the Journal of Biological Chemistry, Yarov-Yarovoy V, McPhee JC, Idsvoog D, Pate C, Scheuer T, Catterall WA: Role of amino acid residues in transmembrane segments S6 and IIS6 of the Na⁺ channel alpha subunit in voltage-dependent gating and drug block. J Biol Chem 2002:277, 35393. © the American Society for Biochemistry and Molecular Biology.)
species that interacts preferentially with Na⁺ channels. The results of experiments on anesthetized mammalian nonmyelinated fibers support this conclusion (Ritchie and Greengard, 1966). In these experiments, conduction could be blocked or unblocked merely by adjusting the pH of the bathing medium to 7.2 or 9.6, respectively, without altering the amount of anesthetic present. The primary role of the cationic form also was demonstrated by Narahashi and Frazier, who perfused the extracellular and axoplasmic surface of the giant squid axon with tertiary and quaternary amine local anesthetics and found that the quaternary amines were active (Narahashi and Frazier, 1971). However, the unprotonated molecular forms also possess some anesthetic activity (Butterworth and Strichartz, 1990).

Recent reports indicate that quaternary local anesthetics such as QX-314 can gain access to the cytoplasmic surface of the nerve cell membrane via TRPV1 channels (transient receptor potential vanilloid subtype channels) (reviewed by Butterworth and Oxford, 2009). TRP channels, and possibly other ion channels, appear to lose selectivity and permit permeation of molecules like QX-314 in the face of prolonged or intense activation.

### Prolongation of Action by Vasoconstrictors

The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. For example, cocaine inhibits the neuronal membrane transporters for catecholamines, thereby potentiating the effect of NE at α adrenergic receptors in the vasculature, resulting in vasoconstriction and reduced cocaine absorption in vascular beds where α adrenergic effects predominate (Chapters 8 and 12). Ropivacaine and bupivacaine also cause vasoconstriction. In clinical practice, a vasoconstrictor, usually epinephrine, is often added to local anesthetics. The vasoconstrictor performs a dual service. By decreasing the rate of absorption, it not only localizes the anesthetic at the desired site, but also allows the rate at which it is destroyed in the body to keep pace with the rate at which it is absorbed into the circulation. This reduces its systemic toxicity. It should be noted, however, that epinephrine also dilates skeletal muscle vascular beds through actions at β₂ adrenergic receptors, and therefore has the potential to increase systemic toxicity of anesthetic deposited in muscle tissue.

Undesired Effects of Local Anesthetics. In addition to blocking conduction in nerve axons in the peripheral nervous system, local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, they have important effects on the CNS, the autonomic ganglia, the neuromuscular junction, and all forms of muscle (for a review, see Covino, 1987; Garfield and Gugino, 1987; Gintant and Hoffman, 1987). The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, in local anesthetics with chiral centers, the $S$-enantiomer is less toxic than the $R$-enantiomer (McClure, 1996).

Central Nervous System. Following absorption, local anesthetics may cause CNS stimulation, producing restlessness and tremor that may progress to clonic convulsions. In general, the more potent the anesthetic, the more readily convulsions may be produced. Alterations of CNS activity are thus predictable from the local anesthetic agent in question and the blood concentration achieved. Central stimulation is followed by depression; death usually is caused by respiratory failure.

The apparent stimulation and subsequent depression produced by applying local anesthetics to the CNS presumably is due solely to depression of neuronal activity; a selective depression of inhibitory neurons is thought to account for the excitatory phase in vivo. Rapid systemic administration of local anesthetics may produce death with no or only transient signs of CNS stimulation. Under these conditions, the concentration of the drug probably rises so rapidly that all neurons are depressed simultaneously. Airway control, along with ventilatory and circulatory support, are essential features of treatment in the late stage of intoxication. Benzodiazepines or rapidly acting barbiturates administered intravenously are the drugs of choice for both the prevention and arrest of convulsions (Chapter 17).

Although drowsiness is the most frequent complaint that results from the CNS actions of local anesthetics, lidocaine may produce dysphoria or euphoria and muscle twitching. Moreover, both lidocaine and procaine may produce a loss of consciousness that is preceded only by symptoms of sedation (Covino, 1987). Whereas other local anesthetics also show the effect, cocaine has a particularly prominent effect on mood and behavior. These effects of cocaine and its potential for abuse are discussed in Chapter 24.

Cardiovascular System. Following systemic absorption, local anesthetics act on the cardiovascular system (Covino, 1987). The primary site of action is the myocardium, where decreases in electrical excitability, conduction rate, and force of contraction occur. In addition, most local anesthetics cause arteriolar dilation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and effects on the CNS are produced. However, on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse and death, probably due to either an action on the pacemaker or the sudden onset of ventricular fibrillation. Ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than bupivacaine. The effects of local anesthetics such as lidocaine and procainamide, which also are used as antiarrhythmic drugs, are discussed in Chapter 29. Finally, it should be stressed that untoward cardiovascular effects of local anesthetic agents may result from their inadvertent intravascular administration, especially if epinephrine also is present.

Smooth Muscle. Local anesthetics depress contractions in the intact bowel and in strips of isolated intestine (Zipf and Dittmann, 1971). They also relax vascular and bronchial smooth muscle, although low concentrations initially may produce contraction (Covino, 1987). Spinal and epidural anesthesia, as well as instillation of local anesthetics into the peritoneal cavity, cause sympathetic nervous system paralysis, which can result in increased tone of GI musculature (described under “Clinical Uses”). Local anesthetics may increase the resting tone and decrease the contractions of isolated human uterine muscle; however, uterine contractions are seldom depressed directly during intrapartum regional anesthesia.

Neuromuscular Junction and Ganglionic Synapse. Local anesthetics also affect transmission at the neuromuscular junction. Procaine, e.g., can block the response of skeletal muscle to maximal motor-nerve volleys and to ACh at concentrations at which the muscle responds normally to direct electrical stimulation. Similar effects occur at autonomic ganglia. These effects are due to block of nicotinic ACh receptors by high concentrations of the local anesthetic (Charnet et al., 1990; Neher and Steinbach, 1978).

Hypersensitivity to Local Anesthetics. Rare individuals are hypersensitive to local anesthetics. The reaction may manifest itself as an allergic dermatitis or a typical asthmatic attack (Covino, 1987). It is important to distinguish allergic reactions from toxic side effects and from the effects of co-administered vasoconstrictors. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. For example, individuals sensitive to procaine also may react to structurally similar compounds (e.g., tetracaine) through reaction to a common metabolite. Although allergic responses to agents of the amide type are uncommon, solutions of such agents may contain preservatives...
such as methylparaben that may provoke an allergic reaction (Covino, 1987). Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfite added as an antioxidant for the catecholamine/vasoconstrictor.

**Metabolism of Local Anesthetics.** The metabolic fate of local anesthetics is of great practical importance, because their toxicity depends largely on the balance between their rates of absorption and elimination. As noted earlier, the rate of absorption of many anesthetics can be reduced considerably by the incorporation of a vasoconstrictor agent in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Since toxicity is related to the free concentration of drug, binding of the anesthetic to proteins in the serum and to tissues reduces the concentration of free drug in the systemic circulation, and consequently reduces toxicity. For example, in intravenous regional anesthesia of an extremity, about half of the original anesthetic dose still is tissue-bound 30 minutes after the restoration of normal blood flow (Arthur, 1987).

Some of the common local anesthetics (e.g., tetracaine) are esters. They are hydrolyzed and inactivated primarily by a plasma esterase, probably plasma cholinesterase. The liver also participates in hydrolysis of local anesthetics. Since spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation.

The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs the initial reactions involving N-dealkylation and subsequent hydrolysis (Arthur, 1987). However, with prilocaine, the initial step is hydrolytic, forming ω-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution. The amide-linked local anesthetics are extensively (55-95%) bound to plasma proteins, particularly α1-acid glycoprotein. Many factors increase (e.g., cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (e.g., oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Plasma proteins are not the sole determinant of local anesthetic availability. Uptake by the lung also may play an important role in the distribution of amide-linked local anesthetics in the body. Reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives.

**COCaine**

**Chemistry.** Cocaine, an ester of benzoic acid and methylecgonine, occurs in abundance in the leaves of the coca shrub. Ecgonine is an amino alcohol base closely related to tropine, the amino alcohol in atropine. It has the same fundamental structure as the synthetic local anesthetics (Figure 20–1).

**Pharmacological Actions and Preparations.** The clinically desired actions of cocaine are the blockade of nerve impulses, as a consequence of its local anesthetic properties, and local vasoconstriction, secondary to inhibition of local NE reuptake. Toxicity and its potential for abuse have steadily decreased the clinical uses of cocaine. Its high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems. Its euphoric properties are due primarily to inhibition of catecholamine uptake, particularly DA, in the CNS. Other local anesthetics do not block the uptake of NE and do not produce the sensitization to catecholamines, vasoconstriction, or mydriasis characteristic of cocaine. Currently, cocaine is used mainly for topical anesthesia of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provides anesthesia and shrinking of the mucosa. Cocaine hydrochloride is provided as a 1%, 4%, or 10% solution for topical application. For most applications, the 1% or 4% preparation is preferred to reduce toxicity. Because of its abuse potential, cocaine is listed as a Schedule II controlled substance by the U.S. Drug Enforcement Agency.

**LIDOCAINE**

Lidocaine (XYLOCAINE, others), an aminoethylamide (Figure 20–1), is the prototypical amide local anesthetic.

**Pharmacological Actions.** Lidocaine produces faster, more intense, longer-lasting, and more extensive anesthesia than does an equal concentration of procaine. Lidocaine is an alternative choice for individuals sensitive to ester-type local anesthetics.

**Absorption, Fate, and Excretion.** Lidocaine is absorbed rapidly after parenteral administration and from the GI and respiratory tracts. Although it is effective when used without any vasoconstrictor, ephedrine decreases the rate of absorption, such that the toxicity is decreased and the duration of action usually is prolonged. In addition to preparations for injection, lidocaine is formulated for topical, ophthalmic, mucosal, and transdermal use.

A lidocaine transdermal patch (LIDODERM) is used for relief of pain associated with postherpetic neuralgia. An oral patch (DENTIPATCH) is available for application to accessible mucous membranes of the mouth prior to superficial dental procedures. The combination of lidocaine (2.5%) and prilocaine (2.5%) in an occlusive dressing (EMLA, others) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia. Lidocaine in combination with tetracaine (PLIAGLIS) in a formulation that generates a “peel” is approved for topical local analgesia prior to superficial dermatological procedures such as filler injections and laser-based treatments. Lidocaine in combination with tetracaine is marketed in a formulation that generates heat upon exposure to air (SYNERA), which is used prior to venous access and superficial dermatological procedures such as excision, electrodesication, and shave biopsy of skin lesions. The mild warming is intended to increase skin temperature by up to 5°C for the purpose of enhancing delivery of local anesthetic into the skin.
Lidocaine is dealkylated in the liver by CYPs to monoethylglycine xylidide and glycine xylidide, which can be metabolized further to monoethylglycine and xylidide. Both monoethylglycine xylidide and glycine xylidide retain local anesthetic activity. In humans, ~75% of the xylidide is excreted in the urine as the further metabolite 4-hydroxy-2, 6-dimethyline (Arthur, 1987).

Toxicity. The side effects of lidocaine seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression usually occurs at serum lidocaine levels that produce marked CNS effects. The metabolites monoethylglycine xylidide and glycine xylidide may contribute to some of these side effects.

Clinical Uses. Lidocaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an antiarrhythmic agent (Chapter 29).

BUPIVACAINE

Pharmacological Actions. Bupivacaine (MARCAINE, SENSORCAINE, others), is a widely used amide local anesthetic; its structure is similar to that of lidocaine except that the amine-containing group is a butyl piperidine (Figure 20–1). Bupivacaine is a potent agent capable of producing prolonged anesthesia. Its long duration of action plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or period of the postoperative period. By taking advantage of indwelling catheters and continuous infusions, bupivacaine can be used to provide several days of effective analgesia.

Toxicity. Bupivacaine is more cardiotoxic than equi-effective doses of lidocaine. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration. Although lidocaine and bupivacaine both rapidly block cardiac Na+ channels during systole, bupivacaine dissociates much more slowly than does lidocaine during diastole, so a significant fraction of Na+ channels at physiological heart rates remains blocked with bupivacaine at the end of diastole (Clarkson and Hondeghem, 1985). Thus, the block by bupivacaine is cumulative and substantially more than would be predicted by its local anesthetic potency. At least a portion of the cardiac toxicity of bupivacaine may be mediated centrally, as direct injection of small quantities of bupivacaine into the medulla can produce malignant ventricular arrhythmias (Thomas et al., 1986). Bupivacaine-induced cardiac toxicity can be very difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia.

OTHER SYNTHETIC LOCAL ANESTHETICS

The number of synthetic local anesthetics is so large that it is impractical to consider them all here. Some local anesthetic agents are too toxic to be given by injection. Their use is restricted to topical application to the eye (Chapter 64), the mucous membranes, or the skin (Chapter 65). Many local anesthetics are suitable, however, for infiltration or injection to produce nerve block; some of these also are useful for topical application. The main categories of local anesthetics are given in the following discussion; agents are listed alphabetically. See Figure 20–1 for their structures.

Local Anesthetics Suitable for Injection

Articaine. Articaine (SEPTOCAINE) is approved in the U.S. for dental and periodontal procedures. Although it is an amide local anesthetic, it also contains an ester, whose hydrolysis terminates its action. Thus, articaine exhibits a rapid onset (1-6 minutes) and duration of action of ~1 hour.

Chloroprocaine. Chloroprocaine (NESACAINE, others) is a chlorinated derivative of procaine. Its major assets are its rapid onset and short duration of action and its reduced acute toxicity due to its rapid metabolism (plasma t1/2 ~25 seconds). Enthusiasm for its use has been tempered by reports of prolonged sensory and motor block after epidural or subarachnoid administration of large doses. This toxicity appears to have been a consequence of low pH and the use of sodium metabisulfite as a preservative in earlier formulations. There are no reports of neurotoxicity with newer preparations of chloroprocaine, which contain calcium EDTA as the preservative, although these preparations also are not recommended for intrathecal administration. A higher than expected incidence of muscular back pain following epidural anesthesia with 2-chloroprocaine has also been reported (Stevens et al., 1993). This back pain is thought to be due to tetany in the paraspinal muscles, which may be a consequence of Ca2+ binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

Mepivacaine. Mepivacaine (CARBOCAINE, POLOCAINE, others) is an intermediate-acting amino amide. Its pharmacological properties are similar to those of lidocaine. Mepivacaine, however, is more toxic to the neonate and thus is not used in obstetrical anesthesia. The increased toxicity of mepivacaine in the neonate is related to ion trapping of this agent because of the lower pH of neonatal blood and the pKa of mepivacaine rather than to its slower metabolism in the neonate. It appears to have a slightly higher therapeutic index in adults than does lidocaine. Its onset of action is similar to that of lidocaine and its duration slightly longer (~20%) than that of lidocaine in the absence of a co-administered vasoconstrictor. Mepivacaine is not effective as a topical anesthetic.

Prilocaine. Prilocaine (CITANEST) is an intermediate-acting amino amide. It has a pharmacological profile similar to that of lidocaine. The primary differences are that it causes little vasodilation and thus can be used without a vasoconstrictor, and its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks (described later). The use of prilocaine is largely limited to dentistry because the drug is unique among the local anesthetics in its propensity to cause methemoglobinemia. This effect is a consequence of the metabolism of the aromatic ring to o-toluidine. Development of methemoglobinemia is dependent on the total dose administered, usually appearing after a dose of 8 mg/kg. If necessary, it can be treated by the intravenous administration of methylene blue (1-2 mg/kg). Methemoglobinemia following prilocaine has limited its use in obstetrical anesthesia, because it
complicates evaluation of the newborn. Also, methemoglobinemia is more common in neonates due to decreased resistance of fetal hemoglobin to oxidant stresses and the immaturity of enzymes in the neonate that convert methemoglobin back to the ferrous state.

**Ropivacaine.** The cardiac toxicity of bupivacaine stimulated interest in developing a less toxic, long-lasting local anesthetic. One result of that search was the development of the amino ethylamide ropivacaine (NAROPIN, others), the S-enantiomer of 1-propyl-2,6-dipropylcarba-zoic acid, which inhibits the action of sulfonamides. Thus, large doses should not be administered to patients taking sulfonamide drugs. In addition to being less cardiotoxic than equivalent doses of bupivacaine, ropivacaine appears to be suitable for both epidural and regional anesthesia, with a duration of action similar to that of bupivacaine. Interestingly, it seems to be even more motor-sparing than bupivacaine.

**Procaine.** Procaine (NOVOCAIN, others), introduced in 1905, was the first synthetic local anesthetic and is an amino ester. It has been supplanted by newer agents, and its use now is confined to infiltration anesthesia and occasionally for diagnostic nerve blocks. This is because of its low potency, slow onset, and short duration of action. While its toxicity is fairly low, it is hydrolyzed in vivo to produce para-aminobenzoic acid, which inhibits the action of sulfonamides. Thus, large doses should not be administered to patients taking sulfonamide drugs.

**Tetracaine.** Tetracaine (PONTOCaine), is a long-acting amino ester. It is significantly more potent and has a longer duration of action than procaine. Tetracaine may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. Currently, it is widely used in spinal anesthesia. Dyclonine hydrochloride has a rapid onset of action and duration of effect comparable to that of procaine. It is absorbed through the skin and mucous membranes. The compound has been used as 0.5% or 1% solution for topical anesthesia during endoscopy, for oral mucositis pain following radiation or chemotherapy, and for anogenital procedures; however, marketing of these solutions has been discontinued in the U.S. Dyclonine is an active ingredient in a number of over-the-counter medications including sore throat lozenges (SUCRETS, others), a patch for cold sores (ORAJEL OVERNIGHT COLD SORE PATCH), and a 0.75% solution (SKIN SHIELD LIQUID BANDAGE).

**Anesthetics of Low Solubility**

Some local anesthetics are poorly soluble in water, and consequently are too slowly absorbed to be toxic. They can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained anesthetic action. Chemically, they are esters of para-aminobenzoic acid lacking the terminal amino group possessed by the previously described local anesthetics. The most important member of the series is benzocaine (ethylaminobenzoate; HURRICANE, OTHERS). Benzocaine is structurally similar to procaine, but lacks the terminal diethylamino group (Figure 20–1). It is incorporated into a large number of topical preparations. Benzocaine can cause methemoglobinemia (see the discussion of methemoglobinemia in the “Prilocaine” section); consequently, dosing recommendations must be followed carefully.

**Local Anesthetics Largely Restricted to Ophthalmological Use**

Anesthesia of the cornea and conjunctiva can be obtained readily by topical application of local anesthetics. However, most of the local anesthetics that have been described are too irritating for ophthalmological use. The first local anesthetic used in ophthalmology, cocaine, has the severe disadvantages of producing mydriasis and corneal sloughing and has fallen out of favor. The two compounds used most frequently today are proparacaine (ALCAINE, OPHTHAINE, OTHERS) and tetracaine (Figure 20–1). In addition to being less irritating during administration, proparacaine has the added advantage of bearing little antigenic similarity to the other benzoate local anesthetics. Thus, it sometimes can be used in individuals sensitive to the amino ester local anesthetics.

For use in ophthalmology, these local anesthetics are instilled as a single drop at a time. If anesthesia is incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus it is longest in normal cornea and shortest in inflamed conjunctiva. In the latter case repeated instillations may be necessary to maintain adequate anesthesia for the duration of the procedure. Long-term administration of topical anesthesia to the eye has been associated with retarded healing, pitting, and sloughing of the corneal epithelium, and predisposition of the eye to inadvertent injury. Thus, these drugs should not be prescribed for self-administration. For drug delivery, pharmacokinetics, and toxicity issues unique to drugs for ophthalmic use, see Chapter 64.
BIOLOGICAL TOXINS: TETRODOTOXIN AND SAXITOXIN

These two biological toxins also block the pore of the Na+ channel. Tetrodotoxin is found in the gonads and other visceral tissues of some fish of the order Tetraodontiformes (to which the Japanese fugu, or puffer fish, belongs); it also occurs in the skin of some newts of the family Salamandridae and of the Costa Rican frog Atelopus. Saxitoxin is elaborated by the dinoflagellates Gonyaulax catenella and G. tamarensis and retained in the tissues of clams and other shellfish that eat these organisms. Given the right conditions of temperature and light, the dinoflagellates Gonyaulax may multiply so rapidly as to discolor the ocean, causing the condition known as red tide. Shellfish feeding on Gonyaulax at this time become extremely toxic to humans and are responsible for periodic outbreaks of paralytic shellfish poisoning (Stommel and Watters, 2004). Although the toxins are chemically different from each other, their mechanisms of action are similar (Ritchie, 1980). Both toxins, in nanomolar concentrations, specifically block the outer mouth of the pore of Na+ channels in the membranes of excitable cells. As a result, the action potential is blocked. The receptor site for these toxins is formed by amino acid residues in the P loop of the Na+ channel α subunit (Figure 20-2) in all four domains (Catterall, 2000; Terlau et al., 1991). Not all Na+ channels are equally sensitive to tetrodotoxin; some Na+ channels in cardiac myocytes and dorsal root ganglion neurons are resistant, and a tetrodotoxin-resistant Na+ channel is expressed when skeletal muscle is denervated. Tetrodotoxin and saxitoxin are two of the most potent poisons known; the minimal lethal dose of each in the mouse is ~ 8 μg/kg. Both toxins have caused fatal poisoning in humans due to paralysis of the respiratory muscles; therefore the treatment of severe cases of poisoning requires support of respiration. Blockade of vasomotor nerves, together with a relaxation of vascular smooth muscle, seems to be responsible for the hypotension that is characteristic of tetrodotoxin poisoning. Early gastric lavage and pressor support also are indicated. If the patient survives paralytic shellfish poisoning for 24 hours, the prognosis is good.

CLINICAL USES OF LOCAL ANESTHETICS

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers two major advantages. First, physiological perturbations associated with general anesthesia are avoided; second, neurophysiological responses to pain and stress can be modified beneficially. As already discussed, local anesthetics can potentially produce deleterious side effects. Proper choice of a local anesthetic and care in its use are the primary determinants in avoiding toxicity. There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Furthermore, peak plasma levels vary widely depending on the area of injection. They are highest with interpleural or intercostal blocks and lowest with subcutaneous infiltration. Thus, recommended maximum doses serve only as general guidelines.

This discussion summarizes the pharmacological and physiological consequences of the use of local anesthetics categorized by method of administration. A more comprehensive discussion of their use and administration is presented in textbooks on regional anesthesia (e.g., Cousins et al., 2008).

Topical Anesthesia

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. Tetracaine (2%), lidocaine (2-10%), and cocaine (1-4%) typically are used. Cocaine is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia. The shrinking of mucous membranes decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as phenylephrine (0.005%). Epinephrine, topically applied, has no significant local effect and does not prolong the duration of action of local anesthetics applied to mucous membranes because of poor penetration. Maximal safe total dosages for topical anesthesia in a healthy 70-kg adult are 300 mg for lidocaine, 150 mg for cocaine, and 50 mg for tetracaine.

Peak anesthetic effect following topical application of cocaine or lidocaine occurs within 2-5 minutes (3-8 minutes with tetracaine), and anesthesia lasts for 30-45 minutes (30-60 minutes with tetracaine). Anesthesia is entirely superficial; it does not extend to submucosal structures. This technique does not alleviate joint pain or discomfort from subdermal inflammation or injury.

Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions. Systemic toxicity has occurred even following the use of local anesthetics to control discomfort associated with severe diaper rash in infants. Absorption is particularly rapid when local anesthetics are applied to the tracheobronchial tree. Concentrations in blood after instillation of local anesthetics into the airway are nearly the same as those following intravenous injection. Surface anesthetics for the skin and cornea have been described earlier in the chapter.

Use of eutectic mixtures of local anesthetics lidocaine (2.5%)/prilocaine (2.5%) (EMLA) and lidocaine (7%)/tetracaine (7%) (PLAGIS) bridges the gap between topical and infiltration anesthesia. The efficacy of each of these combinations lies in the fact that the mixture has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. These creams produce anesthesia to a maximum depth of 5 mm and are applied as a cream on intact skin under an occlusive dressing in advance (~30-60 min) of any procedure. These mixtures are effective for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). The component local anesthetics will be absorbed into the systemic circulation, potentially producing toxic effects, as described earlier. Guidelines are available to calculate the maximum
amount of cream that can be applied and area of skin covered. These mixtures must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.

**Infiltration Anesthesia**

Infiltration anesthesia is the injection of local anesthetic directly into tissue without taking into consideration the course of cutaneous nerves. Infiltration anesthesia can be so superficial as to include only the skin. It also can include deeper structures, including intra-abdominal organs, when these too are infiltrated.

The duration of infiltration anesthesia can be approximately doubled by the addition of epinephrine (5 μg/mL) to the injection solution; epinephrine also decreases peak concentrations of local anesthetics in blood. Epinephrine-containing solutions should not, however, be injected into tissues supplied by end arteries—for example, fingers and toes, ears, the nose, and the penis. The resulting vasoconstriction may cause gangrene. For the same reason, epinephrine should be avoided in solutions injected intracutaneously. Since epinephrine also is absorbed into the circulation, its use should be avoided in those for whom adrenergic stimulation is undesirable.

The local anesthetics used most frequently for infiltration anesthesia are lidocaine (0.5-1%), procaine (0.5-1%), and bupivacaine (0.125-0.25%). When used without epinephrine, up to 4.5 mg/kg of lidocaine, 7 mg/kg of procaine, or 2 mg/kg of bupivacaine can be employed in adults. When epinephrine is added, these amounts can be increased by one-third.

The advantage of infiltration anesthesia and other regional anesthetic techniques is that it can provide satisfactory anesthesia without disrupting normal bodily functions. The chief disadvantage of infiltration anesthesia is that relatively large amounts of drug must be used to anesthetize relatively small areas. This is no problem with minor surgery. When major surgery is performed, however, the amount of local anesthetic that is required makes systemic toxic reactions likely. The amount of anesthetic required to anesthetize an area can be reduced significantly and the duration of anesthesia increased markedly by specifically blocking the nerves that innervate the area of interest. This can be done at one of several levels: subcutaneously, at major nerves, or at the level of the spinal roots.

**Field Block Anesthesia**

Field block anesthesia is produced by subcutaneous injection of a solution of local anesthetic in order to anesthetize the region distal to the injection. For example, subcutaneous infiltration of the proximal portion of the volar surface of the forearm results in an extensive area of cutaneous anesthesia that starts 2-3 cm distal to the site of injection. The same principle can be applied with particular benefit to the scalp, the anterior abdominal wall, and the lower extremity.

The drugs, concentrations, and doses recommended are the same as for infiltration anesthesia. The advantage of field block anesthesia is that less drug can be used to provide a greater area of anesthesia than when infiltration anesthesia is used. Knowledge of the relevant neuroanatomy obviously is essential for successful field block anesthesia.

**Nerve Block Anesthesia**

Injection of a solution of a local anesthetic into or about individual peripheral nerves or nerve plexuses produces even greater areas of anesthesia than do the techniques already described. Blockade of mixed peripheral nerves and nerve plexuses also usually anesthetizes somatic motor nerves, producing skeletal muscle relaxation, which is essential for some surgical procedures. The areas of sensory and motor block usually start several centimeters distal to the site of injection. Brachial plexus blocks are particularly useful for procedures on the upper extremity and shoulder. Intercostal nerve blocks are effective for anesthesia and relaxation of the anterior abdominal wall. Cervical plexus block is appropriate for surgery of the neck. Sciatic and femoral nerve blocks are useful for surgery distal to the knee. Other useful nerve blocks prior to surgical procedures include blocks of individual nerves at the wrist and at the ankle, blocks of individual nerves such as the median or ulnar at the elbow, and blocks of sensory cranial nerves.

There are four major determinants of the onset of sensory anesthesia following injection near a nerve:

- proximity of the injection to the nerve
- concentration and volume of drug
- degree of ionization of the drug
- time

Local anesthetic is never intentionally injected into the nerve, as this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible. Thus the local anesthetic must diffuse from the site of injection into the nerve, where it acts. The rate of diffusion is determined chiefly by the concentration of the drug, its degree of ionization (ionized local anesthetic diffuses more slowly), its hydrophobicity, and the physical characteristics of the tissue surrounding the nerve. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve block. The utility of higher concentrations, however, is limited by systemic toxicity and by direct neural toxicity of concentrated local anesthetic solutions. For a given concentration, local anesthetics with lower \( pK_a \) values tend to have a more rapid onset of action because more drug is uncharged at neutral pH. For example, the onset of action of lidocaine occurs in ~3 minutes; 35% of lidocaine is in the basic form at pH 7.4. In contrast, the onset of action of bupivacaine requires ~15 minutes; only 5-10% of bupivacaine is uncharged at this pH. Increased hydrophobicity might be expected to speed onset by increased penetration into nerve tissue. However, it also will increase binding in tissue lipids. Furthermore, the more hydrophobic local anesthetics also are more potent (and toxic) and thus must be used at lower concentrations, decreasing the concentration gradient for diffusion. Tissue factors also play a role in determining the rate of onset of anesthetic effects. The amount of connective tissue that must be penetrated can be significant in a nerve plexus compared to isolated nerves and can slow or even prevent adequate diffusion of local anesthetic to the nerve fibers.

Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. Especially important physical characteristics are lipid solubility and protein binding. Local anesthetics can be broadly divided into three categories:

- those with a short (20-45 minutes) duration of action in mixed peripheral nerves, such as procaine
- those with an intermediate (60-120 minutes) duration of action, such as lidocaine and mepivacaine
• those with a long (400-450 minutes) duration of action, such as bupivacaine, ropivacaine, and tetracaine

Block duration of the intermediate-acting local anesthetics such as lidocaine can be prolonged by the addition of epinephrine (5 μg/mL). The degree of block prolongation in peripheral nerves following the addition of epinephrine appears to be related to the intrinsic vasodilatory properties of the local anesthetic and thus is most pronounced with lidocaine.

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve-fiber size, internodal distance, and frequency and pattern of nerve-impulse transmission (see above, sections on Frequency and Voltage-Dependence and Differential Sensitivity). Anatomical factors are similarly important. A mixed peripheral nerve or nerve trunk consists of individual nerves surrounded by an investing epineurium. The vascular supply usually is centrally located. When a local anesthetic is deposited about a peripheral nerve, it diffuses from the outer surface toward the core along a concentration gradient (DeJong, 1994; Winnie et al., 1977). Consequently, nerves in the outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Lesser amounts of drug will block only nerves in the mantle and the smaller and more sensitive central fibers. Furthermore, since removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2-4 hours, lidocaine (1-1.5%) can be used in the amounts recommended earlier (see "Infiltration Anesthesia"). Mepivacaine (up to 7 mg/kg of a 1-2% solution) provides anesthesia that lasts about as long as that from lidocaine. Bupivacaine (2-3 mg/kg of a 0.25-0.375% solution) can be used when a longer duration of action is required. Addition of 5 μg/mL epinephrine slows systemic absorption and therefore prolongs duration and lowers the plasma concentration of the intermediate-acting local anesthetics.

Peak plasma concentrations of local anesthetics depend on the amount injected, the physical characteristics of the local anesthetic, whether epinephrine is used, the rate of blood flow to the site of injection, and the surface area exposed to local anesthetic. This is of particular importance in the safe application of nerve block anesthesia, since the potential for systemic reactions is related to peak free serum concentrations. For example, peak concentrations of lidocaine in blood following injection of 400 mg without epinephrine for intercostal nerve blocks average 7 μg/mL; the same amount of lidocaine used for block of the brachial plexus results in peak concentrations in blood of ~3 μg/mL (Covino and Vassallo, 1976). Therefore, the amount of local anesthetic that can be injected must be adjusted according to the anatomical site of the nerve(s) to be blocked to minimize untoward effects. Addition of epinephrine can decrease peak plasma concentrations by 20-30%. Multiple nerve blocks (e.g., intercostal block) or blocks performed in vascular regions require reduction in the amount of anesthetic that can be given safely, because the surface area for absorption or the rate of absorption is increased.

Intravenous Regional Anesthesia (Bier’s Block)

This technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique, an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100-150 mm Hg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5-10 minutes. Pain from the tourniquet and the potential for ischemic nerve injury limits tourniquet inflation to 2 hours or less. However, the tourniquet should remain inflated for at least 15-30 minutes to prevent toxic amounts of local anesthetic from entering the circulation following deflation. Lidocaine, 40-50 mL (0.5 mL/kg in children) of a 0.5% solution without epinephrine is the drug of choice for this technique. For intravenous regional anesthesia in adults using a 0.5% solution without epinephrine, the dose administered should not exceed 4 mg/kg. A few clinicians prefer prilocaine (0.5%) over lidocaine because of its higher therapeutic index. The attractiveness of this technique lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic (e.g., 50 mL of 0.5% lidocaine contains 250 mg of lidocaine). For the last reason and because its longer durations of action offer no advantage, the more cardiotoxic local anesthetic, bupivacaine, is not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand, but can be adapted for the foot and distal leg.

Spinal Anesthesia

Spinal anesthesia follows the injection of local anesthetic into the cerebrospinal fluid (CSF) in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia remains one of the most popular forms of anesthesia. In most adults, the spinal cord terminates above the second lumbar vertebra; between that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

A brief discussion of the physiological effects of spinal anesthesia relating to the pharmacology of the local anesthetics used is presented here. See more specialized texts (e.g., Cousins et al., 2008) for additional details.

Physiological Effects of Spinal Anesthesia. Most of the physiological side effects of spinal anesthesia are a consequence of the sympathetic blockade produced by local anesthetic block of the sympathetic fibers in the spinal nerve roots. A thorough understanding of these physiological effects is necessary for the safe and
successful application of spinal anesthesia. Although some of them may be deleterious and require treatment, others can be beneficial for the patient or can improve operating conditions. Most sympathetic fibers leave the spinal cord between T1 and L2 (Chapter 8, Figure 8–1). Although local anesthetic is injected below these levels in the lumbar portion of the dural sac, cephalad spread of the local anesthetic occurs with all but the smallest volumes injected. This cephalad spread is of considerable importance in the practice of spinal anesthesia and potentially is under the control of numerous variables, of which patient position and baricity (density of the drug relative to the density of the CSF) are the most important (Greene, 1983). The degree of sympathetic block is related to the height of sensory anesthesia; often the level of sympathetic blockade is several spinal segments higher, since the preganglionic sympathetic fibers are more sensitive to low concentrations of local anesthetic. The effects of sympathetic blockade involve both the actions (now partially unopposed) of the parasympathetic nervous system and the response of the unblocked portion of the sympathetic nervous system. Thus, as the level of sympathetic block ascends, the actions of the parasympathetic nervous system are increasingly dominant, and the compensatory mechanisms of the unblocked sympathetic nervous system are diminished. As most sympathetic nerve fibers leave the cord at T1 or below, few additional effects of sympathetic blockade are seen with cervical levels of spinal anesthesia. The consequences of sympathetic blockade will vary among patients as a function of age, physical conditioning, and disease state. Interestingly, sympathetic blockade during spinal anesthesia appears to be minimal in healthy children.

Clinically, the most important effects of sympathetic blockade during spinal anesthesia are on the cardiovascular system. At all but the lowest levels of spinal blockade, some vasodilation will occur. Vasodilation is more marked on the venous than on the arterial side of the circulation, resulting in blood pooling in the venous capacitance vessels. This reduction in circulating blood volume is well tolerated at low levels of spinal anesthesia in healthy patients. With an increasing level of block, this effect becomes more marked and venous return becomes gravity-dependent. If venous return decreases too much, cardiac output and organ perfusion decline precipitously. Venous return can be increased by a modest (10-15 degree) head-down tilt or by elevating the legs. At high levels of spinal blockade, the cardiac accelerometer fibers, which exit the spinal cord at T1-T4, will be blocked. This is detrimental in patients dependent on elevated sympathetic tone to maintain cardiac output (e.g., during congestive heart failure or hypovolemia), and it also removes one of the compensatory mechanisms available to maintain organ perfusion during vasodilation. Thus, as the level of spinal block ascends, the rate of cardiovascular compromise can accelerate if not carefully observed and treated. Sudden asystole also can occur, presumably because of loss of sympathetic innervation in the continued presence of parasympathetic activity at the sinoatrial node (Caplan et al., 1988). In the usual clinical situation, blood pressure serves as a surrogate marker for cardiac output and organ perfusion. Treatment of hypotension usually is warranted when the blood pressure decreases to ~30% of resting values. Therapy is aimed at maintaining brain and cardiac perfusion and oxygenation. To achieve these goals, administration of oxygen, fluid infusion, manipulation of patient position, and the administration of vasoactive drugs are all options. In practice, patients typically are administered a bolus (500-1000 mL) of fluid prior to the administration of spinal anesthesia in an attempt to prevent some of the deleterious effects of spinal blockade. Since the usual cause of hypotension is decreased venous return, possibly complicated by decreased heart rate, drugs with preferential vasoconstrictive and chronotropic properties are preferred. For this reason, ephedrine, 5-10 mg intravenously, often is the drug of choice. In addition to the use of ephedrine to treat deleterious effects of sympathetic blockade, direct-acting α1 adrenergic receptor agonists such as phenylephrine (Chapter 12) can be administered either by bolus or continuous infusion.

A beneficial effect of spinal anesthesia partially mediated by the sympathetic nervous system is on the intestine. Sympathetic fibers originating from T5-L1 inhibit peristalsis; thus, their blockade produces a small, contracted intestine. This, together with a flaccid abdominal musculature, produces excellent operating conditions for some types of bowel surgery. The effects of spinal anesthesia on the respiratory system mostly are mediated by effects on the skeletal musculature. Paralysis of the intercostal muscles will reduce a patient’s ability to cough and clear secretions, which may produce dyspnea in patients with bronchitis or emphysema. Respiratory arrest during spinal anesthesia is seldom due to paralysis of the phrenic nerves or to toxic levels of local anesthetic in the CSF of the fourth ventricle; it is much more likely to be due to medullary ischemia secondary to hypotension.

**Pharmacology of Spinal Anesthesia.** Currently in the U.S., the drugs most commonly used in spinal anesthesia are lidocaine, tetracaine, and bupivacaine. Procaine occasionally is used for diagnostic blocks when a short duration of action is desired. The choice of local anesthetic is primarily determined by the desired duration of anesthesia. General guidelines are to use lidocaine for short procedures, bupivacaine for intermediate to long procedures, and tetracaine for long procedures. As mentioned earlier, the factors contributing to the distribution of local anesthetics in the CSF have received much attention because of their importance in determining the height of block. The most important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. The speed of injection of the local anesthesia solution also may affect the height of the block, just as the position of the patient can influence the rate of distribution of the anesthetic agent and the height of blockade achieved (described in the next section). For a given preparation of local anesthetic, administration of increasing amounts leads to a fairly predictable increase in the level of block attained. For example, 100 mg of lidocaine, 20 mg of bupivacaine, or 12 mg of tetracaine usually will result in a T4 sensory block. More complete tables of these relationships can be found in standard anesthesiology texts. Epinephrine often is added to spinal anesthetics to increase the duration or intensity of block. Epinephrine’s effect on duration of block is dependent on the technique used to measure duration. A commonly used measure of block duration is the length of time it takes for the block to recede by two dermatomes from the maximum height of the block, while a second is the duration of block at some specified level, typically L1. In most studies, addition of 200 μg of epinephrine to tetracaine solutions prolongs the duration of block by both measures. However, addition of epinephrine to lidocaine or bupivacaine does not affect the first measure of duration, but does prolong the block at lower levels of sympathetic block.
levels. In different clinical situations, one or the other measure of anesthesia duration may be more relevant, and this must be kept in mind when deciding whether to add epinephrine to spinal local anesthetics. The mechanism of action of vasoconstrictors in prolonging spinal anesthesia is uncertain. It has been hypothesized that these agents decrease spinal cord blood flow, decreasing clearance of local anesthetic from the CSF, but this has not been convincingly demonstrated. Epinephrine and other α-adrenergic agonists have been shown to decrease nociceptive transmission in the spinal cord, and studies in genetically modified mice suggest that α2 adrenergic receptors play a principal role in this response (Stone et al., 1997). Such actions may contribute to the beneficial effects of epinephrine, clonidine, and dexmedetomidine when these agents are added to spinal local anesthetics.

Drug Baricity and Patient Position. The baricity of the local anesthetic injected will determine the direction of migration within the dural sac. Hyperbaric solutions will tend to settle in the dependent portions of the sac, while hypobaric solutions will tend to migrate in the opposite direction. Isobaric solutions usually will stay in the vicinity where they were injected, diffusing slowly in all directions. Consideration of the patient position during and after the performance of the block and the choice of a local anesthetic of the appropriate baricity is crucial for a successful block during some surgical procedures. Lidocaine and bupivacaine are marketed in both isobaric and hyperbaric preparations, and if desired, can be diluted with sterile, preservative-free water to make them hypobaric.

Complications of Spinal Anesthesia. Persistent neurological deficits following spinal anesthesia are extremely rare. Thorough evaluation of a suspected deficit should be performed in collaboration with a neurologist. Neurological sequelae can be both immediate and late. Possible causes include introduction of foreign substances (such as disinfectants or talc) into the subarachnoid space, infection, hematoma, or direct mechanical trauma. Aside from drainage of an abscess or hematoma, treatment usually is ineffective; thus, avoidance and careful attention to detail while performing spinal anesthesia are necessary.

High concentrations of local anesthetic can cause irreversible block. After administration, local anesthetic solutions are diluted rapidly, quickly reaching nontoxic concentrations. However, there are several reports of transient or longer-lasting neurological deficits following lidocaine spinal anesthesia, particularly with 5% lidocaine (i.e., 180 mmol) in 7.5% glucose (Zaric and Pace, 2009). Spinal anesthesia sometimes is regarded as contraindicated in patients with pre-existing disease of the spinal cord. No experimental evidence exists to support this hypothesis. Nonetheless, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. However, spinal anesthesia may be very useful in patients with fixed, chronic spinal cord injury.

A more common sequela following any lumbar puncture, including spinal anesthesia, is a postural headache with classic features. The incidence of headache decreases with increasing age of the patient and decreasing needle diameter. Headache following lumbar puncture must be thoroughly evaluated to exclude serious complications such as meningitis. Treatment usually is conservative, with bed rest and analgesics. If this approach fails, an epidural blood patch with the injection of autologous blood can be performed; this procedure usually is successful in alleviating postdural puncture headaches, although a second blood patch may be necessary. If two epidural blood patches are ineffective in relieving the headache, the diagnosis of postdural puncture headache should be reconsidered. Intravenous caffeine (500 mg as the benzoate salt administered over 4 hours) also has been advocated for the treatment of postdural puncture headache; however, the efficacy of caffeine is less than that of a blood patch, and relief usually is transient.

Evaluation of Spinal Anesthesia. Spinal anesthesia is a safe and effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. It often is combined with intravenous medication to provide sedation and amnesia. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. The sympathetic blockade that accompanies levels of spinal anesthesia adequate for mid- or upper-abdominal surgery, coupled with the difficulty in achieving visceral analgesia, is such that equally satisfactory and safer operating conditions can be realized by combining the spinal anesthesia with a “light” general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

Epidural Anesthesia
Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Epidural anesthesia can be performed in the sacral hiatus (caudal anesthesia) or in the lumbar, thoracic, or cervical regions of the spine. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action of epidurally administered local anesthetics is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.

The selection of drugs available for epidural anesthesia is similar to that for major nerve blocks. As for spinal anesthesia, the choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. Bupivacaine, 0.5-0.75%, is used when a long duration of surgical block is desired. Due to enhanced cardiotoxicity in pregnant patients, the 0.75% solution is not approved for obstetrical use. Lower concentrations—0.25%, 0.125%, or 0.0625%—of bupivacaine, often with 2 µg/mL of fentanyl added, frequently are used to provide analgesia during labor. They also are useful preparations for providing postoperative analgesia in certain clinical situations. Lidocaine 2% is the most frequently used intermediate-acting epidural local anesthetic. Chloroprocaine, 2% or 3%, provides rapid onset and a very short duration of anesthetic action. However, its use in epidural anesthesia has been clouded by controversy regarding its potential ability to cause neurological complications if the drug is accidentally injected into the subarachnoid space (discussed earlier). The duration of action of epidurally administered local anesthetics frequently is prolonged, and systemic toxicity decreased, by addition of epinephrine. Addition of epinephrine also makes inadvertent
intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia.

For each anesthetic agent, a relationship exists between the volume of local anesthetic injected epidurally and the segmental level of anesthesia achieved. For example, in 20- to 40-year-old, healthy, nonpregnant patients, each 1-1.5 mL of 2% lidocaine will give an additional segment of anesthesia. The amount needed decreases with increasing age and also decreases during pregnancy and in children.

The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only preganglionic sympathetic fibers. As an example, with bupivacaine these effects might be achieved with concentrations of 0.5%, 0.25%, and 0.0625%, respectively. The total amounts of drug that can be injected with safety at one time are approximately those mentioned earlier in the chapter under “Nerve Block Anesthesia” and “Infiltration Anesthesia.” Performance of epidural anesthesia requires a greater degree of skill than does spinal anesthesia. The technique of epidural anesthesia and the volumes, concentrations, and types of drugs used are described in detail in standard texts on regional anesthesia (e.g., Cousins et al., 2008).

A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space. Peak concentrations of lidocaine in blood following injection of 400 mg (without epinephrine) into the lumbar epidural space average 3-4 μg/mL; peak concentrations of bupivacaine in blood average 1 μg/mL after the lumbar epidural injection of 150 mg. Addition of epinephrine (5 μg/mL) decreases peak plasma concentrations by ~25%. Peak blood concentrations are a function of the total dose of drug administered rather than the concentration or volume of solution following epidural injection (Covino and Vassallo, 1976). The risk of inadvertent intravascular injection is increased in epidural anesthesia, as the epidural space contains a rich venous plexus.

Another major difference between epidural and spinal anesthesia is that there is no zone of differential sympathetic block with epidural anesthesia; thus, the level of sympathetic block is close to the level of sensory block. Because epidural anesthesia does not result in the zones of differential sympathetic blockade observed during spinal anesthesia, cardiovascular responses to epidural anesthesia might be expected to be less prominent. In practice this is not the case; the potential advantage of epidural anesthesia is offset by the cardiovascular responses to the high concentration of anesthetic in blood that occurs during epidural anesthesia. This is most apparent when, as is often the case, epinephrine is added to the epidural injection. The resulting concentration of epinephrine in blood is sufficient to produce significant \( \beta \) adrenergic receptor-mediated vasodilation. As a consequence, blood pressure decreases, even though cardiac output increases due to the positive inotropic and chronotropic effects of epinephrine (Chapter 12). The result is peripheral hyperperfusion and hypotension. Differences in cardiovascular responses to equal levels of spinal and epidural anesthesia also are observed when a local anesthetic such as lidocaine is used without epinephrine. This may be a consequence of the direct effects of high concentrations of lidocaine on vascular smooth muscle and the heart. The magnitude of the differences in responses to equal sensory levels of spinal and epidural anesthesia varies, however, with the local anesthetic used for the epidural injection (assuming no epinephrine is used). For example, local anesthetics such as bupivacaine, which are highly lipid soluble, are distributed less into the circulation than are less lipid-soluble agents such as lidocaine.

High concentrations of local anesthetics in blood during epidural anesthesia are especially important when this technique is used to control pain during labor and delivery. Local anesthetics cross the placenta, enter the fetal circulation, and at high concentrations may cause depression of the neonate. The extent to which they do so is determined by dosage, acid-base status, the level of protein binding in both maternal and fetal blood, placental blood flow, and solubility of the agent in fetal tissue. These concerns have been lessened by the trend toward using more dilute solutions of bupivacaine for labor analgesia.

**Epidural and Intrathecal Opiate Analgesia.** Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia (Yaksh and Rudy, 1976). This observation led to the clinical use of spinal and epidural opioids during surgical procedures and for the relief of postoperative and chronic pain (Cousins and Mather, 1984). As with local anesthesia, analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection. Presynaptic opioid receptors inhibit the release of substance \( \text{P} \) and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinthalamic tracts (Willcockson et al., 1986; see also Chapters 8 and 18). Since conduction in autonomic, sensory, and motor nerves is not affected by the opioids, blood pressure, motor function, and non-nociceptive sensory perception typically are not influenced by spinal opioids. The volume-evoked micturition reflex is inhibited, as manifested by urinary retention. Other side effects include pruritus, nausea, and vomiting in susceptible individuals. Delayed respiratory depression and sedation, presumably from cephalad spread of opioid within the CSF, occur infrequently with the doses of opioids currently used.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures. Thus, opioids have found the greatest use in the treatment of postoperative and chronic pain. In selected patients, spinal or epidural opioids can provide excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For post-operative analgesia, spinally administered morphine, 0.2-0.5 mg, usually will provide 8-16 hours of analgesia. Placement of an epidural catheter and repeated boluses or an infusion of opioid permits an increased duration of analgesia. Many opioids have been used epidurally. Morphin, 2-6 mg, every 6 hours, commonly is used for bolus injections, while fentanyl, 20-50 μg/hour, often combined with bupivacaine, 5-20 mg/hour, is used for infusions. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months’ duration. The dose of epidural morphine, e.g., is far less than the...
dose of systemically administered morphine that would be required to provide similar analgesia. This reduces the complications that usually accompany the administration of high doses of systemic opioids, particularly sedation and constipation. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids, but this usually can be managed by increasing the dose.

The epilepsies are common and frequently devastating disorders, affecting ~2.5 million people in the U.S. alone. More than 40 distinct forms of epilepsy have been identified. Epileptic seizures often cause transient impairment of consciousness, leaving the individual at risk of bodily harm and often interfering with education and employment. Therapy is symptomatic in that available drugs inhibit seizures, but neither effective prophylaxis nor cure is available. Compliance with medication is a major problem because of the need for long-term therapy together with unwanted effects of many drugs.

The mechanisms of action of anti-seizure drugs fall into three major categories.

1. The first mechanism is to limit the sustained, repetitive firing of neurons, an effect mediated by promoting the inactivated state of voltage-activated Na⁺ channels.

2. A second mechanism appears to involve enhanced γ-aminobutyric acid (GABA)–mediated synaptic inhibition, an effect mediated either by a presynaptic or postsynaptic action. Drugs effective against the most common forms of epileptic seizures, partial and secondarily generalized tonic-clonic seizures, appear to work by one of these two mechanisms.

3. Drugs effective against absence seizure, a less common form of epileptic seizure, work by a third mechanism, inhibition of voltage-activated Ca²⁺ channels responsible for T-type Ca²⁺ currents.

Although many treatments are available, much effort is being devoted to elucidating the genetic causes and the cellular and molecular mechanisms by which a normal brain becomes epileptic, insights that promise to provide molecular targets for both symptomatic and preventive therapies.

**TERMINOLOGY AND EPILEPTIC SEIZURE CLASSIFICATION**

The term seizure refers to a transient alteration of behavior due to the disordered, synchronous, and rhythmic firing of populations of brain neurons. The term epilepsy refers to a disorder of brain function characterized by the periodic and unpredictable occurrence of seizures. Seizures can be “non-epileptic” when evoked in a normal brain by treatments such as electroshock or chemical convulsants, or “epileptic” when occurring without evident provocation. Pharmacological agents in current clinical use inhibit seizures, and thus are referred to as anti-seizure drugs. Whether any of these prevent the development of epilepsy (epileptogenesis) is uncertain.

Seizures are thought to arise from the cerebral cortex, and not from other central nervous system (CNS) structures such as the thalamus, brainstem, or cerebellum. Epileptic seizures have been classified into partial seizures, those beginning focally in a cortical site, and generalized seizures, those that involve both hemispheres widely from the outset (Commission on Classification and Terminology, 1981). The behavioral manifestations of a seizure are determined by the functions normally served by the cortical site at which the seizure arises. For example, a seizure involving motor cortex is associated with clonic jerking of the body part controlled by this region of cortex. A simple partial seizure is associated with preservation of consciousness. A complex partial seizure is associated with impairment of consciousness. The majority of complex partial seizures originate from the temporal lobe. Examples of generalized seizures include absence, myoclonic, and tonic-clonic. The type of epileptic seizure is one determinant of the drug selected for
therapy. More detailed information is presented in Table 21–1.

Apart from this epileptic seizure classification, an additional classification specifies epileptic syndromes, which refer to a cluster of symptoms frequently occurring together and include seizure types, etiology, age of onset, and other factors (Commission on Classification and Terminology, 1989). More than 50 distinct epileptic syndromes have been identified and categorized into partial versus generalized epilepsies. The partial epilepsies may consist of any of the partial seizure types (Table 21–1) and account for roughly 60% of all epilepsies. The etiology commonly consists of a lesion in some part of the cortex, such as a tumor, developmental malformation, or damage due to trauma or stroke. Such lesions often are evident on brain magnetic resonance imaging (MRI). Alternatively, the etiology may be genetic. The generalized epilepsies are characterized most commonly by one or more of the generalized seizure types listed in Table 21–1 and account for ~40% of all epilepsies. The etiology is usually genetic. The most common generalized epilepsy is referred to as juvenile myoclonic epilepsy, accounting for ~10% of all epileptic syndromes. The age of onset is in the early teens, and the condition is characterized by myoclonic, tonic-clonic, and often absence seizures. Like most of the generalized-onset epilepsies, juvenile myoclonic epilepsy is a complex genetic disorder that is probably due to inheritance of multiple susceptibility genes; there is a familial clustering of cases, but the pattern of inheritance is not

**NATURE AND MECHANISMS OF SEIZURES AND ANTI-SEIZURE DRUGS**

**Partial Epilepsies**

More than a century ago, John Hughlings Jackson, the father of modern concepts of epilepsy, proposed that seizures were caused by “occasional, sudden, excessive, rapid and local discharges of gray matter,” and that a generalized convulsion resulted when normal brain tissue was invaded by the seizure activity initiated in the abnormal focus. This insightful proposal provided a valuable framework for thinking about mechanisms of partial epilepsy. The advent of the electroencephalogram (EEG) in the 1930s permitted the recording of electrical activity from the scalp of humans with epilepsy and demonstrated that the epilepsies are disorders of neuronal excitability.

The pivotal role of synapses in mediating communication among neurons in the mammalian brain suggested that defective synaptic function might lead to a seizure. That is, a reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might be expected to trigger a seizure; pharmacological studies of seizures support this notion. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, with γ-aminobutyric acid (GABA) and glutamate being the principal inhibitory and excitatory neurotransmitters, respectively (Chapter 14). Pharmacological studies disclosed that antagonists of the GABA<sub>γ</sub> receptor or agonists of different glutamate-receptor subtypes (NMDA, AMPA, or kainic acid) (Chapter 14) trigger seizures in experimental animals in vivo. Conversely, pharmacological agents that enhance GABA-mediated synaptic inhibition suppress seizures in diverse models. Glutamate-receptor antagonists also inhibit seizures in diverse models, including seizures evoked by electroshock and chemical convulsants such as pentylenetetrazol.

Such studies support the idea that pharmacological regulation of synaptic function can regulate the propensity for seizures and provide a framework for electrophysiological analyses aimed at elucidating the role of both synaptic and nonsynaptic mechanisms in seizures and epilepsy. Progress in techniques has fostered the progressive refinement of the analysis of seizure mechanisms from the EEG to populations of neurons (field potentials) to individual neurons to individual synapses and individual ion channels on individual neurons. Beginning in the mid-1960s, cellular electrophysiological studies of epilepsy focused on elucidating the mechanisms underlying the depolarization shift (DS), the intracellular correlate of the “interictal spike” (Figure 21–1). The interictal (or between-seizures) spike is a sharp waveform recorded in the EEG of patients with epilepsy; it is asymptomatic in that it is accompanied by no overt change in the patient’s behavior. The location of the interictal spike helps localize the brain region from which seizures originate in a given patient. The DS consists of a large depolarization of the neuronal membrane associated with a burst of action potentials. In most cortical neurons, the DS is generated by a large excitatory synaptic current that can be enhanced by activation of voltage-gated intrinsic membrane currents. Although the mechanisms generating the DS are increasingly understood, it remains unclear whether the interictal spike triggers a seizure, inhibits a seizure, or is an epiphenomenon with respect to seizure occurrence in an epileptic brain. While these questions remain unanswered, the study of the mechanisms of DS generation set the stage for inquiry into the cellular mechanisms of a seizure.

During the 1980s, various in vitro models of seizures were developed in isolated brain slice preparations, in which many synaptic connections are preserved. Electrographic events with features similar to those recorded during seizures in vivo have been produced in hippocampal slices by multiple methods, including altering ionic constituents of media bathing the brain slices (McNamara, 1994) such as low Ca<sup>2+</sup>, zero Mg<sup>2+</sup>, or elevated K<sup>+</sup>. The accessibility and experimental control provided by these preparations has permitted mechanistic investigations into the induction of seizures. Analyses of multiple in vitro models confirmed the importance of synaptic function for initiating a seizure, demonstrating that subtle (e.g., 20%) reductions of inhibitory synaptic function could lead to epileptiform activity and that activation of excitatory synapses could be pivotal in seizure initiation. Other important factors were identified, including the volume of the extracellular space as well as intrinsic properties of a neuron, such as voltage-gated ion channels (e.g., K<sup>+</sup>, Na<sup>+</sup>, and Ca<sup>2+</sup> channels) (Traynelis and Dingledine, 1988). Identification of these diverse synaptic and nonsynaptic factors controlling seizures in vitro provides potential pharmacological targets for regulating seizure susceptibility in vivo.

Additional studies have centered on understanding the mechanisms by which a normal brain is transformed into an epileptic brain. Some common forms of partial epilepsy arise months to years after cortical injury sustained as a consequence of stroke, trauma, or other factors. An effective prophylaxis administered to patients at high risk would be highly desirable. The drugs described in this chapter provide symptomatic therapy; that is, the drugs inhibit seizures in patients with epilepsy. No effective anti-epileptogenic agent has been identified.

Understanding the mechanisms of epileptogenesis in cellular and molecular terms should provide a framework for development of novel therapeutic approaches. The availability of animal models provides an opportunity to investigate the underlying mechanisms.
One model, termed “kindling,” is induced by periodic administration of brief, low-intensity electrical stimulation of the amygdala or other limbic structures. Initial stimulations evoke a brief electrical seizure recorded on the EEG without behavioral change, but repeated (e.g., 10-20) stimulations result in progressive intensification of seizures, culminating in tonic-clonic seizures. Once established, the enhanced sensitivity to electrical stimulation persists for the life of the animal. Despite the exquisite propensity to intense seizures, spontaneous seizures or a truly epileptic condition do not occur until 100-200 stimulations have been administered. The ease of control of kindling induction (i.e., stimulations administered at the investigator’s convenience), its graded onset, and the ease of quantitating epileptogenesis (number of stimulations required to evoke tonic-clonic seizures) simplify experimental study. In mice, deletion of the gene encoding the receptor tyrosine kinase, TrkB, prevents epileptogenesis in the kindling model (He et al., 2004), which advances TrkB and its downstream signaling pathways as attractive targets for developing small molecule inhibitors for prevention of epilepsy or its progression.

Additional models are produced by induction of continuous seizures for hours (“status epilepticus”), with the inciting agent being a chemoconvulsant, such as kainic acid or pilocarpine, or sustained electrical stimulation. The fleeting episode of status epilepticus is followed weeks later by the onset of spontaneous seizures, an intriguing parallel to the scenario of complicated febrile seizures in young children preceding the emergence of spontaneous seizures years later. In contrast to the limited or absent neuronal loss characteristic of the kindling model, overt destruction of hippocampal neurons occurs in the status epilepticus models, reflecting aspects of hippocampal sclerosis observed in humans with severe limbic seizures. Indeed, the discovery that complicated febrile seizures precede and presumably are the cause of hippocampal sclerosis in young children (VanLandingham et al., 1998) establishes yet another commonality between these models and the human condition.

Several questions arise with respect to these models. What transpires during the latent period between status epilepticus and emergence of spontaneous seizures that causes the epilepsy? Might an anti-epileptogenic agent that was effective in one of these models be effective in other models?

Important insights into the mechanisms of action of drugs that are effective against partial seizures have emerged in the past two decades (Rogawski and Loscher, 2004). These insights largely have come from electrophysiological studies of relatively simple in vitro models, such as neurons isolated from the mammalian CNS and maintained in primary culture. The experimental control and accessibility provided by these

![Figure 21–1. Relations among cortical EEG, extracellular, and intracellular recordings in a seizure focus induced by local application of a convulsant agent to mammalian cortex. The extracellular recording was made through a high-pass filter. Note the high-frequency firing of the neuron evident in both extracellular and intracellular recording during the paroxysmal depolarization shift (PDS). (Modified with permission from Ayala GF, Dichter M, Gumnit RJ, et al. Genesis of epileptic interictal spikes. New knowledge of cortical feedback systems suggests a neurophysiological explanation of brief paroxysms. Brain Res, 1973, 52:1–17. Copyright © Elsevier.)](image-url)
models—together with careful attention to clinically relevant concentrations of the drugs—led to clarification of their mechanisms. Although it is difficult to prove unequivocally that a given drug effect observed in vitro is both necessary and sufficient to inhibit a seizure in an animal or humans in vivo, there is an excellent likelihood that the putative mechanisms identified do in fact underlie the clinically relevant anti-seizure effects. Table 21–2 summarizes putative mechanisms of action of anti-seizure drugs.

Electrophysiological analyses of individual neurons during a partial seizure demonstrate that the neurons undergo depolarization and fire action potentials at high frequencies (Figure 21–1). This pattern of neuronal firing is characteristic of a seizure and is uncommon during physiological neuronal activity. Thus, selective inhibition of this pattern of firing would be expected to reduce seizures with minimal unwanted effects. Carbamazepine, lamotrigine, phenytoin, and valproic acid inhibit high-frequency firing at concentrations

known to be effective at limiting seizures in humans (Rogawski and Loscher, 2004). Inhibition of the high-frequency firing is thought to be mediated by reducing the ability of Na\(^+\) channels to recover from inactivation (Figure 21–2). That is, depolarization-triggered opening of the Na\(^+\) channels in the axonal membrane of a neuron is required for an action potential; after opening, the channels spontaneously close, a process termed inactivation. This inactivation is thought to cause the refractory period, a short time after an action potential during which it is not possible to evoke another action potential. Upon recovery from inactivation, the Na\(^+\) channels are again poised to participate in another action potential. Because firing at a slow rate permits sufficient time for Na\(^+\) channels to recover from inactivation, inactivation has little or no effect on low-frequency firing. However, reducing the rate of recovery of Na\(^+\) channels from inactivation would limit the ability of a neuron to fire at high frequencies, an effect that likely underlies the effects of carbamazepine, lamotrigine, phenytoin, topiramate, valproic acid, and zonisamide against partial seizures.

Figure 21–2. Anti-seizure drug-enhanced Na\(^+\) channel inactivation. Some anti-seizure drugs (shown in blue text) prolong the inactivation of the Na\(^+\) channels, thereby reducing the ability of neurons to fire at high frequencies. Note that the inactivated channel itself appears to remain open, but is blocked by the inactivation gate I. A, activation gate.

Insights into mechanisms of seizures suggest that enhancing GABA-mediated synaptic inhibition would reduce neuronal excitability and raise the seizure threshold. Several drugs are thought to inhibit seizures by regulating GABA-mediated synaptic inhibition through an action at distinct sites of the synapse (Rogawski and Loscher, 2004). The principal postsynaptic receptor of synaptically released GABA is termed the GABA\(_A\) receptor (Chapters 14 and 17). Activation of the GABA\(_A\) receptor inhibits the postsynaptic cell by increasing the inflow of Cl\(^-\) ions into the cell, which tends to hyperpolarize the neuron. Clinically relevant concentrations of both benzodiazepines and barbiturates enhance GABA\(_A\) receptor–mediated inhibition through distinct actions on the GABA\(_A\) receptor (Figure 21–3), and this enhanced inhibition probably underlies the effectiveness of these compounds against partial and tonic-clonic seizures in humans. At higher concentrations, such as might be used for status epilepticus, these drugs also can inhibit high-frequency firing of action potentials. A second mechanism of enhancing GABA-mediated synaptic inhibition is thought to underlie the anti-seizure mechanism of tiagabine; tiagabine inhibits the GABA transporter, GAT-1, and reduces neuronal and glial uptake of GABA (Rogawski and Loscher, 2004).

**Generalized-Onset Epilepsies: Absence Seizures**

In contrast to partial seizures, which arise from localized regions of the cerebral cortex, generalized-onset
seizures arise from the reciprocal firing of the thalamus and cerebral cortex (Huguenard and McCormick, 2007). Among the diverse forms of generalized seizures, absence seizures have been studied most intensively. The striking synchrony in appearance of generalized seizure discharges in widespread areas of neocortex led to the idea that a structure in the thalamus and/or brainstem (the “centrencephalon”) synchronized these seizure discharges. Focus on the thalamus in particular emerged from the demonstration that low-frequency stimulation of midline thalamic structures triggered EEG rhythms in the cortex similar to spike-and-wave discharges characteristic of absence seizures. Intra-cerebral electrode recordings from humans subsequently demonstrated the presence of thalamic and neocortical involvement in the spike-and-wave discharge of absence seizures.

Many of the structural and functional properties of the thalamus and neocortex that lead to the generalized spike-and-wave discharges have been elucidated (Huguenard and McCormick, 2007).

The EEG hallmark of an absence seizure is generalized spike-and-wave discharges at a frequency of 3 per second (3 Hz). These bilaterally synchronous spike-and-wave discharges, recorded locally from electrodes in both the thalamus and the neocortex, represent oscillations between the thalamus and neocortex. A comparison of EEG and intracellular recordings reveals that the EEG spikes are associated with the firing of action potentials and the following slow wave with prolonged inhibition. These reverberatory, low-frequency rhythms are made possible by a combination of factors, including reciprocal excitatory synaptic connections between the neocortex and thalamus as well as intrinsic properties of neurons in the thalamus (Huguenard and McCormick, 2007). One intrinsic property of thalamic neurons that is pivotal in the generation of the 3-Hz spike-and-wave discharges is a particular type of Ca\(^{2+}\) current, the low threshold (“T-type”) current. T-type Ca\(^{2+}\) channels are activated at a much more negative membrane potential (hence “low threshold”) than most other voltage-gated Ca\(^{2+}\) channels expressed in the brain. T-type currents are much larger in many thalamic neurons compared to neurons outside the thalamus. Indeed, bursts of action potentials in thalamic neurons are mediated by activation of the T-type currents. T-type currents amplify thalamic membrane potential oscillations, with one oscillation being the 3-Hz spike-and-wave discharge of the absence seizure. Importantly, the principal mechanism by which anti-absence-seizure drugs (ethosuximide, valproic acid) are thought to act is by inhibition of the T-type Ca\(^{2+}\) channels (Figure 21–4) (Rogawski and Loscher, 2004). Thus, inhibiting voltage-gated ion channels is a common mechanism of action among anti-seizure drugs, with anti-partial-seizure drugs inhibiting voltage-activated Na\(^{+}\) channels and anti-absence-seizure drugs inhibiting voltage-activated Ca\(^{2+}\) channels.

### Genetic Approaches to the Epilepsies

Genetic causes contribute to a wide diversity of human epilepsies. Genetic causes are solely responsible for rare forms inherited in an autosomal dominant or autosomal recessive manner. Genetic causes also are mainly responsible for more common forms such as juvenile myoclonic epilepsy (JME) or childhood absence epilepsy (CAE), the majority of which are likely due to inheritance of two or more susceptibility genes. Genetic determinants also may contribute some degree of risk to epilepsies caused by injury of the cerebral cortex.

Enormous progress has been made in understanding the genetics of mammalian epilepsy. Mutant genes have been identified for a number of symptomatic epilepsies, in which the epilepsy is a manifestation of the underlying neurodegenerative disease. Because most patients with epilepsy are neurologically normal, elucidating the mutant genes underlying familial epilepsy in otherwise normal individuals is of particular interest; this has led to the identification of 25 distinct genes implicated in distinct idiopathic epilepsy syndromes that account for < 1% of all of the human epilepsies. Interestingly, almost all of the mutant genes encode voltage- or ligand-gated ion channels (Reid et al., 2008). Mutations have been identified in Na\(^{+}\), K\(^{+}\), Ca\(^{2+}\), and Cl\(^{-}\) channels, in channels gated by GABA and acetylcholine, and most recently, in intracellular Ca\(^{2+}\) release channels (RyR2) activated by Ca\(^{2+}\). The genotype-phenotype correlations of these genetic syndromes are complex; the same mutation in one channel can be associated with divergent clinical syndromes ranging from simple febrile seizures to intractable seizures with intellectual decline. Conversely, clinically indistinguishable epilepsy syndromes have been associated with mutation of distinct genes. The implication of genes encoding ion channels in familial epilepsy is particularly interesting because episodic disorders involving other organs also result from mutations of these genes. For example, episodic disorders of the heart (cardiac arrhythmias), skeletal muscle (periodic paralyses), cerebellum (episodic ataxia), vasculature (familial hemiplegic migraine), and other organs all have been linked to mutations in genes encoding components of voltage-gated ion channels (Ptacek and Fu, 2001).
The cellular electrophysiological consequences of these mutations can inform on the mechanisms of seizures and anti-seizure drugs. For example, generalized epilepsy with febrile seizures (GEFS+) is caused by a point mutation in the β subunit of a voltage-gated Na+ channel (SCN1B). As described previously, several anti-seizure drugs act on Na+ channels to promote their inactivation; the phenotype of the mutated Na+ channel appears to involve defective inactivation (Wallace et al., 1998).

Spontaneous mutations in SCN1A (encoding the α subunit of the major voltage-gated Na+ channel in neurons) that result in truncations and presumed loss of Na+ channel function have been identified in a subset of infants with a catastrophic severe myoclonic epilepsy of infancy. An intriguing clue as to how this genotype may lead to an epileptic phenotype has emerged from the study of SCN1A knock-out mice (Yu et al., 2006). Heterozygote mice have only one functional allele and provide a mouse model of this epileptic syndrome. Because activation of voltage-gated Na+ channels depolarizes and activates a neuron, it seemed odd that a loss of function mutation of SCN1A would result in increased excitability of networks of neurons and epilepsy. This led to the discovery of impaired firing of inhibitory interneurons, but not excitatory principal neurons, in SCN1A heterozygous mice (Yu et al., 2006). These findings suggest that loss of function mutations of SCN1A may cause epilepsy as a consequence of reduced firing of inhibitory interneurons. Because interneurons effect inhibition by releasing GABA, this suggests that drugs acting to enhance GABA-mediated inhibition may be effective anticonvulsants in SCN1A mutant mice and infants with these mutations. Consistent with this hypothesis, preliminary findings reveal that an experimental anti-seizure drug that increases the duration of GABAα receptor channel open times (Quilichini et al., 2006) was beneficial in children with severe myoclonic epilepsy of infancy (Chiron, 2007). If confirmed, this would provide the first instance of rational use of anti-seizure drugs in that insight into the cellular mechanism of the epilepsy would guide selection of drugs acting by a given mechanism.

**ANTI-SEIZURE DRUGS: GENERAL CONSIDERATIONS**

**History.** The first anti-epileptic drug was bromide, which was used in the late 19th century. Phenobarbital was the first synthetic organic agent recognized as having anti-seizure activity. Its usefulness, however, was limited to generalized tonic-clonic seizures, and to a lesser degree, simple and complex partial seizures. It had no effect on absence seizures. Merritt and Putnam developed the electroshock seizure test in experimental animals to screen chemical agents for anti-seizure effectiveness; in the course of screening a variety of drugs, they discovered that diphenylhydantoin (later renamed phenytoin) suppressed seizures in the absence of sedative effects. The electroshock seizure test is extremely valuable, because drugs that are effective against tonic hind limb extension induced by electroshock generally have proven to be effective against partial and tonic-clonic seizures in humans. Another screening test, seizures induced by the chemoconvulsant pentylentetrazol, is most useful in identifying drugs that are effective against myoclonic seizures in humans. These screening tests are still used. The chemical structures of most of the drugs introduced before 1965 were closely related to phenobarbital. These included the hydantoins and the succinimides. Between 1965 and 1990, the chemically distinct structures of the benzodiazepines, an iminostilbene (carbamazepine), and a branched-chain carboxylic acid (valproic acid) were introduced, followed in the 1990s by a phenyltriazine (lamotrigine), a cyclic analog of GABA (gabapentin), a sulfamate-substituted monosaccharide (topiramate), a nipecotic acid derivative (tiagabine), and a pyrrolidine derivative (levetiracetam).

**Therapeutic Aspects.** The ideal anti-seizure drug would suppress all seizures without causing any unwanted effects. Unfortunately, the drugs used currently not only fail to control seizure activity in some patients, but frequently cause unwanted effects that range in severity from minimal impairment of the CNS to death from aplastic anemia or hepatic failure. In 2009, all manufacturers of anti-seizure drugs were required to update their product labeling to include a warning about an increased risk of suicidal thoughts or actions and to develop information targeted at helping patients understand this risk. The risk applies to all anti-seizure drugs used for any indication. Details are online at the FDA website.

The clinician who treats patients with epilepsy is faced with the task of selecting the appropriate drug or combination of drugs that best controls seizures in an individual patient at an acceptable level of untoward effects. As a general rule, complete control of seizures can be achieved in up to 50% of patients, while another 25% can be improved significantly. The degree of success varies as a function of seizure type, cause, and other factors.

To minimize toxicity, treatment with a single drug is preferred. If seizures are not controlled with the initial agent at adequate plasma concentrations, substitution of a second drug is preferred to the concurrent administration of another agent. However, multiple-drug therapy may be required, especially when two or more types of seizure occur in the same patient.

Measurement of drug concentrations in plasma facilitates optimizing anti-seizure medication, especially when therapy is initiated, after dosage adjustments, in the event of therapeutic failure, when toxic effects appear, or when multiple-drug therapy is instituted. However, clinical effects of some drugs do not correlate well with their concentrations in plasma, and recommended concentrations are only guidelines for therapy. The ultimate therapeutic regimen must be determined by clinical assessment of effect and toxicity.

The individual agents are introduced in the next sections, followed by a discussion of some general principles of the drug therapy of the epilepsies.
HYDANTOINS

Phenytoin
Phenytoin (diphenylhydantoin; DILANTIN, others) is effective against all types of partial and tonic-clonic seizures but not absence seizures. Properties of other hydantoins (ethotoin, PEGANONE) are described in previous editions of this book.

History. Phenytoin was first synthesized in 1908 by Biltz, but its anticonvulsant activity was not discovered until 1938. In contrast to the earlier accidental discovery of the anti-seizure properties of bromide and phenobarbital, phenytoin was the product of a search among nonsedative structural relatives of phenobarbital for agents capable of suppressing electroshock convulsions in laboratory animals. It was introduced for the treatment of epilepsy in the same year. Since this agent is not a sedative in ordinary doses, it established that anti-seizure drugs need not induce drowsiness and encouraged the search for drugs with selective anti-seizure action.

Structure-Activity Relationship. A 5-phenyl or other aromatic substituent appears essential for activity against generalized tonic-clonic seizures. Alkyl substituents in position 5 contribute to sedation, a property absent in phenytoin. The carbon 5 position permits asymmetry, but there appears to be little difference in activity between isomers.

Pharmacological Effects
Central Nervous System. Phenytoin exerts anti-seizure activity without causing general depression of the CNS. In toxic doses, it may produce excitatory signs and at lethal levels a type of decerebrate rigidity.

The most significant effect of phenytoin is its ability to modify the pattern of maximal electroshock seizures. The characteristic tonic phase can be abolished completely, but the residual clonic seizure may be exaggerated and prolonged. This seizure-modifying action is observed with many other anti-seizure drugs that are effective against generalized tonic-clonic seizures. By contrast, phenytoin does not inhibit clonic seizures evoked by pentylenetetrazol.

Mechanism of Action. Phenytoin limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord neurons maintained in vitro (McLean and Macdonald, 1986a). This effect is mediated by a slowing of the rate of recovery of voltage-activated Na⁺ channels from inactivation, an action that is both voltage- (greater effect if membrane is depolarized) and use-dependent. These effects of phenytoin are evident at concentrations in the range of therapeutic drug levels in cerebrospinal fluid (CSF) in humans, which correlate with the free (or unbound) concentration of phenytoin in the serum. At these concentrations, the effects on Na⁺ channels are selective, and no changes of spontaneous activity or responses to iontophoretically applied GABA or glutamate are detected. At concentrations 5- to 10-fold higher, multiple effects of phenytoin are evident, including reduction of spontaneous activity and enhancement of responses to GABA; these effects may underlie some of the unwanted toxicity associated with high levels of phenytoin.

Pharmacokinetic Properties. Phenytoin is available in two types of oral formulations that differ in their pharmacokinetics: rapid-release and extended-release forms. Once-daily dosing is possible only with the extended-release formulations, and due to differences in dissolution and other formulation-dependent factors, the plasma phenytoin level may change when converting from one formulation to another. Confusion also can arise because different formulations can include either phenytoin or phenytoin sodium. Therefore, comparable doses can be approximated by considering “phenytoin equivalents,” but serum level monitoring is also necessary to assure therapeutic safety.

The pharmacokinetic characteristics of phenytoin are influenced markedly by its binding to serum proteins, by the nonlinearity of its elimination kinetics, and by its metabolism by hepatic CYPs (Table 21–3). Phenytoin is extensively bound (~90%) to serum proteins, mainly albumin. Small variations in the percentage of phenytoin that is bound dramatically affect the absolute amount of free (active) drug; increased proportions of free drug are evident in the neonate, in patients with hypoalbuminemia, and in uremic patients. Some agents can compete with phenytoin for binding sites on plasma proteins and increase free phenytoin at the time the new drug is added to the regimen. However, the effect on free phenytoin is only short-lived and usually does not cause clinical complications unless inhibition of phenytoin metabolism also occurs. For example, valproate competes for protein binding sites and inhibits phenytoin metabolism, resulting in marked and sustained increases in free phenytoin. Measurement of free rather than total phenytoin permits direct assessment of this potential problem in patient management.

Phenytoin is one of the few drugs for which the rate of elimination varies as a function of its concentration (i.e., the rate is nonlinear). The plasma t₁/₂ of phenytoin ranges between 6 and 24 hours at plasma concentrations below 10 μg/mL but increases with higher concentrations; as a result, plasma drug concentration increases disproportionately as dosage is
increased, even with small adjustments for levels near the therapeutic range.

The majority (95%) of phenytoin is metabolized in the hepatic endoplasmic reticulum by CYP2C9/10 and to a lesser extent CYP2C19 (Table 21–3). The principal metabolite, a parahydroxyphenyl derivative, is inactive. Because its metabolism is saturable, other drugs that are metabolized by these enzymes can inhibit the metabolism of phenytoin and increase its plasma concentration. Conversely, the degradation rate of other drugs that are substrates for these enzymes can be inhibited by phenytoin; one such drug is warfarin, and addition of phenytoin to a patient receiving warfarin can lead to bleeding disorders (Chapter 30). An alternative mechanism of drug interactions arises from phenytoin’s ability to induce diverse CYPs (Chapter 6); co-administration of phenytoin and medications metabolized by these enzymes can lead to an increased degradation of such medications. Of particular note in this regard are oral contraceptives, which are metabolized by CYP3A4; treatment with phenytoin can enhance the metabolism of oral contraceptives and lead to unplanned pregnancy. The potential teratogenic effects of phenytoin underscore the importance of attention to this interaction. Carbamazepine, oxcarbazepine, phenobarbital, and primidone also can induce CYP3A4 and likewise might increase degradation of oral contraceptives.

The low water solubility of phenytoin hindered its intravenous use and led to production of fosphenytoin, a water-soluble prodrug. Fosphenytoin (CEREBYX, others) is converted into phenytoin by phosphatases in liver and red blood cells with a $t_{1/2}$ of 8-15 minutes. Fosphenytoin is extensively bound (95-99%) to human plasma proteins, primarily albumin. This binding is saturable and fosphenytoin displaces phenytoin from protein-binding sites. Fosphenytoin is useful for adults with partial or generalized seizures when intravenous or intramuscular administration is indicated.

### Toxicity

The toxic effects of phenytoin depend on the route of administration, the duration of exposure, and the dosage.

When fosphenytoin, the water-soluble prodrug, is administered intravenously at an excessive rate in the emergency treatment of status epilepticus, the most notable toxic signs are cardiac arrhythmias with or without hypotension, and/or CNS depression. Although cardiac toxicity occurs more frequently in older patients and in those with known cardiac disease, it also can develop in young, healthy patients. These complications can be minimized by administering fosphenytoin at a rate of < 150 mg of phenytoin sodium equivalents per minute. Acute oral overdosage results primarily in signs referable to the cerebellum and vestibular system; high doses have been associated with marked cerebellar atrophy. Toxic effects associated with chronic treatment also are primarily dose-related cerebellar-vestibular effects but also include other CNS effects, behavioral changes, increased frequency of seizures, GI symptoms, gingival hyperplasia, osteomalacia, and megaloblastic anemia. Hirsutism is an annoying untoward effect in young females. Usually, these phenomena can be diminished by proper adjustment of dosage. Serious adverse effects, including those on the skin, bone marrow, and liver, probably are manifestations of

CYP, cytochrome P450; UGT, uridine diphosphate-glucuronosyltransferase.
drug allergy. Although rare, they necessitate withdrawal of the drug. Moderate elevation of the plasma concentrations of hepatic transaminases sometimes are observed; since these changes are transient and may result in part from induced synthesis of the enzymes, they do not necessitate withdrawal of the drug.

Gingival hyperplasia occurs in ~20% of all patients during chronic therapy and is probably the most common manifestation of phenytoin toxicity in children and young adolescents. It may be more frequent in those individuals who also develop coarsened facial features. The overgrowth of tissue appears to involve altered collagen metabolism. Toothless portions of the gums are not affected. The condition does not necessarily require withdrawal of medication and can be minimized by good oral hygiene.

A variety of endocrine effects have been reported. Inhibition of release of anti-diuretic hormone (ADH) has been observed in patients with inappropriate ADH secretion. Hyperglycemia and glycosuria appear to be due to inhibition of insulin secretion. Osteomalacia, with hypocalcemia and elevated alkaline phosphatase activity, has been attributed to both altered metabolism of vitamin D and the attendant inhibition of intestinal absorption of Ca²⁺. Phenytoin also increases the metabolism of vitamin K and reduces the concentration of vitamin K-dependent proteins that are important for normal Ca²⁺ metabolism. Toothless portions of the gums are not affected. The condition does not necessarily require withdrawal of medication and can be minimized by good oral hygiene.

Plasma Drug Concentrations. A good correlation usually is observed between the total concentration of phenytoin in plasma and its clinical effect. Thus, control of seizures generally is obtained with total concentrations above 10 µg/mL, while toxic effects such as nystagmus develop at total concentrations around 20 µg/mL. Control of seizures generally is obtained with free phenytoin concentrations of 0.75-1.25 µg/mL.

Drug Interactions. Concurrent administration of any drug metabolized by CYP2C9 or CYP2C10 can increase the plasma concentration of phenytoin by decreasing its rate of metabolism (Table 21–3). Carbamazepine, which may enhance the metabolism of phenytoin, causes a well-documented decrease in phenytoin concentration. Conversely, phenytoin reduces the concentration of carbamazepine. Interaction between phenytoin and phenobarbital is variable.

Therapeutic Uses

Epilepsy. Phenytoin is one of the more widely used anti-seizure agents, and it is effective against partial and tonic-clonic but not absence seizures. The use of phenytoin and other agents in the therapy of epilepsies is discussed further at the end of this chapter. Phenytoin preparations differ significantly in bioavailability and rate of absorption. In general, patients should consistently be treated with the same drug from a single manufacturer. However, if it becomes necessary to temporarily switch between products, care should be taken to select a therapeutically equivalent product and patients should be monitored for loss of seizure control or onset of new toxicities.

Other Uses. Trigeminal and related neuralgias occasionally respond to phenytoin, but carbamazepine may be preferable. The use of phenytoin in the treatment of cardiac arrhythmias is discussed in Chapter 29.

ANTI-SEIZURE BARBITURATES

The pharmacology of the barbiturates as a class is described in Chapter 17; discussion in this chapter is limited to phenobarbital. Use of other long-acting barbiturates (e.g., mephobarbital, MEBARAL) for therapy of the epilepsies is described in previous editions of this book.

Phenobarbital

Phenobarbital (LUMINAL, others) was the first effective organic anti-seizure agent. It has relatively low toxicity, is inexpensive, and is still one of the more effective and widely used drugs for this purpose.

Structure-Activity Relationship. The structural formula of phenobarbital (5-phenyl-5-ethylbarbituric acid) is shown in Chapter 17. The structure-activity relationships of the barbiturates have been studied extensively. Maximal anti-seizure activity is obtained when one substituent at carbon 5 position is a phenyl group. The 5,5-diphenyl derivative has less anti-seizure potency than does phenobarbital, but it is virtually devoid of hypnotic activity. By contrast, 5,5-dibenzyl barbituric acid causes convulsions.

Anti-Seizure Properties. Most barbiturates have anti-seizure properties. However, only some of these agents, such as phenobarbital, exert maximal anti-seizure action at doses below those required for hypnosis, which determines their clinical utility as anti-seizure agents. Phenobarbital is active in most anti-seizure tests in animals but is relatively nonselective. It inhibits tonic hind limb extension in the maximal electroshock model, clonic seizures evoked by pentylentetrazol, and kindled seizures.

Mechanism of Action. The mechanism by which phenobarbital inhibits seizures likely involves potentiation of synaptic inhibition through an action on the GABA_A receptor. Intracellular recordings of mouse cortical or spinal cord neurons demonstrated that phenobarbital enhances responses to iontophoretically applied GABA.
These effects have been observed at therapeutically relevant concentrations of phenobarbital. Analyses of single channels in outside-out patches isolated from mouse spinal cord neurons demonstrated that phenobarbital increased the GABA<sub>A</sub> receptor–mediated current by increasing the duration of bursts of GABA<sub>A</sub> receptor–mediated currents without changing the frequency of bursts (Twyman et al., 1989). At levels exceeding therapeutic concentrations, phenobarbital also limits sustained repetitive firing; this may underlie some of the anti-seizure effects of higher concentrations of phenobarbital achieved during therapy of status epilepticus.

**Pharmacokinetic Properties.** Oral absorption of phenobarbital is complete but somewhat slow; peak concentrations in plasma occur several hours after a single dose. It is 40-60% bound to plasma proteins and bound to a similar extent in tissues, including brain. Up to 25% of a dose is eliminated by pH-dependent renal excretion of the unchanged drug; the remainder is inactivated by hepatic microsomal enzymes, principally CYP2C9, with minor metabolism by CYP2C19 and CYP2E1. Phenobarbital induces uridine diphosphate-glucuronosyltransferase (UGT) enzymes as well as the CYP2C and CYP3A subfamilies. Drugs metabolized by these enzymes can be more rapidly degraded when co-administered with phenobarbital; importantly, oral contraceptives are metabolized by CYP3A4.

**Toxicity.** Sedation, the most frequent undesired effect of phenobarbital, is apparent to some extent in all patients upon initiation of therapy, but tolerance develops during chronic medication. Nystagmus and ataxia occur at excessive dosage. Phenobarbital can produce irritability and hyperactivity in children, and agitation and confusion in the elderly.

Scarlatiniform or morbilliform rash, possibly with other manifestations of drug allergy, occurs in 1-2% of patients. Exfoliative dermatitis is rare. Hypoprothrombinemia with hemorrhage has been observed in the newborns of mothers who have received phenobarbital during pregnancy; vitamin K is effective for treatment or prophylaxis. As with phenytoin, megaloblastic anemia that responds to folate and osteomalacia that responds to high doses of vitamin D occur during chronic phenobarbital therapy of epilepsy. Other adverse effects of phenobarbital are discussed in Chapter 17.

**Plasma Drug Concentrations.** During long-term therapy in adults, the plasma concentration of phenobarbital averages 10 μg/mL per daily dose of 1 mg/kg; in children, the value is 5-7 μg/mL per 1 mg/kg. Although a precise relationship between therapeutic results and concentration of drug in plasma does not exist, plasma concentrations of 10-35 μg/mL are usually recommended for control of seizures.

The relationship between plasma concentration of phenobarbital and adverse effects varies with the development of tolerance. Sedation, nystagmus, and ataxia usually are absent at concentrations below 30 μg/mL during long-term therapy, but adverse effects may be apparent for several days at lower concentrations when therapy is initiated or whenever the dosage is increased. Concentrations > 60 μg/mL may be associated with marked intoxication in the non-tolerant individual.

Since significant behavioral toxicity may be present despite the absence of overt signs of toxicity, the tendency to maintain patients, particularly children, on excessively high doses of phenobarbital should be resisted. The plasma phenobarbital concentration should be increased above 30-40 μg/mL only if the increment is adequately tolerated and only if it contributes significantly to control of seizures.

**Drug Interactions.** Interactions between phenobarbital and other drugs usually involve induction of the hepatic CYPs by phenobarbital (see Table 21–3 and Chapters 6 and 17). The interaction between phenytoin and phenobarbital is variable. Concentrations of phenobarbital in plasma may be elevated by as much as 40% during concurrent administration of valproic acid.

**Therapeutic Uses.** Phenobarbital is an effective agent for generalized tonic-clonic and partial seizures. Its efficacy, low toxicity, and low cost make it an important agent for these types of epilepsy. However, its sedative effects and its tendency to disturb behavior in children have reduced its use as a primary agent. It is not effective for absence seizures.

**IMINOSTILBENES**

**Carbamazepine**

Carbamazepine (TEGRETOL, CARBATROL, others) was initially approved in the U.S. for use as an anti-seizure agent in 1974. It has been employed since the 1960s for the treatment of trigeminal neuralgia. It is now considered to be a primary drug for the treatment of partial and tonic-clonic seizures.

**Chemistry.** Carbamazepine is related chemically to the tricyclic antidepressants. It is a derivative of iminostilbene with a carbamyl group at the 5 position; this moiety is essential for potent anti-seizure activity.

![Carbamazepine](image)

**Pharmacological Effects.** Although the effects of carbamazepine in animals and humans resemble those of phenytoin in many ways, the two drugs exhibit important differences. Carbamazepine has been found to produce therapeutic responses in manic-depressive patients, including some in whom lithium carbonate is not effective. Further, carbamazepine has anti-diuretic effects that are sometimes associated with increased concentrations of anti-diuretic hormone (ADH) in plasma. The mechanisms responsible for these effects of carbamazepine are not clearly understood.

**Mechanism of Action.** Like phenytoin, carbamazepine limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord or cortical neurons maintained in vitro (McLean and Macdonald, 1986a). This appears to be mediated by a slowing of the rate of recovery of voltage-activated Na<sup>+</sup> channels from inactivation. These effects of carbamazepine are evident at
concentrations in the range of therapeutic drug levels in CSF in humans. The effects of carbamazepine are selective at these concentrations, in that there are no effects on spontaneous activity or on responses to iontophoretically applied GABA or glutamate. The carbamazepine metabolite, 10,11-epoxycarbamazepine, also limits sustained repetitive firing at therapeutically relevant concentrations, suggesting that this metabolite may contribute to the anti-seizure efficacy of carbamazepine.

**Pharmacokinetic Properties.** The pharmacokinetics of carbamazepine are complex. They are influenced by its limited aqueous solubility and by the ability of many anti-seizure drugs, including carbamazepine itself, to increase their conversion to active metabolites by hepatic oxidative enzymes (Table 21–3).

Carbamazepine is absorbed slowly and erratically after oral administration. Peak concentrations in plasma usually are observed 4–8 hours after oral ingestion, but may be delayed by as much as 24 hours, especially following the administration of a large dose. The drug distributes rapidly into all tissues. Approximately 75% of carbamazepine binds to plasma proteins and concentrations in the CSF appear to correspond to the concentration of free drug in plasma.

The predominant pathway of metabolism in humans involves conversion to the 10,11-epoxide. This metabolite is as active as the parent compound in various animals, and its concentrations in plasma and brain may reach 50% of those of carbamazepine, especially during the concurrent administration of phenytoin or phenobarbital. The 10,11-epoxide is metabolized further to inactive compounds, which are excreted in the urine principally as glucuronides. Carbamazepine also is inactivated by conjugation and hydroxylation. Hepatic CYP3A4 is primarily responsible for biotransformation of carbamazepine. Carbamazepine induces CYP2C, CYP3A, and UGT, thus enhancing the metabolism of drugs degraded by these enzymes. Of particular importance in this regard are oral contraceptives, which are also metabolized by CYP3A4.

**Toxicity.** Acute intoxication with carbamazepine can result in stupor or coma, hyperirritability, convulsions, and respiratory depression. During long-term therapy, the more frequent untoward effects of the drug include drowsiness, vertigo, ataxia, diplopia, and blurred vision. The frequency of seizures may increase, especially with overdosage. Other adverse effects include nausea, vomiting, serious hematological toxicity ( aplastic anemia, agranulocytosis), and hypersensitivity reactions (dangerous skin reactions, eosinophilia, lymphadenopathy, splenomegaly). A late complication of therapy with carbamazepine is retention of water, with decreased osmolality and concentration of Na⁺ in plasma, especially in elderly patients with cardiac disease.

Some tolerance develops to the neurotoxic effects of carbamazepine, and they can be minimized by gradual increase in dosage or adjustment of maintenance dosage. Various hepatic or pancreatic abnormalities have been reported during therapy with carbamazepine, most commonly a transient elevation of hepatic transaminases in plasma in 5–10% of patients. A transient, mild leukopenia occurs in ~10% of patients during initiation of therapy and usually resolves within the first 4 months of continued treatment; transient thrombocytopenia also has been noted. In ~2% of patients, a persistent leukopenia may develop that requires withdrawal of the drug. The initial concern that aplastic anemia might be a frequent complication of long-term therapy with carbamazepine has not materialized. In most cases, the administration of multiple drugs or the presence of another underlying disease has made it difficult to establish a causal relationship. The prevalence of aplastic anemia appears to be ~1 in 200,000 patients who are treated with the drug. It is not clear whether monitoring of hematological function can avert the development of irreversible aplastic anemia. Although carbamazepine is carcinogenic in rats, it is not known to be carcinogenic in humans. Possible teratogenic effects are discussed later in the chapter.

**Plasma Drug Concentrations.** There is no simple relationship between the dose of carbamazepine and concentrations of the drug in plasma. Therapeutic concentrations are reported to be 6–12 μg/mL, although considerable variation occurs. Side effects referable to the CNS are frequent at concentrations above 9 μg/mL.

**Drug Interactions.** Phenobarbital, phenytoin, and valproate may increase the metabolism of carbamazepine by inducing CYP3A4; carbamazepine may enhance the biotransformation of phenytoin. Concurrent administration of carbamazepine may lower concentrations of valproate, lamotrigine, tiagabine, and topiramate. Carbamazepine reduces both the plasma concentration and therapeutic effect of haloperidol. The metabolism of carbamazepine may be inhibited by propoxyphene, erythromycin, cimetidine, fluoxetine, and isoniazid.

**Therapeutic Uses.** Carbamazepine is useful in patients with generalized tonic-clonic and both simple and complex partial seizures (Table 21–1). When it is used, renal and hepatic function and hematological parameters should be monitored. The therapeutic use of carbamazepine is discussed further at the end of this chapter.

Carbamazepine is the primary agent for treatment of trigeminal and glossopharyngeal neuralgias. It is also effective for lightening-type (“tabetic”) pain associated with bodily wasting. Most patients with neuralgia benefit initially, but only 70% obtain continuing relief. Adverse effects require discontinuation of medication in 5–20% of patients. The therapeutic range of plasma concentrations for anti-seizure therapy serves as a guideline for its use in neuralgia. Carbamazepine is also used in the treatment of bipolar affective disorders, as discussed further in Chapter 16.

**Oxcarbazepine**

Oxcarbazepine (TRILEPTAL, others) (10,11-dihydro-10-oxocarbamazepine) is a keto analog of carbamazepine.
Oxcarbazepine is a prodrug that is almost immediately converted to its main active metabolite, a 10-monohydroxy derivative, which is inactivated by glucuronide conjugation and eliminated by renal excretion. 

Its mechanism of action is similar to that of carbamazepine. Oxcarbazepine is a less potent enzyme inducer than carbamazepine. Substitution of oxcarbazepine for carbamazepine is associated with increased levels of phenytoin and valproic acid, presumably because of reduced induction of hepatic enzymes. Oxcarbazepine does not induce the hepatic enzymes involved in its own degradation. Although oxcarbazepine does not appear to reduce the anticoagulant effect of warfarin, it does induce CYP3A and thus reduces plasma levels of steroid oral contraceptives. It has been approved for monotherapy or adjunct therapy for partial seizures in adults, as monotherapy for partial seizures in children ages 4-16, and as adjunctive therapy in children 2 years of age and older with epilepsy.

**SUCCINIMIDES**

**Ethosuximide**

Ethosuximide (ZARONTIN, others) is a primary agent for the treatment of absence seizures.

**Structure-Activity Relationship.** The structure-activity relationship of the succinimides is in accord with that for other anti-seizure classes. Methsuximide (CELONTIN) has phenyl substituents and is more active against maximal electroshock seizures. It is no longer in common use. Discussion of its properties can be found in previous editions of this book. Ethosuximide, with alkyl substituents, is the most active of the succinimides against seizures induced by pentylenetetrazol and is the most selective for absence seizures.

**Pharmacological Effects.** The most prominent characteristic of ethosuximide at nontoxic doses is protection against clonic motor seizures induced by pentyleneetetrazol. By contrast, at nontoxic doses ethosuximide does not inhibit tonic hind limb extension of electroshock seizures or kindled seizures. This profile correlates with efficacy against absence seizures in humans.

**Mechanism of Action.** Ethosuximide reduces low threshold Ca \(^{2+}\) currents (T-type currents) in thalamic neurons (Coulter et al., 1989). The thalamus plays an important role in generation of 3-Hz spike-and-wave rhythms typical of absence seizures (Huguenard and McCormick, 2007). Neurons in the thalamus exhibit large-amplitude T-type currents that underlie bursts of action potentials and likely play an important role in thalamic oscillatory activity such as 3-Hz spike-and-wave activity. At clinically relevant concentrations, ethosuximide inhibits the T-type current, as is evident in voltage-clamp recordings of acutely isolated, ventrobasal thalamic neurons from rats and guinea pigs. Ethosuximide reduces this current without modifying the voltage dependence of steady-state inactivation or the time course of recovery from inactivation. By contrast, succinimide derivatives with convulsant properties do not inhibit this current. Ethosuximide does not inhibit sustained repetitive firing or enhance GABA responses at clinically relevant concentrations. Inhibition of T-type currents likely is the mechanism by which ethosuximide inhibits absence seizures.

**Pharmacokinetic Properties.** Absorption of ethosuximide appears to be complete, with peak concentrations in plasma within ~3 hours after a single oral dose. Ethosuximide is not significantly bound to plasma proteins; during long-term therapy, its concentration in the CSF is similar to that in plasma. The apparent volume of distribution averages 0.7 L/kg.

Approximately 25% of the drug is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes, but whether CYPs are responsible is unknown. The major metabolite, the hydroxyethyl derivative, accounts for ~40% of administered drug, is inactive, and is excreted as such and as the glucuronide in the urine. The plasma \(t_{1/2}\) of ethosuximide averages between 40 and 50 hours in adults and ~30 hours in children.

**Toxicity.** The most common dose-related side effects are gastrointestinal complaints (nausea, vomiting, and anorexia) and CNS effects (drowsiness, lethargy, euphoria, dizziness, headache, and hiccough). Some tolerance to these effects develops. Parkinson-like symptoms and photophobia also have been reported. Restlessness, agitation, anxiety, aggressiveness, inability to concentrate, and other behavioral effects have occurred primarily in patients with a prior history of psychiatric disturbance.

Urticaria and other skin reactions, including Stevens-Johnson syndrome, as well as systemic lupus erythematosus, eosinophilia, leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia also have been attributed to the drug. The leukopenia may be transient despite continuation of the drug, but several deaths have resulted from bone marrow depression. Renal or hepatic toxicity has not been reported.

**Plasma Drug Concentrations.** During long-term therapy, the plasma concentration of ethosuximide averages ~2 μg/mL per daily dose of 1 mg/kg. A plasma concentration of 40-100 μg/mL usually is required for satisfactory control of absence seizures.

**Therapeutic Uses.** Ethosuximide is effective against absence seizures but not tonic-clonic seizures.

An initial daily dose of 250 mg in children (3-6 years old) and 500 mg in older children and adults is increased by 250-mg increments at weekly intervals until seizures are adequately controlled or toxicity intervenes. Divided dosage is required occasionally to prevent nausea or drowsiness associated with once-daily dosing. The usual maintenance dose is 20 mg/kg per day. Increased caution is required if the daily dose exceeds 1500 mg in adults or 750-1000 mg in children. The therapeutic use of ethosuximide is discussed further at the end of the chapter.

**VALPROIC ACID**

The anti-seizure properties of valproic acid (DEPAKENE, others) were discovered serendipitously when it was employed as a vehicle for other compounds that were being screened for anti-seizure activity.
Chemistry. Valproic acid (n-dipropylacetic acid) is a simple branched-chain carboxylic acid. Certain other branched-chain carboxylic acids have potencies similar to that of valproic acid in antagonizing pentyletenetetrazol-induced convulsions. However, increasing the number of carbon atoms to nine introduces marked sedative properties. Straight-chain carboxylic acids have little or no activity.

Pharmacological Effects. Valproic acid is strikingly different from phenytoin or ethosuximide in that it is effective in inhibiting seizures in a variety of models. Like phenytoin and carbamazepine, valproate inhibits tonic hind limb extension in maximal electroshock seizures and kindled seizures at nontoxic doses. Like ethosuximide, valproic acid at subtoxic doses inhibits clonic motor seizures induced by pentyletenetetrazol. Its efficacy in diverse models parallels its efficacy against absence as well as partial and generalized tonic-clonic seizures in humans.

Mechanism of Action. Valproic acid produces effects on isolated neurons similar to those of phenytoin and ethosuximide (Table 21–2). At therapeutically relevant concentrations, valproate inhibits sustained repetitive firing induced by depolarization of mouse cortical or spinal cord neurons (McLean and Macdonald, 1986b). The action is similar to that of both phenytoin and carbamazepine and appears to be mediated by a prolonged recovery of voltage-activated Na+ channels from inactivation. Valproic acid does not modify neuronal responses to iontophoretically applied GABA. In neurons isolated from the nodose ganglion, valproate also produces small reductions of T-type Ca2+ currents (Kelly et al., 1990) at clinically relevant but slightly higher concentrations than those that limit sustained repetitive firing; this effect on T-type currents is similar to that of ethosuximide in thalamic neurons (Coulter et al., 1989). Together, these actions of limiting sustained repetitive firing and reducing T-type currents may contribute to the effectiveness of valproic acid against partial and tonic-clonic seizures and absence seizures, respectively.

Another potential mechanism that may contribute to valproate’s anti-seizure actions involves metabolism of GABA. Although valproate has no effect on responses to GABA, it does increase the amount of GABA that can be recovered from the brain after the drug is administered to animals. Valproic acid is a substrate for CYP2C9 and CYP2C19, but metabolism by these enzymes accounts for a relatively minor portion of its elimination. Some of the drug’s metabolites, notably 2-propyl-1-2-pentenoic acid and 2-propyl-4-pentenoic acid, are nearly as potent anti-seizure agents as the parent compound; however, only the former (2-en-valproic acid) accumulates in plasma and brain to a potentially significant extent. The t1/2 of valproate is ~15 hours but is reduced in patients taking other anti-epileptic drugs.

Toxicity. The most common side effects are transient GI symptoms, including anorexia, nausea, and vomiting in ~16% of patients. Effects on the CNS include sedation, ataxia, and tremor; these symptoms occur infrequently and usually respond to a decrease in dosage. Rash, alopecia, and stimulation of appetite have been observed occasionally and weight gain has been seen with chronic valproic acid treatment in some patients. Valproic acid has several effects on hepatic function. Elevation of hepatic transaminases in plasma is observed in up to 40% of patients and often occurs asymptotically during the first several months of therapy.

A rare complication is a fulminant hepatitis that is frequently fatal (Dreifuss et al., 1989). Pathological examination reveals a microvesicular steatosis without evidence of inflammation or hypersensitivity reaction. Children below 2 years of age with other medical conditions who were given multiple anti-seizure agents were especially likely to suffer fatal hepatic injury. At the other extreme, there were no deaths reported for patients over the age of 10 years who received only valproate. Acute pancreatitis and hyperammonemia also have been frequently associated with the use of valproic acid. Valproic acid can also produce teratogenic effects such as neural tube defects.

Plasma Drug Concentrations. Valproate plasma concentrations associated with therapeutic effects are ~30–100 μg/mL. However, there is a poor correlation between the plasma concentration and efficacy. There appears to be a threshold at ~30-50 μg/mL; this is the concentration at which binding sites on plasma albumin begin to become saturated.

Drug Interactions. Valproate primarily inhibits the metabolism of drugs that are substrates for CYP2C9, including phenytoin and phenobarbital. Valproate also inhibits UGT and thus inhibits the metabolism of lamotrigine and lorazepam. A high proportion of valproate is bound to albumin, and the high molar concentrations of valproate in the clinical setting result in valproate’s displacing phenytoin and other drugs from albumin. With respect to phenytoin in particular, valproate’s inhibition of the drug’s metabolism is exacerbated by...
displacement of phenytoin from albumin. The concurrent administration of valproate and clonazepam has been associated with the development of absence status epilepticus; however, this complication appears to be rare.

**Therapeutic Uses.** Valproate is a broad-spectrum anti-seizure drug effective in the treatment of absence, myoclonic, partial, and tonic-clonic seizures. The initial daily dose usually is 15 mg/kg, increased at weekly intervals by 5-10 mg/kg per day to a maximum daily dose of 60 mg/kg. Divided doses should be given when the total daily dose exceeds 250 mg. The therapeutic uses of valproate in epilepsy are discussed further at the end of this chapter.

**BENZODIAZEPINES**

The benzodiazepines are used primarily as sedative-anxiety drugs; their pharmacology is described in Chapters 14 and 17. Discussion here is limited to their use in the therapy of the epilepsies. A large number of benzodiazepines have broad anti-seizure properties, but only clonazepam (KLONOPIN, others) and clorazepate (TRANXENE, others) have been approved in the U.S. for the long-term treatment of certain types of seizures. Midazolam was designated an orphan drug in 2006 for intermittent treatment of bouts of increased seizure activity in refractory patients with epilepsy who are on stable regimens of anti-seizure drugs. Diazepam (VALIUM, DIASTAT; others) and lorazepam (ATIVAN, others) have well-defined roles in the management of status epilepticus. The structures of the benzodiazepines are shown in Chapter 17.

**Anti-Seizure Properties.** In animal models, inhibition of pentylenetetrazol-induced seizures by the benzodiazepines is much more prominent than is their modification of the maximal electroshock seizure pattern. Clonazepam is unusually potent in antagonizing the effects of pentylenetetrazol, but it is almost without action on seizures induced by maximal electroshock. Benzodiazepines, including clonazepam, suppress the spread of kindled seizures and generalized convulsions produced by stimulation of the amygdala, but do not abolish the abnormal discharge at the site of stimulation.

**Mechanism of Action.** The anti-seizure actions of the benzodiazepines, as well as other effects that occur at nonsedating doses, result in large part from their ability to enhance GABA-mediated synaptic inhibition. Molecular cloning and study of recombinant receptors have demonstrated that the benzodiazepine receptor is an integral part of the GABA$_A$ receptor (Chapter 17). At therapeutically relevant concentrations, benzodiazepines act at subsets of GABA$_A$ receptors and increase the frequency, but not duration, of openings at GABA-activated Cl$^-$ channels (Twyman et al., 1989). At higher concentrations, diazepam and many other benzodiazepines can reduce sustained high-frequency firing of neurons, similar to the effects of phenytoin, carbamazepine, and valproate. Although these concentrations correspond to concentrations achieved in patients during treatment of status epilepticus with diazepam, they are considerably higher than those associated with anti-seizure or anxiolytic effects in ambulatory patients.

**Pharmacokinetic Properties.** Benzodiazepines are well absorbed after oral administration, and concentrations in plasma are usually maximal within 1–4 hours. After intravenous administration, they are redistributed in a manner typical of that for highly lipid-soluble agents. Central effects develop promptly, but wane rapidly as the drugs move to other tissues. Diazepam is redistributed especially rapidly, with a $t_{1/2}$ of redistribution of ~1 hour. The extent of binding of benzodiazepines to plasma proteins correlates with lipid solubility, ranging from ~99% for diazepam to ~85% for clonazepam (Appendix II).

The major metabolite of diazepam, N-desethyl-diazepam, is somewhat less active than the parent drug and may behave as a partial agonist. This metabolite also is produced by the rapid decarboxylation of clorazepate following its ingestion. Both diazepam and N-desmethyl-diazepam are slowly hydroxylated to other active metabolites, such as oxazepam. The $t_{1/2}$ of diazepam in plasma is between 1 and 2 days, while that of N-desmethyl-diazepam is ~60 hours. Clonazepam is metabolized principally by reduction of the nitro group to produce inactive 7-amino derivatives. Less than 1% of the drug is recovered unchanged in the urine. The $t_{1/2}$ of clonazepam in plasma is ~23 hours. Lorazepam is metabolized chiefly by conjugation with glucuronic acid; its $t_{1/2}$ in plasma is ~14 hours.

**Toxicity.** The principal side effects of long-term oral therapy with clonazepam are drowsiness and lethargy. These occur in ~50% of patients initially, but tolerance often develops with continued administration. Muscular incoordination and ataxia are less frequent. Although these symptoms usually can be kept to tolerable levels by reducing the dosage or the rate at which it is increased, they sometimes force drug discontinuation.

Other side effects include hypotonia, dysarthria, and dizziness. Behavioral disturbances, especially in children, can be very troublesome; these include aggression, hyperactivity, irritability, and difficulty in concentration. Both anorexia and hyperphagia have been reported. Increased salivary and bronchial secretions may cause difficulties in children. Seizures are sometimes exacerbated, and status epilepticus may be precipitated if the drug is discontinued abruptly. Other aspects of the toxicity of the benzodiazepines are discussed in Chapter 17. Cardiovascular and respiratory depression may occur after the intravenous administration of diazepam, clonazepam, or lorazepam, particularly if other anti-seizure agents or central depressants have been administered previously.

**Plasma Drug Concentrations.** Because tolerance affects the relationship between drug concentration and drug anti-seizure effect, plasma concentrations of benzodiazepines are of limited value.

**Therapeutic Uses.** Clonazepam is useful in the therapy of absence seizures as well as myoclonic seizures in children. However, tolerance to its anti-seizure effects usually develops after 1-6 months of administration, after which some patients will no longer respond to
clonazepam at any dosage. The initial dose of clonazepam for adults should not exceed 1.5 mg per day and for children 0.01-0.03 mg/kg per day. The dose-dependent side effects are reduced if two or three divided doses are given each day. The dose may be increased every 3 days in amounts of 0.25-0.5 mg per day in children and 0.5-1 mg per day in adults. The maximal recommended dose is 20 mg per day for adults and 0.2 mg/kg per day for children. Clonazepam intranasal spray is designated as an orphan drug for recurrent acute repetitive seizures.

While diazepam is an effective agent for treatment of status epilepticus, its short duration of action is a disadvantage, leading to the more frequent use of lorazepam. Although diazepam is not useful as an oral agent for the treatment of seizure disorders, clorazepate is effective in combination with certain other drugs in the treatment of partial seizures. The maximal initial dose of clorazepate is 22.5 mg per day in three portions for adults and children > 12 years and 15 mg per day in two divided doses in children 9-12 years of age. Clorazepate is not recommended for children under the age of 9.

### Gabapentin and Pregabalin

Gabapentin (NEURONTIN, others) and pregabalin (LYRICA) are anti-seizure drugs that consist of a GABA molecule covalently bound to a lipophilic cyclohexane ring or isobutane, respectively. Gabapentin was designed to be a centrally active GABA agonist, with its high lipid solubility aimed at facilitating its transfer across the blood-brain barrier. The structures of gabapentin and pregabalin are:

![Gabapentin and Pregabalin structures](image)

**Pharmacological Effects and Mechanisms of Action.** Gabapentin inhibits tonic hind limb extension in the electroshock seizure model. Interestingly, gabapentin also inhibits clonic seizures induced by pentylenetetrazol. Its efficacy in both these tests parallels that of valproic acid and distinguishes it from phenytoin and carbamazepine. Despite their design as GABA agonists, neither gabapentin nor pregabalin mimics GABA when iontophoretically applied to neurons in primary culture. These compounds bind with high affinity to a protein in cortical membranes with an amino acid sequence identical to that of the Ca\(^{2+}\) channel subunit α2δ-1 (Gee et al., 1996). It has been speculated that the anticonvulsant effects of gabapentin are mediated by α2δ-1 protein, but whether and how the binding of gabapentin to the α2δ-1 regulates neuronal excitability remains unclear. Pregabalin binding is reduced but not eliminated in mice carrying a mutation in the α2δ-1 protein (Field et al., 2006). Analgesic efficacy of pregabalin is eliminated in these mice; whether the anticonvulsant effects of pregabalin are also eliminated was not reported. It is unclear whether the anticonvulsant and analgesic effects of gabapentin and pregabalin are mediated by affecting Ca\(^{2+}\) currents and, if so, how.

**Pharmacokinetics.** Gabapentin and pregabalin are absorbed after oral administration and are not metabolized in humans. These compounds are not bound to plasma proteins and are excreted unchanged, mainly in the urine. Their half-lives, when used as monotherapy, approximate 6 hours. These compounds have no known interactions with other anti-seizure drugs.

**Therapeutic Uses.** Gabapentin and pregabalin are effective for partial seizures, with and without secondary generalization, when used in addition to other anti-seizure drugs.

Double-blind placebo-controlled trials of adults with refractory partial seizures demonstrated that addition of gabapentin or pregabalin to other anti-seizure drugs is superior to placebo (Sivenius et al., 1991; French et al., 2003). A double-blind study of gabapentin (900 or 1800 mg/day) monotherapy disclosed that gabapentin was equivalent to carbamazepine (600 mg/day) for newly diagnosed partial or generalized epilepsy (Chadwick et al., 1998). Gabapentin also is being used for the treatment of migraine, chronic pain, and bipolar disorder.

Gabapentin usually is effective in doses of 900-1800 mg daily in three doses, although 3600 mg may be required in some patients to achieve reasonable seizure control. Therapy usually begins with a low dose (300 mg once on the first day), which is increased in daily increments of 300 mg until an effective dose is reached.

**Toxicity.** Overall, gabapentin is well tolerated with the most common adverse effects of somnolence, dizziness, ataxia, and fatigue. These effects usually are mild to moderate in severity but resolve within 2 weeks of onset during continued treatment. Gabapentin and pregabalin are listed in pregnancy category C.

### Lamotrigine

Lamotrigine (LAMICTAL, others) is a phenyltriazine derivative initially developed as an antifolate agent based on the incorrect idea that reducing folate would effectively combat seizures. Structure-activity studies indicate that its effectiveness as an anti-seizure drug is unrelated to its antifolate properties (Macdonald and Greenfield, 1997).

**Pharmacological Effects and Mechanisms of Action.** Lamotrigine suppresses tonic hind limb extension in the maximal electroshock model and partial and secondarily generalized seizures in the kindling model, but does not inhibit clonic motor seizures induced by pentylenetetrazol. Lamotrigine blocks sustained repetitive firing of mouse spinal cord neurons and delays the recovery from inactivation of recombinant Na\(^+\) channels, mechanisms similar to those of phenytoin and carbamazepine (Xie et al., 1995). This may well...
explain lamotrigine’s actions on partial and secondarily generalized seizures. However, as mentioned in the subsequent “Therapeutic Use” section, lamotrigine is effective against a broader spectrum of seizures than phenytoin and carbamazepine, suggesting that lamotrigine may have actions in addition to regulating recovery from inactivation of Na+ channels. The mechanisms underlying its broad spectrum of actions are incompletely understood. One possibility involves lamotrigine’s inhibition of glutamate release in rat cortical slices treated with veratridine, a Na+ channel activator, raising the possibility that lamotrigine inhibits synaptic release of glutamate by acting at Na+ channels themselves.

**Pharmacokinetics.** Lamotrigine is completely absorbed from the gastrointestinal tract and is metabolized primarily by glucuronidation. The plasma t1/2 of a single dose is 24-30 hours. Administration of phenytoin, carbamazepine, or phenobarbital reduces the t1/2 and plasma concentrations of lamotrigine. Conversely, addition of valproate markedly increases plasma concentrations of lamotrigine, likely by inhibiting glucuronidation. Addition of lamotrigine to valproic acid produces a reduction of valproate concentrations by ~25% over a few weeks. Concurrent use of lamotrigine and carbamazepine is associated with increases of the 10,11-epoxide of carbamazepine and clinical toxicity in some patients.

**Therapeutic Use.** Lamotrigine is useful for monotherapy and add-on therapy of partial and secondarily generalized tonic-clonic seizures in adults and Lennox-Gastaut syndrome in both children and adults. Lennox-Gastaut syndrome is a disorder of childhood characterized by multiple seizure types, mental retardation, and refractoriness to anti-seizure medication.

Lamotrigine monotherapy in newly diagnosed partial or generalized tonic-clonic seizures is equivalent to carbamazepine or phenytoin, monotherapy (Brodie et al., 1995; Steiner et al., 1999). A double-blind, placebo-controlled trial of addition of lamotrigine to existing anti-seizure drugs further demonstrated effectiveness of lamotrigine against tonic-clonic seizures and drop attacks in children with the Lennox-Gastaut syndrome (Motte et al., 1997). Lamotrigine was also found to be superior to placebo in a double-blind study of children with newly diagnosed absence epilepsy (Frank et al., 1999).

Patients who are already taking a hepatic enzyme–inducing anti-seizure drug (such as carbamazepine, phenytoin, phenobarbital, or primidone, but not valproate) should be given lamotrigine initially at 50 mg/day for 2 weeks. The dose is increased to 50 mg twice per day for 2 weeks and then increased in increments of 100 mg/day each week up to a maintenance dose of 300-500 mg/day divided into two doses. For patients taking valproate in addition to an enzyme-inducing anti-seizure drug, the initial dose should be 25 mg every other day for 2 weeks, followed by an increase to 25 mg/day for 2 weeks; the dose then can be increased by 25-50 mg/day every 1-2 weeks up to a maintenance dose of 100-150 mg/day divided into two doses.

**Toxicity.** The most common adverse effects are dizziness, ataxia, blurred or double vision, nausea, vomiting, and rash when lamotrigine was added to another anti-seizure drug. A few cases of Stevens-Johnson syndrome and disseminated intravascular coagulation have been reported. The incidence of serious rash in pediatric patients (~0.8%) is higher than in the adult population (0.3%).

Levetiracetam

Levetiracetam (KEPPRA, others) is a pyrrolidine, the racemically pure S-enantiomer of α-ethyl-2-oxo-1-pyrrolidineacetamide and is FDA-approved for adjunctive therapy for myoclonic, partial-onset, and primary generalized tonic-clonic seizures in adults and children as young as 4 years old.

![Levetiracetam](https://example.com/levetiracetam.png)

**Pharmacological Effects and Mechanism of Action.** Levetiracetam exhibits a novel pharmacological profile insofar as it inhibits partial and secondarily generalized tonic-clonic seizures in the kindling model, yet is ineffective against maximum electroshock- and pentylenetetrazol-induced seizures, findings consistent with clinical effectiveness against partial and secondarily generalized tonic-clonic seizures. The mechanism by which levetiracetam exerts these anti-seizure effects is unknown. No evidence for an action on voltage-gated Na+ channels or either GABA- or glutamate-mediated synaptic transmission has emerged. The correlation between binding affinity of levetiracetam analogs and their potency toward audiogenic seizures suggests that a synaptic vesicle protein, SV2A, mediates the anticonvulsant effects of levetiracetam (Rogawski and Bail, 2008). Uncertainty as to the function of SV2A limits insights into how binding of levetiracetam to SV2A might affect cellular function or neuronal excitability.

**Pharmacokinetics.** Levetiracetam is rapidly and almost completely absorbed after oral administration and is not bound to plasma proteins. Ninety-five percent of the drug and its inactive metabolite are excreted in the urine, 65% of which is unchanged drug; 24% of the drug is metabolized by hydrolysis of the acetamide group. It neither induces nor is a high-affinity substrate for CYP isoenzymes or glucuronidation enzymes and thus is devoid of known interactions with other anti-seizure drugs, oral contraceptives, or anticoagulants.

**Therapeutic Use.** Double-blind, placebo-controlled trials of adults with either refractory partial seizures or uncontrolled generalized tonic-clonic seizures associated with idiopathic generalized epilepsy revealed that addition of levetiracetam to other anti-seizure medications was superior to placebo. Levetiracetam also has efficacy as adjunctive therapy for refractory generalized myoclonic seizures (Andermann et al., 2005). Insufficient evidence is available about its use as monotherapy for partial or generalized epilepsy.

**Toxicity.** Levetiracetam is well tolerated. The most frequently reported adverse effects are somnolence, asthenia, and dizziness.

Tiagabine

Tiagabine (GABITRIL) is a derivative of nipecotic acid and approved by the FDA as adjunct therapy for partial seizures in adults.
Pharmacological Effects and Mechanism of Action. Tiagabine inhibits the GABA transporter, GAT-1, and thereby reduces GABA uptake into neurons and glia. In CA1 neurons of the hippocampus, tiagabine increases the duration of inhibitory synaptic currents, findings consistent with prolonging the effect of GABA at inhibitory synapses through reducing its reuptake by GAT-1. Tiagabine inhibits maximum electroshock seizures and both limbic and secondarily generalized tonic-clonic seizures in the kindling model, results suggestive of clinical efficacy against partial and tonic-clonic seizures. Paradoxically, tiagabine has been associated with the occurrence of seizures in patients without epilepsy and off-label use of the drug is discouraged.

Pharmacokinetics. Tiagabine is rapidly absorbed after oral administration, extensively bound to serum or plasma proteins, and metabolized mainly in the liver, predominantly by CYP3A. Its t1/2 of ~8 hours is shortened by 2-3 hours when co-administered with hepatic enzyme–inducing drugs such as phenobarbital, phenytoin, or carbamazepine.

Therapeutic Use. Double-blind, placebo-controlled trials have established tiagabine’s efficacy as add-on therapy of refractory partial seizures with or without secondary generalization. Its efficacy as monotherapy for newly diagnosed or refractory partial and generalized epilepsy has not been established.

Toxicity. The principal adverse effects include dizziness, somnolence, and tremor; they appear to be mild to moderate in severity and appear shortly after initiation of therapy. Tiagabine and other drugs that enhance effects of synaptically released GABA can facilitate spike-and-wave discharges in animal models of absence seizures. Case reports suggest that tiagabine treatment of patients with a history of spike-and-wave discharges causes exacerbations of their EEG abnormalities. Thus, tiagabine may be contraindicated in patients with generalized absence epilepsy.

Topiramate

Topiramate (TOPAMAX, others) is a sulfamate-substituted monosaccharide that is FDA-approved as initial monotherapy (in patients at least 10 years old) and as adjunctive therapy (for patients as young as 2 years of age) for partial-onset or primary generalized tonic-clonic seizures, for Lennox-Gastaut syndrome in patients 2 years of age and older, and for migraine headache prophylaxis in adults.

Pharmacological Effects and Mechanisms of Action. Topiramate reduces voltage-gated Na⁺ currents in cerebellar granule cells and may act on the inactivated state of the channel similar to phenytoin. In addition, topiramate activates a hyperpolarizing K⁺ current, enhances postsynaptic GABA_A-receptor currents, and limits activation of the AMPA-kainate-subtype(s) of glutamate receptor. Topiramate is a weak carbonic anhydrase inhibitor. Topiramate inhibits maximal electroshock and pentylenetetrazol-induced seizures as well as partial and secondarily generalized tonic-clonic seizures in the kindling model, findings predictive of a broad spectrum of anti-seizure actions clinically.

Pharmacokinetics. Topiramate is rapidly absorbed after oral administration, exhibits little (10-20%) binding to plasma proteins, and is mainly excreted unchanged in the urine. The remainder undergoes metabolism by hydroxylation, hydrolysis, and glucuronidation with no single metabolite accounting for > 5% of an oral dose. Its t1/2 is ~1 day. Reduced estradiol plasma concentrations occur with concurrent topiramate, suggesting the need for higher doses of oral contraceptives when coadministered with topiramate.

Therapeutic Use. A double-blind study revealed topiramate to be equivalent to valproate and carbamazepine in children and adults with newly diagnosed partial and primary generalized epilepsy (Privitera et al., 2003). Additional studies disclosed topiramate to be effective as monotherapy for refractory partial epilepsy (Sachdeo et al., 1997) and refractory generalized tonic-clonic seizures (Biton et al., 1999). Topiramate also was found to be significantly more effective than placebo against both drop attacks and tonic-clonic seizures in patients with Lennox-Gastaut syndrome (Sachdeo et al., 1999).

Toxicity. Topiramate is well tolerated. The most common adverse effects are somnolence, fatigue, weight loss, and nervousness. It can precipitate renal calculi, which is most likely due to inhibition of carbonic anhydrase. Topiramate has been associated with cognitive impairment and patients may complain about a change in the taste of carbonated beverages.

Felbamate

Felbamate (FELBATOL) is a dicarbamate that was approved by the FDA for partial seizures in 1993. An association between felbamate and aplastic anemia in at least 10 cases resulted in a recommendation by the FDA and the manufacturer for the immediate withdrawal of most patients from treatment with this drug. Postmarketing experience revealed an association between felbamate exposure and liver failure.
Pharmacological Effects and Mechanisms of Action. Felbamate is effective in both the maximal electroshock and pentylenetetrazol seizure models. Clinically relevant concentrations of felbamate inhibit NMDA-evoked responses and potentiate GABA-evoked responses in whole-cell, voltage-clamp recordings of cultured rat hippocampal neurons (Rho et al., 1994). This dual action on excitatory and inhibitory transmitter responses may contribute to the wide spectrum of action of the drug in seizure models.

Therapeutic Use. An active control, randomized, double-blind protocol demonstrated the efficacy of felbamate in patients with poorly controlled partial and secondarily generalized seizures (Sachdeo et al., 1992). Felbamate also reduced seizures in patients with Lennox-Gastaut syndrome (Felbamate Study Group in Lennox-Gastaut Syndrome, 1993). The clinical efficacy of this compound, which inhibits responses to NMDA and potentiates those to GABA, underscores the potential value of additional anti-seizure agents with similar mechanisms of action.

Lacosamide

Lacosamide (VIMPAT) is a functionalized amino acid that was approved by the FDA in 2008 as adjunctive therapy for partial-onset seizures in patients 17 years of age and older. An injectable formulation is available for short term use when oral administration is not feasible.

Pharmacological Effects and Mechanism of Action. Lacosamide enhances slow inactivation of voltage-gated Na⁺ channels and limits sustained repetitive firing, the neuronal firing pattern characteristic of partial seizures. Lacosamide also binds collapsin response mediator protein 2 (crmp-2), a phosphoprotein involved in neuronal differentiation and axon outgrowth. Its anti-seizure mechanism of action is more likely mediated by its enhancing slow inactivation of Na⁺ channels.

Therapeutic Use. Double-blind, placebo-controlled studies of adults with refractory partial seizures demonstrated that addition of lacosamide to other drugs was superior to placebo.

Rufinamide

Rufinamide (BANZEL) is a triazole derivative structurally unrelated to other marketed anti-epileptic drugs. It was approved by the FDA in 2008 for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in children 4 years and older and adults.

Pharmacological Effects and Mechanism of Action. Rufinamide enhances slow inactivation of voltage gated Na⁺ channels and limits sustained repetitive firing, the firing pattern characteristic of partial seizures. Whether this is the mechanism by which rufinamide suppresses seizures is presently unclear.

Zonisamide

Zonisamide (ZONEGRAN, others) is a sulfonamide derivative that is FDA approved as adjunctive therapy of partial seizures in adults.

Pharmacological Effects and Mechanism of Action. Zonisamide inhibits the T-type Ca²⁺ currents. In addition, zonisamide inhibits the sustained, repetitive firing of spinal cord neurons, presumably by prolonging the inactivated state of voltage-gated Na⁺ channels in a manner similar to actions of phenytoin and carbamazepine.

Zonisamide inhibits tonic hind limb extension evoked by maximal electroshock and inhibits both partial and secondarily generalized seizures in the kindling model, results predictive of clinical effectiveness against partial and secondarily generalized tonic-clonic seizures. Zonisamide does not inhibit minimal clonic seizures induced by pentylenetetrazol, suggesting that the drug will not be effective clinically against myoclonic seizures.

Pharmacokinetics. Zonisamide is almost completely absorbed after oral administration, has a long t₁/₂ (~63 hours), and is ~40% bound to plasma protein. Approximately 85% of an oral dose is excreted in the urine, principally as unmetabolized zonisamide and a glucuronide of sulfamoylacetyl phenol, which is a product of metabolism by CYP3A4. Phenobarbital, phenytoin, and carbamazepine decrease the plasma concentration/dose ratio of zonisamide, whereas lamotrigine increases this ratio. Conversely, zonisamide has little effect on the plasma concentrations of other anti-seizure drugs.

Therapeutic Use. Double-blind, placebo-controlled studies of partial-onset seizures in patients 17 years of age and older. An injectable formulation is available for short term use when oral administration is not feasible.

Toxicity. Overall, zonisamide is well tolerated. The most common adverse effects include somnolence, ataxia, anorexia, nervousness, and fatigue. Approximately 1% of individuals develop renal calculi during treatment with zonisamide, which may relate to its ability to inhibit carbonic anhydrase. Post-marketing experience indicates that zonisamide can cause metabolic acidosis in some patients. Patients with predisposing conditions (e.g., renal disease, severe respiratory disorders, diarrhea, surgery, ketogenic diet) may be at greater risk. The risk of zonisamide-induced metabolic acidosis also appears to be more frequent and severe in younger patients. Measurement of serum bicarbonate prior to initiating therapy and periodically thereafter, even in the absence of symptoms, is recommended.

Lacosamide

Lacosamide (VIMPAT) is a functionalized amino acid that was approved by the FDA in 2008 as adjunctive therapy for partial-onset seizures in patients 17 years of age and older. An injectable formulation is available for short term use when oral administration is not feasible.

Pharmacological Effects and Mechanism of Action. Lacosamide enhances slow inactivation of voltage-gated Na⁺ channels and limits sustained repetitive firing, the neuronal firing pattern characteristic of partial seizures. Lacosamide also binds collapsin response mediator protein 2 (crmp-2), a phosphoprotein involved in neuronal differentiation and axon outgrowth. Its anti-seizure mechanism of action is more likely mediated by its enhancing slow inactivation of Na⁺ channels.

Therapeutic Use. Double-blind, placebo-controlled studies of adults with refractory partial seizures demonstrated that addition of lacosamide to other drugs was superior to placebo.

Rufinamide

Rufinamide (BANZEL) is a triazole derivative structurally unrelated to other marketed anti-epileptic drugs. It was approved by the FDA in 2008 for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in children 4 years and older and adults.

Pharmacological Effects and Mechanism of Action. Rufinamide enhances slow inactivation of voltage gated Na⁺ channels and limits sustained repetitive firing, the firing pattern characteristic of partial seizures. Whether this is the mechanism by which rufinamide suppresses seizures is presently unclear.
Therapeutic Use. A double-blind, placebo-controlled study of children with Lennox-Gastaut syndrome demonstrated that rufinamide reduced tonic-atonic seizure frequency to a greater extent than placebo.

Vigabatrin

Vigabatrin (SABRIL) was approved by the FDA in 2009 as adjunctive therapy of refractory partial complex seizures in adults. In addition, vigabatrin is designated as an orphan drug for treatment of infantile spasms (described in the subsequent “Therapeutic Use” section). Due to progressive and permanent bilateral vision loss, vigabatrin must be reserved for patients who have failed several alternative therapies; its availability is restricted under the conditions of the SHARE special distribution program.

Pharmacological Effects and Mechanism of Action. Vigabatrin is a structural analog of GABA that irreversibly inhibits the major degradative enzyme for GABA, GABA-transaminase, thereby leading to increased concentrations of GABA in the brain. Its mechanism of action is thought to involve enhancement of GABA-mediated inhibition.

Therapeutic Use. A 2-week, randomized, single masked clinical trial of vigabatrin for infantile spasms in children < 2 years old revealed time- and dose-dependent increases in responders, evident as freedom from spasms for 7 consecutive days. The subset of children in whom infantile spasms were caused by tuberous sclerosis was particularly responsive to vigabatrin.

Acetazolamide Acetazolamide, the prototype for the carbonic anhydrase inhibitors, is discussed in Chapter 25. Its anti-seizure actions have been discussed in previous editions of this textbook. Although it is sometimes effective against absence seizures, its usefulness is limited by the rapid development of tolerance. Adverse effects are minimal when it is used in moderate dosage for limited periods.

GENERAL PRINCIPLES AND CHOICE OF DRUGS FOR THE THERAPY OF THE EPILEPSIES

Early diagnosis and treatment of seizure disorders with a single appropriate agent offers the best prospect of achieving prolonged seizure-free periods with the lowest risk of toxicity. An attempt should be made to determine the cause of the epilepsy with the hope of discovering a correctable lesion, either structural or metabolic. The drugs commonly used for distinct seizure types are listed in Table 21–1. The efficacy combined with the unwanted effects of a given drug determine which particular drug is optimal for a given patient.

The first decision to make is whether and when to initiate treatment (French and Pedley, 2008). For example, it may not be necessary to initiate anti-seizure therapy after an isolated tonic-clonic seizure in a healthy young adult who lacks a family history of epilepsy and who has a normal neurological exam, a normal EEG, and a normal brain MRI scan. The odds of seizure recurrence in the next year (15%) are similar to the risk of a drug reaction sufficiently severe to warrant discontinuation of medication (Bazil and Pedley, 1998). On the other hand, a similar seizure occurring in an individual with a positive family history of epilepsy, an abnormal neurological exam, an abnormal EEG, and an abnormal MRI carries a risk of recurrence approximating 60%, odds that favor initiation of therapy.

Unless extenuating circumstances such as status epilepticus exist, only monotherapy should be initiated. Initial dosing should target steady-state plasma drug concentrations within at least the lower portion of the range associated with clinical efficacy. At the same time the initial dose should be as low as possible to minimize dose-related adverse effects. Dosage is increased at appropriate intervals as required for control of seizures or as limited by toxicity. Such adjustment should be assisted by monitoring of drug concentrations in plasma. Compliance with a properly selected, single drug in maximal tolerated dosage results in complete control of seizures in ~50% of patients. If a seizure occurs despite optimal drug levels, the physician should assess the presence of potential precipitating factors such as sleep deprivation, a concurrent febrile illness, or drugs (e.g., large amounts of caffeine or over-the-counter medications that can lower the seizure threshold).

If compliance has been confirmed yet seizures persist, another drug should be substituted. Unless serious adverse effects of the drug dictate otherwise, dosage always should be reduced gradually to minimize risk of seizure recurrence. In the case of partial seizures in adults, the diversity of available drugs permits selection of a second drug that acts by a different mechanism (see Table 21–2). Among previously untreated patients, 47% became seizure free with the first drug and an additional 14% became seizure free with a second or third drug (Kwan and Brodie, 2000).

If therapy with a second single drug also is inadequate, combination therapy is warranted. This decision
should not be taken lightly, because most patients obtain optimal seizure control with fewest unwanted effects when taking a single drug. Nonetheless, some patients will not be controlled adequately without the simultaneous use of two or more anti-seizure agents. No properly controlled studies have systematically compared one particular drug combination with another. The chances of complete control with this approach are not high; Kwan and Brodie (2000), found that epilepsy was controlled by treatment with two drugs in only 3% of patients. It seems wise to select two drugs that act by distinct mechanisms (e.g., one that promotes Na⁺ channel inactivation and another that enhances GABA-mediated synaptic inhibition). Side effects of each drug and the potential drug interactions also should be considered. As specified in Table 21–3, many of these drugs induce expression of CYPs and thereby impact the metabolism of themselves and/or other drugs (Table 21–3).

Essential to optimal management of epilepsy is the filling out of a seizure chart by the patient or a relative. Frequent visits to the physician may be necessary early in the period of treatment, since hematological and other possible side effects may require a change in medication. Long-term follow-up with neurological examinations and possibly EEG and neuroimaging studies is appropriate. Most crucial for successful management is patient adherence to the drug regimen; noncompliance is the most frequent cause for failure of therapy with anti-seizure drugs.

Measurement of plasma drug concentration at appropriate intervals greatly facilitates the initial adjustment of dosage to minimize dose-related adverse effects without sacrificing seizure control. Periodic monitoring during maintenance therapy can also detect noncompliance. Knowledge of plasma drug concentrations can be especially helpful during multiple-drug therapy. If toxicity occurs, monitoring helps to identify the particular drug(s) responsible and can guide adjustment of dosage.

**Duration of Therapy**

Once initiated, anti-seizure drugs are typically continued for at least 2 years. Tapering and discontinuing therapy should be considered, if the patient is seizure free after 2 years.

Factors associated with high risk for recurrent seizures following discontinuation of therapy include EEG abnormalities, known structural lesions, abnormalities on neurological exam, and history of frequent seizures or medically refractory seizures prior to control. Conversely, factors associated with low risk for recurrent seizures include idiopathic epilepsy, normal EEG, onset in childhood, and seizures easily controlled with a single drug. The risk of recurrent seizures ranges from 12-66% (French and Pedley, 2008). Typically 80% of recurrences will occur within 4 months of discontinuing therapy. The clinician and patient must weigh the risk of recurrent seizure and the associated potential deleterious consequences (e.g., loss of driving privileges) against the various implications of continuing medication including cost, unwanted effects, implications of diagnosis of epilepsy, etc. Medications should be tapered slowly over a period of several months.

---

**Simple and Complex Partial and Secondarily Generalized Tonic-Clonic Seizures**

The efficacy and toxicity of carbamazepine, phenobarbital, and phenytoin for treatment of partial and secondarily generalized tonic-clonic seizures in adults have been examined in a double-blind prospective study (Mattson et al., 1985). Carbamazepine and phenytoin were the most effective agents. The choice between carbamazepine and phenytoin required assessment of toxic effects of each drug. Decreased libido and impotence were associated with all three drugs (carbamazepine 13%, phenobarbital 16%, and phenytoin 11%). In direct comparison with valproate, carbamazepine provided superior control of complex partial seizures (Mattson et al., 1992).

With respect to adverse effects, carbamazepine was more commonly associated with skin rash, but valproate was more commonly associated with tremor and weight gain. Overall, the data demonstrated that carbamazepine and phenytoin are preferable for treatment of partial seizures, but phenobarbital and valproic acid are also efficacious.

Control of secondarily generalized tonic-clonic seizures did not differ significantly with carbamazepine, phenobarbital, or phenytoin (Mattson et al., 1985). Valproate was as effective as carbamazepine for control of secondarily generalized tonic-clonic seizures (Mattson et al., 1992). Since secondarily generalized tonic-clonic seizures usually coexist with partial seizures, these data indicate that among drugs introduced before 1990, carbamazepine and phenytoin are the first-line drugs for these conditions.

One key issue confronting the treating physician is choosing the optimal drug for initiating treatment in new onset epilepsy. At first glance, this issue may appear unimportant because ~50% of newly diagnosed patients become seizure free with the first drug, whether old or new drugs are used (Kwan and Brodie, 2000). However, responsive patients typically receive the initial drug for several years, underscoring the importance of proper drug selection. Among the drugs available before 1990, phenytoin, carbamazepine, and phenobarbital induce hepatic CYPs, thereby complicating use of multiple anti-seizure drugs as well as impacting metabolism of oral contraceptives, warfarin, and many other drugs. These drugs also enhance metabolism of endogenous compounds including gonadal steroids and vitamin D, potentially impacting reproductive function and bone density. By contrast, most of the newer drugs have little if any effect on the CYPs. Factors arguing against use of recently introduced drugs include higher costs and less clinical experience with the compounds.

Ideally, a prospective study would systematically compare newly introduced anti-seizure drugs with drugs available before 1990 in a study design adjusting dose as needed and observing responses for extended periods of time (e.g., 2 years or more), in much the same manner as that used when comparing the older anti-seizure drugs with one another as described earlier (Mattson et al., 1985).
Unfortunately, such a study has not been performed. Many of the studies referenced in description of newer drugs did compare a new with an older anti-seizure drug, but study design did not permit declaring a clearly superior drug; moreover, differences in study design and patient populations preclude comparing a new drug with multiple older drugs or with other new drugs. The use of recently introduced anti-seizure drugs for newly diagnosed epilepsy was analyzed by subcommittees of the American Academy of Neurology and the American Epilepsy Society (French et al., 2004a; French et al., 2004b); the authors concluded that available evidence supported the use of gabapentin, lamotrigine, and topiramate for newly diagnosed partial or mixed seizure disorders. None of these drugs, however, has been approved by the FDA for either of these indications. Insufficient evidence was available on the remaining newly introduced drugs to permit meaningful assessment of their effectiveness for this indication.

Absence Seizures
Ethosuximide and valproate are considered equally effective in the treatment of absence seizures (Mikati and Browne, 1988). Between 50% and 75% of newly diagnosed patients are free of seizures following therapy with either drug. If tonic-clonic seizures are present or emerge during therapy, valproate is the agent of first choice. French and others concluded that available evidence indicates that lamotrigine is also effective for newly diagnosed absence epilepsy despite the fact that lamotrigine is not approved for this indication by the FDA.

Myoclonic Seizures
Valproic acid is the drug of choice for myoclonic seizures in the syndrome of juvenile myoclonic epilepsy, in which myoclonic seizures often coexist with tonic-clonic and absence seizures. Levetiracetam also has demonstrated efficacy as adjunctive therapy for refractory generalized myoclonic seizures.

Febrile Convulsions
Two to four percent of children experience a convulsion associated with a febrile illness. From 25-33% of these children will have another febrile convulsion. Only 2-3% become epileptic in later years, a 6-fold increase in risk compared with the general population. Several factors are associated with an increased risk of developing epilepsy: preexisting neurological disorder or developmental delay, a family history of epilepsy, or a complicated febrile seizure (i.e., the febrile seizure lasted > 15 minutes, was one-sided, or was followed by a second seizure in the same day). If all of these risk factors are present, the risk of developing epilepsy is 10%.

The increased risk of developing epilepsy or other neurological sequelae led many physicians to prescribe anti-seizure drugs prophylactically after a febrile seizure. Uncertainties regarding the efficacy of prophylaxis for reducing epilepsy combined with substantial side effects of phenobarbital prophylaxis (Farwell et al., 1990) argue against the use of chronic therapy for prophylactic purposes (Freeman, 1992). For children at high risk of developing recurrent febrile seizures and epilepsy, rectally administered diazepam at the time of fever may prevent recurrent seizures and avoid side effects of chronic therapy.

Seizures in Infants and Young Children
Infantile spasms with hypsarrhythmia (abnormal inter-ictal high amplitude slow waves and multifocal asynchronous spikes on EEG) are refractory to the usual anti-seizure agents. Corticotropin or the glucocorticoids are commonly used and repository corticotropin (H.P. ACTHAR GEL) was designated as an orphan drug for this purpose in 2003. A randomized study found vigabatrin (γ-vinyl GABA; SABRIL) to be efficacious in comparison to placebo (Appleton et al., 1999). Constriction of visual fields has been reported in a high percentage of patients treated with vigabatrin (Miller et al., 1999). The potential for progressive and permanent vision loss has resulted in vigabatrin being labeled with a black-box warning and marketed under a restrictive distribution program. The drug received orphan drug status for the treatment of infantile spasms in the U.S. in 2000 (and was FDA-approved in 2009 as adjunctive therapy for adults with refractory complex partial seizures). Ganaxolone also has been designated as an orphan drug since 1994 for the treatment of infantile spasms and completed a phase II clinical trial for uncontrolled partial-onset seizures in adults in 2009.

The Lennox-Gastaut syndrome is a severe form of epilepsy which usually begins in childhood and is characterized by cognitive impairments and multiple types of seizures including tonic-clonic, tonic, atonic, myoclonic, and atypical absence seizures. Addition of lamotrigine to other anti-seizure drugs resulted in improved seizure control in comparison to placebo in a double-blind trial (Motte et al., 1997), demonstrating lamotrigine to be an effective and well-tolerated drug for this treatment-resistant form of epilepsy. Felbamate also was found to be effective for seizures in this syndrome, but the occasional occurrence of aplastic anemia and hepatic failure have limited its use (French et al., 1999). Topiramate has also been demonstrated to be effective for Lennox-Gastaut syndrome (Sachdeo et al., 1999).

Status Epilepticus and Other Convulsive Emergencies
Status epilepticus is a neurological emergency. Mortality for adults approximates 20% (Lowenstein and Allerdge, 1998). The goal of treatment is rapid termination of behavioral and electrical seizure activity; the longer the episode of status epilepticus is untreated, the more difficult it is to control and the greater the risk of permanent brain damage. Critical to the management is a clear plan, prompt treatment with effective drugs in adequate doses, and attention to hyperventilation and hypotension. Since hyperventilation may result from high doses of drugs used for treatment, it may be necessary to assist respiration temporarily. Drugs should be administered by the intravenous route only. Because of slow and unreliable absorption, the intramuscular route has no place in treatment of status epilepticus. To assess the optimal initial drug regimen, a double-blind, multicenter trial compared four intravenous treatments: diazepam followed by phenytoin; lorazepam; phenobarbital; and phenytoin alone (Treiman et al., 1998). The treatments had similar efficacies, with success rates ranging from 44-65%. Lorazepam alone was significantly better than phenytoin alone. No significant differences were found with respect to recurrences or adverse reactions.

Anti-Seizure Therapy and Pregnancy
Use of anti-seizure drugs has diverse implications of great importance for the health of women. Issues include interactions with oral contraceptives, potential teratogenic effects, and effects on vitamin K metabolism in pregnant women (Pack, 2006). Guidelines for the care
of women with epilepsy have been published by the

The effectiveness of oral contraceptives appears to be
reduced by concomitant use of anti-seizure drugs. The failure rate
of oral contraceptives is 3.1/100 years in women receiving anti-
seizure drugs compared to a rate of 0.7/100 years in non-epilep-
tic women. One attractive explanation of the increased failure rate
is the increased rate of oral contraceptive metabolism caused by
anti-seizure drugs that induce hepatic enzymes (Table 21–2); par-
ticular caution is needed with anti-seizure drugs that induce
CYP3A4.

Teratogenicity. Epidemiological evidence suggests that anti-seizure
drugs have teratogenic effects (Pack, 2006). These teratogenic effects
add to the deleterious consequences of oral contraceptive failure.
Infants of epileptic mothers are at 2-fold greater risk of major conge-
nital malformations than offspring of non-epileptic mothers (4.8% compared to 2-4%). These malformations include congenital heart
defects, neural tube defects, cleft lip, cleft palate, and others. Inferring
causality from the associations found in large epidemiological stud-
ies with many uncontrolled variables can be hazardous, but a causal
role for anti-seizure drugs is suggested by association of congenital
defects with higher concentrations of a drug or with polytherapy com-
pared to monotherapy. Phenytoin, carbamazepine, valproate, lamot-
rigine, and phenobarbital all have been associated with teratogenic
effects. Newer anti-seizure drugs have teratogenic effects in animals
but whether such effects occur in humans is yet uncertain. One con-
sideration for a woman with epilepsy who wishes to become pregnant
is a trial free of anti-seizure drug; monotherapy with careful atten-
dition to drug levels is another alternative. Polytherapy with toxic lev-
evels should be avoided. Folate supplementation (0.4 mg/day) has been
recommended by the U.S. Public Health Service for all women of
childbearing age to reduce the likelihood of neural tube defects, and
this is appropriate for epileptic women as well.

Anti-seizure drugs that induce CYPs have been associated with
vitamin K deficiency in the newborn, which can result in a
coagulopathy and intracerebral hemorrhage. Treatment with vitamin
K₃, 10 mg/day during the last month of gestation, has been recom-
manded for prophylaxis.

Neurodegenerative disorders are characterized by progressive and irreversible loss of neurons from specific regions of the brain. Prototypical neurodegenerative disorders include Parkinson disease (PD) and Huntington’s disease (HD), where loss of neurons from structures of the basal ganglia results in abnormalities in the control of movement; Alzheimer’s disease (AD), where the loss of hippocampal and cortical neurons leads to impairment of memory and cognitive ability; and amyotrophic lateral sclerosis (ALS), where muscular weakness results from the degeneration of spinal, bulbar, and cortical motor neurons.

As a group, these disorders are relatively common and represent a substantial medical and societal problem. They are primarily disorders of later life, developing in individuals who are neurologically normal, although childhood-onset forms of each of the disorders are recognized. PD is observed in more than 1% of individuals over the age of 65 (Tanner, 1992), whereas AD affects as many as 10% of the same population (Evans et al., 1989). HD, which is a genetically determined autosomal dominant disorder, is less frequent in the population as a whole but affects, on average, 50% of each generation in families carrying the gene. ALS also is relatively rare but often leads rapidly to disability and death (Kurtzke, 1982).

Currently available therapies for neurodegenerative disorders alleviate the disease symptoms but do not alter the underlying neurodegenerative process. Symptomatic treatment for PD, where the neurochemical deficit produced by the disease is well defined, is, in general, relatively successful, and a number of effective agents are available. The available symptomatic treatments for AD, HD, and ALS are much more limited in effectiveness. On the horizon are pharmacological treatments aimed at preventing or retarding progression of neurodegeneration. A wide range of such disease-modifying approaches hold the promise to transform the approach to both the diagnosis and the treatment of neurodegenerative disorders.

**SELECTIVE VULNERABILITY AND NEUROPROTECTIVE STRATEGIES**

**Selective Vulnerability.** A striking feature of neurodegenerative disorders is the exquisite specificity of the disease processes for particular types of neurons. For example, in PD there is extensive destruction of the dopaminergic neurons of the substantia nigra, whereas neurons in the cortex and many other areas of the brain are unaffected. In contrast, neural injury in AD is most severe in the hippocampus and neocortex, and even within the cortex, the loss of neurons is not uniform but varies dramatically in different functional regions (Arnold et al., 1991). Even more striking is the observation that in HD the mutant gene responsible for the disorder is expressed throughout the brain and in many other organs, yet the pathological changes are most prominent in the neostriatum (Landwehrmeyer et al., 1995). In ALS, there is loss of spinal motor neurons and the cortical neurons that provide their descending input (Tandan and Bradley, 1985). The diversity of these patterns of neural degeneration suggests that the process of neural injury results from the interaction of genetic and environmental influences with the intrinsic physiological characteristics of the affected populations of neurons. The intrinsic factors may include susceptibility to...
Excitotoxic injury, regional variation in capacity for oxidative metabolism, and the production of toxic free radicals as by-products of cellular metabolism. New neuroprotective agents may target the factors that convey selective vulnerability.

**Genetics and Environment.** Each of the major neurodegenerative disorders may be familial in nature. HD is exclusively familial; it is transmitted by autosomal dominant inheritance, and the molecular mechanism of the genetic defect has been defined. Nevertheless, environmental factors importantly influence the age of onset and rate of progression of HD symptoms. PD, AD, and ALS are mostly sporadic without clear pattern of inheritance. But for each there are well-recognized genetic forms. For example, there are both dominant (α-synuclein, LRRK2) and recessive (parkin, DJ-1, PINK1) gene mutations that may give rise to PD (Farrer, 2006). In AD, mutations in the genes coding for the amyloid precursor protein (APP) and proteins known as the presenilins (involved in APP processing) lead to inherited forms of the disease (Selkoe and Podlisny, 2002). Mutations in the gene coding for copper-zinc superoxide dismutase (SOD1) account for about 2% of the cases of adult-onset ALS (Boillée et al., 2006). Several other less common mutations have also been described.

In addition to these monogenic forms of neurodegenerative disease, there are also genetic risk factors that influence the probability of disease onset and modify the phenotype. For example, the apolipoprotein E (apo E) genotype constitutes an important risk factor for AD. Three distinct isoforms of this protein exist. Although all isoforms carry out their primary role in lipid metabolism equally well, individuals who are homozygous for the apoE4 allele (“4/4”) have a much higher lifetime risk of AD than do those homozygous for the apoE2 allele (“2/2”). The mechanism by which the apoE4 protein increases the risk of AD is not exactly known. ApoE4 probably has multiple effects, some of which are mediated through altering β-amyloid (Aβ) aggregation or processing, and some of which that are Aβ-independent (Mahley et al., 2006).

Environmental factors including infectious agents, environmental toxins, and acquired brain injury have been proposed in the etiology of neurodegenerative disorders. The role of infection is best documented in the cases of PD that developed following the epidemic of encephalitis lethargica (von Economo’s encephalitis) in the early part of the 20th century. Most contemporary cases of PD are not preceded by encephalitis, and there is no convincing evidence for an infectious contribution to HD, AD, or ALS. Traumatic brain injury has been suggested as a trigger for neurodegenerative disorders, and in the case of AD there is some evidence to support this view (Cummings et al., 1998). At least one toxin, N-methyl-D-aspartate (NMDA) type. Excitotoxic injury contributes to the neuronal death that occurs in acute processes such as stroke and head trauma (Choi and Rothman, 1990). The role of excitotoxicity is less certain in the chronic neurodegenerative disorders; nevertheless, regional and cellular differences in susceptibility to excitotoxic injury, conveyed, e.g., by differences in types of glutamate receptors, may contribute to selective vulnerability. This has led to the development of glutamate antagonists as neuroprotective therapies, with two such agents (memantine and riluzole, described later) currently in clinical use.

Aging is associated with a progressive impairment in the capacity of neurons for oxidative metabolism, perhaps in part because of a progressive accumulation of mutations in the mitochondrial genome. A consequence of impaired oxidative capacities is the production of reactive compounds such as hydrogen peroxide and oxygen radicals. Unchecked, these reactive species can lead to DNA damage, peroxidation of membrane lipids, and neuronal death. This has led to pursuit of drugs that can enhance cellular metabolism.

**Common Cellular Mechanisms of Neurodegeneration.** Despite their varied phenotypes, the neurodegenerative disorders share some common features. For example, misfolded and aggregated proteins are found in every major neurodegenerative disorder: alpha-synuclein, in PD; amyloid-β (Aβ) and tau in AD; huntingtin in HD; and SOD and TDP-43 in ALS. The accumulation of misfolded proteins may result from either genetic mutations producing abnormal structure, or from impaired cellular clearance. Age-related decline in the ability to clear misfolded proteins may be an important predisposing factor, and strategies to augment the clearance of misfolded proteins are being studied as potential therapies.

The term *excitotoxicity* describes the neural injury that results from the presence of excess glutamate in the brain. Glutamate is used as a neurotransmitter by many different neural systems and is believed to mediate most excitatory synaptic transmission in the mammalian brain (see Table 14–3). Although glutamate is required for normal brain function, the presence of excessive amounts of glutamate can lead to excitotoxic cell death (see Figure 14–13). The destructive effects of glutamate are mediated by glutamate receptors, particularly those of the N-methyl-D-aspartate (NMDA) type. Excitotoxic injury contributes to the neuronal death that occurs in acute processes such as stroke and head trauma (Choi and Rothman, 1990). The role of excitotoxicity is less certain in the chronic neurodegenerative disorders; nevertheless, regional and cellular differences in susceptibility to excitotoxic injury, conveyed, e.g., by differences in types of glutamate receptors, may contribute to selective vulnerability. This has led to the development of glutamate antagonists as neuroprotective therapies, with two such agents (memantine and riluzole, described later) currently in clinical use.

Exposure of soldiers to neurotoxic chemicals has been implicated in ALS (as part of “Gulf War syndrome”) (Golomb, 2008). While these examples illustrate the potential of environmental factors to influence neurodegenerative disease, it is clear that the causes identified so far are too few to account for more than a small minority of the cases. Further progress in understanding the causes of neurodegenerative disorders will require a deeper understanding of the interactions between genetic predisposition and environmental factors, an area that is just beginning to be explored.
Parkinson Disease (PD)

Clinical Overview. Parkinsonism is a clinical syndrome consisting of four cardinal features:

- bradykinesia (slowness and poverty of movement)
- muscular rigidity
- resting tremor (which usually abates during voluntary movement)
- an impairment of postural balance leading to disturbances of gait and falling

The most common form of parkinsonism is idiopathic PD, first described by James Parkinson in 1817 as *paralysis agitans*, or the “shaking palsy.” The pathological hallmark of PD is the loss of the pigmented, dopaminergic neurons of the substantia nigra pars compacta, with the appearance of intracellular inclusions known as *Lewy bodies*. Progressive loss of dopamine (DA) containing neurons is a feature of normal aging; however, most people do not lose the 70-80% of dopaminergic neurons required to cause symptomatic PD. Without treatment, PD progresses over 5-10 years to a rigid, akinetic state in which patients are incapable of caring for themselves. Death frequently results from complications of immobility, including aspiration pneumonia or pulmonary embolism. The availability of effective pharmacological treatment has radically altered the prognosis of PD; in most cases, good functional mobility can be maintained for many years. Life expectancy of adequately treated patients is increased substantially, but overall mortality remains higher than that of the general population. In addition, while DA neuron loss is the most prominent feature of the disease, the disorder affects a wide range of other brain structures, including the brainstem, hippocampus, and cerebral cortex (Braak and Del Tredici, 2008). This pathology is likely responsible for the “non-motor” features of PD, which include sleep disorders, depression, and memory impairment. As treatments for the motor features have improved, these non-motor aspects have become important sources of disability for patients (Langston, 2006).

Neural Mechanism of Parkinsonism. Considerable effort has been devoted to understanding how the loss of dopaminergic input to the neurons of the neostriatum gives rise to the clinical features of PD (for review, see Albin et al., 1989; Mink and Thach, 1993; and Wichmann and DeLong, 1993). The basal ganglia that, while incomplete, is still useful.

Dopamine Synthesis, Metabolism, and Receptors. DA, a catecholamine, is synthesized in the terminals of dopaminergic neurons from tyrosine and stored, released, and metabolized by processes described in Chapter 13 and summarized in Figure 22–1. The actions of DA in the brain are mediated by a family of DA-receptor proteins. Two types of DA receptors were identified in the mammalian brain using pharmacological techniques: D1 receptors, which stimulate the synthesis of the intracellular second messenger cyclic AMP; and D2 receptors, which inhibit cyclic AMP synthesis as well as suppress Ca2+ currents and activate receptor-operated K+ currents. More recently, genetic studies revealed at least five distinct DA receptors (D1–D5) (Chapter 13). All the DA receptors are G protein–coupled receptors (GPCRs) (Chapter 3). The D1 and D3 proteins have a long intracellular carboxy-terminal tail and are members of the class defined pharmacologically as D1; they stimulate the formation of cyclic AMP and phosphatidyl inositol hydrolysis. The D2, D4, and D5 receptors share a large third intracellular loop and are of the D2 class. They decrease cyclic AMP formation and modulate K+ and Ca2+ currents. Each of the five DA receptor proteins has a distinct anatomical pattern of expression in the brain. The D1 and D3 proteins are abundant in the striatum and are the most important receptor sites with regard to the causes and treatment of PD. The D4 and D5 proteins are largely extrastriatal, whereas D2 expression is low in the caudate and putamen but more abundant in the nucleus accumbens and olfactory tubercle.

Pathophysiology. The dopaminergic deficit in PD arises from a loss of the neurons in the substantia nigra pars compacta that provide innervation to the striatum (caudate and putamen). The current understanding of the pathophysiology of PD is based on the finding that the striatal DA content is reduced in excess of 80%. This paralleled the loss of neurons from the substantia nigra, suggesting that replacement of DA could restore function (Cotzias et al., 1969; Hornykiewicz, 1973). These fundamental observations led to an extensive investigative effort to understand the metabolism and actions of DA and to learn how a deficit in DA gives rise to the clinical features of PD. We now have a model of the function of the basal ganglia that, while incomplete, is still useful.

Neural Mechanism of Parkinsonism. Considerable effort has been devoted to understanding how the loss of dopaminergic input to the neurons of the neostriatum gives rise to the clinical features of PD (for review, see Albin et al., 1989; Mink and Thach, 1993; and Wichmann and DeLong, 1993). The basal ganglia can be viewed as a modulatory side loop that regulates the flow of information from the cerebral cortex to the motor neurons of the spinal cord (Figure 22–2). The neostriatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of the cortex. Most neurons within the striatum are projection neurons that innervate other basal ganglia structures. A small but important (such as the mitochondrial cofactor coenzyme Q10) and anti-oxidant strategies as treatments to prevent or retard degenerative diseases (Beal, 2005).
subgroup of striatal neurons consists of interneurons that connect neurons within the striatum but do not project beyond its borders. Acetylcholine (ACh) and neuropeptides are used as transmitters by these striatal interneurons.

The outflow of the striatum proceeds along two distinct routes, termed the direct and indirect pathways. The direct pathway is formed by neurons in the striatum that project directly to the output stages of the basal ganglia, the substantia nigra pars reticulata (SNpr) and the globus pallidus interna (GPI); these, in turn, relay to the ventroanterior and ventrolateral thalamus, which provides excitatory input to the cortex. The neurotransmitter of both links of the direct pathway is γ-aminobutyric acid (GABA), which is inhibitory, so that the net effect of stimulation of the direct pathway at the level of the striatum is to increase the excitatory outflow from the thalamus to the cortex. The indirect pathway is composed of striatal neurons that project to the globus pallidus externa (GPe). This structure, in turn, innervates the subthalamic nucleus (STN), which provides outflow to the SNpr and GPl output stage. As in the direct pathway, the first two links—the projections from striatum to GPe and GPe to STN—use the inhibitory transmitter GABA; however, the final link—the projection from STN to SNpr and GPl—is an excitatory glutamatergic pathway. Thus, the net effect of stimulating the indirect pathway at the level of the striatum is to reduce the excitatory outflow from the thalamus to the cerebral cortex.

**Figure 22-1. Dopaminergic nerve terminal.** Dopamine (DA) is synthesized from tyrosine in the nerve terminal by the sequential actions of tyrosine hydrolase (TH) and aromatic amino acid decarboxylase (AADC). DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D1 and D2 receptors. Synaptic DA may be taken up into the neuron via the DA and NE transporters (DAT, NET), or removed by postsynaptic uptake via OCT3 transporters. Cytosolic DA is subject to degradation by monoamine oxidase (MAO) and aldehyde dehydrogenase (ALDH) in the neuron, and by catechol-O-methyl tranferase (COMT) and MAO/ALDH in non-neuronal cells; the final metabolic product is homovanillic acid (HVA). See structures in Figure 22-4. PH, phenylalalanine hydroxylase.
The key feature of this model of basal ganglia function, which accounts for the symptoms observed in PD as a result of loss of dopaminergic neurons, is the differential effect of DA on the direct and indirect pathways (Figure 22–3). The dopaminergic neurons of the substantia nigra pars compacta (SNpc) innervate all parts of the striatum; however, the target striatal neurons express distinct types of DA receptors. The striatal neurons giving rise to the direct pathway express primarily the excitatory D_1 dopamine receptor protein, whereas the striatal neurons forming the indirect pathway express primarily the inhibitory D_2 type. Thus, DA released in the striatum tends to increase the activity of the direct pathway and reduce the activity of the indirect pathway, whereas the depletion that occurs in PD has the opposite effect. The net effect of the reduced dopaminergic input in PD is to increase markedly the inhibitory outflow from the SNpr and Gpi to the thalamus and reduce excitation of the motor cortex.

There are several limitations of this model of basal ganglia function (Parent and Cicchetti, 1998): The anatomical connections are considerably more complex than envisioned originally. In addition, many of the pathways involved use not just one, but several neurotransmitters. For example, the neuropeptides substance P and dynorphin are found predominantly in striatal neurons making up the direct pathway, whereas most of the indirect pathway neurons express enkephalin. These transmitters are expected to have slow modulatory effects on signaling, in contrast to the rapid effects of glutamate and GABA, but the functional significance of these modulatory effects remains unclear. Nevertheless, the model is useful and has important implications for the rational design and use of pharmacological agents in PD. First, it suggests that to restore the balance of the system through stimulation of DA receptors, the complementary effect of actions at both D_1 and D_2 receptors, as well as the possibility of adverse effects that may be mediated by D_3, D_4, or D_5 receptors, must be considered. Second, it explains why replacement of DA is not the only approach to the treatment of PD. Drugs that inhibit cholinergic receptors have long been used for treatment of parkinsonism. Although their mechanisms of action are not completely understood, their effect is likely mediated at the level of the striatal projection neurons, which normally receive cholinergic input from striatal cholinergic interneurons. Only few clinically useful drugs for parkinsonism are presently available based on actions through GABA and glutamate receptors, even though both have crucial roles in the circuitry of the basal ganglia. However, they represent a promising avenue for drug development (Hallet and Standaert, 2004).
Treatment of Parkinson Disease

Commonly used medications for the treatment of PD are summarized in Table 22–1.

Levodopa. Levodopa (L-DOPA, LARODOPA, L-3,4-dihydroxyphenylalanine), the metabolic precursor of DA, is the single most effective agent in the treatment of PD. Levodopa is itself largely inert; both its therapeutic and adverse effects result from the decarboxylation of levodopa to DA. When administered orally, levodopa is absorbed rapidly from the small bowel by the transport system for aromatic amino acids. Concentrations of the

</table>
drug in plasma usually peak between 0.5 and 2 hours after an oral dose. The t1/2 in plasma is short (1-3 hours). The rate and extent of absorption of levodopa depends on the rate of gastric emptying, the pH of gastric juice, and the length of time the drug is exposed to the degradative enzymes of the gastric and intestinal mucosa. Competition for absorption sites in the small bowel from dietary amino acids also may have a marked effect on the absorption of levodopa; administration of levodopa with high-protein meals delays absorption and reduces peak plasma concentrations. Entry of the drug into the CNS across the blood-brain barrier also is mediated by a membrane transporter for aromatic amino acids, and competition between dietary protein and levodopa may occur at this level. In the brain, levodopa is converted to DA by decarboxylation primarily within the presynaptic terminals of dopaminergic neurons in the stratum. The DA produced is responsible for the therapeutic effectiveness of the drug in PD; after release, it is either transported back into dopaminergic terminals by the presynaptic uptake mechanism or metabolized by the actions of MAO and catechol-O-methyltransferase (COMT) (Figure 22–4).

In clinical practice, levodopa is almost always administered in combination with a peripherally acting inhibitor of aromatic L-amino acid decarboxylase, such as carbidopa or benserazide (available outside the U.S.), drugs that do not penetrate well into the CNS. If levodopa is administered alone, the drug is largely decarboxylated by enzymes in the intestinal mucosa and other peripheral sites so that relatively little unchanged drug reaches the cerebral circulation and probably <1% penetrates the CNS. In addition, DA release into the circulation by peripheral conversion of levodopa produces undesirable effects, particularly nausea. Inhibition of peripheral decarboxylase markedly increases the fraction of administered levodopa that remains unmetabolized and available to cross the blood-brain barrier (Figure 22–5) and reduces the incidence of GI side effects.

In most individuals, a daily dose of 75 mg carbidopa is sufficient to prevent the development of nausea. For this reason, the most commonly prescribed form of carbidopa/levodopa (Sinemet, Atamet, others) is the 25/100 form, containing 25 mg carbidopa and 100 mg levodopa. With this formulation, dosage schedules of three or more tablets daily provide acceptable inhibition of decarboxylase in most individuals. Occasionally, individuals will require larger doses of carbidopa to minimize gastrointestinal side effects, and administration of supplemental carbidopa (Lodosyn) may be beneficial. Carbidopa/levodopa is also available in an orally disintegrating tablet (Parcopa). This may be useful in patients with swallowing difficulty, although it is important to note that levodopa is not absorbed through the oral mucosa, and must still be delivered to the small intestine for absorption. Thus, the time to onset of action of Parcopa is not appreciably different from that of standard oral formulations.

Figure 22–4. Metabolism of levodopa (L-DOPA). ALDH, aldehyde dehydrogenase; COMT, catechol-O-methyltransferase; DJβH, dopamine β-hydroxylase; AADC, aromatic L-amino acid decarboxylase; MAO, monoamine oxidase.

Figure 22–5. Pharmacological preservation of L-DOPA and striatal dopamine. The principal site of action of inhibitors of catechol-O-methyltransferase (COMT) (such as tolcapone and entacapone) is in the peripheral circulation. They block the O-methylation of levodopa (L-DOPA) and increase the fraction of the drug available for delivery to the brain. Tolcapone also has effects in the CNS. Inhibitors of MAO-B, such as low-dose selegiline and rasagiline, will act within the CNS to reduce oxidative deamination of DA, thereby enhancing vesicular stores. AADC, aromatic L-amino acid decarboxylase; DA, dopamine; DOPAC, 3,4-dihydroxyphenylacetic acid; MAO, monoamine oxidase; 3MT, 3-methoxytyramine; 3-O-MD, 3-O-methyl DOPA.
Levodopa therapy can have a dramatic effect on all the signs and symptoms of PD. Early in the course of the disease, the degree of improvement in tremor, rigidity, and bradykinesia may be nearly complete. In early PD, the duration of the beneficial effects of levodopa may exceed the plasma lifetime of the drug, suggesting that the nigrostriatal DA system retains some capacity to store and release DA. A principal limitation of the long-term use of levodopa therapy is that with time this apparent “buffering” capacity is lost, and the patient’s motor state may fluctuate dramatically with each dose of levodopa, a condition described as motor complications of levodopa. A common problem is the development of the “wearing off” phenomenon: each dose of levodopa effectively improves mobility for a period of time, perhaps 1-2 hours, but rigidity and akinesia return rapidly at the end of the dosing interval. Increasing the dose and frequency of administration can improve this situation, but this often is limited by the development of dyskinesias, excessive and abnormal involuntary movements. Dyskinesias are observed most often when the plasma levodopa concentration is high, although in some individuals dyskinesias or dystonia may be triggered when the level is rising or falling. These movements can be as uncomfortable and disabling as the rigidity and akinesia of PD. In the later stages of PD, patients may fluctuate rapidly between being “off,” having no beneficial effects from their medications, and being “on” but with disabling dyskinesias, a situation called the on/off phenomenon.

Recent evidence has indicated that induction of motor complications may be the result of an active process of adaptation to variations in brain and plasma levodopa levels. This process of adaptation is apparently complex, involving not only alterations in the function of DA receptors but also downstream changes in the postsynaptic striatal neurons, including modification of NMDA glutamate receptors (Hallett and Standaert, 2004). When levodopa levels are maintained constant by intravenous infusion, dyskinesias and fluctuations are greatly reduced, and the clinical improvement is maintained for up to several days after returning to oral levodopa dosing (Mouradian et al., 1990). A sustained-release formulation consisting of carbidopa/levodopa in an erodable wax matrix (SINEMET CR) has been marketed in an attempt to produce more stable plasma levodopa levels than can be obtained with oral administration of standard carbidopa/levodopa formulations. This formulation is helpful in some cases, but absorption of the sustained-release formulation is not entirely predictable. Other approaches to more continuous delivery of levodopa, including gel and transdermal formulations, are under study.

An important unanswered question regarding the use of levodopa in PD is whether this medication alters the course of the underlying disease or merely modifies the symptoms. A recent randomized trial has provided evidence that levodopa does not have an adverse effect on the course of the underlying disease, but has also confirmed that high doses of levodopa are associated with early onset of dyskinesias (Fahn et al., 2004). Most practitioners have adopted a pragmatic approach, using levodopa only when the symptoms of PD cause functional impairment and other treatments are inadequate or not well tolerated.

In addition to motor complications and nausea, several other adverse effects may be observed with levodopa treatment. A frequent and troubling adverse effect is the induction of hallucinations and confusion, especially in elderly patients or in patients with preexisting cognitive dysfunction. This adverse effect often limits the ability to treat parkinsonian symptoms adequately. Conventional antipsychotic agents, such as the phenothiazines, are effective against levodopa-induced psychosis but may cause marked worsening of parkinsonism, probably through actions at the D 2 DA receptor. An alternative approach has been to use “atypical” antipsychotic agents (Chapter 16). However, not all of these are equally useful in this setting, and some of the “atypical” agents may nevertheless worsen PD symptoms. The two drugs which appear to be most effective and best tolerated in patients with advanced PD are clozapine and quetiapine (Friedman and Factor, 2000).

Peripheral decarboxylation of levodopa and release of DA into the circulation may activate vascular DA receptors and produce orthostatic hypotension. Administration of levodopa with nonspecific inhibitors of MAO, such as phenelzine and tranylcypromine, markedly accentuates the actions of levodopa and may precipitate life-threatening hypertensive crisis and hyperpyrexia; nonspecific MAO inhibitors always should be discontinued at least 14 days before levodopa is administered (note that this prohibition does not include the MAO-B subtype-specific inhibitors selegiline and rasagiline (AZILECT), which, as discussed later, are often administered safely in combination with levodopa). Abrupt withdrawal of levodopa or other dopaminergic medications may precipitate the neuroleptic malignant syndrome of confusion, rigidity, and hyperthermia, a potentially lethal adverse effect.

**Dopamine-Receptor Agonists.** An alternative to levodopa is the use of drugs that are direct agonists of striatal DA receptors, an approach that offers several potential advantages. Since enzymatic conversion of these drugs is not required for activity, they do not depend on the functional capacities of the nigrostriatal neurons. The DA receptor agonists in clinical use have durations of action substantially longer than that of levodopa; they are often used in the management of dose-related fluctuations in motor state, and may be helpful in preventing motor complications. Finally, it has been suggested that DA receptor agonists may have the potential to modify the course of PD by reducing endogenous release of DA as well as the need for exogenous levodopa, thereby reducing free radical formation.

Two orally administered DA receptor agonists are commonly used for treatment of PD: ropinirole (REQUIP) and pramipexole (MIRAPEX).
These agents are better tolerated and have largely replaced the older agents (e.g., bromocriptine, pergolide), which have to be titrated more slowly. Pergolide was withdrawn from the U.S. market in 2007 because of cardiac valve fibrosis. Ropinirole and pramipexole have selective activity at D₂ class sites (specifically at the D₂ and D₃ receptor) and little or no activity at D₁ class sites. Both are well absorbed orally and have similar therapeutic actions. Like levodopa, they can relieve the clinical symptoms of PD. The duration of action of the DA agonists (8-24 hours) often is longer than that of levodopa (6-8 hours), and they are particularly effective in the treatment of patients who have developed on/off phenomena. Ropinirole is also available in a once-daily sustained release formulation (REQUIP XL), which is more convenient and may reduce adverse effects related to intermittent dosing. Both pramipexole and ropinirole may produce hallucinosis or confusion, similar to that observed with levodopa, and may cause nausea and orthostatic hypotension. They should be initiated at low dose and titrated slowly to minimize these effects. The DA agonists, as well as levodopa itself, are also associated with fatigue and somnolence. The somnolence in some cases may be quite severe, and several instances of sudden attacks of irresistible sleepiness leading to motor vehicle accidents have been reported (Frucht et al., 1999). Although an uncommon complication, it is prudent to advise patients of this possibility and to switch to another agent when somnolence is an issue.

**Apomorphine.** Apomorphine (APOKYN) is a dopaminergic agonist that can be administered by subcutaneous injection. It has high affinity for D₄ receptors; moderate affinity for D₂, D₃, D₅, and adrenergic α₁D, α₂B, and α₂C receptors; and low affinity for D₁ receptors. Apomorphine has been used in Europe for many years and is FDA-approved as a “rescue therapy” for the acute intermittent treatment of “off” episodes in patients with a fluctuating response to dopaminergic therapy.

Apomorphine has the same side effects as discussed earlier for the oral DA agonists. In addition, apomorphine is highly emetogenic and requires pre- and post-treatment anti-emetic therapy. Oral trimethobenzamide (TGAN), at a dose of 300 mg three times daily, should be started 3 days prior to the initial dose of apomorphine and continued at least during the first 2 months of therapy. Profound hypotension and loss of consciousness have occurred when apomorphine was administered with ondansetron; hence, the concomitant use of apomorphine with antiemetic drugs of the 5-HT₃ antagonist class is contraindicated. Other potentially serious side effects of apomorphine include QT prolongation, injection-site reactions, and the development of a pattern of abuse characterized by increasingly frequent dosing leading to hallucinations, dyskinesia, and abnormal behavior. Because of these potential adverse effects, use of apomorphine is appropriate only when other measures, such as oral DA agonists or COMT inhibitors, have failed to control the “off” episodes. Apomorphine therapy should be initiated with a 2-mg test dose in a setting where the patient can be monitored carefully. If tolerated, it can be titrated slowly up to a maximum dosage of 6 mg. For effective control of symptoms, patients may require three or more injections daily.

**Catechol-O-Methyltransferase (COMT) Inhibitors.** Drugs for the treatment of PD include inhibitors of the enzyme COMT, which, together with MAO, metabolizes levodopa and DA. COMT transfers a methyl group from the donor S-adenosyl-L-methionine, producing the pharmacologically inactive compounds 3-O-methyl DOPA (from levodopa) and 3-methoxytyramine (from DA; Figure 22–5). When levodopa is administered orally, nearly 99% of the drug is metabolized and does not reach the brain. Most is converted by aromatic l-amino acid decarboxylase (AADC) to DA, which causes nausea and hypotension. Addition of an AADC inhibitor such as carbidopa reduces the formation of DA but increases the fraction of levodopa that is methylated by COMT. The principal therapeutic action of the COMT inhibitors is to block this peripheral conversion of levodopa to 3-O-methyl DOPA, increasing both the plasma t₁/2 of levodopa as well as the fraction of each dose that reaches the CNS.

Two COMT inhibitors presently are available for this use in the United States, tolcapone (TASMAR) and entacapone (COMTAN). In double-blind clinical trials, both agents significantly reduced the “wearing off” symptoms in patients treated with levodopa/carbidopa (Parkinson Study Group, 1997). The two drugs differ only in their pharmacokinetic properties and adverse effects: tolcapone has a relatively long duration of action, allowing for administration two to three times a day, and appears to act by both central and peripheral inhibition of COMT. Entacapone has a short duration of action (2 hours) and usually is administered simultaneously with each dose.

![Molecule Diagram](https://example.com/molecule.png)
of levodopa/carbidopa. The action of entacapone is attributable principally to peripheral inhibition of COMT. The common adverse effects of these agents are similar to those of levodopa/carbidopa alone and include nausea, orthostatic hypotension, vivid dreams, confusion, and hallucinations. An important adverse effect associated with tolcapone is hepatotoxicity. Up to 2% of the patients treated have increased serum alanine aminotransferase and aspartate transaminase; and at least three fatal cases of fulminant hepatic failure in patients taking tolcapone have been observed, leading to addition of a black box warning to the label. At present, tolcapone should be used only in patients who have not responded to other therapies and with appropriate monitoring for hepatic injury. Entacapone has not been associated with hepatotoxicity and requires no special monitoring. Entacapone also is available in fixed-dose combinations with levodopa/carbidopa (STALEVO).

Selective MAO-B Inhibitors. Two isoenzymes of MAO oxidize monoamines. While both isoenzymes (MAO-A and MAO-B) are present in the periphery and inactivate monoamines of intestinal origin, the isoenzyme MAO-B is the predominant form in the striatum and is responsible for most of the oxidative metabolism of DA in the brain. Two selective MAO-B inhibitors are used for the treatment of PD: selegiline (ELDEPRYL, EMSAM, ZELAPAR) and rasagiline (AZILECT). When used at recommended doses, these agents selectively inactivate MAO-B through irreversible inhibition of the enzyme (Elmer and Bertoni, 2008). Both agents exert modest beneficial effects on the symptoms of PD. The basis of this efficacy is presumed to be the inhibition of breakdown of DA in the striatum. Unlike nonspecific inhibitors of MAO (such as phenelzine, tranylcypromine, and isocarboxazid), selective MAO-B inhibitors do not substantially inhibit the peripheral metabolism of catecholamines and can be taken safely with levodopa. These agents also do not exhibit the “cheese effect,” the potentially lethal potentiation of catecholamine action observed when patients on nonspecific MAO inhibitors ingest indirectly acting sympathomimetic amines such as the tyramine found in certain cheeses and wine.

Selegiline has been used for many years as a symptomatic treatment for PD and is generally well tolerated in younger patients with early or mild PD. In patients with more advanced PD or underlying cognitive impairment, selegiline may accentuate the adverse motor and cognitive effects of levodopa therapy. Metabolites of selegiline include amphetamine and methamphetamine, which may cause anxiety, insomnia, and other adverse symptoms. Recently, selegiline has become available in an orally disintegrating tablet (ZELPAR) as well as a transdermal patch (EMSAM). Both of these delivery routes are intended to reduce hepatic first-pass metabolism and limit the formation of the amphetamine metabolites.

Unlike selegiline, rasagiline does not give rise to undesirable amphetamine metabolites. In randomized controlled clinical trials, rasagiline monotherapy was effective in early PD. Adjunctive therapy significantly reduced levodopa-related “wearing off” symptoms in advanced PD.

A consequence of the inhibition of MAO-B in the brain is a reduction in the overall catabolism of DA, which may reduce the formation of potentially toxic free radicals. This observation has led to studies which have examined the question of whether MAO-B inhibition can alter the rate of neurodegeneration in PD. The potential protective role of selegiline in idiopathic PD was evaluated in several multicenter randomized trials; although there was some evidence supporting a neuroprotective effect, the outcomes were obscured by the difficulty of distinguishing long-term neuroprotective effects from short-term symptomatic effects (Parkinson Study Group, 1993; Yacoubian and Standaert, 2008). A more recent study, using a different design, has produced more convincing data suggesting a neuroprotective effect of rasagiline (Olanow, 2008).

Although selective MAO-B inhibitors are generally well tolerated, drug interactions can be troublesome. Similar to the nonspecific MAO inhibitors, selegiline can lead to the development of stupor, rigidity, agitation, and hyperthermia when administered with the analgesic meperidine. Although the mechanics of this interaction is uncertain, selegiline or rasagiline should not be given in combination with meperidine. Adverse effects have been reported from co-administration of MAO-B inhibitors with tricyclic antidepressants or with serotonin-reuptake inhibitors. However, interactions with antidepressants are uncommon, and many patients do take these combinations of medications without apparent adverse interaction; nonetheless, concomitant administration of selegiline or rasagiline with serotonergic drugs should be done with caution, especially in patients on high doses of serotonin-reuptake inhibitors.

Muscarinic Receptor Antagonists. Antagonists of muscarinic acetylcholine receptors were used widely for the treatment of PD before the discovery of levodopa. The biological basis for the therapeutic actions of anticholinergics is not completely understood. They may act within the neostriatum through the receptors that normally mediate the response to intrinsic cholinergic innervation of this structure, which arises primarily from cholinergic striatal interneurons. Several muscarinic cholinergic receptors have been cloned (Chapters 9 and 14); like the DA receptors, these are GPCRs. Five subtypes of muscarinic receptors exist. All five subtypes are probably present in the striatum, although each one has a distinct distribution (Hersch et al., 1994). Anticholinergic drugs currently used in the treatment of PD include trihexyphenidyl (2–4 mg three times per day), benztropine mesylate (1–4 mg two times per day), and diphenhydramine hydrochloride (25–50 mg three or four times per day). Diphenhydramine also is a histamine H1 antagonist (Chapter 32).

All of these drugs have relatively modest antiparkinsonian activity and are only used in the treatment of early PD or as an adjunct to dopaminergic therapy. Adverse effects result from their anticholinergic properties. Most troublesome are sedation and mental
confusion. Other side effects are constipation, urinary retention, and blurred vision through cycloplegia. All anticholinergic drugs must be used with caution in patients with narrow-angle glaucoma (Chapter 65).

**Amantadine.** Amantadine (SYMMETREL), an antiviral agent used for the prophylaxis and treatment of influenza A (Chapter 58), has antiparkinsonian activity. Amantadine appears to alter DA release in the striatum, has anticholinergic properties, and blocks NMDA glutamate receptors. However, it is not well understood which of amantadine’s pharmacological effects are responsible for its antiparkinsonian actions. In any case, the effects of amantadine in PD are modest. It is used as initial therapy of mild PD. It also may be helpful as an adjunct in patients on levodopa with dose-related fluctuations and dyskinesias. The antidysskinetic properties of amantadine have been attributed to actions at NMDA receptors (Hallett and Standaert, 2004), although the closely related NMDA receptor antagonist memantine (discussed later) does not seem to have this effect.

Amantadine is usually administered at a dose of 100 mg twice a day and is well tolerated. Dizziness, lethargy, anticholinergic effects, and sleep disturbance, as well as nausea and vomiting, have been observed occasionally, but even when present, these effects are mild and reversible.

**Neuroprotective Treatments for Parkinson Disease.** It would be desirable to identify a treatment that modifies the progressive degeneration that underlies PD rather than simply controlling the symptoms. Current research strategies are based on the disease mechanisms described earlier (e.g., energy metabolism, oxidative stress, environmental triggers, and excitotoxicity) and on discoveries related to the genetics of PD (Yacoubian and Standaert, 2008). Several studies have examined the potential neuroprotective effects of existing medications. In a randomized controlled trial, levodopa did not worsen the disease state. Some benefits persisted for several weeks after treatment was stopped, but whether this was truly a “neuroprotective” effect remains uncertain (Fahn et al., 2004).

Two trials have attempted to examine the effect of pramipexole or ropinirole on neurodegeneration in PD (Parkinson Study Group, 2002; Whone et al., 2003). Both trials observed that in patients treated with either one of these agonists, there was a reduced rate of loss of markers of dopaminergic neurotransmission measured by brain imaging compared with a similar group of patients treated with levodopa. These intriguing data should be viewed cautiously, particularly because there is considerable uncertainty about the relationship of the imaging results techniques used and the true rate of neurodegeneration (Albin and Frey, 2003).

Inhibition of MAO-B in the brain reduces the overall catabolism of DA, which may decrease the formation of potentially toxic free radicals and consequently the rate of neurodegeneration in PD. The protective role of selegeline in idiopathic PD was evaluated in several multicenter randomized trials. Unfortunately, distinguishing long-term neuroprotective effects from short-term symptomatic effects was difficult in the earlier studies (Parkinson Study Group, 1993; Yacoubian and Standaert, 2008). A different study design showed more convincingly a neuroprotective effect of rasagiline (2008).

Another strategy under study is the use of compounds that augment cellular energy metabolism such coenzyme Q10, a cofactor required for the mitochondrial electron-transport chain. A small study has demonstrated that this drug is well tolerated in PD and has suggested that coenzyme Q10 may slow the course of the disease (Shults et al., 2002). A much larger study is in progress. Therapies directly targeting the molecules which are implicated in the pathogenesis of PD are still in a nascent stage, and may require unconventional delivery strategies such as gene therapy (Lewis and Standaert, 2008).

**Clinical Summary.** Pharmacological treatment of PD should be tailored to the individual patient. Drug therapy is not obligatory in early PD; many patients can be managed for a time with exercise and lifestyle interventions. For patients with mild symptoms, MAO-B inhibitors, amantadine, or (in younger patients) anticholinergics are reasonable choices. In most patients, treatment with a dopaminergic drug, either levodopa or a DA agonist, is eventually required. Large controlled clinical trials provide convincing evidence for a reduced rate of motor fluctuation in patients in which DA agonists are used as initial treatment. This benefit was, however, accompanied by an increased rate of adverse effects, especially somnolence and hallucinations (Parkinson Study Group, 2000; Rascol et al., 2000). Practitioners prefer DA agonist as initial therapy in younger patients in order to reduce the occurrence of motor complications. In older patients or those with substantial comorbidity, levodopa/carbidopa is generally better tolerated.

**ALZHEIMER’S DISEASE (AD)**

**Clinical Overview.** The brain region most vulnerable to neuronal dysfunction and cell loss in AD is the medial temporal lobe, including entorhinal cortex and hippocampus. Typical early AD symptoms are due to dysfunction of these structures resulting in anterograde episodic memory loss: repeated questions, misplaced items, missed appointments, and forgotten details of daily life. A typical patient presents with memory dysfunction that is noticeable by the patient and/or family members, but not severe enough to impair daily function. Because current diagnostic criteria for AD require the presence of dementia (i.e., cognitive impairments sufficient to reduce function), these patients are generally given a diagnosis of mild cognitive impairment (MCI). Patients with MCI progress at a rate of about 10% per
year to AD (Petersen et al., 2005), although not all MCI patients will develop AD. The decline in both cognitive and functional capacity follows a course of gradual but relentless progression in AD, spreading to involve other cognitive domains including visuospatial and executive function. The later stages of the disease are characterized by increasing dependence and progression toward the akinetic-mute state that typifies end-stage neurologic disease. Death, most often from a complication of immobility such as pneumonia or pulmonary embolism, usually ensues within 6-12 years of onset.

At present, the diagnosis of AD is based on the clinical assessment of the patient. Structural neuroimaging and appropriate laboratory tests are used to exclude other disorders that may mimic AD. In the near future, laboratory measures to specifically identify AD, including analysis of biomarkers such as CSF or serum factors, genetic testing, and molecular or functional neuroimaging, are likely to be incorporated into AD diagnostic criteria to enhance the sensitivity of diagnosis, especially at early stages of the disease (Dubois et al., 2007). A direct antemortem confirmatory test currently does not exist.

**Genetics.** Mutations in three genes have been identified as causes of autosomal dominant, early-onset AD: APP, which encodes amyloid-β precursor protein, and PSEN1 and PSEN2, encoding presenilin 1 and 2. All three genes are involved in the production of amyloid-β peptides (Aβ). Aβ is generated by sequential proteolytic cleavage of APP by two enzymes, β-secretase and γ-secretase; the presenilins form the catalytic core of γ-secretase. The genetic evidence, combined with the fact that Aβ accumulates in the brain in the form of soluble oligomers and amyloid plaques, and is toxic when applied to neurons, forms the basis for the amyloid hypothesis of AD pathogenesis (Tanzi and Bertram, 2005).

Autosomal-dominant cases of AD are quite rare, but there is also a significant genetic component to the more common, sporadic, late-onset cases of AD. Many genes have been identified as having alleles that increase AD risk (Bertram et al., 2007). By far the most important of these is APOE, which encodes the lipid carrier protein apolipoprotein E (apoE) (Raber et al., 2004). Individuals inheriting the ε4 allele of APOE have a more than 3-fold higher risk of developing AD. While they make up less than one-fourth of the population, they account for more than half of all AD cases. Several clinical trials have shown a different response rate between apoE4-carriers and noncarriers, suggesting an important potential pharmacogenetic influence of apoE genotype on the choice of therapy. However, at this point genetic testing for apoE status is not a routine part of the clinical evaluation for AD.

**Pathophysiology.** The pathological hallmarks of AD are amyloid plaques, which are extracellular accumulations of Aβ, and intracellular neurofibrillary tangles composed of the microtubule-associated protein tau (Figure 22–6). While the development of amyloid plaques is an early and invariant feature of AD, tangle burden accrues over time in a manner that correlates more closely with the development of cognitive impairment. The current consensus is that Aβ accumulation is an upstream event that triggers tau pathology, resulting in impaired neuronal function and cell loss. In autosomal dominant AD, Aβ accumulates due to mutations that cause its overproduction. The cause of high cerebral Aβ levels in late-onset sporadic AD is unclear but is likely caused by impaired clearance rather than overproduction.
aggregation of Aβ is an important event in AD pathogenesis. While plaques consist of highly ordered fibrils of Aβ, it appears that soluble Aβ oligomers, perhaps as small as dimers, are more highly pathogenic. Tau also aggregates to form the paired helical filaments that make up neurofibrillary tangles. Post-translational modifications of tau including phosphorylation, proteolysis, and other changes cause loss of tau’s normal functions and increase its propensity to aggregate. Mechanisms by which Aβ and tau induce neuronal dysfunction and death may include direct impairment of synaptic transmission and plasticity, excitotoxicity, oxidative stress, and neuroinflammation. The factors underlying the selective vulnerability of particular cortical neurons to the pathological effects of AD are not known.

**Neurochemistry.** The most striking neurochemical disturbance in AD is a deficiency of acetylcholine. The anatomical basis of the cholinergic deficit is atrophy and degeneration of subcortical cholinergic neurons, particularly those in the basal forebrain (nucleus basalis of Meynert) that provide cholinergic innervation to the cerebral cortex. The selective deficiency of ACh in AD, as well as the observation that central cholinergic antagonists such as atropine can induce a confusional state that bears some resemblance to the dementia of AD, has given rise to the “cholinergic hypothesis,” which proposes that a deficiency of ACh is critical in the genesis of the AD symptoms (Perry, 1986). Although viewing AD as a “cholinergic deficiency syndrome” akin to the “dopaminergic deficiency syndrome” of PD provides a useful framework, it is important to note that the deficit in AD is far more complex. AD involves multiple neurotransmitter systems, including glutamate, 5-HT, and neuropeptides, and there is destruction of not only cholinergic neurons but also the cortical and hippocampal targets that receive cholinergic input.

### Treatment of Alzheimer’s Disease

At present, no disease-modifying therapy for AD is available. While aggressive attempts to develop drugs targeting Aβ, tau, apoE, and other molecules involved in AD pathogenesis are underway (Roberson and Mucke, 2006), current treatment is aimed at alleviating symptoms.

**Treatment of Cognitive Symptoms.** Augmentation of the cholinergic transmission is currently the mainstay of AD treatment. Three drugs, donepezil, rivastigmine, and galantamine, are widely used for this purpose; a fourth, tacrine, was the first drug approved to treat AD but is rarely used now because it has much more extensive side effects compared to the newer agents (Table 22–2). All four agents are reversible antagonists of cholinesterases, enzymes that act to limit cholinergic neurotransmission by catalyzing the cleavage of acetylcholine in the synaptic cleft into choline and acetate (Chapter 10). Cholinesterase inhibitors are the usual first-line therapy for symptomatic treatment of cognitive impairments in mild or moderate AD. These agents have a beneficial, albeit quite modest, effect on cognition in clinical AD studies (Birks, 2006). They are also widely used to treat other neurodegenerative diseases with cholinergic deficits, including dementia with Lewy bodies (Bhasin et al., 2007) and vascular dementia (Kavirajan and Schneider, 2007). In addition, they are sometimes used in MCI, where they may also have symptomatic benefit but do not slow the conversion to AD (Raschetti et al., 2007). The drugs are usually well tolerated, with the most common side effects being GI distress, muscle cramping, and abnormal dreams. Because of their cholinergic and

| Table 22–2 |
| Cholinesterase Inhibitors Used for the Treatment of Alzheimer’s Disease |
| Brand name | DONEPEZIL | RIVASTIGMINE | GALANTAMINE | TACRINEa |
| Enzymes inhibitedb | ARICEPT | EXELON, generic AChE, BuChE | RAZADYNE, generic AChE | Cognex AChE, BuChE |

| Metabolismf | CYP2D6, CYP3A4 | Esterases | CYP2D6, CYP3A4 | CYP1A2 |

aTacrine was the first cholinesterase inhibitor approved for the treatment of AD, but is now rarely used because of hepatotoxicity and adverse effects.

bAChE (acetylcholinesterase) is the major cholinesterase in the brain; BuChE (butyrylcholinesterase) is a serum and hepatic cholinesterase that is upregulated in AD brain.

cTypical starting doses are one-half of the maintenance dose and are given for the first month of therapy.

dPDD, Parkinson disease dementia.

eDrugs metabolized by CYP2D6 and CYP3A4 are subject to increased serum levels when co-administered with drugs known to inhibit these enzymes, such as ketoconazole and paroxetine. Similarly, tacrine levels are increased by co-administration with the CYP1A2 inhibitors theophylline, cimetidine, and fluvoxamine.
potentially vagotonic properties, they should be used with caution in patients with bradycardia or syncope.

Memantine (NAMENDA) is used either as an adjunct or an alternative to cholinesterase inhibitors in AD, and is also commonly used to treat other neurodegenerative dementias. Memantine is a noncompetitive antagonist of the NMDA-type glutamate receptor. It interacts with the Mg$^{2+}$ binding site of the channel to prevent excessive activation while sparing normal function (Lipton, 2007). Memantine significantly reduces the rate of clinical deterioration in patients with moderate to severe AD (Raina et al., 2008). Whether this is due to a true disease-modifying effect, possibly reduced excitotoxicity, or to a symptomatic effect of the drug is unclear. Adverse effects of memantine include headache or dizziness, but are usually mild and reversible. The drug is excreted by the kidneys, and dosage should be reduced in patients with severe renal impairment.

### Treatment of Behavioral Symptoms

In addition to cognitive decline, behavioral and psychiatric symptoms in dementia (BPSD) are common, particularly in middle stages of the disease. These symptoms, including irritability and agitation, paranoia and delusional thinking, wandering, anxiety, and depression, are a major source of caregiver distress and often precipitate nursing home placement. Treatment can be difficult, and non-pharmacological approaches should generally be first-line (Beier, 2007; Sink et al., 2005).

A variety of pharmacological options are also available. In addition to their effects on cognitive measures, both cholinesterase inhibitors and memantine reduce some BPSD (Maidment et al., 2008; Trinh et al., 2003). However, their effects are modest, and they do not treat some of the most troublesome symptoms, such as agitation (Howard et al., 2007). Furthermore, because most AD patients are already treated with these drugs, other options are often needed when behavioral symptoms emerge.

Atypical antipsychotics, such as risperidone, olanzapine, and quetiapine (Chapter 16), are the most efficacious therapy for agitation and psychosis in AD. Risperidone and olanzapine are effective, but their use is often limited by adverse effects, including parkinsonism, sedation, and falls (Schneider et al., 2006). In addition, the use of atypical antipsychotics in elderly patients with dementia-related psychosis has been associated with a higher risk of stroke and overall mortality (Douglas and Smeeht, 2008; Schneider et al., 2005), leading the FDA to order inclusion of a boxed warning in the prescribing information for all drugs in this class. Unfortunately, there are few effective alternatives.

Mood stabilizers (Chapter 16) have been the focus of several trials for BPSD. Carbamazepine has shown some benefit in small trials but carries numerous risks in the elderly, especially the potential for drug-drug interactions. There is little evidence of benefit from valproic acid. Lithium is of considerable interest given its ability to inhibit glycogen synthase kinase, which is implicated in AD pathogenesis, but clinical trial results are limited and concerns persist about the narrow therapeutic window in elderly patients. Benzodiazepines (Chapter 17) can be used for occasional control of acute agitation, but are not recommended for long-term management because of their adverse effects on cognition and other risks in the elderly population. The typical antipsychotic haloperidol (Chapter 16) may be useful for aggression, but sedation and extrapyramidal symptoms limit its use to control of acute episodes.

Antidepressants (Chapter 15) can be useful for BPSD, particularly when depression or anxiety contribute. Because of the adverse anticholinergic effects of tricyclic agents, serotonergic antidepressants are favored. These agents are generally well tolerated. Trazodone has modest benefits, but for the most part, selective serotonin reuptake inhibitors (SSRIs) are the preferred class of drugs.

### Clinical Summary

The typical AD patient presenting in early stages of disease should probably be treated with a cholinesterase inhibitor. Patients and families should be counseled that a realistic goal of therapy is to induce a temporary reprieve from progression, or at least a reduction in the rate of decline, rather than long-term recovery of cognition. As the disease progresses, memantine can be added to the regimen. Behavioral symptoms are often treated with a serotonergic antidepressant or, if they are severe enough to warrant the risk of higher mortality, an atypical antipsychotic. Eliminating drugs likely to aggravate cognitive impairments, particularly anticholinergics, benzodiazepines, and other sedative/hypnotics, from the patient’s regimen is another important aspect of AD pharmacotherapy.

### Huntington’s Disease (HD)

#### Clinical Features

HD is a dominantly inherited disorder characterized by the gradual onset of motor incoordination and cognitive decline in midlife. Symptoms develop insidiously, either as a movement disorder manifest by brief, jerk-like movements of the extremities, trunk, face, and neck (chorea) or as personality changes or both. Fine-motor incoordination and impairment of rapid eye movements are early features. Occasionally, especially when the onset of symptoms occurs before age 20, choreic movements are less prominent; instead, bradykinesia and dystonia predominate. As the disorder...
progresses, the involuntary movements become more severe, dysarthria and dysphagia develop, and balance is impaired. The cognitive disorder manifests first as slowness of mental processing and difficulty in organizing complex tasks. Memory is impaired, but affected persons rarely lose their memory of family, friends, and the immediate situation. Such persons often become irritable, anxious, and depressed. Less frequently, paranoia and delusional states are manifest. The outcome of HD is invariably fatal; over a course of 15-30 years, the affected person becomes totally disabled and unable to communicate, requiring full-time care; death ensues from the complications of immobility (Shoulson, 1992).

Pathology and Pathophysiology. HD is characterized by prominent neuronal loss in the striatum (caudate/putamen) of the brain (Vonsattel et al., 1985). Atrophy of these structures proceeds in an orderly fashion, first affecting the tail of the caudate nucleus and then proceeding anteriorly from mediodorsal to ventrolateral. Other areas of the brain also are affected, although much less severely; morphometric analyses indicate that there are fewer neurons in cerebral cortex, hypothalamus, and thalamus. Even within the striatum, the neuronal degeneration of HD is selective. Interneurons and afferent terminals are largely spared, whereas the striatal projection neurons (the medium spiny neurons) are severely affected. This leads to large decreases in striatal GABA concentrations, whereas SST and DA concentrations are relatively preserved (Ferrante et al., 1987).

Selective vulnerability also appears to underlie the most conspicuous clinical feature of HD, the development of chorea. In most adult-onset cases, the medium spiny neurons that project to the GPe and SNpr (the indirect pathway) appear to be affected earlier than those projecting to the GPe (the direct pathway; Figure 22–5) (Albin et al., 1992). The disproportionate impairment of the indirect pathway increases excitatory drive to the neocortex, producing involuntary choreiform movements (Figure 22–7). In some individuals, rigidity rather than chorea is the predominant clinical feature; this is especially common in juvenile-onset cases. Here, the striatal neurons giving rise to both the direct and indirect pathways are impaired to a comparable degree.

Genetics. HD is an autosomal dominant disorder with nearly complete penetrance. The average age of onset is between 35 and 45 years, but the range varies from as early as age 2 to as late as the middle 80s. Although the disease is inherited equally from mother and father, more than 80% of those developing symptoms before age 20 inherit the defect from the father. This is an example of anticipation, or the tendency for the age of onset of a disease to decline with each succeeding generation, which also is observed in other neurodegenerative diseases with similar genetic mechanisms. Known homozygotes for HD show clinical characteristics identical to the typical HD heterozygote, indicating that the unaffected chromosome does not attenuate the disease symptomatology. Until the discovery of the genetic defect responsible for HD, de novo mutations causing HD were thought to be unusual; but it is now clear that the disease can arise from unaffected parents, especially when one carries an “intermediate allele,” as described in the next paragraph.

The discovery of the genetic mutation responsible for HD was the product of an arduous 10-year, multi-investigator collaborative effort. In 1993, a region near the end of the short arm of chromosome 4 was found to contain a polymorphic (CAG)n trinucleotide repeat that was significantly expanded in all individuals with HD (Huntington’s Disease Collaborative Research Group, 1993). The CAG repeat is unstable, and may expand during DNA synthesis associated with meiosis. This is particularly common during spermatogenesis, and accounts for the phenomenon of anticipation. The range of CAG repeat length in normal individuals is between 9 and 34 triplets, with a median repeat length on normal chromosomes of 19. The repeat length in HD varies from 40 to over 100. Repeat lengths of 35-39 represent intermediate alleles; some of these individuals develop HD late in life, whereas others are not affected. Repeat length is correlated inversely with age of onset. The younger the age of onset, the higher the probability of a large repeat number. This correlation is most powerful in individuals with onset before age 30, with onset above age 30, the correlation is weaker. Thus, repeat length cannot serve as an adequate predictor of age of onset in most individuals. Several other neurodegenerative diseases also arise through expansion of a CAG repeat, including hereditary spinocerebellar ataxias and Kennedy’s disease, a rare inherited disorder of motor neurons.

Selective Vulnerability. The mechanism by which the expanded trinucleotide repeat leads to the clinical and pathological features of HD is unknown. The HD mutation lies within a large gene (10 kilobases)
designated IT15. It encodes a protein of approximately 348,000 DA. The trinucleotide repeat, which encodes the amino acid glutamine, occurs at the 5’ end of IT15 and is followed directly by a second, shorter repeat of (CCG), that encodes proline. The protein, named huntingtin, does not resemble any other known protein, and the normal function of the protein has not been identified. Mice with a genetic knockout of huntingtin die early in embryonic life, so it must have an essential cellular function. It is thought that the mutation results in a gain of function—that is, the mutant protein acquires a new function or property not found in the normal protein. The nature of the function gained remains uncertain, although some evidence points to effects on cellular energy metabolism and gene transcription (Imarisio, 2008).

### Treatment of Huntington’s Disease

#### Symptomatic Treatment.

Treatment for symptomatic HD emphasizes the selective use of medications (Shoulson, 1992). None of the currently available medications slows the progression of the disease. HD patients are frequently very sensitive to side effects of medications. Treatment is needed for patients who are depressed, irritable, paranoid, excessively anxious, or psychotic. Depression can be treated effectively with standard antidepressant drugs with the caveat that drugs with substantial anticholinergic profiles can exacerbate chorea. Fluoxetine (Chapter 15) is effective treatment for both the depression and the irritability manifest in symptomatic HD. Carbamazepine (Chapter 21) also has been found to be effective for depression. Paranoia, delusional states, and psychosis are treated with antipsychotic drugs, but usually at lower doses than those used in primary psychiatric disorders (Chapter 16). These agents also reduce cognitive function and impair mobility and thus should be used in the lowest doses possible and should be discontinued when the psychiatric symptoms resolve. In individuals with predominantly rigid HD, clozapine, quetiapine (Chapter 16), or carbamazepine may be more effective for treatment of paranoia and psychosis.

The movement disorder of HD per se only rarely justifies pharmacological therapy. For those with large-amplitude chorea causing frequent falls and injury, tetrabenazine (XENAZINE-NITOMAN) has recently become available in the U.S. for the treatment of chorea associated with HD. Tetrabenazine, and the related drug reserpine, are inhibitors of the vesicular monoamine transporter 2 (VMAT2), and cause presynaptic depletion of catecholamines. Tetrabenazine is a reversible inhibitor; inhibition by reserpine is irreversible and may lead to long-lasting effects. Both drugs may cause hypotension and depression with suicidality; the shorter duration of effect of tetrabenazine greatly simplifies the clinical management. Antipsychotic agents also can be used, but these often do not improve overall function because they decrease fine motor coordination and increase rigidity. Many HD patients exhibit worsening of involuntary movements as a result of anxiety or stress. In these situations, judicious use of sedative or anxiolytic benzodiazepines can be very helpful. In juvenile-onset cases where rigidity rather than chorea predominates, DA agonists have had variable success in the improvement of rigidity. These individuals also occasionally develop myoclonus and seizures that can be responsive to clonazepam, valproic acid, and other anticonvulsants (Chapter 21).

#### Clinical Summary.

HD is an autosomal dominant disorder caused by mutations in the IT15 gene that encodes huntingtin. The gene defect leads to progressive motor and cognitive symptoms. At present there is no effective treatment for the primary disorder, although antidepressant and antipsychotic medications may be useful to control specific symptoms and catecholamine depleting agents may be useful to control the motor features of the disease.

### AMYOTROPHIC LATERAL SCLEROSIS (ALS)

#### Clinical Features and Pathology.

ALS (or Lou Gehrig’s disease) is a disorder of the motor neurons of the ventral horn of the spinal cord (lower motor neurons) and the cortical neurons that provide their afferent input (upper motor neurons). The disorder is characterized by rapidly progressive weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Sensory, autonomic, and ocular motor function is generally spared. While it was previously thought that higher cortical function was also unaffected, many ALS patients exhibit behavioral changes and cognitive dysfunction, and there is clinical, genetic, and neuropathological overlap between ALS and frontotemporal dementia spectrum disorders (Strong et al., 2009). ALS usually is progressive and fatal. Most patients die of respiratory compromise and pneumonia after 2–3 years, although some individuals have a more indolent course and survive for many years. The pathology of ALS corresponds closely to the clinical features: There is prominent loss of the spinal and brainstem motor neurons that project to striated muscles (although the oculomotor neurons are spared), as well as loss of the large pyramidal motor neurons in layer V of motor cortex, which are the origin of the descending corticospinal tracts.

#### Etiology.

About 10% of ALS cases are familial (FALS), usually with an autosomal dominant pattern of inheritance. Most of the mutations responsible have not been identified, but an important subset of FALS patients are families with a mutation in the gene for the enzyme SOD1 (Rosen et al., 1993). Mutations in this protein account for about 20% of cases of FALS. Most of the mutations are
alterations of single amino acids, but more than 30 different alleles have been found in different kindreds. Transgenic mice expressing mutant human SOD1 develop a progressive degeneration of motor neurons that closely mimics the human disease, providing an important animal model for research and pharmaceutical trials. Interestingly, many of the mutations of SOD1 that can cause disease do not reduce the capacity of the enzyme to perform its primary function, the catabolism of superoxide radicals. Thus, as may be the case in HD, mutations in SOD1 may confer a toxic “gain of function,” the precise nature of which is unclear.

More recently, mutations in the TARDBP gene encoding TAR DNA-binding protein (TDP-43) and in the FUS/TLS gene have been identified as causes of FALS (Lagier-Tourenne and Cleveland, 2009). Both TDP-43 and FUS/TLS bind DNA and RNA, and regulate transcription and alternative splicing.

More than 90% of ALS cases are sporadic. Of these, a few are caused by de novo mutations in SOD1, TDP-43, FUS/TLS, or other genes, but for the majority of sporadic cases the etiology remains unclear. Possible pathogenic mechanisms underlying sporadic ALS include autoimmunity, excitotoxicity, free radical toxicity, and viral infection (Rothstein, 2009), although none is well supported by available data. There is evidence that glutamate reuptake may be abnormal in the disease, leading to accumulation of glutamate and excitotoxic injury (Rothstein et al., 1992). The only currently approved therapy for ALS, riluzole, is based on these observations (Brooks, 2009).

**Treatment of ALS**

**Riluzole.** Riluzole (2-amino-6-[trifluoromethoxy]benzothiazole; RILUTEK) is an agent with complex actions in the nervous system (Doble, 1996; Zarate and Manji, 2008).

![Riluzole](image)

Riluzole is absorbed orally and is highly protein bound. It undergoes extensive metabolism in the liver by both CYP–mediated hydroxylation and glucuronidation. Its t1/2 is about 12 hours. In vitro studies have shown that riluzole has both presynaptic and postsynaptic effects. It inhibits glutamate release, but it also blocks postsynaptic NMDA- and kainate-type glutamate receptors and inhibits voltage-dependent Na+ channels. Some of the effects of riluzole in vitro are blocked by pertussis toxin, implicating the drug’s interaction with an as yet-unidentified G protein–coupled receptor (GPCR). In clinical trials riluzole has modest but genuine effects on the survival of patients with ALS.

Meta-analyses of the available trials indicate that riluzole extends survival by 2-3 months (Miller et al., 2007). The recommended dose is 50 mg twice daily, taken 1 hour before or 2 hours after a meal. Riluzole usually is well tolerated, although nausea or diarrhea may occur. Rarely, riluzole may produce hepatic injury with elevations of serum transaminases, and periodic monitoring of these is recommended. Although the magnitude of the effect of riluzole on ALS is small, it represents a significant therapeutic milestone in the treatment of a disease refractory to all previous treatments.

**Symptomatic Therapy of ALS: Spasticity.** Spasticity is an important component of the clinical features of ALS and the feature most amenable to present forms of treatment. Spasticity often leads to considerable pain and discomfort and further reduces mobility, which already is compromised by weakness. Spasticity is defined as an increase in muscle tone characterized by an initial resistance to passive displacement of a limb at a joint, followed by a sudden relaxation (the so-called clasp-knife phenomenon). Spasticity results from loss of descending inputs to the spinal motor neurons, and the character of the spasticity depends on which nervous system pathways are affected (Sheean, 2008). Whole repertoires of movement can be generated directly at the spinal cord level; it is beyond the scope of this chapter to describe these in detail. The monosynaptic tendon-stretch reflex is the simplest of the spinal mechanisms contributing to spasticity. Primary Ia afferents from muscle spindles, activated when the muscle is stretched rapidly, synapse directly on motor neurons going to the stretched muscle, causing it to contract and resist the movement. A collateral of the primary Ia afferent pathways form a “Ia-coupled interneuron” that inhibits the motor neurons innervating the antagonist of the stretched muscle, allowing contraction of the muscle to be unopposed. Upper motor neurons from the cerebral cortex (the pyramidal neurons) suppress spinal reflexes and the lower motor neurons indirectly by activating the spinal cord inhibitory interneuron pools (Figure 22–8).

The pyramidal neurons use glutamate as a neurotransmitter. When the pyramidal influences are removed, the reflexes are released from inhibition and become more active, leading to hyperreflexia. Other descending pathways from the brainstem, including the rubro-, reticulo-, and vestibulospinal pathways and the descending catecholamine pathways, also influence spinal reflex activity. When just the pyramidal pathway is affected, extensor tone in the legs and flexor tone in the arms are increased. When the vestibulospinal and catecholamine pathways are impaired, increased flexion of all extremities is observed, and light cutaneous stimulation can lead to disabling whole-body spasms. In ALS, pyramidal pathways are impaired with relative preservation of the other descending pathways, resulting in hyperactive deep-tendon reflexes, impaired fine motor coordination, increased extensor tone in the legs, and increased flexor tone in the arms. The gag reflex often is overactive as well.

The best agent for the symptomatic treatment of spasticity in ALS is baclofen (Lioresal), a GABA<sub>B</sub> receptor agonist. Initial doses...
of 5-10 mg/day are recommended, which can be increased to as much as 200 mg/day if necessary. If weakness occurs, the dose should be lowered. Alternatively, baclofen can be delivered directly into the space around the spinal cord using a surgically implanted pump and an intrathecal catheter. This approach minimizes the adverse effects of the drug, especially sedation, but it carries the risk of potentially life-threatening CNS depression. Moreover, abrupt withdrawal of intrathecal baclofen can cause rebound spasticity, rhabdomyolitis, multi-organ failure, and even death. Intrathecal baclofen should be used only by physicians trained in delivering chronic intrathecal therapy.

Tizanidine (ZANAFLEX) is an agonist of \( \alpha_2 \) adrenergic receptors in the CNS. It reduces muscle spasticity and is assumed to act by increasing presynaptic inhibition of motor neurons. Tizanidine is primarily used in the treatment of spasticity in multiple sclerosis or after stroke, but it also may be effective in patients with ALS. Treatment should be initiated at a low dose of 2-4 mg at bedtime and titrated upward gradually. Drowsiness, asthenia, and dizziness may limit the dose that can be administered. Benzodiazepines (Chapter 17) such as clonazepam (KLONIPIN) are effective antispasticity agents, but they may contribute to respiratory depression in patients with advanced ALS. Dantrolene (DANTRIUM) also is approved in the U.S. for the treatment of muscle spasm. In contrast to the other agents discussed, dantrolene acts directly on skeletal muscle fibers, impairing \( \text{Ca}^{2+} \) release from the sarcoplasmic reticulum. Because it can exacerbate muscular weakness, it is not used in ALS but is effective in treating spasticity associated with stroke or spinal cord injury and in treating malignant hyperthermia (Chapter 8). Dantrolene may cause hepatotoxicity, so it is important to monitor liver associated enzymes before and during therapy with the drug.

**Clinical Summary.** ALS is a progressive degenerative disease of spinal motor neurons leading to weakness and eventually paralysis. It is the most rapidly progressive of the common neurodegenerative disorders and often is fatal within 2-3 years of onset. The only therapy established to alter the course of ALS is the drug riluzole, which acts through inhibition of glutamate release as well as other mechanisms. The effect of this treatment is modest, prolonging survival by a few months.

**BIBLIOGRAPHY**

Mouradian MM, Heuser IJ, Baronti F, Chase TN. Modification of central dopaminergic mechanisms by continuous levodopa...

The two-carbon alcohol ethanol (CH₃CH₂OH), or beverage alcohol, is one of the most versatile drugs known to man, with multiple direct effects on a diverse range of neurochemical systems. Produced in nature, rewarding in its effects, and easy to manufacture, it has been taken by humans since the beginning of recorded history, is consumed by a large majority of people in the Western world, and is likely to contribute to more morbidity, mortality, and public health costs than all of the illicit drugs combined. Yet most pharmacologists, pharmacists, and healthcare providers receive only minimal education about ethanol and the mechanisms through which it contributes to such diverse pathology.

This chapter presents an overview of the effects of ethanol on various physiological systems, then focuses on the mechanisms of ethanol’s effects in the central nervous system (CNS) as the basis for understanding the rewards, disease processes, and treatments for ethanol-related conditions. First, it is worthwhile to recount the history of the human use of alcoholic beverages.

Human Consumption of Ethanol: A Brief History. The use of alcoholic beverages has been documented since at least 10,000 BC (Hanson, 1995). By about 3000 BC, the Greeks, Romans, and inhabitants of Babylon continued to incorporate ethanol into religious festivals, while also using these beverages for pleasure, to facilitate socialization, as a source of nutrition, and as part of medicinal practices. The role of ethanol in society continued through biblical times, with beverage alcohol incorporated into most religions, and occupying a central role in daily life. Over the last 2000 years, alcoholic beverages have been identified in most cultures, including pre-Columbian America in ~200 AD, and the Islamic world in the 700s.

Whiskey was invented in ~1400 in Ireland and rapidly increased in popularity; champagne was developed in France in 1670. In 1690, the English government enacted a law encouraging the consumption of distilled spirits, and the production of gin subsequently increased from about 0.5 million gallons in 1685 to 5 million by 1727 and 18 million gallons by the early 1800s.

The dangers of heavy consumption of beverage alcohol have been recognized by almost all cultures, with most stressing the importance of moderation. Despite these warnings, problems with ethanol are as ancient as the pattern of use of this beverage itself, and were noted early on in India, Greece, and Rome. The increase in use of ethanol in the 1800s, along with industrialization and need for a more dependable work force, contributed to the development of more widespread organized efforts to discourage drunkenness. The subsequent temperance movements set the stage for the prohibition against drinking instituted in the U.S. in 1920. In 1933, the long tradition of the use of alcohol, as well as the large minority of the population who favored the availability of alcoholic beverages, resulted in the repeal of the constitutional amendment enacting prohibition.

Beverage alcohol has widespread use in today’s society, with an average age of first use of ~15 years in most Western countries. Almost two-thirds of women and as many as 80% of men in these countries have consumed alcoholic beverages, with one-half to two-thirds reporting alcohol consumption within the past year (Faden, 2006). The highest quantities and frequencies of drinking are usually observed in the late teens to early 20s, and in the U.S., the average adult consumes alcoholic beverages containing the equivalent of 2.2 gallons (8.3 L) of absolute alcohol per year. Among drinkers, as many as half have had a temporary alcohol-related problem such as missing school or work, alcohol-related amnesia (blackouts), or operating a motor vehicle after consuming alcohol. More severe repetitive problems with alcohol (known as abuse and dependence) have a lifetime risk in men of almost 20% and in women of 10-15% (Hasin et al., 2007). The annual costs associated with heavy drinking and associated problems have been estimated to be $185 billion in the U.S. in recent years, and this drug contributes to 100,000 deaths per year in the U.S. alone, including as many as 20,000 alcohol-related fatal car accidents annually (Harwood et al., 1999; Rehm et al., 2007). Thus, the delivery of optimal medical care in modern times is greatly affected by the use of beverage alcohol, with this drug adversely affecting many body systems, interacting with medications and other drugs, and responsible for a great deal of the healthcare dollar.

Ethanol Consumption. Compared with other drugs, surprisingly large amounts of alcohol are required for physiological effects, resulting in its consumption more as a food than a drug. The alcohol content of beverages typically ranges from 4-6% (volume/volume) for beer, 10-15% for wine, and 40% and higher for distilled spirits.
Ethanol. After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and distributes into total-body water (0.5–0.7 L/kg). Peak blood levels occur about 30 minutes after ingestion of ethanol when the stomach is empty. Because absorption occurs more rapidly from the small intestine than from the stomach, delays in gastric emptying (owing, e.g., to the presence of food) slow ethanol absorption. Because of first-pass metabolism by gastric and liver alcohol dehydrogenase (ADH), oral ingestion of ethanol leads to lower BELs than would be obtained if the same quantity were administered intravenously. Gastric metabolism of ethanol is lower in women than in men, which may contribute to the greater susceptibility of women to ethanol (Lieber, 2000; Schukit, 2006a). Aspirin increases ethanol bioavailability by inhibiting gastric ADH.

Ethanol is metabolized largely by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by aldehyde dehydrogenase (ALDH) (Figure 23–1). Each metabolic step requires NAD⁺; thus oxidation of 1 mol ethanol (46 g) to 1 mol acetic acid requires 2 mol NAD⁺ (approximately 1.3 kg). This greatly exceeds the supply of NAD⁺ in the liver; indeed, NAD⁺ availability limits ethanol metabolism to about 8 g or 10 mL (approximately 170 mmol) per hour in a 70-kg adult, or approximately 120 mg/kg per hour. Thus, hepatic ethanol metabolism functionally saturates at relatively low blood levels compared with the high BELs achieved, and ethanol metabolism is a zero-order process (constant amount per unit time). Small amounts of ethanol are excreted in urine, sweat, and breath, but metabolism to acetate accounts for 90–98% of ingested ethanol, mostly owing to hepatic metabolism by ADH and ADLH.

A hepatic cytochrome P450, CYP2E1, also can contribute (Figure 23–1), especially at higher ethanol concentrations and under conditions such as alcoholism, where its activity may be induced. Catalase also can produce acetaldehyde from ethanol, but hepatic H₂O₂ availability usually is too low to support significant flux of ethanol through this pathway. Although CYP2E1 usually is not a major factor in ethanol metabolism, it can be an important site of interactions of ethanol with other drugs. CYP2E1 is induced by chronic consumption of ethanol, increasing the clearance of its substrates and the activation of certain toxins such as CCl₄. There can be decreased clearance of the same drugs, however, after acute consumption of ethanol because ethanol competes with them for oxidation by the enzyme system (e.g., phenytoin and warfarin).

The large increase in the hepatic NADH:NAD⁺ ratio during ethanol oxidation has profound consequences in addition to limiting the rate of ethanol metabolism. Enzymes requiring NAD⁺ are inhibited; thus lactate accumulates, activity of the tricarboxylic acid cycle is reduced, and acetyl coenzyme A (acetyl CoA) accumulates (and it is produced in quantity from ethanol-derived acetic acid; Figure 23-1). The combination of increased NADH and elevated–acetyl CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides. Ketone bodies accrue, exacerbating lactic acidosis. Ethanol metabolism by the CYP2E1 pathway produces elevated NAD⁺, limiting the availability of NADPH for the regeneration of reduced glutathione (GSH), thereby enhancing oxidative stress.
The mechanisms underlying hepatic disease resulting from heavy ethanol use probably reflect a complex combination of these metabolic factors, CYP2E1 induction (and enhanced activation of toxins and production of H₂O₂ and oxygen radicals), and possibly enhanced release of endotoxin as a consequence of ethanol’s effect on gram-negative flora in the GI tract. Effects of heavy ethanol ingestion on various organs are summarized in the following discussion; damage to tissues very likely reflects the poor nutritional status of alcoholics (malabsorption and lack of vitamins A and D and thiamine), suppression of immune function by ethanol, and a variety of other generalized effects.

**Methanol.** One carbon alcohol, methanol (CH₃OH), is also known as methyl and wood alcohol. It is an important industrial reagent and solvent found in products such as paint removers, shellac, and antifreeze (Lushine et al., 2003); methanol is added to industrial-use ethanol to mark it unsafe for human consumption.

Methanol is rapidly absorbed via the oral route, inhalation, and through the skin, with the latter two routes most relevant to industrial settings. Methanol also is metabolized by ADH and ALDH, with damaging consequences (described later in the chapter). Competition between methanol and ethanol for ADH forms the basis of the use of ethanol in methanol poisoning. Several drugs inhibit alcohol metabolism, including fomepizole (4-methylpyrazole) an ADH inhibitor useful in ethylene glycol poisoning, and disulfiram, an ALDH inhibitor used in treating alcoholism (described later in the chapter). Ethanol also can competitively inhibit the metabolism of other substrates of ADH and CYP2E1, such as methanol and ethylene glycol, and therefore is an effective antidote.

**Figure 23-1. Metabolism of ethanol and methanol.**
methanol is taken along with ethanol. As little as 15 mL of methanol can produce toxicity, including blindness, with doses in excess of 70 mL capable of producing death. Methanol poisoning consists of headache, GI distress, and pain (partially related to pancreatic injury), difficulty breathing, restlessness, and blurred vision associated with hyperemic optic disks. Severe metabolic acidosis can develop due to the accumulation of formic acid, and the respiratory depression can be severe, especially in the context of coma. The visual disturbances associated with methanol intoxication are a prominent part of the picture, and occur as a consequence of injury to ganglion cells of the retina by the metabolite, formic acid, with subsequent inflammation, atrophy, and potential bilateral blindness. The clinical picture can also include necrosis of the pancreas.

**Genetic Variation in Ethanol Metabolism.** The enzymes involved in ethanol metabolism (Figure 23–1) are mainly ADH and ALDH, and secondarily, catalase and CYP2E1. Several of these enzymes have genetic variants that alter alcohol metabolism and susceptibility to its effects.

The genetics of the ADH isoforms are important for understanding risk factors for severe repetitive ethanol problems. The three relevant forms are ADH1A, 1B, and 1C (genes on chromosome 4 q22). These class I ADHs have $K_m<34$ mmol (0.15 g/dL) and are responsible for 70% of the ethanol metabolizing capacity at BECs of 22 mM (i.e., ~0.10 g/dL) (Edenberg et al., 2006). These ADH forms are the rate-limiting step in ethanol metabolism, reducing the blood ethanol concentrations by ~4–5 mM (0.015–0.020 g/dL) per hour, the approximate levels of alcohol resulting from the consumption of one standard drink.

The ADH1A gene has no polymorphisms known to significantly affect the rate of alcohol metabolism. The ADH1B gene has a polymorphism, ADH1B*2, with arginine 47 replaced by histidine to produce a variant form of ADH with a 40-fold higher $V_{max}$ than ADH1B. This polymorphism is seen in 30-45% of Chinese, Japanese, and Koreans, less than 10% of most Europeans, but in 50-90% of Russians and Jews (Edenberg et al., 2006). The potential faster metabolism of ethanol may result in a transient slightly higher blood level of acetaldehyde and is reported to be associated with a lower risk for heavy drinking and ethanol-related problems. A second polymorphism for ADH1B, ADH1B*3 (arginine 269 replaced by cysteine), has a 30-fold higher $V_{max}$ ADH1B*3 is seen in about 30% of Africans and also is associated with lower risk of heavy drinking and ethanol problems.

A third ADH gene found in the chromosome 4q22 cluster, ADH1C, exhibits two polymorphisms in high linkage disequilibrium, the $\gamma_1$ and $\gamma_2$ forms. The $V_{max}$ of $\gamma_1$ is twice that of $\gamma_2$, and this ADH1C*1 allele is hypothesized to be associated with a slightly faster metabolism of ethanol and/or a higher level of acetaldehyde. The independent effects of ADH1C*1 and ADH1B*2 alleles are difficult to determine. The ADH cluster on chromosome 4 also contains class II ADHs with $K_m = 34$ mM (~0.15 g/dL). The class II forms contribute about 30% of the ethanol metabolizing capacity noted above. There are polymorphisms hypothesized to be associated with the alcoholism risk, but less information is known about these forms (Luo et al., 2007).

Other systems also contribute to the metabolism of ethanol to acetaldehyde including via catalase (Kuo et al., 2008). In addition, at higher BELs, the microsomal ethanol metabolizing system (MEOS) is important, especially CYP2E1, but also CYPs1A2 and 3A4. Variations of the CYP2E1 gene located on chromosome 10 have been hypothesized to relate to the level of sensitivity or reaction to the ethanol observed in the brain.

Acetaldehyde is produced from the breakdown of ethanol at the rate of approximately one standard drink per hour. As shown in Figure 23–1, the acetaldehyde is then rapidly broken down through the actions of ALDH2, primarily in the mitochondria of liver cells. The actions of ALDH2, a phase 2 enzyme (Chapter 6), are important because low levels of acetaldehyde may be perceived as rewarding and stimulating, while high blood levels of this substance produce severe adverse reactions that can include vomiting, diarrhea, and unstable blood pressure (Husemoen et al., 2008). There is a mutation in the ALDH2 gene (12q24), ALDH2*2 (resulting from a substitution of glycine 487 with lysine). Homozygotes with a nonfunctional ALDH2*2 occur in 5–10% of Japanese, Chinese, and Korean individuals, for whom severe adverse reactions occur after consumption of one drink or less. Consequently, their risk for severe repetitive heavy drinking is close to zero. This reaction operates through the same mechanism that occurs with drinking after taking the ALDH2 inhibitor, disulfiram. Heterozygotes for this polymorphism (ALDH2*2, 2*1) make up 30–40% of Asian individuals who, after consuming ethanol experience a facial flush and an enhanced sensitivity to beverage alcohol, but who do not necessarily report an overall adverse response to the drug (Wall and Ehlers, 1995). The heterozygotes tend to drink lower quantities of ethanol than the general population, although repeated intake may relate to an enhanced risk for adverse ethanol-related organ damage (including esophageal cancer and, perhaps, pancreatitis), possibly associated with higher acetaldehyde levels. While additional ALDH mutations occur, less is known about potential associations between these polymorphisms and the risk from alcohol.

**EFFECTS OF ETHANOL ON PHYSIOLOGICAL SYSTEMS**

William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (act 2, scene 3) of *Macbeth*. The Porter, awakened from an alcohol-induced sleep by Macduff, explains three effects of alcohol and then wrestles with a fourth effect that combines the contradictory aspects of soaring over-confidence with physical impairment:

**Porter:** . . . and drink, sir, is a great provoker of three things.

**Macduff:** What three things does drink especially provoke?

**Porter:** Marry, sir, nose-painting [cutaneous vasodilation], sleep [CNS depression], and urine [a consequence of the inhibition of antidiuretic hormone (vasopressin) secretion, exacerbated by volume loading]. Lechery, sir, it provokes and unprovokes: it provokes the desire but it takes away the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off; it persuades him and disheartens him, makes him stand to and not stand to [the imagination desires what the corpus cavernosum cannot deliver]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.
More recent research has added details to Shakespeare’s enumeration—see the bracketed additions to the Porter’s words in the preceding paragraph and the section on organ systems later in the chapter—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates a frequently observed influence of modest concentrations of ethanol on the CNS. The sections that follow detail ethanol’s effects on physiological systems.

**Central Nervous System**

Although the public often views alcoholic drinks as stimulating, ethanol primarily is a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other depressants such as barbiturates and benzodiazepines, can have anti-anxiety actions and produce behavioral disinhibition at a wide range of dosages. Individual signs of intoxication vary from expansive and vivacious affect to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function generally is impaired, and a condition of general anesthesia ultimately prevails. However, there is little margin between the anesthetic actions and lethal effects (usually owing to respiratory depression).

Although the public often views alcoholic drinks as stimulating, ethanol primarily is a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other depressants such as barbiturates and benzodiazepines, can have anti-anxiety actions and produce behavioral disinhibition at a wide range of dosages. Individual signs of intoxication vary from expansive and vivacious affect to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function generally is impaired, and a condition of general anesthesia ultimately prevails. However, there is little margin between the anesthetic actions and lethal effects (usually owing to respiratory depression).

About 10% of alcohol drinkers progress to levels of consumption that are physically and socially detrimental. Chronic abuse is accompanied by tolerance, dependence, and craving for the drug (see Tolerance, Dependence, and Chronic Ethanol Use, and Chapter 24). Alcoholism is characterized by compulsive use despite clearly deleterious social and medical consequences. Alcoholism is a progressive illness, and brain damage from chronic alcohol abuse contributes to the deficits in cognitive functioning and judgment seen in alcoholics. Alcoholism is a leading cause of dementia in the U.S. (Oslin et al., 1998). Chronic alcohol abuse results in shrinkage of the brain owing to loss of both white and gray matter (Kril and Halliday, 1999). The frontal lobes are particularly sensitive to damage by alcohol, and the extent of damage is determined by the amount and duration of alcohol consumption, with older alcoholics being more vulnerable than younger ones (Pfefferbaum et al., 1998). It is important to note that ethanol itself is neurotoxic, and although malnutrition or vitamin deficiencies probably play roles in complications of alcoholism such as Wernicke’s encephalopathy and Korsakoff’s psychosis, most of the alcohol-induced brain damage in Western countries is due to alcohol itself. In addition to loss of brain tissue, alcohol abuse also reduces brain metabolism (as determined by positron-emission tomography), and this hypometabolic state reboinds to a level of increased metabolism during detoxification. The magnitude of decrease in metabolic state is determined by the number of years of alcohol use and the age of the patients (Volkow et al., 1994).

**Actions of Ethanol on Neurochemical Pathways and Signaling.**

Ethanol affects almost all brain systems. The changes across neurochemical pathways occur simultaneously and the alterations often interact. An additional complication in describing CNS effects is the rapid adaptation to ethanol observed in the brain, with the result that the acute effects of the first dose of ethanol are often the opposite of the neurochemical consequences from repeated administration and those observed during falling blood ethanol levels and withdrawal syndromes (Schuckit, 2006b).

Alcohol perturbs the balance between excitatory and inhibitory influences in the brain, resulting in anxiety, ataxia, and sedation. This is accomplished by either enhancing inhibitory or antagonizing excitatory neurotransmission. Ethanol likely produces its effects by simultaneously altering the functioning of a number of proteins that can affect neuronal excitability (Table 23–1). A key issue has been to identify proteins that determine neuronal excitability and are sensitive to ethanol at the concentrations (5-20 mM) that produce behavioral effects. Many of the prominent effects are on ligand-gated and voltage-gated ion channels and GPCR systems.

**Ion Channels.** The primary mediators of inhibitory neurotransmission in the brain are the ligand-gated γ-aminobutyric acid A (GABA<sub>A</sub>) receptors, whose function is markedly enhanced by a number of classes of sedative, hypnotic, and anesthetic agents, including barbiturates, benzodiazepines, and volatile anesthetics (Chapter 14). Substantial data implicate the GABA<sub>A</sub> receptor as an important target for the in vivo actions of ethanol. Stimulation of this multi-subunit, ligand-gated Cl<sup>-</sup> channel system contributes to feelings of sleepiness, muscle relaxation, and the acute anticonvulsant properties associated with all GABA-boosting drugs (Krystal et al.,
Acutely, ethanol results in GABA release; chronic heavy use alters the pattern of expression of genes impacting on GABA_\textsubscript{A} subunits. Intoxication of ethanol can be viewed as a GABA-rich state, and withdrawal phenomena are related in part to GABA_\textsubscript{A} activity deficiencies. Several GABA_\textsubscript{A} receptor gene polymorphisms correlate with a predisposition toward heavy drinking and alcohol use disorders (Dick et al., 2006a,b).

The nicotinic ACh receptor is also sensitive to the effects of ethanol. Drinking acutely increases ACh in the ventral tegmental area, with a subsequent increase in DA in the nucleus accumbens (Joslyn et al., 2008). Varenicline, a partial agonist at the \(\alpha_\text{B}_1\) subtype of the nicotinic ACh receptor (Chapter 11), decreases ethanol-seeking behavior and ethanol consumption in a rodent model, similar to its actions to effects on nicotine dependence (Steensland et al., 2007). Effects of ethanol on these receptors may be particularly important because there is an association between nicotine exposure (smoking) and alcohol consumption in humans. Furthermore, several studies indicate that nicotine increases alcohol consumption in animal models (Smith et al., 1999).

Excitatory ionotropic glutamate receptors are divided into the \(\gamma\text{-methyl-D-aspartate (NMDA)}\) and non-NMDA receptor classes, with the latter consisting of kainate- and AMPA-receptor subtypes (see Chapter 14). Ethanol inhibits the function of the NMDA- and kainate-receptor subtypes; AMPA receptors are largely resistant to alcohol (Carta et al., 2003). As with the GABA_\textsubscript{A} receptors, phosphorylation of the glutamate receptor can modulate sensitivity to ethanol.

A number of other types of channels are sensitive to alcohol at concentrations routinely achieved in vivo. Ethanol enhances the activity of large conductance, \(\text{Ca}^{2+}\)-activated \(\text{K}^+\) channels in neurohypophyseal terminals (Dopico et al., 1999), perhaps contributing to the reduced release of oxytocin and vasopressin after ethanol consumption. Ethanol inhibits N- and P/Q-type \(\text{Ca}^{2+}\) channels in a manner that can be antagonized by channel phosphorylation by PKA (Solem et al., 1997). BK (Maxi-K, slo1) channels also are a target for alcohol action (Davies et al., 2003). G protein–gated inwardly rectifying \(\text{K}^+\) channels (GIRK or Kir channels) can be activated by the \(\beta\gamma\) subunits of the \(G_\text{G}\) family, by PIP_\text{2}, and, via a different mechanism, by alcohols. Small alcohols bind to a hydrophobic binding pocket on GIRKs, leading to channel activation via stabilization of the open conformation (Aryal et al., 2009).

**Other Neurotransmitter Systems.** Dopamine-related systems have central importance regarding the feelings of reward and craving associated with all intoxicating substances (Koob and Kreek, 2007). Of special importance are alterations in DA activity in the ventral tegmental and related areas, especially the nucleus accumbens, which are likely to play a major role in feelings of euphoria and reward. Acute alcohol results in an increase in synaptic DA; repeated administration is associated with changes in both \(D_1\) and \(D_2\) receptors that may be important in the perpetuation of alcohol use as well as in relapse (Voroin et al., 2008).

The impact of ethanol on dopaminergic pathways is closely linked to changes in stress-related systems. These changes are hypothesized to relate to reinforcement from beverage alcohol and other drugs of abuse, as well as withdrawal symptoms and negative moods related to problems with regulation of the DA-rich brain reward systems. Dopaminergic activity in the nucleus accumbens is affected by multiple types of opioid receptors, and acute ethanol causes the release of \(\beta\) endorphins (Job et al., 2007). These actions subsequently activate \(\mu\) opioid receptors in the ventral tegmentum and nucleus accumbens, with associated release of DA. Thus, many of the effects of alcohol on reward systems, and changes in how the CNS reacts to ethanol (including sensitization), may relate to alterations in opioid systems (Pastor and Aragon, 2006).

The acute administration of ethanol is associated with a significant increase in 5-HT in the synaptic space; continued use of ethanol produces an up-regulation of 5-HT receptors. Lower levels of 5-HT in the synapse, perhaps related to a more rapid reuptake by the 5-HT transporter, is associated with higher levels of alcohol intake and, potentially, lower levels of intensity of reaction to beverage alcohol (Barr et al., 2005). Changes in DA systems are likely to relate to alterations in 5-HT as well.

Cannabinoid receptors, especially \(CB_1\) encoded by the gene CNR1, are also affected by ethanol (Hutchinson et al., 2008; Perra et al., 2008). \(CB_1\) is a GPCR that is densely represented in the ventral tegmentum, nucleus accumbens, and prefrontal cortex. Activation of \(CB_1\) occurs with acute ethanol administration and affects the release of DA, GABA, and glutamate, and reward circuits of the brain. Antagonists of \(CB_1\) receptors, such as rimonabant, may block the effect of ethanol on dopaminergic systems.

**Protein Kinases and Signaling Enzymes.** Knockout mice lacking the \(\gamma\) isoform of PKC display reduced effects of ethanol measured behaviorally and a loss of enhancement by ethanol of GABA’s effects measured in vitro (Harris et al., 1995). Intracellular signal-transduction cascades, such as MAPK, tyrosine kinases, and neurotransmitter factor receptors, also are thought to be affected by ethanol (Valenzuela and Harris, 1997). Translocation of PKC and PKA between subcellular compartments also is sensitive to alcohol (Constantinescu et al., 1999).

Ethanol enhances the activities of several isoforms of adenylyl cyclase, with AC7 being the most sensitive (Tabakoff and Hoffman, 1998). This promotes increased production of cyclic AMP and thus increased activity of PKA. Ethanol’s actions appear to be mediated by activation of \(G_\text{i}\) and promotion of the interaction between \(G_1\) and adenylyl cyclase.

**Ethanol Consumption and CNS Function.** There are a series of relatively common and temporary effects of ethanol with relatively high prevalence rates reflecting changes in the GABA system that are generally caused by CNS depressants. Large doses of ethanol can interfere with encoding of memories, producing anterograde amnesia, commonly referred to as alcoholic blackouts; affected individuals are unable to recall all or part of experiences during the period of heavy intake. At even 2-3 drinks, ethanol consumption can produce disturbances in sleep architecture, with frequent awakenings and restless sleep; high doses are associated with vivid and disturbing dreams late as a consequence of earlier suppression of night rapid eye movement dream state at higher blood ethanol levels. Perhaps reflecting the effect of ethanol on respirations as well as the muscle-relaxant effects of this drug, heavier drinking can be associated with sleep apnea, especially in older alcohol-dependent subjects (Sakurai et al., 2007). The transient CNS effects of heavy ethanol consumption that produce a hangover—the “next morning” syndrome of headache, thirst, nausea, and cognitive impairment—contribute to much time lost from work and school, and may reflect mechanisms...
similar to mild alcohol withdrawal, dehydration, and/or mild acidosi (Stephens et al., 2008).

Chronic heavy drinking reportedly increases the probability of developing a more permanent cognitive deficit often referred to as alcoholic dementia. However, the signs of cognitive deficits and brain atrophy observed soon after a heavy drinking period often reverse over the subsequent several weeks to months following abstinence (Bartsch et al., 2007). The thiamine depletion that can accompany heavy ethanol consumption contributes to Wernicke-Korsakoff syndromes; however, the ataxia and ophalmpoaresis of Wernicke's, and the severe ataxergode and retrograde amniesias of Korsakoff's, are seen in <1% of chronic alcohol-dependent individuals. Additional severe neurological syndromes associated with chronic heavy use of alcohol include cerebellar degeneration with associated atrophy of the cerebellum vermis (seen in ~1% of alcoholics), and a peripheral neuropathy (observed in ~10% of alcoholics) (Alexander-Kaufman et al., 2007; Peters et al., 2006). The specific mechanisms associated with damage to the cerebellum and peripheral nerves have not been definitively identified.

Heavy doses of ethanol over multiple days or weeks are also associated with several temporary but disturbing “alcohol-induced” psychiatric syndromes (Schuckit, 2006a). As many as 40% of alcohol-dependent humans develop severe alcohol-related depressive symptoms that can include temporary suicidal thoughts and behaviors. Similarly, a range of anxiety conditions, including those characterized by panic attacks and generalized anxiety, are likely in a large minority of alcohol-dependent individuals during the withdrawal syndrome. Perhaps 3% of alcohol-dependent men and women report experiencing temporary auditory hallucinations and paranoid delusions that resemble schizophrenia beginning during periods of heavy intoxication; all of these psychiatric syndromes are likely to markedly improve within several days to a month of abstinence, with residual mild symptoms continuing to diminish thereafter. While no definitive data on the mechanisms for these alcohol-induced psychiatric conditions are available, it is logical to assume that alcohol-related changes in CNS pathways (NE and 5-HT levels, the balance between GABA and NMDA receptor activity, dopaminergic activity) may operate here in a manner similar to those seen in depression, anxiety, and schizophrenic disorders.

**Cardiovascular System**

Ethanol intake greater than three standard drinks per day elevates the risk for heart attacks and bleeding-related strokes (Hvidtfeldt et al., 2008). Indeed, vascular-related diseases are among the leading causes of early death in alcohol-dependent individuals. The risk includes a 6-fold increased risk for coronary artery disease, a heightened risk for cardiac arrhythmias, and an elevated rate of congestive heart failure. The causes are complex and observations are complicated by certain positive effects of small amounts of ethanol.

**Serum Lipoproteins and Cardiovascular Effects.** In most countries, the risk of mortality due to coronary heart disease (CHD) is correlated with a high dietary intake of saturated fat and elevated serum cholesterol levels. France is an exception to this rule, with relatively low mortality from CHD despite the consumption of high quantities of saturated fats (the “French paradox”). Epidemiological studies suggest that widespread wine consumption (20-30 g ethanol per day) is one of the factors conferring a cardioprotective effect, with 1-3 drinks per day resulting in a 10-40% decreased risk of coronary heart disease compared with abstainers. In contrast, daily consumption of greater amounts of alcohol leads to an increased incidence of non-coronary causes of cardiovascular failure, such as arrhythmias, cardiomyopathy, and hemorrhagic stroke, offsetting the beneficial effects of alcohol on coronary arteries; that is, alcohol has a J-shaped dose-mortality curve. Reduced risks for CHD are seen at intakes as low as one-half drink per day (Libby et al., 2007). Young women and others at low risk for heart disease derive little benefit from light to moderate alcohol intake, whereas those of both sexes who are at high risk and who may have had a myocardial infarction clearly benefit. Data based on a number of prospective, cohort, cross-cultural, and case-control studies in diverse populations consistently reveal lower rates of angina pectoris, myocardial infarction, and peripheral artery disease in those consuming light (1-20 g/day) to moderate (21-40 g/day) amounts of alcohol.

One possible mechanism by which alcohol could reduce the risk of CHD is through its effects on blood lipids. Changes in plasma lipoprotein levels, particularly increases in high-density lipoprotein (HDL; Chapter 31), have been associated with the protective effects of ethanol. HDL binds cholesterol and returns it to the liver for elimination or reprocessing, decreasing tissue cholesterol levels. Ethanol-induced increases in HDL-cholesterol thus could antagonize cholesterol accumulation in arterial walls, lessening the risk of infarction. Approximately half the risk reduction associated with ethanol consumption is explained by changes in total HDL levels (Langer et al., 1992). HDL is found as two subfractions, named HDL and HDL. Increased levels of HDL (and possibly also HDL) are associated with reduced risk of myocardial infarction. Levels of both subfractions are increased following alcohol consumption and decrease when alcohol consumption ceases. Apolipoproteins A-I and A-II are constituents of HDL. Increased levels of both apolipoproteins A-I and A-II are associated with individuals who are daily heavy drinkers. In contrast, there are reports of decreased serum apolipoprotein(a) levels following acute alcohol consumption. Elevated apolipoprotein(a) levels have been associated with an increased risk for the development of atherosclerosis.

All forms of alcoholic beverages confer cardio-protection. A variety of alcoholic beverages increase HDL levels while decreasing the risk of myocardial infarction. The flavonoids found in red wine (and purple grape juice) may have an additional antiatherogenic role by protecting low-density lipoprotein (LDL) from oxidative damage. Oxidized LDL has been implicated in several steps of...
atherogenesis (Chapter 31). Another way in which alcohol consumption conceivably could play a cardioprotective role is by altering factors involved in blood clotting. Alcohol consumption elevates the levels of tissue plasminogen activator, a clot-dissolving enzyme (Chapter 30), decreasing the likelihood of clot formation. Decreased fibrinogen concentrations seen following ethanol consumption also could be cardioprotective (Rimm et al., 1999), and epidemiological studies have linked the moderate consumption of ethanol to an inhibition of platelet activation (Rubin, 1999).

Should abstainers from alcohol be advised to consume ethanol in moderate amounts? The answer is no. There have been no randomized clinical trials to test the efficacy of daily alcohol use in reducing rates of coronary heart disease and mortality, and it is inappropriate for physicians to advocate alcohol ingestion solely to prevent heart disease. Many abstainers avoid alcohol because of a family history of alcoholism or for other health reasons, and it is imprudent to suggest that they begin drinking. Other lifestyle changes or medical treatments should be encouraged if patients are at risk for the development of CHD.

**Hypertension.** Heavy alcohol use can raise diastolic and systolic blood pressure. Studies indicate a positive, non-linear association between alcohol use and hypertension that is unrelated to age, education, smoking status, or the use of oral contraceptives. Consumption above 30 g alcohol per day (more than 2 standard drinks) is associated with a 1.5-2.3 mm Hg rise in diastolic and systolic blood pressure.

The prevalence of hypertension attributable to excess alcohol consumption is not known, but studies suggest a range of 5-11%. The prevalence probably is higher for men than for women because of higher alcohol consumption by men. A reduction in or cessation of alcohol use in heavy drinkers may need the reduction for antihypertensive medication or reduce the blood pressure to the normal range. A safe amount of alcohol consumption for hypertensive patients who are light drinkers (1-2 drinks per occasion and less than 14 drinks per week) has not been determined. Factors to consider are a personal history of ischemic heart disease, a history of binge drinking, or a family history of alcoholism or of cerebrovascular accident. Hypertensive patients with any of these risk factors should abstain from alcohol use.

**Cardiac Arrhythmias.** Alcohol has a number of pharmacological effects on cardiac conduction, including prolongation of the QT interval, prolongation of ventricular repolarization, and sympathetic stimulation. Atrial arrhythmias associated with chronic alcohol use include supraventricular tachycardia, atrial fibrillation, and atrial flutter. Some 15-20% of idiopathic cases of atrial fibrillation may be induced by chronic ethanol use (Libby et al., 2007). Ventricular tachycardia may be responsible for the increased risk of unexplained sudden death that has been observed in persons who are alcohol-dependent (Kupari and Koskinen, 1998). During continued alcohol use, treatment of these arrhythmias may be more resistant to cardioversion, digoxin, or Ca2+ channel blocking agents. Patients with recurrent or refractory atrial arrhythmias should be questioned carefully about alcohol use.

**Cardiomyopathy.** Ethanol is known to have dose-related toxic effects on both skeletal and cardiac muscle. Numerous studies have shown that alcohol can depress cardiac contractility and lead to cardiomyopathy. Echocardiography demonstrates global hypokinesis. Approximately half of all patients with idiopathic cardiomyopathy are alcohol-dependent. Although the clinical signs and symptoms of idiopathic and alcohol-induced cardiomyopathy are similar, alcohol-induced cardiomyopathy has a better prognosis if patients are able to stop drinking. Women are at greater risk of alcohol-induced cardiomyopathy than are men (Urbano–Marquez et al., 1995). Since 40-50% of persons with alcohol-induced cardiomyopathy who continue to drink die within 3-5 years, abstinence remains the primary treatment.

**Stroke.** Clinical studies indicate an increased incidence of hemorrhagic and ischemic stroke in persons who drink more than 40-60 g alcohol per day (Hansagi et al., 1995). Many cases of stroke follow prolonged binge drinking, especially when stroke occurs in younger patients. Proposed etiological factors include:

- alcohol-induced cardiac arrhythmias and associated thrombus formation
- high blood pressure from chronic alcohol consumption and subsequent cerebral artery degeneration
- acute increases in systolic blood pressure and alterations in cerebral artery tone
- head trauma

The effects on hemostasis, fibrinolysis, and blood clotting are variable and could prevent or precipitate acute stroke (Numminen et al., 1996). The effects of alcohol on the formation of intracranial aneurysms are controversial, but the statistical association disappears when one controls for tobacco use and gender (Qureshi et al., 1998).

**Skeletal Muscle**

Alcohol has a number of effects on skeletal muscle. Chronic, heavy, daily alcohol consumption is associated with decreased muscle strength, even when adjusted for...
other factors such as age, nicotine use, and chronic illness. Heavy doses of alcohol also can cause irreversible damage to muscle, reflected by a marked increase in the activity of creatine kinase in plasma.

Muscle biopsies from heavy drinkers also reveal decreased glycogen stores and reduced pyruvate kinase activity (Vernet et al., 1995). Approximately 50% of chronic heavy drinkers have evidence of type II fiber atrophy. These changes correlate with reductions in muscle protein synthesis and serum carnosinase activities (Wassif et al., 1993). Most patients with chronic alcoholism show electromyographical changes, and many show evidence of a skeletal myopathy similar to alcoholic cardiomyopathy.

**Body Temperature**

Ingestion of ethanol causes a feeling of warmth because alcohol enhances cutaneous and gastric blood flow. Increased sweating also may occur. Heat, therefore, is lost more rapidly, and the internal body temperature falls. After consumption of large amounts of ethanol, the central temperature-regulating mechanism becomes depressed, and the fall in body temperature may become pronounced. The action of alcohol in lowering body temperature is greater and more dangerous when the ambient environmental temperature is low. Studies of deaths from hypothermia suggest that alcohol is a major risk factor in these events. Patients with ischemic limbs secondary to peripheral vascular disease are particularly susceptible to cold damage.

**Diuresis**

Alcohol inhibits the release of vasopressin (antidiuretic hormone) from the posterior pituitary gland, resulting in enhanced diuresis. The volume loading that accompanies imbibing complements the diuresis that occurs as a result of reduced vasopressin secretion.

Alcoholics have less urine output than do control subjects in response to a challenge dose with ethanol, suggesting that tolerance develops to the diuretic effects of ethanol (Collins et al., 1992). Alcoholics withdrawing from alcohol exhibit increased vasopressin release and a consequent retention of water, as well as dilutional hyponatremia.

**Gastrointestinal System**

**Esophagus.** Alcohol frequently is either the primary etiologic factor or one of multiple causal factors associated with esophageal dysfunction. Ethanol also is associated with the development of esophageal reflux, Barrett’s esophagus, traumatic rupture of the esophagus, Mallory-Weiss tears, and esophageal cancer.

When compared with nonalcoholic nonsmokers, alcohol-dependent patients who smoke have a 10-fold increased risk of developing cancer of the esophagus. There is little change in esophageal function at low blood alcohol concentrations, but at higher blood alcohol concentrations, a decrease in peristalsis and decreased lower esophageal sphincter pressure occur. Patients with chronic reflux esophagitis may respond to proton pump inhibitors and abstinence from alcohol.

**Stomach.** Heavy alcohol use can disrupt the gastric mucosal barrier and cause acute and chronic gastritis. Ethanol appears to stimulate gastric secretions by exciting sensory nerves in the buccal and gastric mucosa and promoting the release of gastrin and histamine. Beverages containing more than 40% alcohol also have a direct toxic effect on gastric mucosa. While these effects are seen most often in chronic heavy drinkers, they can occur after moderate and short-term alcohol use. The diagnosis may not be clear because many patients have normal endoscopic examinations and upper gastrointestinal radiographs. Clinical symptoms include acute epigastric pain that is relieved with antacids or histamine H₂ receptor blockers.

Alcohol is not thought to play a role in the pathogenesis of peptic ulcer disease. Unlike acute and chronic gastritis, peptic ulcer disease is not more common in alcoholics. Nevertheless, alcohol exacerbates the clinical course and severity of ulcer symptoms. It appears to act synergistically with Helicobacter pylori to delay healing (Lieber, 1997). Acute bleeding from the gastric mucosa, while uncommon, can be a life-threatening emergency. Upper GI bleeding is associated more commonly with esophageal varices, traumatic rupture of the esophagus, and clotting abnormalities.

**Intestines.** Many alcoholics have chronic diarrhea as a result of malabsorption in the small intestine (Addolorato et al., 1997). The major symptom is frequent loose stools. The rectal fissures and pruritus ani that frequently are associated with heavy drinking probably are related to chronic diarrhea. The diarrhea is caused by structural and functional changes in the small intestine (Papa et al., 1998); the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes frequently are reversible after a period of abstinence. Treatment is based on replacing essential vitamins and electrolytes, slowing transit time with an agent such as loperamide, and abstaining from all alcoholic beverages. Patients with severe magnesium deficiencies (serum Mg²⁺ < 1 mEq/L) or symptomatic patients (a positive Chvostek’s sign or asterixis) should receive 1 g MgSO₄ intravenously or intramuscularly every 4 hours until the serum [Mg²⁺] > 1 mEq/L.

**Pancreas.** Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the U.S. While
pancreatitis has been known to occur after a single episode of heavy alcohol use, prolonged heavy drinking is common in most cases. Acute alcoholic pancreatitis is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Computed tomography is being used increasingly for diagnostic testing. While most attacks are not fatal, hemorrhagic pancreatitis can develop and lead to shock, renal failure, respiratory failure, and death. Management usually involves intravenous fluid replacement—often with nasogastric suction—and opioid pain medication. The etiology of acute pancreatitis probably is related to a direct toxic metabolic effect of alcohol on pancreatic acinar cells.

Two-thirds of patients with recurrent alcoholic pancreatitis will develop chronic pancreatitis. Chronic pancreatitis is treated by replacing the endocrine and exocrine deficiencies that result from pancreatic insufficiency. The development of hyperglycemia often requires insulin for control of blood-sugar levels (Chapter 43). Pancreatic enzyme capsules containing lipase, amylase, and proteases may be necessary to treat malabsorption (Chapter 46).

Liver. Ethanol produces a constellation of dose-related deleterious effects in the liver (Fickert and Zatloukal, 2000). The primary effects are fatty infiltration of the liver, hepatitis, and cirrhosis. Because of its intrinsic toxicity, alcohol can injure the liver in the absence of dietary deficiencies (Lieber, 2000). The accumulation of fat in the liver is an early event and can occur in normal individuals after the ingestion of relatively small amounts of ethanol. This accumulation results from inhibition of both the tricarboxylic acid cycle and the oxidation of fat, in part owing to the generation of excess NADH produced by the actions of ADH and ALDH (Figure 23–1).

Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. Normal liver tissue is replaced by fibrous tissue. Alcohol can affect stellate cells in the liver directly; chronic alcohol use is associated with transformation of stellate cells into collagen-producing, myofibroblast-like cells, resulting in deposition of collagen around terminal hepatic venules (Lieber, 2000). The histological hallmark of alcoholic cirrhosis is the formation of Mallory bodies, which are thought to be related to an altered intermediate cytoskeleton (Denk et al., 2000).

A number of molecular mechanisms for alcoholic cirrhosis have been proposed. In nonhuman primate models, alcohol alters phospholipid peroxidation. Ethanol decreases phosphatidylycholine levels in hepatic mitochondria, a change associated with decreased oxidase activity and O₂ consumption. Cytokines, such as transforming growth factor β and tumor necrosis factor α, can increase rates of fibrinogenesis and fibrosis in the liver. Acetaldehyde is thought to have a number of adverse effects, including depletion of glutathione (Lieber, 2000), depletion of vitamins and trace metals, and decreased transport and secretion of proteins owing to inhibition of tubulin polymerization. Acetaminophen-induced hepatic toxicity (Chapters 4, 6, and 34) has been associated with alcoholic cirrhosis as a result of alcohol-induced increases in microsomal production of toxic acetaminophen metabolites (Whitcomb and Block, 1994). Liver failure secondary to cirrhosis and resulting in impaired clearance of toxins such as ammonia also may contribute to alcohol-induced hepatic encephalopathy. Ethanol also appears to increase intracellular free hydroxy-ethyl radical formation.

Vitamins and Minerals
The almost complete lack of protein, vitamins, and most other nutrients in alcoholic beverages predisposes those who consume large quantities of alcohol to nutritional deficiencies. Alcoholics often present with these deficiencies owing to decreased intake, decreased absorption, or impaired utilization of nutrients. The peripheral neuropathy, Korsakoff’s psychosis, and Wernicke’s encephalopathy seen in alcoholics probably are caused by deficiencies of the B complex of vitamins (particularly thiamine), although direct toxicity produced by alcohol itself has not been ruled out (Harper, 1998). Chronic alcohol abuse decreases the dietary intake of retinoids and carotenoids and enhances the metabolism of retinol by the induction of degradative enzymes (Lieber, 2000). Retinol and ethanol compete for metabolism by ADH; vitamin A supplementation therefore should be monitored carefully in alcoholics when they are consuming alcohol to avoid retinol-induced hepatotoxicity. The chronic consumption of alcohol inflicts an oxidative stress on the liver owing to the generation of free radicals, contributing to ethanol-induced liver injury. The antioxidant effects of α-tocopherol (vitamin E) may ameliorate some of this ethanol-induced toxicity in the liver. Plasma levels of α-tocopherol often are reduced in myopathic alcoholics compared with alcoholic patients without myopathy.

Chronic alcohol consumption has been implicated in osteoporosis (Chapter 44). The reasons for this decreased bone mass remain unclear, although impaired osteoblastic activity has been implicated. Acute administration of ethanol produces an initial reduction in serum parathyroid hormone (PTH) and Ca²⁺ levels, followed by a rebound increase in PTH that does not restore Ca²⁺ levels to normal. Alcohol-induced osteopenia improves with abstinence (Alvisa-Negrin J, et al., 2009). Since vitamin D requires hydroxylation in the liver for activation, alcohol-induced liver damage can indirectly affect the role of vitamin D in the intestinal and renal absorption of Ca²⁺.

Sexual Function
Despite the widespread belief that alcohol can enhance sexual activities, the opposite effect is generally noted. Many drugs of abuse, including alcohol, have disinhibiting effects that may lead initially to increased libido.

Both acute and chronic alcohol use can lead to impotence in men. Increased blood alcohol concentrations lead to decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. The incidence of impotence may be as high as 50% in...
patients with chronic alcoholism. Additionally, many chronic alcohols develop testicular atrophy and decreased fertility. The mechanism involved in this is complex and likely involves altered hypothalamic function and a direct toxic effect of alcohol on Leydig cells. Gynecomastia is associated with alcoholic liver disease and is related to increased cellular response to estrogen and to accelerated metabolism of testosterone.

Sexual function in alcohol-dependent women is less clearly understood. Many female alcoholics complain of decreased libido, decreased vaginal lubrication, and menstrual cycle abnormalities. Their ovaries often are small and without follicular development. Some data suggest that fertility rates are lower for alcoholic women. The presence of comorbid disorders such as anorexia nervosa or bulimia can aggravate the problem. The prognosis for patients who abstain is favorable in the absence of significant hepatic or gonadal failure (O’Farrell et al., 1997).

**Hematological and Immunological Effects**

Chronic alcohol use is associated with a number of anemias. Microcytic anemia can occur because of chronic blood loss and iron deficiency. Macrocytic anemias and increases in mean corpuscular volume are common and may occur in the absence of vitamin deficiencies. Normochromic anemias also can occur owing to effects of chronic illness on hematopoiesis. In the presence of severe liver disease, morphological changes can include the development of burr cells, schistocytes, and ringed sideroblasts. Alcohol-induced sideroblastic anemia may respond to vitamin B<sub>6</sub> replacement (Wartenberg, 1998).

Alcohol use also is associated with reversible thrombocytopenia, although platelet counts under 20,000/mm<sup>3</sup> are rare. Bleeding is uncommon unless there is an alteration in vitamin K<sub>1</sub>-dependent clotting factors (Chapter 30); proposed mechanisms have focused on platelet trapping in the spleen and marrow.

Alcohol also affects granulocytes and lymphocytes (Schirmer et al., 2000). Effects include leukopenia, alteration of lymphocyte subsets, decreased T-cell mitogenesis, and changes in immunoglobulin production. These disorders may play a role in alcohol-related liver disease. In some patients, depressed leukocyte migration into inflamed areas may account in part for the poor resistance of alcoholics to some types of infection (e.g., Klebsiella pneumonia, listeriosis, and tuberculosis). Alcohol consumption also may alter the distribution and function of lymphoid cells by disrupting cytokine regulation, in particular that involving interleukin 2 (IL-2). Alcohol appears to play a role in the development of infection with the human immunodeficiency virus-1 (HIV). In vitro studies with human lymphocytes suggest that alcohol can suppress CD4 T-lymphocyte function and concanavalin A–stimulated IL-2 production and enhance in vitro replication of HIV. Moreover, persons who abuse alcohol have higher rates of high-risk sexual behavior.

**ACUTE ETHANOL INTOXICATION**

Signs of intoxication typical of CNS depression are seen in most people following 2-3 drinks, with the most prominent effect seen at the times of peak BEL, ~30-60 minutes following consumption on an empty stomach. These symptoms include an initial feeling of stimulation (perhaps due to inhibition of CNS inhibitory systems), giddiness, muscle relaxation, and impaired judgment. Higher blood levels (~80 mg/dL or ~17 mM) are associated with slurred speech, incoordination, unsteady gait, and potential impairments of attention; levels between 80 and 200 mg/dL (~17-43 mM) are associated with more intense mood lability, and greater cognitive deficits, potentially accompanied by aggressiveness, and anterograde amnesia (an alcoholic blackout) (Schuckit, 2009c).

Blood ethanol levels >200 mg/dL can produce nystagmus and unwanted falling asleep; levels of 300 mg/dL (~65 mM) and higher can produce failing vital signs, coma, and death. All of these symptoms are likely to be exacerbated and occur at a lower BEC when ethanol is taken along with other CNS depressants (e.g., diazepam or similar benzodiazepines), or with any drug or medication for which sleepiness and unconsciousness are likely.

An increased reaction time, diminished fine motor control, impulsivity, and impaired judgment become evident when the concentration of ethanol in the blood is 20-30 mg/dL. More than 50% of persons are grossly intoxicated by a concentration of 150 mg/dL. In fatal cases, the average concentration is about 400 mg/dL, although alcohol-tolerant individuals often can withstand comparable alcohol levels. The definition of intoxication varies by state and country. In the U.S., most states set the ethanol level defined as intoxication at 80 mg/dL. There is increasing evidence that lowering the limit to 50-80 mg/dL can reduce motor vehicle injuries and fatalities significantly. While alcohol can be measured in saliva, urine, sweat, and blood, measurement of levels in exhaled air remains the primary method of assessing the level of intoxication.

Many factors, such as body weight and composition and the rate of absorption from the GI tract, determine the concentration of ethanol in the blood after ingestion of a given amount of ethanol. On average, the ingestion of 3 standard drinks (42 g ethanol) on an empty stomach results in a maximum blood concentration of 67-92 mg/dL in men. After a mixed meal, the maximal blood concentration from three drinks is 30-53 mg/dL in men. Concentrations of alcohol in blood will be higher in women than in men consuming the same amount of alcohol because, on average, women are smaller than men, have less body water per unit of weight into which ethanol can distribute, and have less gastric ADH activity than men. For individuals with normal hepatic function, ethanol is metabolized at a rate of one standard drink every 60-90 minutes.

The characteristic signs and symptoms of alcohol intoxication are well known. Nevertheless, an erroneous diagnosis of drunkenness...
may occur with patients who appear inebriated but who have not ingested ethanol. Diabetic coma, e.g., may be mistaken for severe alcoholic intoxication. Drug intoxication, cardiovascular accidents, and skull fractures also may be confused with alcohol intoxication. The odor of the breath of a person who has consumed ethanol is due not to ethanol vapor but to impurities in alcoholic beverages. Breath odor in a case of suspected intoxication can be misleading because there can be other causes of breath odor similar to that after alcohol consumption. Blood alcohol levels are necessary to confirm the presence or absence of alcohol intoxication (Schuckit, 2006b).

The treatment of acute alcohol intoxication is based on the severity of respiratory and CNS depression. Acute alcohol intoxication can be a medical emergency, and a number of young people die every year from this disorder. Patients who are comatose and who exhibit evidence of respiratory depression should be intubated to protect the airway and to provide ventilatory assistance (see Chapter 4). The stomach may be lavaged, but care must be taken to prevent pulmonary aspiration of the return flow. Since ethanol is freely miscible with water, ethanol can be removed from blood by hemodialysis (Schuckit, 2006b).

Acute alcohol intoxication is not always associated with coma, and careful observation is the primary treatment. Usual care involves observing the patient in the emergency room for 4–6 hours while the patient metabolizes the ingested ethanol. Blood alcohol levels will be reduced by ~15 mg/dL per hour. During this period, some individuals may display extremely violent behavior. Sedatives and antipsychotic agents have been employed to quiet such patients. Great care must be taken, however, when using sedatives to treat patients who have ingested an excessive amount of another CNS depressant, such as ethanol, because of synergistic effects.

**CLINICAL USES OF ETHANOL**

Dehydrated alcohol may be injected in close proximity to nerves or sympathetic ganglia to relieve the long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol also have been employed for inoperable pain. For example, lumbar paravertebral injections of ethanol may destroy sympathetic ganglia and thereby produce vasodilation, relieve pain, and promote healing of lesions in patients with vascular disease of the lower extremities.

Systemically administered ethanol is confined to the treatment of poisoning by methyl alcohol and ethylene glycol. The ingestion results in formation of methanol’s metabolites, formaldehyde and formic acid (Figure 23–1). Formic acid causes nerve damage; its effects on the retina and optic nerve can cause blindness. Treatment consists of sodium bicarbonate to combat acidosis, hemodialysis, and the administration of ethanol, which slows formate production by competing with methanol for metabolism by alcohol dehydrogenase.

The use of alcohol to treat patients in alcohol withdrawal or obstetrical patients with premature contractions is no longer recommended (Chapter 24).

**TOLERANCE, DEPENDENCE, AND CHRONIC ETHANOL USE**

*Tolerance* is defined as a reduced behavioral or physiological response to the same dose of ethanol (Chapter 24). There is a marked acute tolerance that is detectable soon after administration of ethanol. Acute tolerance can be demonstrated by measuring behavioral impairment at the same BELs on the ascending limb of the absorption phase of the BEL–time curve (minutes after ingestion of alcohol) and on the descending limb of the curve as BELs are lowered by metabolism (one or more hours after ingestion). Behavioral impairment and subjective feelings of intoxication are much greater at a given BEL on the ascending than on the descending limb. There also is a chronic tolerance that develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance often has a metabolic component owing to induction of alcohol-metabolizing enzymes.

*Physical dependence* is demonstrated by the elicitation of a withdrawal syndrome when alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of alcohol consumption and include sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and in severe cases, seizures. In addition, two or more days after withdrawal, some individuals experience *delirium tremens*, characterized by hallucinations, delirium, fever, and tachycardia. Delirium tremens can be fatal. Another aspect of dependence is craving and drug-seeking behavior, often termed *psychological dependence*.

Ethanol tolerance and physical dependence are studied readily in animal models. Strains of mice with genetic differences in tolerance and dependence have been characterized, and a search for the relevant genes and ethanol-sensitive miRNAs is under way (Miranda et al., 2010). Neurobiological mechanisms of tolerance and dependence are not understood completely, but chronic alcohol consumption results in changes in synaptic and intracellular signaling likely owing to changes in gene expression. Most of the systems that are acutely affected by ethanol also are affected by chronic exposure, resulting in an adaptive or maladaptive response that can cause tolerance and dependence (see Table 23–1). In particular, chronic actions of ethanol likely require changes in signaling by glutamate and GABA receptors and downstream signaling pathways. The increase in NMDA-receptor function after chronic alcohol ingestion could contribute to the CNS hyperexcitability and neurotoxicity seen during ethanol withdrawal.

Arginine vasopressin, acting on V₄ receptors, maintains tolerance to ethanol in laboratory animals even after chronic ethanol administration has ceased (Hoffman et al., 1990).

The neurobiological basis of the switch from controlled, volitional alcohol use to compulsive and uncontrolled addiction remains obscure. Impairment of the dopaminergic reward system and the resulting increase in alcohol consumption in an attempt to regain activation of the system is a possibility. In addition, the prefrontal cortex is particularly sensitive to damage from alcohol abuse and influences decision making and emotion, processes clearly compromised in the alcoholic (Pfeifferbaum et al., 1998). Thus, impairment of executive function in cortical regions by chronic alcohol consumption...
may be responsible for some of the lack of judgment and control that is expressed as obsessive alcohol consumption. The loss of brain volume and impairment of function seen in the chronic alcoholic is at least partially reversible by abstinence but will worsen with continued drinking. Early diagnosis and treatment of alcoholism are important in limiting the brain damage that promotes the progression to severe addiction.

**Etiology of Alcohol Use Disorders and the Role of Genes**

A wide range of social, cultural, interpersonal, and biological factors combine to contribute to the risk for heavier drinking and alcohol use disorders (Schuckit, 2009b). The initial decision to consume alcohol is predominantly a response to the environment and culture in which one lives. Environmental and cultural factors that contribute to alcohol use include stress, expectations regarding the effects alcohol is likely to produce, drinking patterns within one’s culture and peer group, availability of alcohol, and attitudes toward drunkenness. These nonbiological forces contribute to perhaps 70-80% of the initial decision to drink and at least 40% of the transition from drinking to alcohol-related problems and alcohol use disorders. Correspondingly, ~60% of the susceptibility to alcohol use disorders results from heritable factors (Table 23–2).

The search for the genes and alleles responsible for alcoholism is complicated by the polygenic nature of the disease and the general difficulty in defining multiple genes responsible for complex diseases. As noted earlier in the chapter, polymorphisms in the enzymes of ethanol metabolism seem to explain why some populations (mainly Asian) are protected from alcoholism. This has been attributed to genetic differences in alcohol- and aldehyde-metabolizing enzymes. Specifically, genetic variants of ADH that exhibit high activity and variants of ALDH that exhibit low activity protect against heavy drinking, probably because alcohol consumption by individuals who have these variants results in accumulation of acetaldehyde, which produces a variety of unpleasant effects (Li, 2000).

In contrast to these protective genetic variants, there are few consistent data about genes responsible for increased risk for alcoholism. A genetic mechanism associated with an enhanced risk for both alcohol and other drug use disorders operates through the intermediate characteristic (or phenotype) of impulsivity and disinhibition (King et al., 2004). The identified polymorphisms include two variations of the GABA_\text{A} receptors (Dick et al., 2006a,b), a variation in ADH4 hypothesized to be related to personality characteristics (Edenberg et al., 2006), and a muscarinic cholinergic receptor gene, CHRM2 (Jones et al., 2006).

Another phenotype related to an enhanced risk for alcohol use disorders (but not other drug use disorders) is associated with a low level of response (perhaps reflecting low sensitivity) to ethanol (Schuckit, 2009b). The need for higher amounts of ethanol to achieve the desired effects may contribute to the decision to drink more per occasion, which in turn leads to altered expectations of the effects of beverage alcohol, an enhanced probability of selecting heavier-drinking peers, as well as problematic approaches to dealing with stress (Schuckit et al., 2008). To date, genetic contributions to the level of response have been tentatively identified for two GABA_\text{A} subunits (Dick et al., 2006a,b), a polymorphism in the promoter region of the 5-HT transporter that is associated with lower levels of 5-HT in the synaptic space (Barr et al., 2005), a polymorphism of the K^+ channel-related KCNMA1 (Schuckit et al., 2005), and a variant nicotinic Ach receptor that is also related to an increased risk for heavy smoking and related consequences (Joslyn et al., 2008). Antisocial alcoholism has been linked with polymorphisms of several 5-HT receptors (Ducci et al., 2009). Polymorphisms in dopaminergic and opioid systems and in genes that correlate with a predisposition to bipolar disorder, schizophrenia, and several anxiety disorders may also contribute to a general vulnerability to a range of substance abuse disorders.

**TERATOGENIC EFFECTS: FETAL ALCOHOL SYNDROME**

Children born to alcoholic mothers display a common pattern of distinct dysmorphology known as fetal alcohol syndrome (FAS) (Jones and Smith, 1973; Lemoine et al., 1968). The diagnosis of FAS typically is based on the observance of a triad of abnormalities in the newborn, including:

- a cluster of craniofacial abnormalities
- CNS dysfunction
- pre- and/or postnatal stunting of growth

Hearing, language, and speech disorders also may become evident as the child ages (Church and Kaltenbach, 1997). Children who do not meet all the criteria for a diagnosis of FAS still may show physical and mental deficits consistent with a partial phenotype,
termed fetal alcohol effects (FAEs) or alcohol-related neurodevelopmental disorders. FAS is seen in offspring born to ~5% of heavy-drinking females. The incidence of FAS is believed to be in the range of 0.5–1 per 1000 live births in the general U.S. population, with rates as high as 2–3 per 1000 in African-American and Native-American populations. A lower socioeconomic status of the mother rather than racial background per se appears to be primarily responsible for the higher incidence of FAS observed in those groups (Abel, 1995). The incidence of FAEs is likely higher than that of FAS, making alcohol consumption during pregnancy a major public health problem.

Craniofacial abnormalities commonly observed in the diagnosis of FAS consist of a pattern of microcephaly, a long and smooth philtrum, shortened palpebral fissures, a flat midface, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum (Mattson et al., 1992). The severity of alcohol effects can vary greatly and depends on the drinking patterns and amount of alcohol consumed by the mother. Maternal drinking in the first trimester has been associated with craniofacial abnormalities; facial dysmorphology also is seen in mice exposed to ethanol at the equivalent time in gestation.

CNS dysfunction following in utero exposure to alcohol manifests in the form of hyperactivity, attention deficits, mental retardation, and learning disabilities. FAS is the most common cause of preventable mental retardation in the Western world (Abel and Sokol, 1987), with afflicted children consistently scoring lower than their peers on a variety of IQ tests. It now is clear that FAS represents the severe end of a spectrum of alcohol effects. A number of studies have documented intellectual deficits, including mental retardation, in children not displaying the craniofacial deformities or retarded growth seen in FAS. Although cognitive improvements are seen with time, decreased IQ scores of FAS children tend to persist as they mature, indicating that the deleterious prenatal effects of alcohol are irreversible. Although a correlation exists between the amount of alcohol consumed by the mother and infant scores on mental and motor performance tests, there is considerable variation in performance on such tests among children of mothers consuming similar quantities of alcohol. The peak BEL reached may be a critical factor in determining the severity of deficits seen in the offspring. Although the evidence is not conclusive, there is a suggestion that even moderate alcohol consumption (two drinks per day) in the second trimester of pregnancy is correlated with impaired academic performance of offspring at age 6 (Goldschmidt et al., 1996). Maternal age also may be a factor. Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol (Jacobson et al., 1996).

Children exposed prenatally to alcohol most frequently present with attentional deficits and hyperactivity, even in the absence of intellectual deficits or craniofacial abnormalities. Furthermore, attentional problems have been observed in the absence of hyperactivity, suggesting that the two phenomena are not necessarily related. Fetal alcohol exposure also has been identified as a risk factor for alcohol abuse by adolescents (Baer et al., 1998). Apart from the risk of FAS or FAEs to the child, the intake of high amounts of alcohol by a pregnant woman, particularly during the first trimester, greatly increases the chances of spontaneous abortion.

Studies with laboratory animals have demonstrated many of the consequences of in utero exposure to ethanol observed in humans, including hyperactivity, motor dysfunction, and learning deficits. In animals, in utero exposure to ethanol alters the expression patterns of a wide variety of proteins, changes neuronal migration patterns, and results in brain region–specific and cell type–specific alterations in neuronal numbers. Indeed, specific periods of vulnerability may exist for particular neuronal populations in the brain. Genetics also may play a role in determining vulnerability to ethanol: There are differences among strains of rats in susceptibility to the prenatal effects of ethanol. Finally, multidrug abuse, such as the concomitant administration of cocaine with ethanol, enhances fetal damage and mortality.

**PHARMACOTHERAPY OF ALCOHOLISM**

The core of care is a process of interventions and sessions that help enhance changes in how the person views their problem, along with efforts to help them alter the problematic behaviors (Schuckit, 2009). With cognitive-behavioral approaches serving as the core of treatment, and a 20% or greater rate of spontaneous remission in alcohol use disorders, the role of medications can be difficult to evaluate. Thus, only those pharmacological approaches that have been shown to be superior to placebo through double-blind control trials are worth considering in clinical practice.

Currently, three drugs are approved in the U.S. for treatment of alcoholism: disulfiram (ANTABUSE), naltrexone (REVIA), and acamprosate (Table 23–3). Disulfiram has a long history of use but has fallen into disfavor because of its side effects and problems with patient adherence to therapy. Naltrexone and acamprosate were introduced more recently. The goal of these medications is to assist the patient in maintaining abstinence.

**Naltrexone**

Naltrexone is chemically related to the highly selective opioid-receptor antagonist naloxone (NARCAN) but has higher oral bioavailability and a longer duration of action. Neither drug has appreciable opioid-receptor agonist effects. These drugs were used initially in the treatment of opioid overdose and dependence because of their ability to antagonize all the actions of opioids (Chapters 18 and 24). There is evidence that naltrexone blocks activation by alcohol of dopaminergic pathways in the brain that are thought to be critical to reward.

Naltrexone helps to maintain abstinence by reducing the urge to drink and increasing control when a “slip” occurs. It is not a
“cure” for alcoholism and does not prevent relapse in all patients. Naltrexone works best when used in conjunction with some form of psychosocial therapy, such as cognitive behavioral therapy (Anton et al., 1999). It typically is administered after detoxification and given at a dose of 50 mg/day for several months. Adherence to the regimen is important to ensure the therapeutic value of naltrexone and has proven to be a problem for some patients. The most common side effect of naltrexone is nausea, which is more common in women than in men and subsides if the patients abstain from alcohol. When given in excessive doses, naltrexone can cause liver damage. It is contraindicated in patients with liver failure or acute hepatitis and should be used only after careful consideration in patients with active liver disease.

Nalmefene (REVEX) is another opioid antagonist that appears promising in preliminary clinical tests (Mason et al., 1999). It has a number of advantages over naltrexone, including greater oral bioavailability, longer duration of action, and lack of dose-dependent liver toxicity.

Acamprosate

Acamprosate (N-acetylhomotaurine; CAMPRAL) is an analogue of GABA.

A number of double-blind, placebo-controlled studies have demonstrated that acamprosate (1.3-2 g/day) decreases drinking frequency and reduces relapse drinking in abstinent alcoholics and appears to have efficacy similar to that of naltrexone. Studies in laboratory animals have shown that acamprosate decreases alcohol intake without affecting food or water consumption. Acamprosate generally is well tolerated by patients, with diarrhea being the main side effect (Garbutt et al., 1999). No abuse liability has been noted. The drug undergoes minimal metabolism in the liver, is excreted primarily by the kidneys, and has an elimination $t_{1/2}$ of 18 hours after oral administration. Concomitant use of disulfiram appears to increase the effectiveness of acamprosate, without any adverse drug interactions being noted (Besson et al., 1998).

Disulfiram

Disulfiram (tetraethylthiuram disulfide; ANTABUSE) was ingested in the course of an investigation of its potential anthelminthic efficacy by two Danish physicians, who became ill at a cocktail party and were quick to realize that the compound had altered their responses to alcohol. They initiated a series of pharmacological and clinical studies that provided the basis for the use of disulfiram as an adjunct in the treatment of chronic alcoholism. Similar responses to alcohol ingestion are produced by various congeners of disulfiram, namely, cyanamide, the fungus Coprinus atramentarius, the hypoglycemic sulfonylureas, metronidazole, and certain cephalosporins.

Disulfiram, given alone, is a relatively nontoxic substance, but it inhibits ALDH activity and causes the blood acetaldehyde concentration to rise to 5-10 times above the level achieved when ethanol is given to an individual not pretreated with disulfiram. Acetaldehyde, produced as a result of the oxidation of ethanol by ADH, ordinarily does not accumulate in the body because it is further oxidized almost as soon as it is formed. Following the administration of disulfiram, both cytosolic and mitochondrial forms of ALDH are irreversibly inactivated to varying degrees, and the concentration of acetaldehyde rises. It is unlikely that disulfiram itself is responsible for the enzyme inactivation in vivo; several active
metabolites of the drug, especially diethylthiomethylcarbamate, behave as suicide-substrate inhibitors of ALDH in vitro. These metabolites reach significant concentrations in plasma following the administration of disulfiram (Johansson, 1992).

The ingestion of alcohol by individuals previously treated with disulfiram gives rise to marked signs and symptoms of acetaldehyde poisoning. Within 5-10 minutes, the face feels hot and soon afterward becomes flushed and scarlet in appearance. As the vasodilatation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, copious vomiting, sweating, thirst, chest pain, considerable hypotension, orthostatic syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is replaced by pallor, and the blood pressure may fall to shock levels.

Alarming reactions may result from the ingestion of even small amounts of alcohol in persons being treated with disulfiram. The use of disulfiram as a therapeutic agent thus is not without danger, and it should be attempted only under careful medical and nursing supervision. Patients must be warned that as long as they are taking disulfiram, the ingestion of alcohol in any form will make them sick and may endanger their lives. Patients must learn to avoid disguised forms of alcohol, as in sauces, fermented vinegar, cough syrups, and even after-shave lotions and back rubs.

The drug never should be administered until the patient has abstained from alcohol for at least 12 hours. In the initial phase of treatment, a maximal daily dose of 500 mg is given for 1-2 weeks. Maintenance dosage then ranges from 125-500 mg daily depending on tolerance to side effects. Unless sedation is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH (Johansson, 1992).

Disulfiram and/or its metabolites can inhibit many enzymes with crucial sulfhydryl groups, and it thus has a wide spectrum of biological effects. It inhibits hepatic CYPs and thereby interferes with the metabolism of phenytoin, chlordiazepoxide, barbiturates, warfarin, and other drugs.

Disulfiram by itself usually is innocuous, but it may cause acenform eruptions, urticaria, lassitude, tremor, restlessness, headache, dizziness, a garlic-like or metallic taste, and mild GI disturbances. Peripheral neuropathies, psychosis, and ketosis also have been reported.

Other Agents

Ondansetron, a 5-HT₃-receptor antagonist and antiemetic drug (Chapters 13 and 46), reduces alcohol consumption in laboratory animals and currently is being tested in humans. Preliminary findings suggest that ondansetron is effective in the treatment of early-onset alcoholics, who respond poorly to psychosocial treatment alone, although the drug does not appear to work well in other types of alcoholics. Ondansetron administration lowers the amount of alcohol consumed, particularly by drinkers who consume fewer than 10 drinks per day (Sellers et al., 1994). It also decreases the subjective effects of ethanol on 6 of 10 scales measured, including the desire to drink (Johnson et al., 1993), while at the same time not having any effect on the pharmacokinetics of ethanol.

Topiramate, a drug used for treating seizure disorders (Chapter 21), appears useful for treating alcohol dependence. Compared with the placebo group, patients taking topiramate achieved more abstinent days and a lower craving for alcohol (Johnson et al., 2003). The mechanism of action of topiramate is not well understood but is distinct from that of other drugs used for the treatment of dependence (e.g., opioid antagonists), suggesting that it may provide a new and unique approach to pharmacotherapy of alcoholism.

The terminology used in discussing drug dependence, abuse, and addiction has long been confusing. Confusion stems from the fact that repeated use of certain prescribed medications can produce neuroplastic changes resulting in two distinctly abnormal states. The first is dependence, sometimes called “physical” dependence, produced when there is progressive pharmacological adaptation to the drug resulting in tolerance. In the tolerant state, repeating the same dose of drug produces a smaller effect. If the drug is abruptly stopped, a withdrawal syndrome ensues in which the adaptive responses are now unopposed by the drug. Thus, withdrawal symptoms are opposite to the original drug effects. The appearance of withdrawal symptoms is the cardinal sign of “physical” dependence. As thus defined, dependence can occur with the use of opioids, β blockers, antidepressants, benzodiazepines, and stimulants, even when these agents are used as prescribed for therapeutic purposes. The state of “physical” dependence is a normal response, easily treatable by tapering the drug dose, and is not in itself a sign of addiction.

The second abnormal state that can be produced by repeated drug use occurs in only a minority of those who initiate drug use. It leads progressively to compulsive, out-of-control drug use. Unfortunately, in 1987 the American Psychiatric Association (APA) chose to use the word “dependence” when defining the state of uncontrolled drug use more commonly known as addiction. The word “addiction” was at that time considered pejorative and thus to be avoided. The result, over the last two decades, is that confusion has developed between dependence as a normal response and dependence as addiction. The newest version of the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) due to be released in 2012 will correct this confusion.

This distinction between dependence and addiction is important because patients with pain sometimes are deprived of adequate opioid medication simply because they have shown evidence of tolerance or they exhibit withdrawal symptoms if the analgesic medication is stopped or reduced abruptly.

Modern neuroscience has greatly increased our understanding of the phenomenology of addiction. Using animal models as well as human brain imaging studies and clinical observations, addiction can be defined fundamentally as a form of maladaptive memory. It begins with the administration of substances (e.g., cocaine) or behaviors (e.g., the thrill of gambling) that directly and intensely activate brain reward circuits. Activation of these circuits motivates normal behavior and most humans simply enjoy the experience without being compelled to repeat it. For some (~16% of those who try cocaine) the experience produces strong conditioned associations to environmental cues that signal the availability of the drug or the behavior. Thus, reflexive activation of reward circuits becomes involuntary and with a very rapid onset. The cues acquire strong salience that overwhelms other behaviors. The individual becomes drawn into compulsive repetition of the experience focusing on the immediate pleasure despite negative long-term consequences and neglect of important social responsibilities. Of course, underlying this behavior are poorly understood changes in neural circuits (Kalivas and O’Brien, 2008).

The framers of DSM-V are strongly motivated to devise a classification well-grounded in neuroscientific evidence. Unfortunately, complex psychiatric disorders still have no proven genetic basis nor are there reliable biomarkers of these disorders. Thus, the plan is to make DSM-V a flexible document that can be further revised as reliable, replicated data are developed.

**Origins of Substance Dependence**

The chronic, relapsing nature of addiction fulfills criteria for a chronic disease (McLellan et al., 2000), but because of the voluntary component at initiation, the disease concept is controversial. Most of those who initiate drug use do not progress to become addicts. Many variables operate simultaneously to influence the likelihood that a beginning drug user will lose control and develop...
an addiction. These variables can be organized into three categories: agent (drug), host (user), and environment (Table 24–1).

**Agent (Drug) Variables.** Drugs vary in their capacity to produce immediate good feelings in the user. Drugs that reliably produce intensely pleasant feelings (euphoria) are more likely to be taken repeatedly. *Reinforcement* refers to the capacity of drugs to produce effects that make the user wish to take them again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused.

Reinforcing properties of a drug can be measured reliably in animals. Generally, animals such as rats or monkeys equipped with intravenous catheters connected to lever-regulated pumps will work to obtain injections of the same drugs in roughly the same order of potency that humans will. Thus, medications can be screened for their potential for abuse in humans by the use of animal models. Other drugs such as ethanol can be self-administered by the oral route by experimental animals. Animals can also model relapse to drug-taking in humans. For example, rats learn to drink alcohol in preference to water. If alcohol availability is removed, the animals go through withdrawal. They will restart (“relapse” to) alcohol drinking if presented with cues previously associated with alcohol availability or if given mild stress (foot shock).

Reinforcing properties of drugs are associated with their capacity to increase neuronal activity in critical brain areas (Chapter 14). Cocaine, amphetamine, ethanol, opiates, cannabinoids, and nicotine all reliably increase extracellular fluid dopamine (DA) levels in the ventral striatum, specifically the nucleus accumbens region. In experimental animals, usually rats, brain microdialysis permits sampling of extracellular fluid while the animals are freely moving or receiving drugs. Smaller increases in DA in the nucleus accumbens also are observed when the rat is presented with sweet foods or a sexual partner. In contrast, drugs that block DA receptors generally produce bad feelings, i.e., dysphoric effects. Neither animals nor humans will take such drugs spontaneously. Despite strong correlative findings, a causal relationship between DA and euphoria/dysphoria has not been established, and other findings emphasize additional roles of serotonin (5-HT), glutamate, norepinephrine (NE), endogenous opioids, and γ-aminobutyric acid (GABA) in mediating the reinforcing effects of drugs.

The abuse liability of a drug is enhanced by rapidity of onset because effects that occur soon after administration are more likely to initiate the chain of events that leads to loss of control over drug-taking. The pharmacokinetic variables that influence the time it takes a drug to reach critical receptor sites in the brain are explained in more detail in Chapter 2. The history of cocaine use illustrates the changes in abuse liability of the same compound, depending on the form and the route of administration.

When coca leaves are chewed, cocaine is absorbed slowly through the buccal mucosa. This method produces low cocaine blood levels and correspondingly low levels in the brain. The mild stimulant effects produced by the chewing of coca leaves have a gradual onset, and this practice has produced few, if any, behavior problems despite use over thousands of years by natives of the Andes mountains. Beginning in the late 19th century, scientists isolated cocaine hydrochloride from coca leaves and refined the technology for extraction of pure cocaine. Cocaine could be taken in higher doses by oral ingestion (GI absorption) or by absorption through the nasal
mucosa, producing higher cocaine levels in the blood and a more rapid onset of stimulation. Subsequently, it was found that a solution of cocaine hydrochloride could be administered intravenously, giving a more rapid onset of stimulatory effects. Each newly available cocaine preparation that provided greater speed of onset and an increment in blood level was paralleled by a greater likelihood of addiction. In the 1980s, the availability of cocaine to the American public was increased further with the invention of crack cocaine. Crack, sold illegally and at a low price ($1-3 per dose), is alkaloidal cocaine (free base), which can be readily vaporized by heating. Simply inhaling the vapors produces blood levels comparable to those resulting from intravenous cocaine owing to the large surface area for absorption into the pulmonary circulation following inhalation. The cocaine-containing blood then enters the left side of the heart and reaches the cerebral circulation without dilution by the systemic circulation. Thus, inhalation of crack cocaine is much more addictive than chewing, drinking, or sniffing cocaine. Inhalation, with rapid attainment of effective drug levels in the brain, also is the preferred route for users of nicotine and cannabis.

Although the drug variables are important, they do not fully explain the development of addiction. Most people who experiment with drugs of high addictive potential (addiction liability) do not intensify their drug use and lose control. The risk for developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 24–2). This does not imply that the pharmacological addiction liability of nicotine is twice that of cocaine. Rather, there are other variables listed in the categories of host factors and environmental conditions that influence the development of addiction.

**Host (User) Variables.** In general, effects of drugs vary among individuals. Even blood levels can show wide variation when the same dose of a drug on a milligram-per-kilogram basis is given to different people. Polymorphism of genes that encode enzymes involved in absorption, metabolism, and excretion and in receptor-mediated responses may contribute to the different degrees of reinforcement or euphoria observed among individuals (Chapters 6 and 7).

Children of alcoholics show an increased likelihood of developing alcoholism, even when adopted at birth and raised by nonalcoholic parents. The studies of genetic influences in this disorder show only an increased risk for developing alcoholism, not a 100% determinism, consistent with a polygenic disorder that has multiple determinants. Even identical twins, who share the same genetic endowment, do not have 100% concordance when one twin is alcoholic. However, the concordance rate for identical twins is much higher than that for fraternal twins. The abuse of alcohol and other drugs tends to have some familial characteristics, suggesting that common mechanisms may be involved.

*The ever-used and addiction percentages are those of the general population. The risk of addiction is specific to the drug indicated and refers to the percentage who met criteria for addiction among those who reported having used the agent at least once (i.e., each value in column 4 was obtained by expressing the number in column 3 as a percentage of the number in column 2, subject to errors of rounding). Source: Anthony et al., 1994.*

**Dependence among Users 1990–1992**

*Innate tolerance to alcohol as measured by level of response to alcohol administered under experimental conditions may represent a biological trait that contributes to the development of alcoholism (Chapter 23). While innate tolerance increases vulnerability to alcoholism, impaired metabolism may protect against it. See Chapter 23 for a discussion of the genetic variation common in Asian populations that results in facial flushing and reduced alcohol intake or no alcohol intake in those homozygous for the gene variant. Similarly, individuals who inherit a gene associated with slow nicotine metabolism may experience unpleasant effects when beginning to smoke and reportedly have a lower probability of becoming nicotine dependent.

Psychiatric disorders constitute another category of host variables. Drugs may produce immediate, subjective effects that relieve preexisting symptoms. People with anxiety, depression, insomnia, or even subtle symptoms such as shyness may find, on experimentation or by accident, that certain drugs give them relief. However, the apparent beneficial effects are transient, and repeated use of the drug may lead to tolerance and eventually compulsive, uncontrolled drug use. While psychiatric symptoms are seen commonly in drug abusers presenting for treatment, most of these symptoms begin after the person starts abusing drugs. Thus, drugs of abuse appear to produce more psychiatric symptoms than they relieve.

**Environmental Variables.** Initiating and continuing illegal drug use appear to be influenced significantly by societal norms and peer pressure. Taking drugs may be seen initially as a form of rebellion against authority. In some communities, drug users and drug dealers are role models who seem to be successful and respected; thus, young people emulate them. There also may be a
paucity of other options for pleasure, diversion, or income. These factors are particularly important in communities where educational levels are low and job opportunities scarce.

**Pharmacological Phenomena**

**Tolerance.** While abuse and addiction are complex conditions combining the many variables outlined earlier, there are a number of relevant pharmacological phenomena that occur independent of social and psychological dimensions. First are the changes in the way the body responds to a drug with repeated use. **Tolerance,** the most common response to repetitive use of the same drug, can be defined as the reduction in response to the drug after repeated administrations. Figure 24–1 shows an idealized dose-response curve for an administered drug. As the dose of the drug increases, the observed effect of the drug increases. With repeated use of the drug, however, the curve shifts to the right (tolerance). Thus, a higher dose is required to produce the same effect that was once obtained at a lower dose. Diazepam, e.g., typically produces sedation at doses of 5-10 mg in a first-time user, but those who repeatedly use it to produce a kind of “high” may become tolerant to doses of several hundreds of milligrams; some abusers have had documented tolerance to >1000 mg/day. As outlined in Table 24–3, there are many forms of tolerance likely arising through multiple mechanisms.

Tolerance to some drug effects develops much more rapidly than to other effects of the same drug. For example, tolerance develops rapidly to the euphoria produced by opioids such as heroin, and addicts tend to increase their dose in order to re-experience that elusive “high.” In contrast, tolerance to the gastrointestinal effects of opioids develops more slowly. The discrepancy between tolerance to euphoric effects (rapid) and tolerance to effects on vital functions (slow), such as respiration and blood pressure, can lead to potentially fatal overdoses in sedative abusers trying to re-experience the euphoria they recall from earlier use.

**Innate tolerance** refers to genetically determined lack of sensitivity to a drug that is observed the first time that the drug is administered. Innate tolerance was discussed earlier as a host variable that influences the development of addiction. See Chapter 23 for discussion of the inheritance of level of response to ethanol.

**Acquired tolerance** can be divided into three major types: pharmacokinetic, pharmacodynamic, and learned tolerance, and includes acute, reverse, and cross-tolerance (Table 24–3).

**Pharmacokinetic or dispositional tolerance** refers to changes in the distribution or metabolism of a drug after repeated administrations such that a given dose produces a lower blood concentration than the same dose did on initial exposure. The most common mechanism is an increase in the rate of metabolism of the drug. For example, barbiturates stimulate the production of higher levels of hepatic CYPs, causing more rapid removal and breakdown of barbiturates from the circulation. Since the same enzymes metabolize many other drugs, they too are metabolized more quickly. This results in a decrease in their plasma levels as well and a reduction in their therapeutic effects.

**Pharmacodynamic tolerance** refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is reduced. Examples include drug-induced changes in receptor density or efficiency of receptor coupling to signal-transduction pathways (Chapters 3 and 14).

**Learned tolerance** refers to a reduction in the effects of a drug owing to compensatory mechanisms that are acquired by past experiences. One type of learned tolerance is called **behavioral tolerance.** This simply describes the skills that can be developed through repeated experiences with attempting to function despite a state of mild to moderate intoxication. A common example is learning to walk a straight line despite the motor impairment produced by alcohol intoxication. This probably involves both acquisition of motor skills and the learned awareness of one’s deficit, causing the person to walk more carefully. At higher levels of intoxication, behavioral tolerance is overcome, and the deficits are obvious.

**Figure 24–1. Shifts in a dose-response curve with tolerance and sensitization.** With tolerance, there is a shift of the curve to the right such that doses higher than initial doses are required to achieve the same effects. With sensitization, there is a leftward shift of the curve such that for a given dose, there is a greater effect than seen after the initial dose.
Conditioned tolerance (situation-specific tolerance) develops when environmental cues such as sights, smells, or situations consistently are paired with the administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, and so on, there is usually a reflexive counteraction or adaptation in the direction of maintaining the status quo. If a drug always is taken in the presence of specific environmental cues (e.g., smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur even before the drug reaches its sites of action. If the drug always is preceded by the same cues, the adaptive response to the drug will be learned, and this will prevent the full manifestation of the drug’s effects (tolerance). This mechanism of conditioned tolerance production follows classical (pavlovian) principles of learning and results in drug tolerance under circumstances where the drug is “expected.” When the drug is received under novel or “unexpected” circumstances, conditioned tolerance does not occur, and drug effects are enhanced.

The term acute tolerance refers to rapid tolerance developing with repeated use on a single occasion, such as in a “binge.” For example, cocaine often is used in a binge, with repeated doses over one to several hours, sometimes longer, producing a decrease in response to subsequent doses of cocaine during the binge. This is the opposite of sensitization, observed with an intermittent dosing schedule, described in the next section.

Sensitization. With stimulants such as cocaine or amphetamine, reverse tolerance, or sensitization, can occur. This refers to an increase in response with repetition of the same dose of the drug. Sensitization results in a shift to the left of the dose-response curve (Figure 24–1). For example, with repeated daily administration to rats of a dose of cocaine that produces increased motor activity, the effect increases over several days, even though the dose remains constant. A conditioned response also can be a part of sensitization to cocaine. Simply putting a rat into a cage where cocaine is expected or giving a placebo injection after several days of receiving cocaine under the same circumstances produces an increase in motor activity as though cocaine actually were given, i.e., a conditioned response. Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually ~1 day.

Sensitization has been studied in rats equipped with microdialysis cannulas for monitoring extracellular DA (Kalivas and Duffy, 1990) (Figure 24–2). The initial response to 10 mg/kg of cocaine administered intraperitoneally is an increase in measured DA levels. After seven daily injections, the DA increase is significantly greater than on the first day, and the behavioral response also is greater. Figure 24–2 also provides an example of a conditioned response (learned drug effect): injection of saline produced both an increase in DA levels and an increase in behavioral activity when administered 3 days after cocaine injections had stopped. Little research on sensitization has been conducted in human subjects, but the results suggest that the phenomenon can occur. It has been postulated that stimulant psychosis results from a sensitized response after long intermittent periods of use.

Cross-tolerance occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same structural and mechanistic category. Understanding cross-tolerance is important in the medical management of persons dependent on any drug. Detoxification is a form of treatment for drug dependence that involves giving gradually decreasing doses of the drug to prevent withdrawal symptoms, thereby weaning the patient from the drug of dependence (see “Detoxification” later in the chapter). Detoxification can be accomplished with any medication in the same category as the initial drug of dependence. For example, users of heroin also are tolerant to other opioids. Thus, the detoxification of heroin-dependent patients can be accomplished with any medication that activates opioid receptors.

Physical Dependence

Physical dependence is a state that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. Drugs can affect numerous systems that previously were in equilibrium; these systems find a new balance in the presence of inhibition or stimulation by a specific drug. A person in this adapted or physically dependent state requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is another imbalance, and the affected systems again must go through a process of readjusting to a new equilibrium without the drug.

Withdrawal Syndrome. The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence.
Withdrawal signs and symptoms occur when drug administration in a physically dependent person is terminated abruptly. Withdrawal symptoms have at least two origins:

- Removal of the drug of dependence
- CNS hyper-arousal owing to readaptation to the absence of the drug of dependence

Pharmacokinetic variables are of considerable importance in the amplitude and duration of the withdrawal syndrome. Withdrawal symptoms are characteristic for a given category of drugs and tend to be opposite to the original effects produced by the drug before tolerance developed. Thus, abrupt termination of a drug (such as an opioid agonist) that produces miotic (constricted) pupils and slow heart rate will produce a withdrawal syndrome including dilated pupils and tachycardia. Tolerance, physical dependence, and withdrawal are all biological phenomena. They are the natural consequences of drug use and can be produced in experimental animals and in any human being who takes certain medications repeatedly. These symptoms in themselves do not imply that the individual is involved in misuse or addictive behavior. This form of dependence should not be confused with addiction (compulsive drug-taking). Patients who take medicine for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than gradually. For example, a hypertensive patient receiving a β adrenergic receptor blocker such as metoprolol may have a good therapeutic response, but if the drug is stopped abruptly, the patient may experience a withdrawal syndrome consisting of rebound increased blood pressure temporarily higher than that prior to beginning the medication. This response is thought to be due to adaptive synthesis of β receptors that, in sudden absence of antagonist, facilitate an excessive β adrenergic response in cardiac cells.

Medical addict is a term used to describe a patient in treatment for a medical disorder who has become “addicted” to the available prescribed drugs; the patient begins taking them in excessive doses, out of control. An example would be a patient with chronic pain, anxiety, or insomnia who begins using the prescribed medication more often than directed by the physician. If the physician restricts the prescriptions, the patient may begin seeing several doctors without the knowledge of the primary physician. Such patients also may visit emergency rooms for the purpose of obtaining additional medication. This scenario is very uncommon, considering the large number of patients who receive medications capable of producing tolerance and physical dependence. Fear of producing such medical addicts results in needless suffering among patients with pain, because physicians needlessly limit appropriate medications. Tolerance and physical dependence are inevitable consequences of chronic treatment with opioids and certain other drugs, but tolerance and physical dependence by themselves do not imply “addiction.”

**CLINICAL ISSUES**

The treatment of physical dependence will be discussed with reference to the specific drug of abuse and dependence problems characteristic to each category: CNS depressants, including alcohol and other sedatives; nicotine and tobacco; opioids; psychostimulants, such as amphetamine and cocaine; cannabinoids; psychedelic drugs; and inhalants (volatile solvents, nitrous oxide, and ethyl ether). Abuse of combinations of drugs across these categories is common. Alcohol is so widely available that it is combined with practically all other categories. Some combinations reportedly are taken because of their interactive effects. An example is the combination of heroin and cocaine (“speedball”), which will be described with the opioid category. Alcohol and cocaine is another very common combination. When confronted with a patient exhibiting signs of overdose or withdrawal, the physician must be aware of these possible combinations because each drug may require specific treatment.

**CNS Depressants**

**Ethanol.** Experimentation with ethanol is almost universal, and a high proportion of users find the experience pleasant. More than 90% of American adults report experience with ethanol (commonly called “alcohol”), and ~70% report some level of current use. The lifetime prevalence of alcohol use disorders (alcoholism) in men is almost 20% and in women is 10-15% (Hasin et al., 2007). This drug is discussed more fully in Chapter 23. Ethanol is classified as a depressant because it indeed produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, often are perceived as stimulation owing to a suppression of inhibitory systems. Those who perceive only sedation from alcohol generally choose not to drink when evaluated in a test procedure (de Wit et al., 1989).

Alcohol impairs recent memory and, in high doses, produces the phenomenon of “blackouts”: the drinker has no memory of his or her behavior while intoxicated. The effects of alcohol on memory are unclear, but evidence suggests that reports from patients about their reasons for drinking and their behavior during a binge are not reliable. Alcohol-dependent persons often say that they drink to relieve anxiety or depression. When allowed to drink under observation, however, alcoholics typically become more dysphoric as drinking continues.
The margin of safety (therapeutic index) is decreased. A dose does not increase proportionately to the sedating dose, and thus alcoholics who do not appear grossly sedated. In these cases, the lethal level increases, the sedating effects increase, with eventual coma and death occurring at high alcohol levels. The initial sensitivity (innate tolerance) to alcohol varies greatly among individuals and is related to family history of alcoholism (Wilhelmsen et al., 2003). Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300-400 mg/dL) can be found in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose, and thus the margin of safety (therapeutic index) is decreased.

Heavy consumers of alcohol not only acquire tolerance but also inevitably develop a state of physical dependence. This often leads to drinking in the morning to restore blood alcohol levels diminished during the night. Eventually, they may awaken during the night and take a drink to avoid the restless produced by falling alcohol levels. The alcohol-withdrawal syndrome (Table 24–4) generally depends on the size of the average daily dose and usually is “treated” by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life-threatening until they occur in conjunction with other problems, such as infection, trauma, malnutrition, or electrolyte imbalance. In the setting of such complications, the syndrome of delirium tremens becomes likely.

Alcohol addiction produces cross-tolerance to other sedatives such as benzodiazepines. This tolerance is operative in abstinent alcoholics, but while the alcoholic is drinking, the sedating effects of alcohol add to those of other sedatives, making the combination more dangerous. This is particularly true for benzodiazepines, which are relatively safe in overdose when given alone but potentially are lethal in combination with alcohol.

The chronic use of alcohol and other sedatives is associated with the development of depression (McLelllan et al., 1979), and the risk of suicide among alcoholics is one of the highest of any diagnostic category. Cognitive deficits have been reported in alcoholics tested while sober. These deficits usually improve after weeks to months of abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics (e.g., thiamine deficiency).

Alcohol is toxic to many organ systems. As a result, the medical complications of alcohol abuse and dependence include liver disease, cardiovascular disease, endocrine and GI effects, and malnutrition, in addition to the CNS dysfunctions outlined earlier. Ethanol readily crosses the placental barrier, producing the fetal alcohol syndrome, a major cause of mental retardation (Chapter 23).

**Pharmacological Interventions.**

**Detoxification.** A patient who presents in a medical setting with an alcohol-withdrawal syndrome should be considered to have a potentially lethal condition. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 24–4, a short-acting benzodiazepine such as oxazepam can be used at a dose of 15-30 mg every 6-8 hours according to the stage and severity of withdrawal; some authorities recommend a long-acting benzodiazepine. More severe recent memory impairment is tested while sober. These deficits usually improve after weeks to months of abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics (e.g., thiamine deficiency).

**Pharmacotherapy.** Detoxification is only the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is accomplished mainly by behavioral approaches. Medications that aid in the prevention of relapse are under development. Disulfiram (ANTABUSE; Chapter 23) has been useful in some programs that focus behavioral efforts on ingestion of the medication. Disulfiram blocks aldehyde dehydrogenase, the second step in ethanol metabolism, resulting in the accumulation of acetaldehyde, which produces an unpleasant flushing reaction when alcohol is ingested. Knowledge of this unpleasant reaction helps the patient to resist taking a drink. Although quite effective pharmacologically, disulfiram has not been found to be effective in controlled clinical trials because so many patients failed to ingest the medication.

Naltrexone ( REVIA; Chapter 23), an opioid receptor antagonist that blocks the reinforcing properties of alcohol, is FDA-approved as an adjunct in the treatment of alcoholism. Chronic administration of naltrexone resulted in a decreased rate of relapse to alcohol drinking in the majority of published double-blind clinical trials (Pettinati et al., 2006). It works best in combination with behavioral treatment programs that encourage adherence to medication and abstinence from alcohol. A depot preparation with a duration of 30 days (VIVITROL) was approved by the FDA in 2006; it greatly improves medication adherence, the major problem with the use of medications in alcoholism.

A significant development in identifying a potential endophenotype of alcoholism has grown out of the clinical experience with naltrexone. Animal studies have demonstrated that alcohol causes the release of endogenous opioids in brain reward systems and the disinhibition or activation of DA neurons, a condition common to all drugs of abuse. Blocking opioid receptors prevents this dopaminergic effect and results in less stimulation or reward from alcohol (Ray and Hutchison, 2007). A functional allele of the gene for the μ opioid receptor that naltrexone blocks has been associated with alcohol stimulation and with good response to naltrexone treatment among alcoholics (Anton et al., 2006).

Acamprosate (Campral), another FDA-approved medication for alcoholism (Mason, 2003), is a competitive inhibitor of the N-methyl-D-aspartate (NMDA)–type glutamate receptor. The drug appears to normalize the dysregulated neurotransmission associated with chronic ethanol intake and thereby to attenuate one of the mechanisms that lead to relapse (Chapter 23).

**Benzodiazepines.** Benzodiazepines are among the most commonly prescribed medications worldwide; they are used mainly for the treatment of anxiety disorders and insomnia (Chapters 15 and 17). Considering their widespread use, intentional abuse of prescription benzodiazepines is relatively uncommon. When a benzodiazepine is taken for up to several weeks, there is little tolerance and no difficulty in stopping the medication when the condition no longer warrants its use. After several months, the proportion of patients who become tolerant increases, and reducing the dose or stopping the medication produces withdrawal symptoms (Table 24–5).

It can be difficult to distinguish withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was prescribed initially. Some patients may increase their dose over time because tolerance definitely develops to the sedative effects. Many patients and their physicians, however, contend that anti-anxiety benefits continue to occur long after tolerance to the sedating effects. Moreover, these patients continue to take the medication for years according to medical directions without increasing their dose and are able to function very effectively as long as they take the benzodiazepine. The degree to which tolerance develops to the anxiolytic effects of benzodiazepines is a subject of controversy. There is, however, good evidence that significant tolerance does not develop to all benzodiazepine actions because some effects of acute doses on memory persist in patients who have taken benzodiazepines for years. According to a task force that reviewed the issues and published guidelines on the proper medical use of benzodiazepines (American Psychiatric Association, 1990), intermittent use only when symptoms occur retards the development of tolerance and therefore is preferable to daily use. Patients with a history of alcohol- or other drug-abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

While relatively few patients who receive benzodiazepines for medical indications abuse their medication, there are individuals who specifically seek benzodiazepines for their ability to produce a “high.” Among these abusers, there are differences in drug popularity; benzodiazepines that have a rapid onset, such as diazepam and alprazolam, tend to be the most desirable. The drugs may be obtained by simulating a medical condition and deceiving physicians or simply through illicit channels. Unsupervised use can lead to self-administration of large doses and therefore tolerance to the benzodiazepine’s sedating effects. For example, while 5–20 mg/day of diazepam is a typical dose for a patient receiving prescribed medication, abusers may take over 1000 mg/day and not appear grossly sedated.

Abusers may combine benzodiazepines with other drugs to increase the effect. For example, it is part of the “street lore” that taking diazepam 30 minutes after an oral dose of methadone will produce an augmented high not obtainable with either drug alone.

While there is some illicit use of benzodiazepines as a primary drug of abuse, most of the unsupervised use seems to be by abusers of other drugs who are attempting to self-medicate the side effects or withdrawal effects of their primary drug of abuse. Thus, cocaine addicts often take diazepam to relieve the irritability and agitation produced by cocaine binges, and opioid addicts find that diazepam and other benzodiazepines relieve some of the anxiety symptoms of opioid withdrawal when they are unable to obtain their preferred drug.

**Pharmacological Interventions.** If patients receiving long-term benzodiazepine treatment by prescription wish to stop their medication, the process may take months of gradual dose reduction. Withdrawal symptoms (Table 24–5) may occur during this outpatient detoxification, but in most cases the symptoms are mild. If anxiety symptoms return, a non-benzodiazepine such as buspirone may be prescribed, but this agent usually is less effective than benzodiazepines for treatment of anxiety in these patients. Some authorities recommend transferring the patient to a long t1/2 benzodiazepine during detoxification; others recommend the anticonvulsants carbamazepine and phenobarbital. Controlled studies comparing different treatment regimens are lacking.

Since patients who have been on low doses of benzodiazepines for years usually have no adverse effects, the physician and patient should decide jointly whether detoxification and possible transfer to a new anxiolytic are worth the effort.

The specific benzodiazepine receptor antagonist flumazenil has been found useful in the treatment of overdose and in reversing the effects of long-acting benzodiazepines used in anesthesia. It has been used experimentally in the treatment of persistent withdrawal symptoms after cessation of long-term benzodiazepine treatment.

### Table 24–5

**Benzodiazepine Withdrawal Symptoms**

**Following moderate dose usage**
- Anxiety, agitation
- Increased sensitivity to light and sound
- Paresthesias, strange sensations
- Muscle cramps
- Myoclonic jerks
- Sleep disturbance
- Dizziness

**Following high-dose usage**
- Seizures
- Delirium
Deliberate abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a complex clinical pharmacological problem requiring knowledge of the pharmacokinetics of each drug. The patient’s history may be unreliable not simply because of lying but also because the patient frequently does not know the true identity or dose of drugs purchased on the street. Medication for detoxification should not be prescribed by the “cookbook” approach but by careful titration and patient observation. The withdrawal syndrome from diazepam, for instance, may not become evident until the patient develops a seizure in the second week of hospitalization. One approach to complex detoxification is to focus on the CNS-depressant drug and temporarily hold the opioid component constant with a low dose of methadone. Opioid detoxification can begin later. A long-acting benzodiazepine such as diazepam or clorazepate (TRANXENE, others) or a long-acting barbiturate such as phenobarbital can be used to block the sedative withdrawal symptoms. The phenobarbital dose should be determined by a series of test doses and subsequent observations to determine the level of tolerance. Most complex detoxifications can be accomplished using this phenobarbital loading-dose strategy (Robinson et al., 1981).

After detoxification, the prevention of relapse requires a long-term outpatient rehabilitation program similar to the treatment of alcoholism. No specific medications have been found to be useful in the rehabilitation of sedative abusers; but, of course, specific psychiatric disorders such as depression or schizophrenia, if present, require appropriate medications.

**Barbiturates and Older Sedatives.** The use of barbiturates and older non-benzodiazepine sedating medications (e.g., meprobamate, glutethimide, chloral hydrate) has declined greatly in recent years owing to the increased safety and to the efficacy of the benzodiazepines and the newer agents zolpidem, eszopiclone, zaleplon, and ramelteon (Chapters 15 and 17). Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways. Treatment of abuse and addiction should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic agent is withdrawn. Insomnia rarely should be treated with medication as a primary disorder except when produced by short-term stressful situations. Insomnia often is a symptom of an underlying chronic problem, such as depression or respiratory dysfunction, or may be due simply to a change in sleep requirements with age. Prescription of sedative medications, however, can change the physiology of sleep with subsequent tolerance to these medication effects. When the sedative is stopped, there is a rebound effect with worsened insomnia. This medication-induced insomnia requires detoxification by gradual dose reduction.

**Nicotine**

The basic pharmacology of nicotine and agents for smoking cessation are discussed in Chapter 11. Because nicotine provides the reinforcement for cigarette smoking, the most common cause of preventable death and disease in the U.S., it is arguably the most dangerous dependence-producing drug. The dependence produced by nicotine can be extremely durable, as exemplified by the high failure rate among smokers who try to quit. Although >80% of smokers express a desire to quit, only 35% try to stop each year, and fewer than 5% are successful in unaided attempts to quit (American Psychiatric Association, 2000).

Cigarette (nicotine) addiction is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower magnitude. While there are many casual users of alcohol and cocaine, few individuals who smoke cigarettes smoke a small enough quantity (≤5 cigarettes per day) to avoid dependence. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 seconds. Thus, each puff produces some discrete reinforcement. With 10 puffs per cigarette, the one-pack-per-day smoker reinforces the habit 200 times daily. The timing, setting, situation, and preparation all become associated repetitively with the effects of nicotine.

Nicotine has both stimulant and depressant actions. The smoker feels alert, yet there is some muscle relaxation. Nicotine activates the nucleus accumbens reward system in the brain; increased extracellular DA has been found in this region after nicotine injections in rats. Nicotine affects other systems as well, including the release of endogenous opioids and glucocorticoids.

There is evidence for tolerance to the subjective effects of nicotine. Smokers typically report that the first cigarette of the day after a night of abstinence gives the “best” feeling. Smokers who return to cigarettes after a period of abstinence may experience nausea if they return immediately to their previous dose. Persons naive to the effects of nicotine will experience nausea at low nicotine blood levels, and smokers will experience nausea if nicotine levels are raised above their accustomed levels.

Negative reinforcement refers to the benefits obtained from the termination of an unpleasant state. In dependent smokers, the urge to smoke correlates with a low blood nicotine level, as though smoking were a means to achieve a certain nicotine level and thus avoid withdrawal symptoms. Some smokers even awaken during the night to have a cigarette, which ameliorates the effect of low nicotine blood levels that could disrupt sleep. If the nicotine level is maintained artificially by a slow intravenous infusion, the number of cigarettes smoked and in the number of puffs decrease. Thus, smokers may be smoking to achieve the reward of nicotine effects, to avoid the pain of nicotine withdrawal, or most likely a combination of the two. Nicotine withdrawal symptoms are listed in Table 24–6.
Depressed mood (dysthymic disorder, affective disorder) is associated with nicotine dependence, but it is not known whether depression predisposes one to begin smoking or depression develops during the course of nicotine dependence. Depression increases significantly during smoking withdrawal, and this is cited as one reason for relapse.

Pharmacological Interventions. The nicotine withdrawal syndrome can be alleviated by nicotine-replacement therapy, available with a prescription (e.g., NICOTROL inhaler and nasal spray) or without (e.g., NICORETTE gum and others; COMMIT lozenges and others; and NICODERM CQ transdermal patch and others). Figure 24–3 shows the blood nicotine concentrations achieved by different methods of nicotine delivery. Because nicotine gum and a nicotine patch do not achieve the peak levels seen with cigarettes, they do not produce the same magnitude of subjective effects as smoking. These methods do, however, suppress the symptoms of nicotine withdrawal. Thus, smokers should be able to transfer their dependence to the alternative delivery system and gradually reduce the daily nicotine dose with minimal symptoms. Although this results in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. Comparisons with placebo treatment show large benefits of nicotine replacement at 6 weeks, but the effect diminishes with time. The nicotine patch produces a steady blood level (Figure 24–3) and seems to have better patient compliance than that observed with nicotine gum. Verified abstinence rates at 12 months are reported to be in the range of 20%. The necessary goal of complete abstinence contributes to the poor success rate; when ex-smokers “slip” and begin smoking a little, they usually relapse quickly to their prior level of dependence.

The search for better medications to treat nicotine addiction has become an important goal of the pharmaceutical industry, and other types of medication have been tested in clinical trials. A sustained-release preparation of the antidepressant bupropion (ZYBAN; Chapter 15), improves abstinence rates among smokers and remains a useful option. The cannabinoid CB1 receptor inverse agonist rimonabant improves abstinence rates and reduces the weight gain seen frequently in ex-smokers. Unfortunately, the CB1 inverse agonist mechanism led to a high frequency of depressive and neurologic symptoms, ending its development in the U.S. Varenicline, a partial agonist at the α4β2 subtype of the nicotinic acetylcholine receptor, improves abstinence rates but has also been linked to risk of developing suicidal ideation. Varenicline partially stimulates nicotinic receptors, thereby reducing craving and preventing most withdrawal symptoms. It has high receptor affinity, thus blocking access to nicotine, so if the treated smoker relapses, there is little reward and abstinence is more likely to be maintained. In one recent clinical trial, the abstinence rate for varenicline at 1 year was 36.7% versus 7.9% for placebo (Williams et al., 2007).

Opioids

Opioid drugs are used primarily for the treatment of pain (Chapter 18). Some of the CNS mechanisms that reduce the perception of pain also produce a state of well-being or euphoria. Thus, opioid drugs also are taken outside medical channels for the purpose of obtaining the effects on mood. This potential for abuse has generated much research on separating the mechanism of analgesia from that of euphoria in the hope of eventually developing a potent analgesic that does not activate the brain reward system.

Arrows (lower panel) indicate when the nicotine patch was put on and taken off. (From Benowitz et al., 1988, and Srivastava et al, 1991, with permission. Benowitz et al, 1988 Copyright © Macmillan Publishers Ltd. Srivastava et al, 1991 Copyright © Springer Science and Business Media.)
systems. Although this research has led to advances in understanding the physiology of pain, the standard medications for severe pain remain the derivatives of the opium poppy (opiates) and synthetic drugs that activate the same receptors (opioids). Drugs modeled after the endogenous opioid peptides may one day provide more specific options for the treatment of pain, but none of these currently is available for clinical use. Analgesic medications that do not act at opioid receptors, such as the nonsteroidal anti-inflammatory drugs (NSAIDs), have an important role in mild to moderate types of pain, but for severe pain, the opioid drugs are most effective. Progress in pain control stems from a greater understanding of the mechanism of tolerance to μ opiate receptor–mediated analgesia, which involves NMDA receptors (Trujillo and Akil, 1991). Experimentally, by combining morphine with dextromethorphan, an NMDA-receptor antagonist, tolerance is impaired and analgesia is enhanced without an increase in the dose of opioid.

The subjective effects of opioid drugs are useful in the management of acute pain. This is particularly true in high-anxiety situations, such as the crushing chest pain of myocardial infarction, when the relaxing, anxiolytic effects complement the analgesia. Normal volunteers with no pain given opioids in the laboratory may report the effects as unpleasant because of side effects such as nausea, vomiting, and sedation. Patients with pain usually do not develop abuse or addiction problems. Of course, patients receiving opioids over time develop tolerance routinely, and if the medication is stopped abruptly, they will show the signs of an opioid-withdrawal syndrome, the evidence for physical dependence.

Opioids should never be withheld from patients with cancer out of fear of producing addiction. If chronic opioid medication is indicated, it is preferable to prescribe an orally active, slow-onset opioid with a long duration of action. These qualities reduce the likelihood of producing euphoria at onset and withdrawal symptoms as the medication wears off. In selected patients, methadone is an excellent choice for the management of chronic severe pain. Controlled-release oral morphine (MS CONTIN, others) and controlled-release oxycodone (OXYCONTIN, others) are other possibilities. Rapid-onset, short-duration opioids are excellent for acute short-term use, such as during the postoperative period. As tolerance and physical dependence develop, however, the patient may experience the early symptoms of withdrawal between doses, and during withdrawal, the threshold for pain decreases. Thus, for chronic administration, long-acting opioids are preferred. While methadone is long acting because of its metabolism to active metabolites, the long-acting version of oxycodone has been formulated to release slowly, thereby changing a short-acting opioid into a long-acting one. Unfortunately, this mechanism can be subverted by breaking the tablet and making the full dose of oxycodone immediately available. This has led to diversion of oxycodone to illicit traffic because high-dose oxycodone produces euphoria that is sought by opiate abusers. The diversion of prescription opioids such as oxycodone and hydrocodone to illegal markets has become an important source of opiate abuse in the U.S.

The risk for addiction is highest in patients complaining of pain with no clear physical explanation or in patients with evidence of a chronic, non-life-threatening disorder. Examples are chronic headaches, backaches, abdominal pain, or peripheral neuropathy. Even in these cases, an opioid may be considered as a brief emergency treatment, but long-term treatment with opioids should be used only after other alternatives have been exhausted. In the relatively rare patient who develops abuse, the transition from legitimate use to abuse often begins when the patient returns to his physician earlier than scheduled, asking for a new prescription, or visits emergency rooms of multiple hospitals, complaining of acute pain and asking for an opioid injection.

Heroin is the most frequently abused opiate. There is no legal supply of heroin for clinical use in the U.S. Despite claims that heroin has unique analgesic properties for the treatment of severe pain, double-blind trials have found it to be no more effective than hydromorphone. However, heroin is widely available on the illicit market, and its price dropped sharply in the 1990s, continuing to the present, with purity increased 10-fold.

Previously, street heroin in the U.S. was highly diluted: Each 100-mg bag of powder had only ~4 mg heroin (range: 0–8 mg), and the rest was filler such as quinine. In the mid-1990s, street heroin reached 45–75% purity in many large cities, with some samples testing as high as 90%. This increase in purity has led to increased levels of physical dependence among heroin addicts. Users who interrupt regular dosing develop more severe withdrawal symptoms. Whereas heroin previously required intravenous injection, the more potent supplies can be smoked or administered nasally (snorted), making the initiation of heroin use accessible to people who would not insert a needle into their veins. There is no accurate way to count the number of heroin addicts, but based on extrapolation from overdose deaths, number of applicants for treatment, and number of heroin addicts arrested, the estimates range from 800,000 to 1 million in the U.S.; based on a stratified national sample of adults, ~1 in 4 individuals who report any use of heroin become addicted (Anthony et al., 1994). Recent law enforcement actions may presage the emergence of a domestic supply of heroin precursor (raw opium) harvested from Papaver somniferum grown in the Pacific Northwest of the U.S. (Baer, 2009).

Tolerance, Dependence, and Withdrawal. Injection of a heroin solution produces a variety of sensations described as warmth, taste, or high and intense pleasure ("rush") often compared with sexual orgasm. There are some differences among the opioids in their acute effects, with morphine producing more of a histamine-releasing effect and meperidine producing more excitation or confusion. Even experienced opioid addicts, however, cannot distinguish between heroin and hydromorphone in double-blind tests.

Thus, the popularity of heroin may be due to its availability on the illicit market and its rapid onset. After intravenous injection, the effects begin in less than a minute. Heroin has high lipid solubility,
crosses the blood-brain barrier quickly, and is deacetylated to the active metabolites 6-monooctyl morphine and morphine. After the intense euphoria, which lasts from 45 seconds to several minutes, there is a period of sedation and tranquility (“on the nod”) lasting up to an hour. The effects of heroin wear off in 3-5 hours, depending on the dose. Experienced users may inject two to four times per day. Thus, the heroin addict is constantly oscillating between being “high” and feeling the sickness of early withdrawal (Figure 24–4). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids. For example, the hypothalamic-pituitary-gonadal axis and the hypothalamic-pituitary-adrenal axis are abnormal in heroin addicts. Women on heroin have irregular menses, and men have a variety of sexual performance problems. Mood also is affected. Heroin addicts are relatively docile and compliant after taking heroin, but during withdrawal, they become irritable and aggressive.

Based on patient reports, tolerance develops early to the euphoria-producing effects of opioids. There also is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties. Heroin users tend to increase their daily dose, depending on their financial resources and the availability of the drug. If a supply is available, the dose can be increased progressively 100 times. Even in highly tolerant individuals, the possibility of overdose remains if tolerance is exceeded. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a far more potent opioid, such as fentanyl (SUBLIMAZE, others).

Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. There is a significant risk for opioid abuse and dependence among physicians and other health care workers who have access to potent opioids, tempting them toward unsupervised experimentation. Physicians often begin by assuming that they can manage their own dose, and they may rationalize their behavior based on the beneficial effects of the drug. Over time, however, the typical unsupervised opioid user loses control, and behavioral changes are observed by family and co-workers. Apart from the behavioral changes and the risk of overdose, especially with very potent opioids, chronic use of opioids is relatively nontoxic.

Opioids frequently are used in combinations with other drugs. A common combination is heroin and cocaine (“speedball”). Users report an improved euphoria because of the combination, and there is evidence of an interaction, because cocaine reduces the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic cocaine users.

The mortality rate for street heroin users is very high. Early death comes from involvement in crime to support the habit; from the uncertain dose, purity, and even identity of what is purchased on the street; and from serious infections associated with nonsterile drugs and sharing of injection paraphernalia. Heroin users commonly acquire bacterial infections producing skin abscesses; endocarditis; pulmonary infections, especially tuberculosis; and viral infections producing hepatitis C and acquired immune deficiency syndrome (AIDS).

As with other addictions, the first stage of treatment addresses physical dependence and consists of detoxification (Kosten and O’Conner, 2003). The opioid-withdrawal syndrome (Table 24–7) is very unpleasant but not life-threatening. It begins within 6-12 hours after the last dose of a short-acting opioid and as long as 72-84 hours after a very long-acting opioid medication. Heroin addicts go through early stages of this syndrome frequently when heroin is scarce or expensive. Some therapeutic communities as a matter of policy elect not to treat withdrawal so that the addict can experience the suffering while being given group support. The duration and intensity of the syndrome are related to the clearance of the individual drug. Heroin withdrawal is brief (5-10 days) and intense. Methadone withdrawal is slower in onset and lasts longer. Protracted withdrawal also is likely to be longer with methadone. (See more detailed discussions of protracted withdrawal under “Long-Term Management” later in the chapter.)

Pharmacological Interventions. Opioid withdrawal signs and symptoms can be treated by three different approaches. The first and most commonly used approach depends on cross-tolerance and consists of transfer to a prescription opioid medication and then gradual dose reduction. The same principles of detoxification apply as for other types of physical dependence. It is convenient to change the patient from a short-acting opioid such as heroin to a long-acting one such as methadone. Detoxification and subsequent maintenance of opiate dependence with methadone is specifically limited to accredited opioid treatment programs (OTPs) and is regulated by Federal Opioid Treatment Standards. The initial dose of methadone is typically 20-30 mg. This is a test dose to determine the level needed to reduce observed withdrawal symptoms. The first day’s total dose then can be calculated depending on the response and then reduced by 20% per day during the course of detoxification.

A second approach to detoxification involves the use of oral clonidine (CATAPRES, others), a medication approved only for the treatment of hypertension. Clonidine is an α2 adrenergic agonist that decreases adrenergic neurotransmission from the locus ceruleus. Many of the autonomic symptoms of opioid withdrawal such as nausea, vomiting, cramps, sweating, tachycardia, and hypertension result from the loss of opioid suppression of the locus ceruleus system during the abstinence syndrome. Clonidine, acting upon distinct receptors but by cellular mechanisms that mimic opioid effects, can alleviate many of the symptoms of opioid withdrawal, but not the generalized aches and opioid craving. When using clonidine to treat withdrawal, the dose must be titrated according to the stage and severity of withdrawal, beginning with 0.2 mg orally; postural hypotension is commonly a side effect. A similar drug, lofexidine (currently in clinical trials in the U.S.), has greater selectivity for α2,α2 adrenergic receptors and is associated with less of the hypotension that limits the usefulness of clonidine in this setting.

A third method of treating opioid withdrawal involves activation of the endogenous opioid system without medication. The techniques proposed include acupuncture and several methods of CNS activation using transcutaneous electrical stimulation. While attractive theoretically, this has not yet been found to be practical. Rapid antagonist-precipitated opioid detoxification under general anesthesia has received considerable publicity because it promises detoxification in several hours while the patient is unconscious and not experiencing withdrawal discomfort. A mixture of medications has been used, but morbidity and mortality as reported in the lay press are unacceptable, with no demonstrated advantage in long-term outcome (Collins et al., 2005).

Long-Term Management. If patients are simply discharged from the hospital after withdrawal from opioids, there is a high probability of a quick return to compulsive opioid use. Addiction is a chronic disorder that requires long-term management. Numerous factors influence relapse. One factor is that the withdrawal syndrome does not end in 5-7 days. There are subtle signs and symptoms often called the protracted withdrawal syndrome (Table 24–7) that persist for up to 6 months. Physiological measures tend to oscillate as though a new set point were being established; during this phase, outpatient drug-free treatment has a low probability of success, even when the patient has received intensive prior treatment while protected from relapse in a residential program.

The most successful treatment for heroin addiction consists of stabilization on methadone in accordance with state and federal regulations. Patients who relapse repeatedly during drug-free treatment can be transferred directly to methadone without requiring detoxification. The dose of methadone must be sufficient to prevent withdrawal symptoms for at least 24 hours. The introduction of buprenorphine, a partial agonist at μ opioid receptors (Chapter 18), represents a major change in the treatment of opioid addiction. This drug produces minimal withdrawal symptoms when discontinued and has a low potential for overdose, a long duration of action, and the ability to block heroin effects. Treatment can take place in a qualified physician’s private office rather than in a special center, as required for methadone. When taken sublingually, buprenorphine (SUBLUTEX) is active, but it also has the potential to be dissolved and injected (abused). A buprenorphine-naloxone combination (SUBOXONE) is also available. When taken orally (sublingually), the naloxone moiety is not effective, but if the patient abuses the medication by injecting, the naloxone will block or diminish the subjective high that could be produced by buprenorphine alone.

Agonist or Partial-Agonist Maintenance. Patients receiving methadone or buprenorphine will not experience the ups and downs produced by heroin (Figure 24–4). Drug craving diminishes and may disappear. Neuroendocrine rhythms eventually are restored (Kreek et al., 2002). Because of cross-tolerance (from methadone to heroin), patients who inject street heroin report a reduced effect from usual heroin doses. This cross-tolerance effect is dose-related, so higher methadone maintenance doses result in less illicit opioid use, as determined by random urine testing. Buprenorphine, as a partial agonist, has a ceiling effect at ~16 mg of the sublingual tablet equaling no more than 60 mg methadone. If the patient has a higher level of physical dependence, a full agonist (methadone) must be used. Patients become tolerant to the sedating effects of methadone and can attend school or function in a job. Opioids also have a persistent, mild, stimulating effect noticeable after tolerance to the sedating effect, such that reaction time is quicker and vigilance is increased while on a stable dose of methadone.

Antagonist Treatment. Another pharmacological option is opioid antagonist treatment. Naltrexone (REVIA, others; Chapter 18) is an antagonist with a high affinity for the μ opioid receptor (MOR); it will competitively block the effects of heroin or other MOR agonists. Naltrexone has almost no agonist effects of its own and will not satisfy craving or relieve protracted withdrawal symptoms. For these reasons, naltrexone treatment does not appeal to the average heroin addict, but it can be used after detoxification for patients with high motivation to remain opioid-free. Physicians, nurses, and pharmacists who have frequent access to opioid drugs make excellent candidates for this treatment approach. A depot formulation of naltrexone that provides 30 days of medication after a single injection (VIVITROL) has been approved for the treatment of alcoholism. This formulation eliminates the necessity of daily pill-taking and prevents relapse when the recently detoxified patient leaves a protected environment.

Cocaine and Other Psychostimulants

Cocaine. More than 23 million Americans have used cocaine at some time. Although chronic use and use by
high school students has declined, the number of frequent users (at least weekly) has remained steady since 1991 at ~600,000. Not all users become addicts, and the variables that influence this risk are discussed at the beginning of this chapter. A key factor is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, “crack”) suitable for smoking and in the hydrochloride powder form suitable for nasal or intravenous use. Drug abuse in men occurs about twice as frequently as in women. However, free basing is particularly common in young women of child-bearing age, who may use cocaine in this manner as commonly as do men.

The reinforcing effects of cocaine and cocaine analogs correlate best with their effectiveness in blocking the transporter that recovers DA from the synapse. This leads to increased DA concentrations at critical brain sites (Ritz et al., 1987). However, cocaine also blocks both NE and 5-HT reuptake, and chronic use of cocaine leads to reductions in the neurotransmitter metabolites 3-methoxy-4-hydroxyphenylethanolamine (MOPEG or MHPG) and 5-hydroxyindoleacetic acid (5-HIAA).

The general pharmacology and medicinal use of cocaine as a local anesthetic are discussed in Chapter 20. Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drug. Repeated doses may lead to involuntary motor activity, stereotyped behavior, and paranoia. Irritability and increased risk of violence are found among heavy chronic users. The $t_{1/2}$ of cocaine in plasma is ~50 minutes, but inhalant (crack) users typically desire more cocaine after 10-30 minutes. Intranasal and intravenous uses also result in a high of shorter duration than would be predicted by plasma cocaine levels, suggesting that a declining plasma concentration is associated with termination of the high and resumption of cocaine seeking. This theory is supported by positron-emission tomographic imaging studies using $^{11}$C-labeled cocaine, which show that the time course of subjective euphoria parallels the accumulation and decline of the drug in the corpus striatum (Volkow et al., 2003).

The major route for cocaine metabolism involves hydrolysis of each of its two ester groups. Benzoylcegonine, produced on loss of the methyl group, represents the major urinary metabolite and can be found in the urine for 2-5 days after a binge. As a result, the benzoylcegonine test is a valid method for detecting cocaine use; the metabolite remains detectable in the urine of heavy users for up to 10 days. Cocaine frequently is used in combination with other drugs, as discussed previously. Ethanol is frequently abused with cocaine, as it reduces the irritability induced by cocaine. Dual addiction to alcohol and cocaine is common. When cocaine and alcohol are taken concurrently, cocaine may be transesterified to cocaethylene, which is equipotent to cocaine in blocking DA reuptake (Hearn et al., 1991).

Addiction is the most common complication of cocaine abuse. Intranasal users can continue intermittent use for years. Others become compulsive users despite elaborate methods to maintain control. In general, stimulants tend to be abused much more irregularly than opioids, nicotine, and alcohol. Binge use is very common, and a binge may last hours to days, terminating only when supplies of the drug are exhausted.

**Toxicity.** Other risks of cocaine, beyond the potential for addiction, include cardiac arrhythmias, myocardial ischemia, myocarditis, aortic dissection, cerebral vasocostriction, and seizures. Death from trauma also is associated with cocaine use. Cocaine may induce premature labor and abruptio placentae (Chasnoff et al., 1989). The developmental abnormalities reported in infants born to cocaine users may be the result of cocaine effects as well as multiple other factors (the infant’s prematurity, multiple-drug and alcohol exposure, and inadequate pre- and postnatal care).

Cocaine has been reported to produce a prolonged and intense orgasm if taken prior to intercourse, and users often indulge in compulsive and promiscuous sexual activity. However, chronic cocaine use reduces sexual drive. Chronic use is also associated with psychiatric disorders, including anxiety, depression, and psychosis, and while some of these disorders undoubtedly existed prior to addiction, many are likely attributable to the drug (McLellan et al., 1979).

**Tolerance, Dependence, and Withdrawal.** Sensitization, a consistent finding in animal studies of cocaine and other stimulants, is produced by intermittent use and typically is manifested as behavioral hyperactivity. In human cocaine users, the euphoric effect typically is not subject to sensitization. On the contrary, most experienced users become desensitized and, over time, require more cocaine to obtain euphoria, i.e., tolerance develops. In the laboratory, tolerance is rapidly induced by repeated administration of the same dose in one session (tachyphylaxis). Sensitization may involve conditioning (Figure 24–2). Cocaine users often report a strong response on seeing cocaine before it is administered, consisting of physiological arousal and increased drug craving with concomitant activation of brain limbic structures (Childress et al., 1999). Sensitization in humans has been linked to paranoid, psychotic manifestations of cocaine use (Satel et al., 1991). Since cocaine typically is used intermittently, even heavy users go through frequent periods of withdrawal or “crash.” The symptoms of withdrawal seen in users admitted to hospitals are listed in Table 24–8. Careful studies of cocaine users during withdrawal show gradual diminution of these symptoms over 1-3 weeks (Weddington et al., 1990). Residual depression, often seen after cocaine withdrawal, should be treated with antidepressant agents if it persists (Chapter 15).

**Pharmacological Interventions.** Since cocaine withdrawal is generally mild, treatment of withdrawal symptoms usually is not required. The major problem in treatment is not detoxification but helping the patient to resist the urge to resume compulsive cocaine use. Rehabilitation programs involving individual and group psychotherapy based on the principles of Alcoholics Anonymous, and behavioral treatments based

</table>
on reinforcing cocaine-free urine tests, result in significant improvement in the majority of cocaine users (Alterman et al., 1994; Higgins et al., 1994). Nonetheless, there is great interest in finding a medication that can aid in the rehabilitation of cocaine addicts.

Numerous medications have been tried in placebo-controlled clinical trials with cocaine addicts, but no medication has yet consistently improved upon the results of behavior therapy alone. Animal models suggest that enhancing GABAergic inhibition can reduce reinstatement of cocaine self-administration, and a controlled clinical trial of topiramate (TOPAMAX) showed a significant reduction in cocaine use. Topiramate also reduced the relapse rate in alcoholics, prompting current studies in patients dually dependent on cocaine and alcohol. Baclofen (Lioresal, others), a GABA_B agonist, was found in a single-site trial to reduce relapse in cocaine addicts, but was not effective in a multisite trial. A different approach was taken using modafinil (Provigil), a medication that increases alertness and is approved for the treatment of narcolepsy. This medication was found to reduce the euphoria produced by cocaine and to relieve cocaine withdrawal symptoms. Modafinil is currently being tested in clinical trials of cocaine, methamphetamine, alcohol, and other substance abuse disorders. A novel approach to cocaine addiction employs a vaccine that produces cocaine-binding antibodies. Preliminary studies showed some success in reducing cocaine use. Larger trials are in progress. For now, behavioral therapy remains the treatment of choice, with medication indicated for specific co-existing disorders such as depression.

**Amphetamine and Related Agents.** Subjective effects similar to those of cocaine are produced by amphetamine, dextroamphetamine, methamphetamine, phenmetrazine, methylphenidate, and diethylpropion. Amphetamines increase synaptic DA, NE, and 5-HT primarily by stimulating pre-synaptic release rather than by blockade of reuptake, as is the case with cocaine. Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, although clinical deterioration may progress more rapidly. In animal studies, methamphetamine in doses comparable with those used by human abusers produces neurotoxic effects, as reflected by histologic changes in dopaminergic and serotonergic neurons.

Methamphetamine can be synthesized from ephedrine in small, clandestine laboratories. Methamphetamine addiction has become a major public health problem, particularly in the western half of the U.S. Behavioral and medical treatments for methamphetamine addiction are similar to those used for cocaine. Until recently, ephedrine was a widely available nonprescription stimulant (a “wake-up” pill). Oral stimulants, such as those prescribed in a weight-reduction program, have short-term efficacy because of tolerance development. Only a small proportion of patients introduced to these appetite suppressants subsequently exhibits dose escalation or drug-seeking from various physicians; such patients may meet diagnostic criteria for abuse or addiction.

**Caffeine.** Caffeine, a mild stimulant, is the most widely used psychoactive drug in the world. It is present in soft drinks, coffee, tea, cocoa, chocolate, and numerous prescription and over-the-counter drugs. It mildly increases NE and DA release and enhances neural activity in numerous brain areas. Caffeine is absorbed from the digestive tract and is distributed rapidly throughout all tissues and easily crosses the placental barrier. Many of caffeine’s effects are believed to occur by means of competitive antagonism at adenosine receptors; as a methylxanthine, caffeine also inhibits cyclic nucleotide phosphodiesterases. Adenosine is a neuromodulator that influences a number of functions in the CNS, as is cyclic AMP (Chapter 14). The mild sedating effects that occur when adenosine activates particular adenosine-receptor subtypes can be antagonized by caffeine.

Tolerance occurs rapidly to the stimulating effects of caffeine. Thus, a mild withdrawal syndrome has been produced in controlled studies by abruptly discontinuing the intake of as little as one to two cups of coffee per day. Caffeine withdrawal consists of feelings of fatigue and sedation. With higher doses, headaches and nausea have been reported during withdrawal; vomiting is rare (Silverman et al., 1992). Although a withdrawal syndrome can be demonstrated, few caffeine users report loss of control of caffeine intake or significant difficulty in reducing or stopping caffeine, if desired (Dews et al., 1999). Thus, caffeine is not listed in the category of addicting stimulants (American Psychiatric Association, 2000).

**Cannabinoids (Marijuana)**

The cannabis plant has been cultivated for centuries both for the production of hemp fiber and for its presumed medicinal and psychoactive properties. The smoke from burning cannabis contains many chemicals, including 61 different cannabinoids that have been identified. One of these, Δ-9-tetrahydrocannabinol (Δ-9-THC), produces most of the characteristic pharmacological effects of smoked marijuana.

Marijuana is the most commonly used illegal drug in the U.S. Surveys over the period 2006-2009 report that ~32% of highschool seniors have tied marijuana, down from a high of 51% in 1974, but up from 22% in 1992 (Johnston et al., 2010).

Cannabinoid receptors CB_1 (mainly CNS) and CB_2 (peripheral) have been identified and cloned. An arachidonic acid derivative, anandamide, has been proposed as an endogenous ligand for CB receptors. While the physiological function of these receptors and their endogenous ligands is incompletely understood, they are likely to have important functions because they are dispersed widely with high densities in the cerebral cortex, hippocampus, striatum, and cerebellum (Iversen, 2003). Specific CB_1 antagonists have been
developed and tested in controlled clinical trials. One of these, rimonabant, was found to reduce relapse in cigarette smokers and to produce weight loss in obese patients; however, its development has been abandoned because of depressive and neurologic side effects.

The pharmacological effects of Δ-9-THC vary with the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effect most frequently sought is the “high” and “mellowing out.” This effect is described as different from the high produced by a stimulant or opiate. Effects vary with dose, but typically last ~2 hours. During the high, cognitive functions, perception, reaction time, learning, and memory are impaired. Coordination and tracking behavior may be impaired for several hours beyond the perception of the high, with obvious implications for the operation of a motor vehicle and performance in the workplace or at school.

Marijuana also produces complex behavioral changes such as giddiness and increased hunger. There are unsubstantiated claims of increased pleasure from sex and increased insight during a marijuana high. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur; several surveys indicate that 50-60% of marijuana users have reported at least one anxiety experience. These reactions are seen commonly with higher doses and with oral ingestion rather than smoked marijuana, because smoking permits the titration of dose according to the effects. While there is no convincing evidence that marijuana can produce a lasting schizophrenia-like syndrome, association studies suggest a correlation of early marijuana use with an increased risk of later developing schizophrenia. Numerous clinical reports suggest that marijuana use may precipitate a recurrence of psychosis in people with a history of schizophrenia.

One of the most controversial of the reputed effects of marijuana is the production of an “amotivational syndrome.” This syndrome is not an official diagnosis, but it has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. When heavy marijuana use accompanies these symptoms, the drug is often cited as the cause, even though there are no data that demonstrate a causal relationship between marijuana smoking and these behavioral characteristics. There is no evidence that marijuana damages brain cells or produces any permanent functional changes, although there are animal data indicating impairment of maze learning that persists for weeks after the last dose. These findings are consistent with clinical reports of gradual improvement in mental state after cessation of chronic high-dose marijuana use.

Marijuana has medicinal effects, including antiemetic properties that relieve side effects of anticancer chemotherapy. It also has muscle-relaxing effects, anticonvulsant properties, and the capacity to reduce the elevated intraocular pressure of glaucoma. These medical benefits come at the cost of the psychoactive effects that often impair normal activities. Thus, there is no clear advantage of marijuana over conventional treatments for any of these indications (Joy et al., 1999). An oral capsule containing Δ-9-THC (dronabinol; MARINOL, others) is approved for anorexia associated with weight loss in patients with HIV infection and for cancer chemotherapy-induced nausea and vomiting.

With the cloning of cannabinoid receptors, the discovery of endogenous ligands, and the synthesis of specific agonists and antagonists, it is likely that new orally effective medications will be developed without the undesirable properties of smoked marijuana and without the deleterious effects of inhaling smoke particles and the chemical products of high-temperature combustion.

**Tolerance, Dependence, and Withdrawal.** Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, but also disappears rapidly (Martin et al., 2004). Tolerance to large doses persists in experimental animals for long periods after cessation of drug use. Withdrawal symptoms and signs typically are not seen in clinical populations. In fact, few patients ever seek treatment for marijuana addiction. Human subjects develop a withdrawal syndrome when they receive regular oral doses of the agent (Table 24–9). This syndrome, however, is only seen clinically in persons who use marijuana on a daily basis and then suddenly stop.

**Pharmacological Interventions.** Marijuana abuse and addiction have no specific treatments. Heavy users may suffer from accompanying depression and thus may respond to antidepressant medication, but this should be decided on an individual basis considering the severity of the affective symptoms after the marijuana effects have dissipated. The residual drug effects may continue for several weeks. The CB1 receptor antagonist rimonabant has been reported to block the acute effects of smoked marijuana, but development of this drug has been halted due to safety concerns (discussed under “Pharmacological Interventions” in the nicotine section earlier in the chapter).

**Psychedelic Agents**

Perceptual distortions that include hallucinations, illusions, and disorders of thinking such as paranoia can be produced by toxic doses of many drugs. These phenomena also may follow withdrawal from toxic sedatives such as alcohol. There are, however, certain drugs that have as their primary effect the production of disturbances of perception, thought, or mood at low doses with minimal effects on memory and orientation. These are commonly called hallucinogenic drugs, but their

use does not always result in frank hallucinations. In the late 1990s, the use of “club drugs” at all-night dance parties became popular. Such drugs include methylenedioxymethamphetamine (MDMA, “ecstasy”), lysergic acid diethylamide (LSD), phenethylcine (PCP), and ketamine (KETALAR). They often are used in association with illegal sedatives such as flunitrazepam (ROHYPNOL) or γ-hydroxybutyrate (GHB). The latter drug has the reputation of being particularly effective in preventing memory storage, and has been implicated in “date rapes.”

While psychedelic effects can be produced by a variety of different drugs, there are two main categories of psychedelic compounds, indoleamines and phenethylamines. The indoleamine hallucinogens include LSD, N,N-dimethyltryptamine (DMT), and psilocybin. The phenethylamines include mescaline, dimethoxymethylanphetamine (DOM), methylenedioxyamphetamine (MDA), and MDMA. Both groups have a relatively high affinity for 5-HT2 receptors (Chapter 13), but they differ in their affinity for other subtypes of 5-HT receptors. There is a good correlation between the relative affinity of these compounds for 5-HT2 receptors and their potency as hallucinogens in humans (Titler et al., 1988). The 5-HT2 receptor is further implicated in the mechanism of hallucinations by the observation that antagonists of that receptor, such as ritanserin, are effective in blocking the behavioral and electrophysiological effects of hallucinogenic drugs in animal models. However, LSD interacts with many receptor subtypes at nanomolar concentrations, and it is not possible to attribute the psychedelic effects to any single 5-HT receptor subtype (Peroutka, 1994).

**LSD.** LSD is the most potent hallucinogenic drug and produces significant psychedelic effects with a total dose of at least as 25-50 μg. This drug is > 3000 times more potent than mescaline. LSD is sold on the illicit market in a variety of forms. A popular contemporary system involves postage stamp-sized papers impregnated with varying doses of LSD (50-300 μg or more). While most street samples sold as LSD actually contain LSD, samples of mushrooms and other botanicals sold as sources of psilocybin and other psychedelics have a low probability of containing the advertised hallucinogen.

The effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40-60 minutes, peaking at 2-4 hours, and gradually returning to baseline over 6-8 hours. At a dose of 100 μg, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The subject may focus attention on unusual items such as the pattern of hairs on the back of the hand.

A “bad trip” usually consists of severe anxiety, although at times it is marked by intense depression and suicidal thoughts. Visual disturbances usually are prominent. The bad trip from LSD may be difficult to distinguish from reactions to anticholinergic drugs and phencyclidine. There are no documented toxic fatalities from LSD use, but fatal accidents and suicides have occurred during or shortly after intoxication. Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of a hallucinogen. Schizophrenic episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders (McLellan et al., 1979).

Claims about the potential of psychedelic drugs for enhancing psychotherapy and for treating addictions and other mental disorders have not been supported by controlled treatment outcome studies. Consequently, there is no current indication for these drugs as medications.

**Tolerance, Physical Dependence, and Withdrawal.** Frequent, repeated use of psychedelic drugs is unusual, and thus tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after three or four daily doses, but no withdrawal syndrome has been observed. Cross-tolerance among LSD, mescaline, and psilocybin has been demonstrated in animal models.

**Pharmacological Intervention.** Because of the unpredictability of psychedelic drug effects, any use carries some risk. Dependence and addiction do not occur, but users may require medical attention because of “bad trips.” Severe agitation may respond to diazepam (20 mg orally). “Talking down” by reassurance also is effective and is the management of first choice. Antipsychotic medications (Chapter 16) may intensify the experience and thus are not indicated.

A particularly troubling after-effect of the use of LSD and similar drugs is the occasional occurrence of episodic visual disturbances. These originally were called “flashbacks” and resembled the experiences of prior LSD trips. Flashbacks belong to an official diagnostic category called the **hallucinogen persisting perception disorder** (HPPD; American Psychiatric Association, 1994). The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive afterimages (Abraham and Aldridge, 1993). The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, antipsychotic agents, and anxiety states.

**MDMA (“Ecstasy”) and MDA.** MDA and MDA are phenylethylamines that have stimulant as well as psychedelic effects. MDMA became popular during the 1980s on college campuses because of testimonials that it enhances insight and self-knowledge. It was recommended by some psychotherapists as an aid to the process of therapy, although no controlled data exist to support this contention. Acute effects are dose-dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is one or two 100-mg tablets and lasts 3-6 hours, although dosage and potency of street samples are variable (~100 mg per tablet).

MDA and MDMA produce degeneration of serotonergic nerve cells and axons in rats. While nerve degeneration has not been
demonstrated in humans, the cerebrospinal fluid of chronic MDMA users has low levels of serotonin metabolites (Ricaurte et al., 2000). Thus, there is possible neurotoxicity with no evidence that the claimed benefits of MDMA actually occur.

**Phencyclidine (PCP).** PCP deserves special mention because of its widespread availability and because its pharmacological effects are different from those of the psychedelics such as LSD. PCP was developed originally as an anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classified as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s, first in an oral form and then in a smoked version enabling a better regulation of the dose. The effects of PCP have been observed in normal volunteers under controlled conditions. As little as 50 μg/kg produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing also is produced and resembles that of schizophrenia. Abusers taking higher doses may appear to be reacting to hallucinations and may exhibit hostile or assaultive behavior. Anesthetic effects increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged nonreactive pupils.

PCP binds with high affinity to sites located in the cortex and limbic structures, resulting in blocking of N-methyl-D-aspartate (NMDA)–type glutamate receptors (Chapter 14). LSD and other psychedelics do not bind to NMDA receptors. There is evidence that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, there is interest in PCP analogs that block NMDA receptors but with fewer psychoactive effects. Both PCP and ketamine (“Special K”), another “club drug,” produce similar effects by altering the distribution of the neurotransmitter glutamate.

**Tolerance, Dependence, and Withdrawal.** PCP is reinforcing in monkeys, as evidenced by self-administration patterns that produce continuous intoxication. Humans tend to use PCP intermittently, but a small fraction may use it daily. Tolerance to the behavioral effects of PCP develops in animals, but this has not been studied systematically in humans. Signs of a PCP withdrawal syndrome have been observed in monkeys after interruption of daily access to the drug, and include somnolence, tremor, seizures, diarrhea, piloerection, bruxism, and vocalizations.

**Pharmacological Intervention.** Overdose must be treated by life support because there is no antagonist of PCP effects and no proven way to enhance excretion, although acidification of the urine has been proposed. PCP coma may last 7-10 days. The agitated or psychotic state produced by PCP can be treated with diazepam. Prolonged psychotic behavior requires antipsychotic medication. Because of the anticholinergic activity of PCP, antipsychotic agents with significant anticholinergic effects such as chlorpromazine should be avoided.

**Inhalants**

Abused inhalants consist of many different categories of chemicals that are volatile at room temperature and produce abrupt changes in mental state when inhaled. Examples include toluene (from model airplane glue), kerosene, gasoline, carbon tetrachloride, amyl nitrite, and nitrous oxide. There are characteristic patterns of response for each substance. Solvents such as toluene typically are used by children. The material usually is placed in a plastic bag and the vapors inhaled. After several minutes of inhalation, dizziness and intoxication occur. Aerosol sprays containing fluorocarbon propellants are another source of solvent intoxication. Prolonged exposure or daily use may result in damage to several organ systems. Clinical problems include cardiac arrhythmias, bone marrow depression, cerebral degeneration, and damage to liver, kidney, and peripheral nerves. Death occasionally has been attributed to inhalant abuse, probably from cardiac arrhythmias, especially accompanying exercise or upper airway obstruction.

Amyl nitrite produces dilation of smooth muscle, has been used in the past for the treatment of angina, and continues to be available by prescription as a component of cyanide antidote kits and for certain diagnostic procedures. It is a yellow, volatile, flammable liquid with a fruity odor. In recent years, amyl nitrite and butyl nitrite have been used to relax smooth muscle and enhance orgasm, particularly by male homosexuals. These agents are commercially available as room deodorizers and can produce a feeling of “rush,” flushing, and dizziness. Adverse effects include palpitations, postural hypotension, and headache progressing to loss of consciousness.

Anesthetic gases such as nitrous oxide and halothane sometimes are used as intoxicants by medical personnel. Nitrous oxide also is abused by food-service employees because it is supplied for use as a propellant in disposable aluminum mini tanks for whipping cream canisters. Nitrous oxide produces euphoria and analgesia and then loss of consciousness. Compulsive use and chronic toxicity are reported rarely, but there are obvious risks of overdose (coma) and chronic use (neuropathy) associated with the abuse of this anesthetic.

**CLINICAL SUMMARY**

The management of drug abuse and addiction must be individualized according to the drugs involved and the associated psychosocial problems of the individual patient. An understanding of the pharmacology of the drug or combination of drugs ingested by the patient is essential to rational and effective treatment. This may be a matter of urgency for the treatment of overdose or for the detoxification of a patient who is experiencing withdrawal symptoms. It must be recognized, however, that the treatment of the underlying addictive disorder requires months or years of rehabilitation. The behavior patterns encoded in memory during thousands of prior drug ingestions do not disappear with detoxification from the drug, even after a typical 28-day inpatient rehabilitation program. Long periods of outpatient...
treatment are necessary. There probably will be periods of relapse and remission. While complete abstinence is the preferred goal, in reality, most patients are at risk to resume drug-seeking behavior and require one or more periods of retreatment. Maintenance medication can be effective in some circumstances, such as methadone, buprenorphine, or naltrexone for opioid dependence, and disulfiram, naltrexone, or acamprosate for alcoholism. The process can best be compared to the treatment of other chronic disorders such as diabetes, asthma, or hypertension. Long-term medication may be necessary, and cures are not likely. When viewed in the context of chronic disease, the available treatments for addiction are quite successful in that the majority of patients improve, but improvement does not necessarily persist after treatment has ceased (McLellan et al., 2000; O'Brien, 1994).

Long-term treatment is accompanied by improvements in physical status as well as in mental, social, and occupational function. Unfortunately, there is general pessimism in the medical community about the benefits of treatment such that most of the therapeutic effort is directed at the complications of addiction, such as pulmonary, cardiac, and hepatic disorders. Prevention of these complications can be accomplished by addressing the underlying addictive disorder.

What engineer, wishing to regulate the composition of the internal environment of the body on which the function of every bone, gland, muscle, and nerve depends, would devise a scheme that operated by throwing the whole thing out 16 times a day and rely on grabbing from it, as it fell to earth, only those precious elements which he wanted to keep?

Homer Smith, From Fish to Philosopher

As the philosophizing physiologist, Homer Smith, noted, the kidney filters the extra cellular fluid volume across the renal glomeruli an average of 16 times a day, and the renal nephrons precisely regulate the fluid volume of the body and its electrolyte content via processes of secretion and reabsorption. Disease states such as hypertension, heart failure, renal failure, nephrotic syndrome, and cirrhosis may disrupt this balance. Diuretics increase the rate of urine flow and Na+ excretion and are used to adjust the volume and/or composition of body fluids in these disorders. Precise regulation of body fluid osmolality is also essential. It is controlled by a finely tuned homeostatic mechanism that operates by adjusting both the rate of water intake and the rate of solute-free water excretion by the kidneys—that is, water balance. Abnormalities in this homeostatic system can result from genetic diseases, acquired diseases, or drugs and may cause serious and potentially life-threatening deviations in plasma osmolality.

This chapter first describes renal anatomy and physiology, then introduces diuretics with regard to chemistry, mechanism of action, site of action, effects on urinary composition, and effects on renal hemodynamics, and finally, integrates diuretic pharmacology with a discussion of mechanisms of edema formation and the role of diuretics in clinical medicine. Specific therapeutic applications of diuretics are presented in Chapters 27 (hypertension) and 28 (heart failure).

The second half of this chapter describes the physiological mechanisms that regulate plasma osmolality and factors that perturb those mechanisms, and examines pharmacological approaches for treating disorders of water balance.

**RENALError message: 'll ANATOMY AND PHYSIOLOGY**

The basic urine-forming unit of the kidney is the nephron, which consists of a filtering apparatus, the glomerulus, connected to a long tubular portion that reabsorbs and conditions the glomerular ultrafiltrate. Each human kidney is composed of ~1 million nephrons. The nomenclature for segments of the tubular portion of the nephron has become increasingly complex as renal physiologists have subdivided the nephron into shorter and shorter named segments. These subdivisions were based initially on the axial location of the segments but increasingly have been based on the morphology of the epithelial cells lining the various nephron segments. Figure 25–1 illustrates subdivisions of the nephron.

**Glomerular Filtration.** In the glomerular capillaries, a portion of plasma water is forced through a filter that has three basic components: the fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slit diaphragms formed by epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into the urinary (Bowman’s) space, whereas formed elements and macromolecules are retained by the filtration barrier. For each nephron unit, the rate of filtration (single-nephron glomerular filtration rate [SNGFR]) is a function of the hydrostatic pressure in the glomerular capillaries (\(P_{GC}\)), the hydrostatic pressure in Bowman’s space (which can be equated with pressure in the proximal tubule, \(P_T\)), the mean colloid osmotic pressure in the glomerular capillaries (\(\Pi_{GC}\)), the colloid osmotic pressure in the proximal tubule (\(\Pi_T\)), and the ultra-filtration coefficient (\(K_f\)), according to the equation

\[
SNGFR = K_f [(P_{GC} - P_T) - (\Pi_{GC} - \Pi_T)]
\]  

(25-1)

If \(P_{GC} - P_T\) is defined as the transcapillary hydraulic pressure difference (\(\Delta P\)), and if \(\Pi_T\) is negligible (as it usually is because little protein is filtered), then

\[
SNGFR = K_f (\Delta P - \Pi_{GC})
\]  

(25-2)
Figure 25–1. Anatomy and nomenclature of the nephron.
Overview of Nephron Function. The kidney is designed to filter large quantities of plasma, reabsorb substances that the body must conserve, and leave behind and/or secrete substances that must be eliminated. The two kidneys in humans produce together ~120 mL of ultrafiltrate per minute, yet only 1 mL/min of urine is produced. Therefore, >99% of the glomerular ultrafiltrate is reabsorbed at a staggering energy cost. The kidneys consume 7% of total-body oxygen intake despite the fact that the kidneys make up only 0.5% of body weight.

The proximal tubule is contiguous with Bowman’s capsule and takes a tortuous path until finally forming a straight portion that diverges into the renal medulla. Based on the morphology of the epithelial cells lining the tubule, the proximal tubule has been subdivided into S1, S2, and S3 segments. Normally, ~65% of filtered Na+ is reabsorbed in the proximal tubule, and since this part of the tubule is highly permeable to water, reabsorption is essentially isotonic.

Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the descending thin limb (DTL), which penetrates the inner medulla, makes a hairpin turn, and then forms the ascending thin limb (ATL). At the juncture between the inner and outer medulla, the tubule once again changes morphology and becomes the thick ascending limb, which is made up of three segments: a medullary portion (MTAL), a cortical portion (CTAL), and a postmacular segment. Together the proximal straight tubule, DTL, ATL, MTAL, CTAL, and postmacular segment are known as the loop of Henle. The DTL is highly permeable to water, yet its permeability to NaCl and urea is low. In contrast, the ATL is permeable to NaCl and urea but is impermeable to water. The thick ascending limb actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na+ is reabsorbed in the loop of Henle, mostly in the thick ascending limb, which has a large reabsorptive capacity.

The thick ascending limb passes between the afferent and efferent arterioles and makes contact with the afferent arteriole by means of a cluster of specialized columnar epithelial cells known as the macula densa. The macula densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too high, the macula densa sends a chemical signal (perhaps adenosine or ATP) to the afferent arteriole of the same nephron, causing it to constrict. This, in turn, causes a reduction in \( P_{GC} \) and \( Q_A \) and decreases SNGFR. This homeostatic mechanism, known as tubuloglomerular feedback (TGF), serves to protect the organism from salt and volume wasting. Besides mediating the TGF response, the macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule changes morphology once again to become the distal convoluted tubule (DCT). The postmacular segment of the thick ascending limb and the distal convoluted tubule often are referred to as the early distal tubule. Like the thick ascending limb, the DCT actively transports NaCl and is impermeable to water. Since these characteristics impart the ability to produce a dilute urine, the thick ascending limb and the DCT are collectively called the diluting segment of the nephron, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the thick ascending limb, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (described later in this section). There are marked species differences in transporter expression in the DCT. The DCT has been subdivided into DCT1 and DCT2. DCT1 expresses the thiazide-sensitive NaCl co-transporter but does not express genes involved in transepithelial Ca2+ transport such as the Ca2+ entry channel, TRPV5, and the Na+/Ca2+ exchanger. DCT2 expresses Ca2+ transport proteins and amiloride-sensitive epithelial Na+ channels.

The collecting duct system (connecting tubule + initial collecting tubule + cortical collecting duct + outer and inner medullary collecting ducts—segments 10–14 in Figure 25–1) is an area of fine control of ultrafiltrate composition and volume. It is here that final adjustments in electrolyte composition are made, a process modulated by the adrenal steroid aldosterone. In addition, antidiuretic hormone modulates permeability of this part of the nephron to water.

The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of ADH, the collecting duct system is impermeable to water, and a dilute urine is excreted. In the presence of ADH, the collecting duct system is permeable to water, so water is reabsorbed. The movement of water out of the tubule is driven by the steep concentration gradient that exists between tubular fluid and medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the ability of mammals and birds to concentrate urine, and therefore is a key adaptation necessary for living in a terrestrial environment. This is accomplished by a combination of the unique topography of the loop of Henle and the specialized permeability features of the loop’s subsegments. Although the precise mechanisms giving rise to the medullary hypertonicity have remained elusive, the “passive countercurrent multiplier hypothesis” is an intuitively attractive model that is qualitatively accurate. According to this hypothesis, the process begins with active transport in the thick ascending limb, which concentrates NaCl in the interstitium of the outer medulla. Since this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting-duct system, water is extracted if, and only if, ADH is present. Since the cortical and outer medullary collecting ducts have a low permeability to urea, urea is concentrated in the tubular fluid. The inner medullary collecting duct, however, is permeable to urea, so urea diffuses into the...
inner medulla, where it is trapped by countercurrent exchange in the vasa recta. Since the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, thus contributing to the hypertonicity of the medullary interstitium.

**General Mechanism of Renal Epithelial Transport.** Figure 25–2 illustrates seven mechanisms by which solutes may cross renal epithelial cell membranes (see also Figure 5–4). If bulk water flow occurs across a membrane, solute molecules will be transferred by convection across the membrane, a process known as **solvent drag**. Solute with sufficient lipid solubility also may diffuse in the membrane and diffuse across the membrane down their electrochemical gradients (simple diffusion). Many solutes, however, have limited lipid solubility, and transport must rely on integral proteins embedded in the cell membrane. In some cases the integral protein merely provides a conductive pathway (pore) through which the solute may diffuse passively (**channel-mediated diffusion**). In other cases the solute may bind to the integral protein and, owing to a conformational change in the protein, be transferred across the cell membrane down an electrochemical gradient (**carrier-mediated (facilitated) diffusion** or **uniport**). However, this process will not result in net movement of solute against an electrochemical gradient. If solute must be moved “uphill” against an electrochemical gradient, then either primary active transport or secondary active transport is required. With primary active transport, ATP hydrolysis is coupled directly to conformational changes in the integral protein, thus providing the necessary free energy (**ATP-mediated transport**). Often, ATP-mediated transport is used to create an electrochemical gradient for a given solute, and the free energy of that solute gradient is then released to drive the “uphill” transport of other solutes. This process requires **symport** (co-transport of solute species in the same direction) or **antiport** (countertransport of solute species in opposite directions) and is known as **secondary active transport**.

The kinds of transport achieved in a particular nephron segment depend mainly on which transporters are present and whether they are embedded in the luminal or basolateral membrane. A general model of renal tubular transport is shown in Figure 25–3 and can be summarized as follows:

1. Na⁺, K⁺-ATPase (sodium pump) in the basolateral membrane hydrolyzes ATP, which results in the transport of Na⁺ into the intercellular and interstitial spaces, the movement of K⁺ into the cell, and the establishment and maintenance of an electrochemical gradient for Na⁺ across the cell membrane directed inward. Although other ATPases exist in selected renal epithelial cells and participate in the transport of specific solutes (e.g., Ca²⁺-ATPase and H⁺-ATPase), the bulk of all transport in the kidney is due to the abundant supply of Na⁺, K⁺-ATPase in the basolateral membranes of renal epithelial cells and the separation of Na⁺ and K⁺ across the cell membrane.

2. Na⁺ may diffuse across the luminal membrane by means of Na⁺ channels into the epithelial cell down the electrochemical gradient for Na⁺ that is established by the basolateral Na⁺, K⁺-ATPase. In addition, free energy available in the electrochemical gradient for Na⁺ is tapped by integral proteins in the luminal membrane, resulting in co-transport of various solutes against their electrochemical gradients by symporters (e.g., Na⁺-glucose, Na⁺-H₂PO₄⁻, and Na⁺-amino acid). This process results in movement of Na⁺ and co-transported solutes out of the tubular lumen into the cell. Also, antiporters (e.g., Na⁺-H⁺) move Na⁺ out of and some solutes into the tubular lumen.

3. Na⁺ exits the basolateral membrane into the intercellular and interstitial spaces by means of the Na⁺ pump or symporters or antiporters in the basolateral membrane.

4. The action of Na⁺-linked symporters in the luminal membrane causes the concentration of substrates for these symporters to rise in the epithelial cell. These electrochemical gradients then permit simple diffusion or mediated transport (e.g., symporters,
antiporters, uniporters, and channels) of solutes into the intercellular and interstitial spaces.

5. Accumulation of $\text{Na}^+$ and other solutes in the intercellular space creates a small osmotic pressure differential across the epithelial cell. In water-permeable epithelium, water moves into the intercellular spaces driven by the osmotic pressure differential. Water moves through aqueous pores in both the luminal and the basolateral cell membranes, as well as through tight junctions (paracellular pathway). Bulk water flow carries some solutes into the intercellular space by solvent drag.

6. Movement of water into the intercellular space concentrates other solutes in the tubular fluid, resulting in an electrochemical gradient for these substances across the epithelium. Membrane-permeable solutes then move down their electrochemical gradients into the intercellular space by both the transcellular (e.g., simple diffusion, symporters, antiporters, uniporters, and channels) and paracellular pathways. Membrane-impermeable solutes remain in the tubular lumen and are excreted in the urine with an obligatory amount of water.

Figure 25–3. Generic mechanism of renal epithelial cell transport (see text for details). $S$, symporter; $A$, antiporter; $CH$, ion channel; WP, water pore; $U$, uniporter; ATPase, $\text{Na}^+,\text{K}^+$-ATPase (sodium pump); $X$ and $Y$, transported solutes; $P$, membrane-permeable (reabsorbable) solutes; $I$, membrane-impermeable (nonreabsorbable) solutes; PD, potential difference across indicated membrane or cell.
7. As water and solutes accumulate in the intercellular space, hydrostatic pressure increases, thus providing a driving force for bulk water flow. Bulk water flow carries solute (solute convection) out of the intercellular space into the interstitial space and, finally, into the peritubular capillaries. The movement of fluid into peritubular capillaries is governed by the same Starling forces that determine transcapillary fluid movement for any capillary bed.

**Mechanism of Organic Acid and Organic Base Secretion.** The kidney is a major organ involved in the elimination of organic chemicals from the body. Organic molecules may enter the renal tubules by glomerular filtration of molecules not bound to plasma proteins or may be actively secreted directly into tubules. The proximal tubule has a highly efficient transport system for organic acids and an equally efficient but separate transport system for organic bases. Current models for these secretory systems are illustrated in Figure 25–4. Both systems are powered by the sodium pump in the basolateral membrane, involve secondary and tertiary active transport, and use a facilitated-diffusion step. There are at least nine different organic acid and five different organic base transporters; the precise roles that these transporters play in organic acid and base transport remain ill defined (Dresser et al., 2001). A family of organic anion transporters (OATs) countertransport organic anions with dicarboxylates (Figure 25–4A). OATs most likely exist as α-helical dodecaspans connected by short segments of ~10 or fewer amino acids, except for large interconnecting stretches of amino acids between helices 1 and 2 and helices 6 and 7 (Eraly et al., 2004); see Chapter 5.

**Renal Handling of Specific Anions and Cations.** Reabsorption of Cl− generally follows reabsorption of Na+. In segments of the tubule with low-resistance tight junctions (i.e., “leaky” epithelium), such as the proximal tubule and thick ascending limb, Cl− movement can occur paracellularly. With regard to transcellular Cl− flux, Cl− crosses the luminal membrane by antiport with formate and oxalate (proximal tubule), symport with Na+/K+ (thick ascending limb), symport with Na+ (DCT), and antiport with HCO3− (collecting-duct system). Cl− crosses the basolateral membrane by symport with K+ (proximal tubule and thick ascending limb), antiport with Na+/HCO3− (proximal tubule), and Cl− channels (thick ascending limb, DCT, collecting-duct system).

Eighty to ninety percent of filtered K+ is reabsorbed in the proximal tubule (diffusion and solvent drag) and thick ascending limb (diffusion) largely through the paracellular pathway. In contrast, the DCT and collecting-duct system secrete variable amounts of K+ by a conductive (channel-mediated) pathway. Modulation of the rate of K+ secretion in the collecting-duct system, particularly by aldosterone, allows urinary K+ excretion to be matched with dietary intake. The transepithelial potential difference (VT), lumen-positive in the thick ascending limb and lumen-negative in the collecting-duct system, provides an important driving force for K+ reabsorption and secretion, respectively.

Most of the filtered Ca2+ (~70%) is reabsorbed by the proximal tubule by passive diffusion through a paracellular route. Another 25% of filtered Ca2+ is reabsorbed by the thick ascending limb in part by a paracellular route driven by the lumen-positive VT and in part by active transcellular Ca2+ reabsorption modulated by parathyroid hormone (PTH; see Chapter 44). Most of the remaining Ca2+ is reabsorbed in DCT by a transcellular pathway. The transcellular pathway in the thick ascending limb and DCT involves passive Ca2+ influx across the luminal membrane through Ca2+ channels (TRPV5), followed by Ca2+ extrusion across the basolateral membrane by a Ca2+-ATPase. Also, in DCT and CNT, Ca2+ crosses the basolateral membrane by Na+-Ca2+ exchanger (antiport).

Inorganic phosphate (P) is largely reabsorbed (80% of filtered load) by the proximal tubule. The Na+-P_2 symmetric transporter uses the free energy of the Na+ electrochemical gradient to transport P_2 into
the cell. The Na⁺-P₂ symporter is inhibited by PTH. P₂ exits the basolateral membrane down its electrochemical gradient by a poorly understood transport system.

Only 20-25% of Mg²⁺ is reabsorbed in the proximal tubule, and only 5% is reabsorbed by the DCT and collecting-duct system. The bulk of Mg²⁺ is reabsorbed in the thick ascending limb by a paracellular pathway driven by the lumen-positive Vₜ. However, transcellular movement of Mg²⁺ also may occur with basolateral exit by Na⁺-Mg²⁺ antiport or an Mg²⁺-ATPase.

The renal tubules play an extremely important role in the reabsorption of HCO₃⁻ and secretion of protons (tubular acidification) and thus participate critically in the maintenance of acid-base balance. These processes are described in the section on carbonic anhydrase inhibitors.

**PRINCIPLES OF DIURETIC ACTION**

By definition, diuretics are drugs that increase the rate of urine flow; however, clinically useful diuretics also increase the rate of Na⁺ excretion (natriuresis) and of an accompanying anion, usually Cl⁻. NaCl in the body is the major determinant of extracellular fluid volume, and most clinical applications of diuretics are directed toward reducing extracellular fluid volume by decreasing total-body NaCl content. A sustained imbalance between dietary Na⁺ intake and Na⁺ loss is incompatible with life. A net positive Na⁺ balance would result in volume overload with pulmonary edema, and a net negative Na⁺ balance would result in volume depletion and cardiovascular collapse. Although continued diuretic administration causes a sustained net deficit in total-body Na⁺, the time course of natriuresis is finite because renal compensatory mechanisms bring Na⁺ excretion in line with Na⁺ intake, a phenomenon known as diuretic braking. These compensatory, or braking, mechanisms include activation of the sympathetic nervous system, activation of the rennin–angiotensin–aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), renal epithelial cell hypertrophy, increased renal epithelial transporter expression, and perhaps alterations in natriuretic hormones such as atrial natriuretic peptide (Ellison, 1999). This is shown in Figure 25–5.

Historically, the classification of diuretics was based on a mosaic of ideas such as site of action (loop diuretics), efficacy (high-ceiling diuretics), chemical structure (thiazide diuretics), similarity of action with other diuretics (thiazide-like diuretics), and effects on K⁺ excretion (K⁺-sparing diuretics). However, since the mechanism of action of each of the major classes of diuretics is now well understood, a classification scheme based on mechanism of action is used in this chapter.

Diuretics not only alter the excretion of Na⁺ but also may modify renal handling of other cations (e.g., K⁺, H⁺, Ca²⁺, and Mg²⁺), anions (e.g., Cl⁻, HCO₃⁻, and H₂PO₄⁻), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 25–1 gives a comparison of the general effects of the major diuretic classes.

**INHIBITORS OF CARBONIC ANHYDRASE**

Acetazolamide (DIAMOX, others) is the prototype of a class of agents that have limited usefulness as diuretics but have played a major role in the development of fundamental concepts of renal physiology and pharmacology.
When sulfanilamide was introduced as a chemotherapeutic agent, metabolic acidosis was recognized as a side effect. This observation led to the demonstration that sulfanilamide is an inhibitor of carbonic anhydrase. Subsequently, an enormous number of sulfonamides were synthesized and tested for their ability to inhibit carbonic anhydrase; of these compounds, acetazolamide has been studied most extensively. There are three orally administered carbonic anhydrase inhibitors—acetazolamide, dichlorphenamide (not marketed in the U.S.), and methazolamide. The common molecular motif of available carbonic anhydrase inhibitors is an unsubstituted sulfonamide moiety (Table 25–2).

**Mechanism and Site of Action.** Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic anhydrase, an enzyme tethered to the membrane by a glycosylphosphatidylnositol linkage), as well as in the cytoplasm (type II carbonic anhydrase). Carbonic anhydrase plays a key role in NaHCO₃ reabsorption and acid secretion.

In the proximal tubule, the free energy in the Na⁺ gradient established by the basolateral Na⁺ pump is used by an Na⁺-H⁺ antiporter (also referred to as an Na⁺-H⁺ exchanger [NHE]) in the luminal membrane to transport H⁺ into the tubular lumen in exchange for Na⁺ (Figure 25–6). In the lumen, H⁺ reacts with filtered HCO₃⁻ to form H₂CO₃, which decomposes rapidly to CO₂ and water in the presence of carbonic anhydrase in the brush border. Normally, the reaction occurs slowly, but carbonic anhydrase reversibly accelerates this reaction several thousand times. CO₂ is lipophilic and rapidly diffuses across the luminal membrane into the
epithelial cell, where it reacts with water to form $H_2CO_3$, a reaction catalyzed by cytoplasmic carbonic anhydrase (Figure 25–6). Continued operation of the Na$^+$-H$^+$ antiporter maintains a low proton concentration in the cell, so $H_2CO_3$ ionizes spontaneously to form $H^+$ and $HCO_3^-$, creating an electrochemical gradient for $HCO_3^-$ across the basolateral membrane. The electrochemical gradient for $HCO_3^-$ is used by an Na$^+$-$HCO_3^-$ symporter (also referred to as the Na$^+$-$HCO_3^-$ co-transporter [NBC]) in the basolateral membrane to transport NaHCO$_3$ into the interstitial space. The net effect of this process is transport of NaHCO$_3$ from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl$^-$ in the tubular lumen, and consequently, Cl$^-$ diffuses down its concentration gradient into the interstitium by the paracellular pathway.

Carbonic anhydrase inhibitors potently inhibit (IC$_{50}$ for acetazolamide is 10 nM) both the membrane-bound and cytoplasmic forms of carbonic anhydrase, resulting in nearly complete abolition of NaHCO$_3$ reabsorption in the proximal tubule. Studies with a high-molecular-weight carbonic anhydrase inhibitor that inhibits only luminal enzyme because of limited cellular permeability indicate that inhibition of both membrane-bound and cytoplasmic pools of carbonic anhydrase contributes to the diuretic activity of carbonic anhydrase inhibitors. Because of the large excess of carbonic anhydrase in proximal tubules, a high percentage of enzyme activity must be inhibited before an effect on electrolyte excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase also is involved in secretion of titratable acid in the collecting duct system (a process that involves a proton pump); therefore, the collecting duct system is a secondary site of action for this class of drugs.

**Effects on Urinary Excretion.** Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO$_3^-$ excretion to ~35% of filtered load. This, along with inhibition of titratable acid and NH$_4^+$ secretion in the collecting-duct system, results in an increase in urinary pH to ~8 and development of a metabolic acidosis.

![Figure 25–6. NaHCO$_3$ reabsorption in proximal tubule and mechanism of diuretic action of carbonic anhydrase inhibitors.](image-url)
However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO$_3^-$ is rescued from excretion by poorly understood mechanisms that may involve carbonic anhydrase-independent HCO$_3^-$ reabsorption at downstream sites. Inhibition of the transport mechanism described in the preceding section results in increased delivery of Na$^+$ and Cl$^-$ to the loop of Henle, which has a large reabsorptive capacity and captures most of the Cl$^-$ and a portion of the Na$^+$. Thus only a small increase in Cl$^-$ excretion occurs, HCO$_3^-$ being the major anion excreted along with the cations Na$^+$ and K$^+$. The fractional excretion of Na$^+$ may be as much as 5%, and the fractional excretion of K$^+$ can be as much as 70%. The increased excretion of K$^+$ is in part secondary to increased delivery of Na$^+$ to the distal nephron. The mechanism by which increased distal Na$^+$ delivery enhances K$^+$ excretion is described in the section on inhibitors of Na$^+$ channels.

Other mechanisms contributing to enhanced K$^+$ excretion include flow-dependent enhancement of K$^+$ secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin-angiotensin-aldosterone system. Carbonic anhydrase inhibitors increase phosphate excretion (mechanism unknown) but have little or no effect on Ca$^{2+}$ or Mg$^{2+}$ excretion. The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting, probably because the resulting metabolic acidosis decreases the filtered load of HCO$_3^-$ to the point that the uncatalyzed reaction between CO$_2$ and water is sufficient to achieve HCO$_3^-$ reabsorption. Studies in rabbits show that the K$_t$ for luminal carbonic anhydrase inhibition in outer medulla is increased >100-fold over the concentration required in control tubules. These results suggest that acidosis induces a conformational change in the protein making it less sensitive to inhibition by acetazolamide (Tsuroka, 1998).

**Effects on Renal Hemodynamics.** By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase delivery of solutes to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces renal blood flow (RBF) and glomerular filtration rate (GFR).

**Other Actions.** Carbonic anhydrase is present in a number of extrarenal tissues, including the eye, gastric mucosa, pancreas, central nervous system (CNS), and erythrocytes. Carbonic anhydrase in the ciliary processes of the eye mediates formation of large amounts of HCO$_3^-$ in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous humor and consequently reduces intraocular pressure. Acetazolamide frequently causes paresthesias and somnolence, suggesting an action of carbonic anhydrase inhibitors in the CNS. The efficacy of acetazolamide in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of acetazolamide in the CNS also contribute to its anticonvulsant action. Owing to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO$_2$ levels in peripheral tissues and decrease CO$_2$ levels in expired gas. Large doses of carbonic anhydrase inhibitors reduce gastric acid secretion, but this has no therapeutic application. Acetazolamide causes vasodilation by opening vascular Ca$^{2+}$-activated K$^+$ channels; however, the clinical significance of this effect is unclear.

**Absorption and Elimination.** Carbonic anhydrase inhibitors are avidly bound by carbonic anhydrase, and accordingly, tissues rich in this enzyme will have higher concentrations of carbonic anhydrase inhibitors following systemic administration. See Table 25–2 for structures and pharmacokinetic data.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions.** Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamide-like renal lesions, and allergic reactions in patients hypersensitive to sulfonamides. With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalinization or metabolic acidosis, including:

- diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis)
- calculus formation and ureteral colic owing to precipitation of calcium phosphate salts in an alkaline urine
- worsening of metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease)
- reduction of the urinary excretion rate of weak organic bases

**Therapeutic Uses.** Although acetazolamide is used for treatment of edema, the efficacy of carbonic anhydrase inhibitors as single agents is low, and carbonic anhydrase inhibitors are not employed widely in this regard. The combination of acetazolamide with diuretics that block Na$^+$ reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na$^+$ (<0.2%) who are resistant to diuretic monotherapy (Knauf and Mutschler, 1997). Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis.

The major indication for carbonic anhydrase inhibitors is open-angle glaucoma. Two products developed specifically for this use are dorzolamide (TRUSOPT, others) and brinzolamide (AZOPT), which are available only as ophthalmic drops. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute angle-closure glaucoma to lower intraocular pressure before surgery (Chapter 64). Acetazolamide also is used for the treatment of epilepsy (Chapter 21). The rapid development of tolerance, however, may limit the usefulness of carbonic anhydrase inhibitors for epilepsy.
Acetazolamide can provide symptomatic relief in patients with high-altitude illness or mountain sickness; however, it is more appropriate to give acetazolamide as a prophylactic measure. Acetazolamide also is useful in patients with familial periodic paralysis. The mechanism for the beneficial effects of acetazolamide in altitude sickness and familial periodic paralysis is not clear, but it may be related to the induction of a metabolic acidosis. Other off-label clinical uses include the treatment of dural ectasia in individuals with Marfan syndrome, of sleep apnea, and of idiopathic intracranial hypertension. Finally, carbonic anhydrase inhibitors can be useful for correcting a metabolic alkalosis, especially one caused by diuretic-induced increases in \(H^+\) excretion.

### Osmotic Diuretics

Osmotic diuretics are agents that are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert pharmacologically. Osmotic diuretics are administered in doses large enough to increase significantly the osmolality of plasma and tubular fluid. Table 25–3 lists four osmotic diuretics—glycerin (OSMOGLYN), isosorbide, mannitol (OSMITROL, others), and urea (currently not available in the U.S.).

**Mechanism and Site of Action.** For many years it was thought that osmotic diuretics act primarily in the proximal tubule as nonreabsorbable solutes that limit the osmosis of water into the interstitial space and thereby reduce luminal Na\(^+\) concentration to the point that net Na\(^+\) reabsorption ceases. Although early micropuncture studies supported this concept, subsequent studies suggested that this mechanism, while operative, may be of only secondary importance and that the major site of action of osmotic diuretics is the loop of Henle.

By extracting water from intracellular compartments, osmotic diuretics expand extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes NaCl and urea from the renal medulla, thus reducing medullary toxicity. Under some circumstances, prostaglandins may contribute to the renal vasodilation and medullary washout induced by osmotic diuretics. A reduction in medullary toxicity causes a decrease in the extraction of water from the DTL, which in turn limits the concentration of NaCl in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of NaCl in the ATL. In addition, the marked ability of osmotic diuretics to inhibit Mg\(^{2+}\) reabsorption, a cation that is reabsorbed mainly in the thick ascending limb, suggests that osmotic diuretics also interfere with transport processes in the thick ascending limb. The mechanism of this effect is unknown.

In summary, osmotic diuretics act both in proximal tubule and loop of Henle, with the latter being the primary site of action. Also, osmotic diuretics probably act by an osmotic effect in the tubules and by reducing medullary toxicity.

Effects on Urinary Excretion. Osmotic diuretics increase urinary excretion of nearly all electrolytes, including Na⁺, K⁺, Ca²⁺, Mg²⁺, Cl⁻, HCO₃⁻, and phosphate.

Effects on Renal Hemodynamics. Osmotic diuretics increase RBF by a variety of mechanisms. Osmotic diuretics dilate the afferent arteriole, which increases \( P_{GC} \) and dilute the plasma, which decreases \( \Pi_{GC} \). These effects would increase GFR were it not for the fact that osmotic diuretics also increase \( P_r \). In general, superficial SNGFR is increased, but total GFR is little changed.

Absorption and Elimination. Pharmacokinetic data on the osmotic diuretics are listed in Table 25–3. Glycerin and isosorbide can be given orally, whereas mannitol and urea must be administered intravenously.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions. Osmotic diuretics are distributed in the extracellular fluid and contribute to the extracellular osmolality. Thus, water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hyponatremia, which may explain the common adverse effects, including headache, nausea, and vomiting. On the other hand, loss of water in excess of electrolytes can cause hypernatremia and dehydration. Osmotic diuretics are contraindicated in patients who are anuric owing to severe renal disease. Urea may cause thrombosis or pain if extravasation occurs, and it should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both mannitol and urea are contraindicated in patients with active cranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

Therapeutic Uses. One use for mannitol is in the treatment of dialysis disequilibrium syndrome. Too rapid a removal of solutes from the extracellular fluid by hemodialysis results in a reduction in the osmolality of extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment.

By increasing the osmotic pressure of plasma, osmotic diuretics extract water from the eye and brain. All osmotic diuretics are used to control intraocular pressure during acute attacks of glaucoma and for short-term reductions in intraocular pressure both preoperatively and postoperatively in patients who require ocular surgery. Also, mannitol and urea are used to reduce cerebral edema and brain mass before and after neurosurgery.

### INHIBITORS OF Na⁺-K⁺-2Cl⁻ SYMPORT (LOOP DIURETICS, HIGH-CEILING DIURETICS)

Drugs in this group of diuretics inhibit activity of the Na⁺-K⁺-2Cl⁻ symporter in the thick ascending limb of the loop of Henle; hence these diuretics also are referred to as loop diuretics. Although the proximal tubule reabsorbs ~65% of filtered Na⁺, diuretics acting only in the proximal tubule have limited efficacy because the thick ascending limb has a great reabsorptive capacity and reabsorbs most of the rejectate from the proximal tubule. Diuretics acting predominantly at sites past the thick ascending limb also have limited efficacy because only a small percentage of the filtered Na⁺ load reaches these more distal sites. In contrast, inhibitors of Na⁺-K⁺-2Cl⁻ symport in thick ascending limb are highly efficacious, and for this reason, they sometimes are called high-ceiling diuretics. The efficacy of inhibitors of Na⁺-K⁺-2Cl⁻ symport in the thick ascending limb of the loop of Henle is due to a combination of two factors: (1) approximately 25% of the filtered Na⁺ load normally is reabsorbed by the thick ascending limb, and (2) nephron segments past the thick ascending limb do not possess the reabsorptive capacity to rescue the flood of rejectate exiting the thick ascending limb.

Chemistry. Inhibitors of Na⁺-K⁺-2Cl⁻ symport are a chemically diverse group (Table 25–4). Only furosemide (Lasix, others), bumetanide (Bumex, others), ethacrynic acid (Edecrin, others), and torsemide (Demadex, others) are available currently in the U.S. Furosemide and bumetanide contain a sulfonamide moiety. Ethacrynic acid is a phe-noxyacetic acid derivative and torsemide is a sulfonlurea.

Mechanism and Site of Action. Inhibitors of Na⁺-K⁺-2Cl⁻ symport act primarily in the thick ascending limb. Micropuncture of the DCT demonstrates that loop diuretics increase delivery of solutes out of the loop of Henle. Also, in vitro microperfusion of the loop of Henle and in situ microperfusion of CTAL indicate inhibition of transport by low concentrations of furosemide in the perfusate. Some inhibitors of Na⁺-K⁺-2Cl⁻ symport may have additional effects in the proximal tubule; however, the significance of these effects is unclear.

It was thought initially that Cl⁻ was transported by a primary active electrogenic transporter in the luminal membrane independent of Na⁺. Discovery of furosemide-sensitive Na⁺-K⁺-2Cl⁻ symport in other tissues prompted a more careful investigation of the Na⁺ dependence of Cl⁻ transport in isolated perfused rabbit CTAL. Scrupulous removal of Na⁺ from the luminal perfusate demonstrated the dependence of Cl⁻ transport on Na⁺.

It is now well accepted that flux of Na⁺, K⁺, and Cl⁻ from the lumen into epithelial cells in thick ascending limb is mediated by an

Na⁺–K⁺–2Cl⁻ symporter (Figure 25–7). This symporter captures free energy in the Na⁺ electrochemical gradient established by the basolateral Na⁺ pump and provides for “uphill” transport of K⁺ and Cl⁻ into the cell. K⁺ channels in the luminal membrane (called ROMK) provide a conductive pathway for the apical recycling of this cation, and basolateral Cl⁻ channels (called CLC-Kb) provide a basolateral exit mechanism for Cl⁻. Luminal membranes of epithelial cells in thick ascending limb have a large conductive pathway (channels) for K⁺; therefore, apical membrane voltage is determined by the equilibrium potential for K⁺ ($E_K$) and is hyperpolarized. In contrast, the basolateral membrane has a large conductive pathway (channels) for Cl⁻, so the basolateral membrane voltage is less negative than $E_K$. 

---

<sup>1</sup>Not available in the United States. <sup>2</sup>For furosemide, metabolism occurs predominantly in the kidney. <sup>3</sup>Abbreviations: R, renal excretion of intact drug; M, metabolism; ID, insufficient data.
THICK ASCENDING LIMB

Figure 25–7. NaCl reabsorption in thick ascending limb and mechanism of diuretic action of Na⁺-K⁺-2Cl⁻ symporter inhibitors. Numbers in parentheses indicate stoichiometry. Designated voltages are the potential differences across the indicated membrane or cell. The mechanisms illustrated here apply to the medullary, cortical, and postmacular segments of the thick ascending limb. S, symporter; CH, ion channel; BL, basolateral membrane; LM, luminal membrane.

that is, conductance for Cl⁻ depolarizes the basolateral membrane. Hyperpolarization of the luminal membrane and depolarization of the basolateral membrane result in a transepithelial potential difference of ~10 mV, with the lumen positive with respect to the interstitial space. This lumen-positive potential difference repels cations (Na⁺, Ca²⁺, and Mg²⁺) and thereby provides an important driving force for the paracellular flux of these cations into the interstitial space.

Inhibitors of Na⁺-K⁺-2Cl⁻ symporter bind to the Na⁺-K⁺-2Cl⁻ symporter in the thick ascending limb and block its function, bringing salt transport in this segment of the nephron to a virtual standstill. The molecular mechanism by which this class of drugs blocks the Na⁺-K⁺-2Cl⁻ symporter is unknown, but evidence suggests that these drugs attach to the Cl⁻ binding site located in the symporter’s transmembrane domain (Isenring and Forbush, 1997). Inhibitors of Na⁺-K⁺-2Cl⁻ symporter also inhibit Ca²⁺ and Mg²⁺ reabsorption in the thick ascending limb by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations.

Na⁺-K⁺-2Cl⁻ symporters are an important family of transport molecules found in many secretory and absorbing epithelia. The rectal gland of the dogfish shark is a particularly rich source of the protein, and a cDNA encoding an Na⁺-K⁺-2Cl⁻ symporter was isolated from a cDNA library obtained from the dogfish shark rectal gland by screening with antibodies to the shark symporter (Xu et al., 1994). Molecular cloning revealed a deduced amino acid sequence of 1191 residues containing 12 putative membrane-spanning domains flanked by long N and C termini in the cytoplasm. Expression of this protein resulted in Na⁺-K⁺-2Cl⁻ symporter that was sensitive to bumetanide. The shark rectal gland Na⁺-K⁺-2Cl⁻ symporter cDNA was used subsequently to screen a human colonic cDNA library, and this provided Na⁺-K⁺-2Cl⁻ symporter cDNA probes from this tissue. These latter probes were used to screen rabbit renal cortical and renal medullary libraries, which allowed cloning of the rabbit renal Na⁺-K⁺-2Cl⁻ symporter (Payne and Forbush, 1994). This symporter is 1099 amino acids in length, is 61% identical to the dogfish shark secretory Na⁺-K⁺-2Cl⁻ symporter, has 12 predicted transmembrane helices, and contains large N- and C-terminal cytoplasmic regions. Subsequent studies demonstrated that Na⁺-K⁺-2Cl⁻ symporters are of two varieties (Kaplan et al., 1996). The “absorptive” symporter (called ENCC2, NKCC2, or BSCI) is expressed only in the kidney, is localized to the apical membrane and subapical intracellular vesicles of the thick ascending limb, and is regulated by cyclic AMP/PKA (Obermüller et al., 1996; Plata et al., 1999). At least six different isoforms of the absorptive symporter are generated by alternative mRNA splicing (Mount et al., 1999), and alternative splicing of the absorptive symporter determines the dependency of transport on K⁺ (Plata et al., 2001). The “secretory” symporter (called ENCC3, NKCC1, or BSC2) is a “housekeeping” protein that is expressed widely and, in epithelial cells, is localized to the basolateral membrane. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (e.g., 4-fold difference for bumetanide). A model of Na⁺-K⁺-2Cl⁻ symporter has been proposed based on ordered binding of ions to the symporter (Lytle et al., 1998). Mutations in genes coding for the absorptive Na⁺-K⁺-2Cl⁻ symporter, the apical K⁺ channel, the basolateral Cl⁻ channel, or the chloride channel subunit Barttin are causes of Bartter syndrome (inherited hypokalemic alkalosis with salt wasting and hypotension) (Simon and Lifton, 1998).

Effects on Urinary Excretion. Owing to blockade of the Na⁺-K⁺-2Cl⁻ symporter, loop diuretics increase urinary Na⁺ and Cl⁻ excretion profoundly (i.e., up to 25% of the filtered Na⁺ load). Abolition of the transepithelial potential difference also results in marked increases in Ca²⁺ and Mg²⁺ excretion. Given in excessive amounts, loop diuretics can lead to dehydration and electrolyte depletion. Some (e.g., furosemide) but not all (e.g., bumetanide) sulfonamide-based loop diuretics have weak carbonic anhydrase–inhibiting activity. Drugs with carbonic anhydrase–inhibiting activity increase urinary excretion of HCO₃⁻ and phosphate. The mechanism by which inhibition of carbonic anhydrase increases phosphate excretion is not known. All inhibitors of Na⁺-K⁺-2Cl⁻ symporter increase urinary K⁺ and titratable acid excretion. This effect is due in part to increased Na⁺ delivery to the distal tubule. The mechanism by which increased distal Na⁺ delivery enhances K⁺ and H⁺ excretion is discussed in the section on Na⁺ channel inhibitors. Other mechanisms contributing to enhanced K⁺ and H⁺ excretion include flow-dependent enhancement of ion secretion by the collecting duct,
nonosmotic vasopressin release, and activation of the rennin–angiotensin–aldosterone axis.

Acutely, loop diuretics increase uric acid excretion, whereas chronic administration of these drugs results in reduced uric acid excretion. Chronic effects of loop diuretics on uric acid excretion may be due to enhanced proximal tubule transport or secondary to volume depletion, leading to increased uric acid reabsorption, or to competition between diuretic and uric acid for the organic acid secretory mechanism in proximal tubule, leading to reduced uric acid secretion. Asymptomatic hyperuricemia is a common consequence of loop diuretics, but painful episodes of gout are rarely reported.

By blocking active NaCl reabsorption in the thick ascending limb, inhibitors of Na⁺-K⁺-2Cl⁻ symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney’s ability to concentrate urine during diuresis. Also, since the thick ascending limb is part of the diluting segment, inhibitors of Na⁺-K⁺-2Cl⁻ symport markedly impair the kidney’s ability to excrete a dilute urine during water diuresis.

**Effects on Renal Hemodynamics.** If volume depletion is prevented by replacing fluid losses, inhibitors of Na⁺-K⁺-2Cl⁻ symport generally increase total RBF and redistribute RBF to the midcortex. However, the effects on RBF are variable. The mechanism of the increase in RBF is not known but may involve prostaglandins. Nonsteroidal anti-inflammatory drugs (NSAIDs) attenuate the diuretic response to loop diuretics in part by preventing prostaglandin-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer can detect NaCl concentrations in the tubular fluid. Therefore, unlike carbonic anhydrase inhibitors, loop diuretics do not decrease GFR by activating TGF. Loop diuretics are powerful stimulators of renin release. This effect is due to interference with NaCl transport by the macula densa and, if volume depletion occurs, to reflex activation of the sympathetic nervous system and stimulation of the intrarenal baroreceptor mechanism. Prostaglandins, particularly prostacyclin, may play an important role in mediating the renin-release response to loop diuretics.

**Other Actions.** Loop diuretics may cause direct vascular effects. Loop diuretics, particularly furosemide, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by prostaglandins and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. Furosemide and ethacrynic acid can inhibit Na⁺,K⁺-ATPase, glycolysis, mitochondrial respiration, the microsomal Ca²⁺ pump, adenylyl cyclase, phosphodiesterase, and prostaglandin dehydrogenase; however, these effects do not have therapeutic implications. In vitro, high doses of inhibitors of Na⁺-K⁺-2Cl⁻ symport can inhibit electrolyte transport in many tissues. Only in the inner ear, where alterations in the electrolyte composition of endolymph may contribute to drug-induced ototoxicity, is this effect important clinically. Irreversible ototoxicity is more common at high doses, with rapid IV administration, and during concomitant therapy with other drugs known to be ototoxic (e.g., aminoglycoside antibiotics, cisplatin, vancomycin).

**Absorption and Elimination.** The oral bioavailabilities, plasma t₁/₂, and routes of elimination of inhibitors of Na⁺-K⁺-2Cl⁻ symport are listed in Table 25–4. Because furosemide, bumetanide, ethacrynic acid, and torsemide are bound extensively to plasma proteins, delivery of these drugs to the tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule, and thereby gain access to their binding sites on the Na⁺-K⁺-2Cl⁻ symport in the luminal membrane of the thick ascending limb. Probenecid shifts the plasma concentration-response curve to furosemide to the right by competitively inhibiting furosemide secretion by the organic acid transport system.

Approximately 65% of furosemide is excreted unchanged in urine, and the remainder is conjugated to glucuronic acid in the kidney. Thus, in patients with renal but not liver disease, the elimination t₁/₂ of furosemide is prolonged. In contrast, bumetanide and torsemide have significant hepatic metabolism, so the elimination t₁/₂ of these loop diuretics are prolonged by liver but not renal disease.

Although average oral availability of furosemide is ~60%, bioavailability varies (10-100%). In contrast, oral availabilities of bumetanide and torsemide are reliably high. Heart failure patients have fewer hospitalizations and better quality of life with torsemide than with furosemide, perhaps because of its more reliable absorption.

As a class, loop diuretics have short elimination t₁/₂, and prolonged-release preparations are not available. Consequently, often the dosing interval is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that torsemide has a longer t₁/₂ than other agents available in the U.S. (Table 25–4). As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na⁺, which often nullifies the overall effect of the loop diuretic on total-body Na⁺. This phenomenon of “postdiuretic Na⁺ retention” can be overcome by restricting dietary Na⁺ intake or by more frequent administration of the loop diuretic (Ellison, 1999). Furosemide, with its short t₁/₂, often produces a poor response when administered only once daily, a common clinical error.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions.** Adverse effects unrelated to diuretic efficacy are rare, and most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can cause serious depletion of total-body Na⁺.

This may manifest as hyponatremia and/or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic episodes, and in patients with liver disease, hepatic encephalopathy. Increased Na⁺ delivery to the distal tubule, particularly when combined with activation of the rennin–angiotensin system, leads to increased urinary K⁺ and H⁺ excretion, causing a hypochloremic alkalosis. If dietary K⁺ intake is not sufficient, hypokalemia may develop, and this may induce
cardiac arrhythmias, particularly in patients taking cardiac glycosides. Increased Mg²⁺ and Ca²⁺ excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Recent evidence suggests that loop diuretics should be avoided in postmenopausal osteopenic women, in whom increased Ca²⁺ excretion may have deleterious effects on bone metabolism (Rejmík et al., 2003).

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually, but not always, reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. Ethacrynic acid appears to induce ototoxicity more often than do other loop diuretics and should be reserved for use only in patients who cannot tolerate other loop diuretics. Loop diuretics also can cause hyperuricemia (occasionally leading to gout) and hyperglycemia (infrequently precipitating diabetes mellitus) and can increase plasma levels of low-density lipoprotein (LDL) cholesterol and triglycerides while decreasing plasma levels of high-density lipoprotein (HDL) cholesterol. Other adverse effects include skin rashes, photosensitivity, paresthesias, bone marrow depression, and GI disturbances. Glucose intolerance frequently can be demonstrated but precipitation of diabetes mellitus has been reported only rarely.

Contraindications to the use of loop diuretics include severe Na⁺ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are co-administered with:
- aminoglycosides, carboplatin, paclitaxel and several other agents (synergism of ototoxicity)
- anticoagulants (increased anticoagulant activity)
- digitalis glycosides (increased digitalis-induced arrhythmias)
- lithium (increased plasma levels of lithium)
- propranolol (increased plasma levels of propranolol)
- sulfonylureas (hyperglycemia)
- cisplatin (increased risk of diuretic-induced ototoxicity)
- NSAIDs (blunted diuretic response and salicylate toxicity when given with high doses of salicylates)
- probenecid (blunted diuretic response)
- thiazide diuretics (synergism of diuretic activity of both drugs leading to profound diuresis)
- amphotericin B (increased potential for nephrotoxicity and toxicity and intensification of electrolyte imbalance)

**Therapeutic Uses.** All loop diuretics except torsemide are available as oral and injectable formulations. Bumetanide is labeled for once daily administration and may be used in patients allergic to furosemide (the bumetanide:furosemide conversion ratio is approximately 1:40). A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with a brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for treatment of chronic congestive heart failure when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (Chapter 28). In this regard, a meta-analysis of randomized clinical trials demonstrates that diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity (Faris et al., 2002).

**Diuretics** are used widely for treatment of hypertension (Chapter 28), and controlled clinical trials demonstrating reduced morbidity and mortality have been conducted with Na⁺-Cl⁻ symport (thiazides and thiazide-like diuretics) but not Na⁺-K⁺-2Cl⁻ symport inhibitors. Nonetheless, Na⁺-K⁺-2Cl⁻ symport inhibitors appear to lower blood pressure as effectively as Na⁺-Cl⁻ symport inhibitors while causing smaller perturbations in the lipid profile. However, the relative potency and short elimination half-lives of loop diuretics render them less useful for hypertension than thiazide-type diuretics.

The edema of nephrotic syndrome often is refractory to less potent diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this renal disease. Loop diuretics also are employed in the treatment of edema and ascites of liver cirrhosis; however, care must be taken not to induce volume contraction. In patients with a drug overdose, loop diuretics can be used to induce a forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney’s capacity to produce a concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the treatment of life-threatening hypotension.

Loop diuretics also are used to treat edema associated with chronic kidney disease. Higher doses of loop diuretics are often required in patients with chronic kidney disease. The dose-response curve is shifted to the right (Figure 25–8). Animal studies have demonstrated that loop diuretics increase $P_{\text{GC}}$ by activating the renin-angiotensin system, an effect that could accelerate renal injury (Lane et al., 1998). Most patients with ARF receive a trial dose of a loop diuretic in an attempt to convert oliguric ARF to nonoliguric ARF. However, there is no evidence that loop diuretics prevent ATN or improve outcome in patients with ARF, and as mentioned earlier, the appearance of undesired effects increases with dose.

**INHIBITORS OF Na⁺-Cl⁻ SYMPORT (THIAZIDE AND THIAZIDE-LIKE DIURETICS)**

Benzothiadiazides were synthesized in an effort to enhance the potency of inhibitors of carbonic anhydrase. However, unlike carbonic anhydrase inhibitors (that primarily increase NaHCO₃ excretion), benzothia diazides predominantly increase NaCl excretion, an effect shown to be independent of carbonic anhydrase inhibition.
against its electrochemical gradient. Cl– then exits the basolateral membrane passively by a Cl– channel. Thiazide diuretics inhibit the Na+-Cl– symporter. In this regard, Na+ or Cl– binding to the Na+-Cl– symporter modifies thiazide-induced inhibition of the symporter, suggesting that the thiazide-binding site is shared or altered by both Na+ and Cl–.

Using a functional expression strategy (Cl–-dependent Na+ uptake in Xenopus oocytes), Gamba and colleagues (1993) isolated a cDNA clone from the urinary bladder of the winter flounder that codes for an Na+-Cl– symporter. This Na+-Cl– symporter is inhibited by a number of thiazide diuretics (but not by furosemide, acetazolamide, or an amiloride derivative) and has 12 putative membrane-spanning domains, and its sequence is 47% identical to the cloned dogfish shark rectal gland Na+-K+-2Cl– symporter. Subsequently, the rat and human Na+-Cl– symporters were cloned. The human Na+-Cl– symporter has a predicted sequence of 1021 amino acids, 12 transmembrane domains, and 2 intracellular hydrophilic amino and carboxyl termini and maps to chromosome 16q13. The Na+-Cl– symporter (called ENCCI or TSC) is expressed predominantly in kidney and is localized to the apical membrane of DCT epithelial cells (Bachmann et al., 1995). Expression of the Na+-Cl– symporter is regulated by aldosterone (Velázquez et al., 1996). Mutations in the Na+-Cl– symporter cause a form of inherited hypokalemic alkalosis called Gitelman syndrome (Simon and Lifton, 1998).

**Effects on Urinary Excretion.** As would be expected from their mechanism of action, inhibitors of Na+-Cl– symport increase Na+ and Cl– excretion. However, thiazides are only moderately efficacious (i.e., maximum excretion of filtered Na+ load is only 5%) because ~90% of the filtered Na+ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO3– and phosphate excretion and probably accounts for their weak proximal tubular effects. Like inhibitors of Na+-K+-2Cl– symport, inhibitors of Na+-Cl– symport increase K+ and titratable acid excretion by the same mechanisms discussed for loop diuretics. Acute thiazide administration increases uric acid excretion. However, uric acid excretion is reduced following chronic administration by the same mechanisms discussed for loop diuretics. The acute effects of inhibitors of Na+-Cl– symport on Ca2+ excretion are variable; when administered chronically, thiazide diuretics decrease Ca2+ excretion. The mechanism involves increased proximal reabsorption owing to volume depletion, as well as direct effects of thiazides to increase Ca2+ reabsorption in the DCT. Thiazide diuretics may cause a mild magnesuria by a poorly understood mechanism, and there is increasing awareness that long-term use of thiazide diuretics may cause magnesium deficiency, particularly in the elderly. Since inhibitors of Na+-Cl– symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the kidney’s ability to excrete dilute urine during water repletion.

**Figure 25–8. Dose-response curve of furosemide in chronic kidney disease.** With chronic kidney disease the dose-response curve of furosemide and other loop diuretics shifts to the right. This may occur as a result of impaired proximal tubular secretion of the diuretic into the tubular lumen. This can occur for at least two reasons: (1) competition for peritubular uptake and luminal secretion by organic anions that accumulate in uremia such as urate and (2) metabolic acidosis.

**Chemistry.** Inhibitors of Na+-Cl– symport are sulfonamides (Table 25–5), and many are analogs of 1,2,4-benzothiadiazine-1,1-dioxide. Because the original inhibitors of Na+-Cl– symport were benzothiadiazine derivatives, this class of diuretics became known as *thiazide diuretics*. Subsequently, drugs that are pharmacologically similar to thiazide diuretics (but not by furosemide, acetazolamide, or an amiloride derivative) and has 12 putative membrane-spanning domains, and its sequence is 47% identical to the cloned dogfish shark rectal gland Na+-K+-2Cl– symporter. Subsequently, the rat and human Na+-Cl– symporters were cloned. The human Na+-Cl– symporter has a predicted sequence of 1021 amino acids, 12 transmembrane domains, and 2 intracellular hydrophilic amino and carboxyl termini and maps to chromosome 16q13. The Na+-Cl– symporter (called ENCCI or TSC) is expressed predominantly in kidney and is localized to the apical membrane of DCT epithelial cells (Bachmann et al., 1995). Expression of the Na+-Cl– symporter is regulated by aldosterone (Velázquez et al., 1996). Mutations in the Na+-Cl– symporter cause a form of inherited hypokalemic alkalosis called Gitelman syndrome (Simon and Lifton, 1998).

**Mechanism and Site of Action.** Some studies using split-droplet and stationary-microperfusion techniques described reductions in proximal tubule reabsorption by thiazide diuretics; however, free-flow micropuncture studies have not consistently demonstrated increased solute delivery out of the proximal tubule following administration of thiazides. In contrast, micropuncture and *in situ* microperfusion studies clearly indicate that thiazide diuretics inhibit NaCl transport in DCT. The DCT expresses thiazide binding sites and is accepted as the primary site of action of thiazide diuretics; the proximal tubule may represent a secondary site of action.

Figure 25–9 illustrates the current model of electrolyte transport in DCT. As with other nephron segments, transport is powered by a Na+ pump in the basolateral membrane. Free energy in the electrochemical gradient for Na+ is harnessed by an Na+-Cl– symporter in the luminal membrane that moves Cl– into the epithelial cell against its electrochemical gradient. Cl– then exits the basolateral membrane passively by a Cl– channel. Thiazide diuretics inhibit the Na+-Cl– symporter. In this regard, Na+ or Cl– binding to the Na+-Cl– symporter modifies thiazide-induced inhibition of the symporter, suggesting that the thiazide-binding site is shared or altered by both Na+ and Cl–.

Abbreviations: R, renal excretion of intact drug; M, metabolism; B, excretion of intact drug into bile; U, unknown pathway of elimination; ID, insufficient data.
Thiazide diuretics also decrease glucose tolerance, and latent diabetes mellitus may be unmasked during therapy. Recent concerns have also been raised in randomized prospective blood-pressure lowering trials regarding an increased incidence of type II diabetes mellitus compared to other antihypertensive agents such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. The mechanism of impaired glucose tolerance is not completely understood but appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia may be related in some way to K⁺ depletion, in that hyperglycemia is reduced when K⁺ is given along with the diuretic. In addition to contributing to hyperglycemia, thiazide-induced hypokalemia impairs its antihypertensive effect and cardiovascular protection (Franse et al., 2000) afforded by thiazides in patients with hypertension. Thiazide diuretics also may increase plasma levels of LDL cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonamides.

With regard to drug interactions, thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonylureas, and insulin and may increase the effects of anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, nonselective or selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). Amphotericin B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

A potentially lethal drug interaction warranting special emphasis is that involving thiazide diuretics and quinidine. Prolongation of the QT interval by quinidine can lead to the development of polymorphic ventricular tachycardia (torsades de pointes) owing to triggered activity originating from early after-depolarizations (Chapter 29). Torsades de pointes may deteriorate into fatal ventricular fibrillation. Hypokalemia increases the risk of quinidine-induced torsades de pointes, and thiazide diuretics cause hypokalemia. Thiazide diuretic–induced K⁺ depletion may account for many cases of quinidine-induced torsades de pointes. In addition, alkalization of the urine by thiazides increases the systemic exposure to quinidine by reducing its elimination.

**Therapeutic Uses.** Thiazide diuretics are used for the treatment of edema associated with heart (congestive heart failure), liver (hepatic cirrhosis), and renal (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis) disease. With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is <30-40 mL/min.

---

**Figure 25–9.** NaCl reabsorption in distal convoluted tubule and mechanism of diuretic action of Na⁺-Cl⁻ symport inhibitors. Numbers in parentheses indicate stoichiometry. S, symporter; CH, ion channel; BL, basolateral membrane; LM, luminal membrane.

**Abstraction and Elimination.** Pharmacokinetic parameters of Na⁺-Cl⁻ symporter inhibitors are listed in Table 25–5.

Note the wide range of half-lives for this class of drugs. Sulfonamides are organic acids and therefore are secreted into the proximal tubule by the organic acid secretory pathway. Since thiazides must gain access to the tubular lumen to inhibit the Na⁺-Cl⁻ symporter, drugs such as probenecid can attenuate the diuretic response to thiazides by competing for transport into proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions.** Thiazide diuretics rarely cause CNS (e.g., vertigo, headache, paresthesias, xanthopsia, and weakness), GI (e.g., anorexia, nausea, vomiting, cramping, diarrhea, constipation, cholecystitis, and pancreatitis), hematological (e.g., blood dyscrasias), and dermatological (e.g., photosensitivity and skin rashes) disorders. The incidence of erectile dysfunction is greater with Na⁺-Cl⁻ symport inhibitors than with several other antihypertensive agents (e.g., β adrenergic receptor antagonists, Ca²⁺-channel blockers, or angiotensin converting enzyme inhibitors) (Grimm et al., 1997), but usually is tolerable. As with loop diuretics, most serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance. These adverse effects include extracellular volume depletion, hypotension, hypokalemia, hyponatremia, hypochloremia, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia. Thiazide diuretics have caused fatal or near-fatal hyponatremia, and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance, and latent diabetes mellitus may be unmasked during therapy. Recent concerns have also been raised in randomized prospective blood-pressure lowering trials regarding an increased incidence of type II diabetes mellitus compared to other antihypertensive agents such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. The mechanism of impaired glucose tolerance is not completely understood but appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia may be related in some way to K⁺ depletion, in that hyperglycemia is reduced when K⁺ is given along with the diuretic. In addition to contributing to hyperglycemia, thiazide-induced hypokalemia impairs its antihypertensive effect and cardiovascular protection (Franse et al., 2000) afforded by thiazides in patients with hypertension. Thiazide diuretics also may increase plasma levels of LDL cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonamides.

With regard to drug interactions, thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonylureas, and insulin and may increase the effects of anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, nonselective or selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). Amphotericin B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

A potentially lethal drug interaction warranting special emphasis is that involving thiazide diuretics and quinidine. Prolongation of the QT interval by quinidine can lead to the development of polymorphic ventricular tachycardia (torsades de pointes) owing to triggered activity originating from early after-depolarizations (Chapter 29). Torsades de pointes may deteriorate into fatal ventricular fibrillation. Hypokalemia increases the risk of quinidine-induced torsades de pointes, and thiazide diuretics cause hypokalemia. Thiazide diuretic–induced K⁺ depletion may account for many cases of quinidine-induced torsades de pointes. In addition, alkalization of the urine by thiazides increases the systemic exposure to quinidine by reducing its elimination.

**Therapeutic Uses.** Thiazide diuretics are used for the treatment of edema associated with heart (congestive heart failure), liver (hepatic cirrhosis), and renal (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis) disease. With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is <30-40 mL/min.
Thiazide diuretics decrease blood pressure in hypertensive patients by increasing the slope of the renal pressure-natriuresis relationship (Figure 26–7), and thiazide diuretics are used widely for the treatment of hypertension either alone or in combination with other antihypertensive drugs (Chapter 28). In this regard, thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications. Moreover, thiazides have additive or synergistic effects when combined with other classes of antihypertensive agents. A common dose for hypertension is 25 mg/day of hydrochlorothiazide or the dose equivalent of another thiazide. The ALLHAT study (ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group, 2002) provides strong evidence that thiazide diuretics are the best initial therapy for uncomplicated hypertension, a conclusion endorsed by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (Chobanian et al., 2003) (Chapter 27). Studies also suggest that the antihypertensive response to thiazides is influenced by polymorphisms in the angiotensin-converting enzyme and α-adducin genes (Sciarrone et al., 2003).

Thiazide diuretics, which reduce urinary Ca²⁺ excretion, sometimes are employed to treat Ca²⁺ nephrolithiasis and may be useful for treatment of osteoporosis (Chapter 44). Thiazide diuretics also are the mainstay for treatment of nephrogenic diabetes insipidus, reducing urine volume by up to 50%. Although it may seem counterintuitive to treat a disorder of increased urine volume with a diuretic, thiazides reduce the kidney’s ability to excrete free water. They do so by increasing proximal tubular water reabsorption (secondary to volume contraction) and by blocking the ability of the distal convoluted tubule to form dilute urine. This latter effect results in an increase in urine osmolality. Since other halides are excreted by renal processes similar to those for Cl⁻, thiazide diuretics may be useful for the management of Br⁻ intoxication.

**INHIBITORS OF RENAL EPITHELIAL Na⁺ CHANNELS (K⁺-SPARING DIURETICS)**

Triamterene (DYRENIUM) and amiloride (MIDAMOR, others) are the only two drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their antikaliuretic actions to offset the effects of other diuretics that increase K⁺ excretion. Consequently, triamterene and amiloride, along with spironolactone (described in the next section), often are classified as potassium (K⁺)-spparing diuretics.

**Chemistry.** Amiloride is a pyrazinylguanidine derivative, and triamterene is a pteridine (Table 25–6). Both drugs are organic bases and are transported by the organic base secretory mechanism in proximal tubule.

**Mechanism and Site of Action.** Available data suggest that triamterene and amiloride have similar mechanisms of action, which is illustrated in Figure 25–10.

Principal cells in the late distal tubule and collecting duct have, in their luminal membranes, epithelial Na⁺ channels that provide a conductive pathway for Na⁺ entry into the cell down the electrochemical gradient created by the basolateral Na⁺ pump. The higher permeability of the luminal membrane for Na⁺ depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K⁺ into the lumen by K⁺ channels (ROMK) in the luminal membrane. Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics increase Na⁺ delivery to the late distal tubule and collecting duct, a situation that often is associated with increased K⁺ and H⁺ excretion. It is likely that the elevation in luminal Na⁺ concentration in distal nephron induced by such diuretics augments depolarization

of the luminal membrane and thereby enhances the lumen-negative $V_\text{T}$, which facilitates K⁺ excretion. In addition to principal cells, the collecting duct also contains type A intercalated cells that mediate H⁺ secretion into the tubular lumen. Tubular acidification is driven by a luminal H⁺-ATPase (proton pump), and this pump is aided by partial depolarization of the luminal membrane. The luminal H⁺-ATPase is of the vacuolar-type and is distinct from the gastric H⁺-K⁺-ATPase that is inhibited by drugs such as omeprazole. However, increased distal Na⁺ delivery is not the only mechanism by which diuretics increase K⁺ and H⁺ excretion. Activation of the renin-angiotensin-aldosterone axis by diuretics also contributes to diuretic-induced K⁺ and H⁺ excretion, as discussed later in the section on mineralocorticoid antagonists.

Considerable evidence indicates that amiloride blocks epithelial Na⁺ channels in the luminal membrane of principal cells in late distal tubule and collecting duct. The amiloride-sensitive Na⁺ channel (called ENaC) consists of three subunits (α, β, and γ) (Kleyman et al., 1999). Although the α subunit is sufficient for channel activity, maximal Na⁺ permeability is induced when all three subunits are coexpressed in the same cell, probably forming a tetrameric structure consisting of two α subunits, one β subunit, and one γ subunit. Studies in Xenopus oocytes expressing ENaC suggest that triamterene and amiloride bind ENaC by similar mechanisms. The $K_\text{i}$ of amiloride for ENaC is submicromolar, and molecular studies identified critical domains in ENaC that participate in amiloride binding (Kleyman et al., 1999). Liddle syndrome is an autosomal dominant form of low-renin, volume-expanded hypertension that is due to mutations in the β or γ subunits, leading to increased basal ENaC activity.

**Effects on Urinary Excretion.** Since the late distal tubule and collecting duct have a limited capacity to reabsorb solutes, Na⁺ channel blockade in this part of the nephron only mildly increases Na⁺ and Cl⁻ excretion rates (~2% of filtered load). Blockade of Na⁺ channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Since the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases K⁺, H⁺, Ca²⁺, and Mg²⁺ excretion rates. Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence chronic administration of amiloride and triamterene may decrease uric acid excretion.

**Effects on Renal Hemodynamics.** Amiloride and triamterene have little or no effect on renal hemodynamics and do not alter TGF.

**Other Actions.** Amiloride, at concentrations higher than needed to elicit therapeutic effects, also blocks the Na⁺-H⁺ and Na⁺-Ca²⁺ antiporters and inhibits Na⁺, K⁺-ATPase.

**Absorption and Elimination.** Pharmacokinetic data for amiloride and triamterene are listed in Table 25–6.

Amiloride is eliminated predominantly by urinary excretion of intact drug. Triamterene is metabolized extensively to an active metabolite, 4-hydroxyltramterene sulfate, and this metabolite is excreted in urine. The pharmacological activity of 4-hydroxyltramterene sulfate is comparable with that of the parent drug. Therefore, triamterene toxicity may be enhanced in both hepatic disease (decreased metabolism of triamterene) and renal failure (decreased urinary excretion of active metabolite).

**Toxicity, Adverse Effects, Contraindications, Drug Interactions.** The most dangerous adverse effect of renal Na⁺-channel inhibitors is hyperkalemia, which can be life-threatening. Consequently, amiloride and triamterene are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (e.g., patients with renal failure, patients receiving other K⁺-sparking diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K⁺ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving Na⁺-channel inhibitors.
Pentamidine and high-dose trimethoprim are used often to treat Pneumocystis jirovecii pneumonia in patients with acquired immune deficiency syndrome (AIDS). Because these compounds are weak inhibitors of ENaC, they too may cause hyperkalemia. Risk with trimethoprim is related to both the dosage employed and the underlying level of renal function. It was first reported with high-dose therapy (200 mg/kg/day) in 1983. Subsequent reports of hyperkalemia occurred in HIV-infected patients with normal renal function on high doses of the drug. In one series of 30 such patients, 50% developed a serum K+ concentration >5.0 mEq/L and 10% >6.0 mEq/L. In a prospective study of otherwise healthy outpatients, the frequency was lower with a serum K+ concentration >5.5 mEq/L in only 6%. Within 3-10 days after onset of treatment, 10-21% of patients develop a K+ concentration >5.5 mEq/L (Perazella, 2000). Risk factors for severe hyperkalemia are older age, high-dose therapy, renal impairment, hypoaldosteronism, and treatment with other drugs that impair renal K+ excretion (e.g., NSAIDs and ACE inhibitors). Serum K+ concentration should be monitored after 3-4 days of trimethoprim treatment especially in those at increased risk. Likewise, routine monitoring of the serum K+ level is essential in patients receiving K+-sparring diuretics. Cirrhotic patients are prone to megaloblastosis because of folic acid deficiency, and triamterene, a weak folic acid antagonist, may increase the likelihood of this adverse event. Triamterene also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, GI, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of amiloride are nausea, vomiting, diarrhea, and headache; those of triamterene are nausea, vomiting, leg cramps, and dizziness.

Therapeutic Uses. Because of the mild natriuresis induced by Na+-channel inhibitors, these drugs seldom are used as sole agents in treatment of edema or hypertension. Rather, their major utility is in combination with other diuretics; indeed, each is marketed in a fixed-dose combination with a thiazide: triamterene/hydrochlorothiazide (DYAZIDE, MAXZIDE, others), amiloride/hydrochlorothiazide (generic).

Co-administration of an Na+-channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na+-channel inhibitors to reduce K+ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics; consequently, the combination of an Na+-channel inhibitor with a thiazide or loop diuretic tends to result in normal plasma K+ values. Liddle syndrome can be treated effectively with Na+-channel inhibitors. Approximately 5% of people of African origin carry a T594M polymorphism in the β subunit of ENaC, and amiloride is particularly effective in lowering blood pressure in patients with hypertension who carry this polymorphism (Baker et al., 2002). Aerosolized amiloride has been shown to improve mucociliary clearance in patients with cystic fibrosis. By inhibiting Na+ absorption from the surfaces of airway epithelial cells, amiloride augments hydration of respiratory secretions and thereby improves mucociliary clearance. Amiloride also is useful for lithium-induced nephrogenic diabetes insipidus because it blocks Li+ transport into collecting tubule cells.

### Antagonists of Mineralocorticoid Receptors (Aldosterone Antagonists, K+-Sparing Diuretics)

Mineralocorticoids cause salt and water retention and increase K+ and H+ excretion by binding to specific mineralocorticoid receptors. Early studies indicated that some spiro lactones block the effects of mineralocorticoids; this finding led to the synthesis of specific antagonists for the mineralocorticoid receptor (MR). Currently, two MR antagonists are available in the U.S., spironolactone (a 17-spirolactone; ALDACTONE, others) and eplerenone (INSPIRA, others); two others are available elsewhere (Table 25–7).

Mechanism and Site of Action. Epithelial cells in late distal tubule and collecting duct contain cytosolic MRs with a high aldosterone affinity. MRs are members of the superfamily of receptors for steroid hormones, thyroid hormones, vitamin D, and retinoids. Aldosterone enters the epithelial cell from the basolateral membrane and binds to MRs; the MR-aldosterone complex translocates to the nucleus, where it binds to specific sequences of DNA (hormone-responsive elements) and thereby regulates the expression of multiple gene products called aldosterone-induced proteins (AIPs). Consequently, transepithelial NaCl transport is enhanced, and the lumen-negative transepithelial voltage is increased. The latter effect increases the driving force for K+ and H+ secretion into the tubular lumen.

The discovery of gene mutation responsible for rare monogenic diseases that cause hypertension such as Liddle syndrome and apparent mineralocorticoid excess helped clarify how aldosterone regulates Na+ transport in the distal nephron (Figure 25–11). Mutations in the carboxy-terminal PY motif of either the β or γ subunits of ENaC are associated with Liddle syndrome. The PY motif is an area involved in protein-protein interaction. The PY motif of ENaC interacts with the ubiquitin ligase Nedd4-2, a protein that ubiquinates ENaC. This then results in internalization of ENaC and proteasome-mediated degradation. Subsequent studies revealed that Nedd4-2 is phosphorylated and inactivated by SGK1 (serum and glucocorticoid-stimulated kinase) and that SGK1 is up-regulated after ~30 minutes by aldosterone. By tracing back the pathophysiological mechanism of Liddle syndrome, one of the mechanisms whereby aldosterone acts in the collecting duct was identified. Aldosterone up-regulates SGK1, which phosphorylates and inactivates Nedd4-2. As a result, ENaC is not ubiquitinated and removed from the membrane, thereby increasing Na+ reabsorption. When the mineralocorticoid receptor was cloned and tested in vitro it was noted to have equal affinity for mineralocorticoid and glucocorticoids. It had been assumed that the mineralocorticoid receptor would have specificity for mineralocorticoids, but surprisingly this was not the case. Given that glucocorticoids circulate at 100- to 1000-fold higher concentrations than mineralocorticoids, this observation led to an entirely new mechanism: upon activation, the glucocorticoid receptor also stimulates SGK1, which in turn up-regulates Nedd4-2 and removes ENaC.
higher concentration than mineralocorticoids, it was unclear how mineralocorticoids would ever bind to their receptor. The mineralocorticoid receptor would be predominantly occupied by glucocorticoids. This mystery was solved with the cloning of the enzyme type II 11-β-hydroxysteroid dehydrogenase (HSD). Mineralocorticoid target tissues expresses type II 11-β-HSD, which converts cortisol to the inactive cortisone. This allows mineralocorticoids to bind to the receptor. The type II 11-β-HSD enzyme is genetically absent in the inherited disorder of apparent mineralocorticoid excess.

Drugs such as spironolactone and eplerenone competitively inhibit the binding of aldosterone to the MR. Unlike the MR-aldosterone complex, the MR-spironolactone complex is not able to induce the synthesis of AIPs. Since spironolactone and eplerenone block biological effects of aldosterone, these agents also are referred to as aldosterone antagonists.

MR antagonists are the only diuretics that do not require access to the tubular lumen to induce diuresis.

**Effects on Urinary Excretion.** The effects of MR antagonists on urinary excretion are very similar to those induced by renal epithelial Na⁺-channel inhibitors. However, unlike Na⁺-channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous aldosterone levels. The higher the endogenous

aldosterone level, the greater the effects of MR antagonists on urinary excretion.

**Effects on Renal Hemodynamics.** MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

**Other Actions.** Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to the 9,11-epoxide group, eplerenone has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with spironolactone. High spironolactone concentrations were reported to interfere with steroid biosynthesis by inhibiting steroid hydroxylases (e.g., CYPs 11A1, 11B1, 11B2, and C21; see Chapters 40 and 41). These effects have limited clinical relevance.

**Absorption and Elimination.** Spironolactone is absorbed partially (~65%), is metabolized extensively (even during its first passage through the liver), undergoes enterohepatic recirculation, is highly protein bound, and has a short t_{1/2} (~1.6 hours). The t_{1/2} is prolonged to 9 hours in patients with cirrhosis.

Spironolactone undergoes metabolism by both deacylation and dethioacetylation to a variety of metabolites with prolonged t_{1/2}; of these, 7α thiomethyl spironolactone is the primary active metabolite.

Although not available in the U.S., canrenoate and the K⁺ salt of canrenone are in clinical use. Canrenone is not active per se but is converted to canrenone. Eplerenone has good oral availability and is eliminated primarily by metabolism by CYP3A4 to inactive metabolites, with a t_{1/2} of ~5 hours.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions.** As with other K⁺-sparking diuretics, MR antagonists may cause life-threatening hyperkalemia. Indeed, hyperkalemia is the principal risk of MR
antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia either because of disease or administration of other medications. MR antagonists also can induce metabolic acidosis in cirrhotic patients.

Saliycylates may reduce the tubular secretion of canrenone and decrease diuretic efficacy of spironolactone, and spironolactone may alter the clearance of digitalis glycosides. Owing to its affinity for other steroid receptors, spironolactone may cause gynecomastia, impotence, decreased libido, hirsutism, deepening of the voice, and menstrual irregularities. Spironolactone also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindi-
cated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. Spironolactone may cause skin rashes and, rarely, blood dyscrasias. Breast cancer has occurred in patients taking spironolactone chronically (cause and effect not established), and high doses of spironolactone are associated with malignant tumors in rats. Whether or not therapeutic spironolactone doses can induce malignancies remains an open question. Strong inhibitors of CYP3A4 may increase plasma levels of eplerenone, and such drugs should not be administered to patients taking eplerenone, and vice versa. Other than hyperkalemia and GI disorders, the rate of adverse events for eplerenone is similar to that of placebo (Pitt et al., 2003).

Therapeutic Uses. As with other K⁺-sparing diuretics, spironolactone often is coadministered with thiazide or loop diuretics in the treatment of edema and hyperten-
sion, and spironolactone in combination with hydrochlorothiazide (ALDACTAZIDE, others) is marketed. Such combinations result in increased mobilization of edema fluid while causing lesser perturbations of K⁺ homeostasis. Spironolactone is particularly useful in the treatment of resistant hypertension due to primary hyperaldosteronism (adrenal adenomas or bilateral adrenal hyperplasia) and of refractory edema associated with secondary aldosteronism (cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites). Spironolactone is considered the diuretic of choice in patients with hepatic cirrhosis. Spironolactone, added to standard therapy, substantially reduces morbidity and mortality (Pitt et al., 1999) and ventricular arrhythmias (Ramires et al., 2000) in patients with heart failure (Chapter 28).

Clinical experience with eplerenone is less than that with spironolactone. Eplerenone appears to be a safe and effective antihypertensive drug (Ouzan et al., 2002). It is somewhat more specific for the MR and therefore the incidence of progesterone-related adverse effects (e.g., gynecomastia) is lower than with spironolactone. In patients with acute myocardial infarction complicated by left ventric-
ular systolic dysfunction, addition of eplerenone to optimal medical therapy significantly reduces morbidity and mortality (Pitt et al., 2003).

INHIBITORS OF THE NONSPECIFIC CATION CHANNEL: ATRIAL NATRIURETIC PEPTIDES

The inner medullary collecting duct (IMCD) is a major site of action of natriuretic peptides. Although five different natriuretic peptides exist, only four are relevant with respect to human physiology: atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. ANP and BNP are produced by the heart in response to wall stretch, CNP is of endothelial and renal cell origin, while urodilatin is found in urine and acts as a paracrine regulator of Na⁺ transport (Lee and Burnett, 2007). Human recombinant ANP (carperitide, available only in Japan) and BNP (nesiritide [NATRECOR]) are currently available therapeutic agents of this class.

Mechanism and Site of Action. The IMCD is the final site along the nephron where Na⁺ is reabsorbed. Up to 5% of the filtered Na⁺ load can be reabsorbed here. Na⁺ enters the IMCD cell across the apical membrane down an electrochemical gradient through Na⁺ channels and exits via the Na⁺/K⁺-ATPase (Figure 25–12). Two types of Na⁺

---

**Figure 25–12. Inner medullary collecting duct (IMCD) Na⁺ transport and its regulation.** Na⁺ enters the IMCD cell in one of two ways. The first is via ENaC, and the second is through a cyclic nucleotide gated nonspecific cation channel (CNGC) that transports Na⁺, K⁺, and NH₄⁺ and is gated by cyclic GMP. Na⁺ then exits the cell via the Na⁺/K⁺-ATPase. It is the CNGC that is the primary pathway for Na⁺ entry, and is inhibited by natriuretic peptides. Atrial natriuretic peptides (ANP) bind to surface receptors (natriuretic peptide receptors A, B, and C). The A and B receptors are isoforms of particulate guanylate cyclase that catalyze the conversion of GTP to cyclic GMP. Cyclic GMP inhibits the CNGC directly, and indirectly through PKG. PKG activation also inhibits Na⁺ exit via the Na⁺/K⁺-ATPase.
channels are expressed in IMCD. The first is an amiloride-sensitive, 28pS, nonselective, cyclic nucleotide gated cation (CNG) channel. This channel is highly selective for cations over anions, has equal permeability for Na⁺ and K⁺, and is inhibited by GMP, PKG, PKC, ATP, and atrial natriuretic peptides via their capacity to stimulate membrane-bound guanylyl cyclase activity and elevate cellular cGMP. Its open probability is increased by rises in intracellular Ca²⁺ concentration. CNG channels are expressed in all nephron segments with the possible exception of the thin limb of Henle’s loop. The second type of Na⁺ channel expressed in the IMCD is the low-conductance 4 pS highly-selective Na⁺ channel E_NaC. It appears that the majority of Na⁺ reabsorption in the IMCD is mediated via the CNG channel.

ANP has a 17 amino acid core ring and a cysteine bridge. It is produced in the cardiac atria in response to wall stretch. It binds to the natriuretic peptide receptor (NPR) A and increases intracellular cyclic GMP resulting in inhibition of the CNG channel and natriuresis. It also inhibits production of renin and aldosterone. BNP is produced in the ventricle, also binds to the NPR-A receptor and acts in a similar fashion as ANP. CNP binds to the NPR-B receptor and increases cGMP in vascular smooth muscle and mediates vasodilation. Urodilatin arises from the same precursor molecule as ANP but has four additional amino acids at the N terminus. It binds with lower affinity than ANP to the NPR-B receptor and has effects in glomeruli and IMCD. As a result of these effects, natriuretic peptides have been utilized to treat congestive heart failure. Human recombinant ANP (carperitide) is available in Japan but not yet in the U.S., where human recombinant BNP (nesiritide) is available. Urodilatin (ularitide) remains in preclinical trials in the U.S. and Europe. Only the use of nesiritide is discussed in the following sections. Nesiritide effects renal Na⁺ excretion by inhibiting the CNG nonspecific-cation channel, as well as through inhibiting both the renin-angiotensin-aldosterone system and endothelin production.

Effects on Urinary Excretion. Nesiritide inhibits Na⁺ transport in both the proximal and distal nephron but its primary effect is in the IMCD. Urinary Na⁺ excretion increases with nesiritide but the effect may be attenuated by upregulation of Na⁺ reabsorption in upstream segments of the nephron.

Effects on Renal Hemodynamics. GFR increases administered nesiritide in normal subjects, but in treated patients with congestive heart failure GFR may increase, decrease, or remain unchanged.

Other Actions. Administration of nesiritide decreases systemic and pulmonary resistances and left ventricular filling pressure, and induces a secondary increase in cardiac output. In one study, mean arterial pressure, pulmonary capillary wedge pressure, and right atrial pressure declined 17%, 48%, and 56%, respectively. Declines in blood pressure with administration are dose related.

Elimination. Natriuretic peptides are administered intravenously and have short t₁/₂ values. Nesiritide has a distribution t₁/₂ of 2 minutes and a mean terminal t₁/₂ of 18 minutes. Its volume of distribution is small, 0.19 L/kg. It is cleared via three mechanisms: binding to the NPR-C receptor, degradation via a neutral endopeptidase, and renal excretion. There is no need to adjust the dose for renal insufficiency.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. There are concerns about adverse renal effects and reports of increased short-term mortality in patients treated with nesiritide. Increases in serum creatinine concentration may be related to decreases in extracellular fluid volume, higher doses of diuretics used, decreases in blood pressure, and activation of the renin-angiotensin-aldosterone system. The Vasodilation in the Management of Acute CHF (VAMC) trial showed no increased risk with low-dose diuretics but an increased risk with high-dose diuretics (>160 mg furosemide), rising with increasing doses. The risk of hypotension was 4.4% and lasted an average of 2.2 hours. Oral ACE inhibitors may increase the risk of hypotension with nesiritide. Data on whether 30-day mortality is increased by nesiritide are conflicting. There are no data to suggest that nesiritide reduces mortality in the short term or long term in patients with acute decompensated CHF.

Therapeutic Uses. Use of nesiritide should be limited to patients with acutely decompensated CHF with shortness of breath at rest; the drug should not be used in place of diuretics. Nesiritide reduces symptoms and improves hemodynamic parameters in those with dyspnea at rest who are not hypotensive. Nesiritide is available for administration as a continuous intravenous infusion; there is little experience with administering nesiritide for longer than 48 hours.

CLINICAL USE OF DIURETICS

Site and Mechanism of Diuretic Action. An understanding of the sites and mechanisms of action of diuretics enhances comprehension of the clinical aspects of diuretic pharmacology. Figure 25–13 provides an overview of the sites and mechanisms of actions of diuretics. Much of the pharmacology of diuretics can be deduced from this figure.

Mechanism of Edema Formation. A complex set of interrelationships (Figure 25–14) exists among the cardiovascular system, kidneys, CNS (Na⁺ appetite, thirst regulation), and tissue capillary beds (distribution of extracellular fluid volume [ECFV]), so perturbations at one of these sites can affect all other sites. A primary law of the kidney is that Na⁺ excretion is a steep function of mean arterial blood pressure (MABP), such that small increases in MABP cause marked increases in Na⁺ excretion (Guyton, 1991). Over any given time interval, the net change in total-body Na⁺ (either positive or negative) is simply the dietary Na⁺ intake minus the urinary excretion rate minus other losses (e.g., sweating, fecal losses, and vomiting). When a net positive Na⁺ balance occurs, the Na⁺ concentration in the extracellular fluid (ECF) will increase, stimulating water intake (thirst) and reducing urinary water output.
(by ADH release). Opposite changes occur during a net negative Na⁺ balance.

Changes in water intake and output adjust ECFV toward normal, thereby expanding or contracting total ECFV. Total ECFV is distributed among many body compartments; however, since ECF volume on the arterial side of the circulation pressurizes the arterial tree, it is this fraction of ECFV that determines MABP, and it is this fraction of ECFV that is “sensed” by the cardiovascular system and kidneys. Since MABP is a major determinant of Na⁺ output, a closed loop is established (Figure 25–14). This loop cycles until net Na⁺ accumulation is zero; i.e., in the long run, Na⁺ intake must equal Na⁺ loss.

The preceding discussion implies that three fundamental types of perturbations contribute to venous congestion and/or edema formation:

1. A shift to the right in the renal pressure-natriuresis relationship (e.g., chronic renal failure) causes reduced Na⁺ excretion for any level of MABP. If all other factors remain constant, this would increase total-body Na⁺, ECFV, and MABP. The additional ECFV would be distributed throughout various body compartments according to the state of cardiac function and prevailing Starling forces and would predispose toward venous congestion and/or edema. Even so, in the absence of any other predisposing factors for venous congestion and/or edema, a rightward shift in the renal pressure-natriuresis curve generally causes hypertension with only a slight (usually immeasurable) increase in ECFV. As elucidated by Guyton (1991), ECFV expansion triggers a series of events: expanded ECFV → augmented cardiac output → enhanced vascular tone (i.e., total-body autoregulation) → increased total peripheral resistance → elevated MABP → pressure natriuresis → reduction of ECFV and cardiac output toward normal. Most likely, a
sustained rightward shift in the renal pressure-natriuresis curve is a necessary and sufficient condition for long-term hypertension but is only a predisposing factor for venous congestion and/or edema.

2. An increase in dietary Na⁺ intake would have the same effects as a rightward shift in the renal pressure-natriuresis relationship (i.e., increased MABP and predisposition to venous congestion/edema). However, changes in salt intake may have minimal or large effects depending on the shape of the patient’s renal pressure-natriuresis curve.

3. Any pathophysiological alterations in the forces that govern the distribution of ECFV among the various body compartments would cause abnormal amounts of ECFV to be trapped at the site of altered forces. This would deplete the “sensed” ECFV, which would be restored back to normal by the mechanisms described earlier. ECFV may be trapped at several sites by different mechanisms. For instance, cirrhosis of the liver increases lymph in the space of Disse, leading to spillover by the glissonian wall into the peritoneal cavity (ascites). Left-sided heart failure, both acute and chronic, increases hydrostatic pressure in the lung capillaries, leading to pulmonary edema. Chronic right-sided heart failure redistributes ECFV from the arterial to the venous circulation, resulting in venous, hepatic, and splenic congestion and peripheral tissue edema. Decreased plasma protein levels, particularly albumin (e.g., in nephrotic syndrome, severe burns, and hepatic disease), increase the distribution of ECFV into interstitial spaces, causing generalized peripheral edema. Peripheral edema also may be “idiopathic” owing to unknown alterations in Starling forces at the capillary bed.

The Role of Diuretics in Clinical Medicine. Another implication of the mechanisms illustrated in Figure 25–14 is that three fundamental strategies exist for mobilizing edema fluid:

- Correction of the underlying disease
- Restriction of Na⁺ intake
- Administration of diuretics
The most desirable course of action would be to correct the primary disease; however, this often is impossible. For instance, increased hepatic sinusoidal pressure in cirrhosis of the liver and urinary loss of protein in nephrotic syndrome are due to structural alterations in the portal circulation and glomeruli, respectively, that may not be remediable.

Restriction of Na+ intake is the favored nonpharmacologic approach to treatment of edema and hypertension and should be attempted; however, compliance is a major obstacle. Diuretics, therefore, remain the cornerstone for treatment of edema or volume overload, particularly that owing to congestive heart failure, ascites, chronic renal failure, and nephrotic syndrome.

Whether a patient should receive diuretics and, if so, what therapeutic regimen should be used (type of diuretic, dose, route of administration, and speed of mobilization of edema fluid) depend on the clinical situation. Massive pulmonary edema in patients with acute left-sided heart failure is a medical emergency requiring rapid, aggressive therapy including intravenous administration of a loop diuretic. In this setting, use of oral diuretics or diuretics with lesser efficacy is inappropriate. On the other hand, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. As mentioned previously, meta-analysis indicates that loop and thiazide diuretics decrease morbidity and mortality in heart failure patients (Faris et al., 2002), and two randomized clinical trials with MR antagonists also demonstrate reduced morbidity and mortality in heart failure patients receiving optimal therapy with other drugs (Pitt et al., 1999, 2003). Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during the paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of more powerful loop diuretics usually are required. In nephrotic syndrome, diuretic response often is disappointing. In chronic renal failure and cirrhosis, edema will not pose an immediate health risk. Even so, uncomfortable, oppressive, and/or disfiguring edema can greatly reduce quality of life, and the decision to treat will be based in part on quality-of-life issues. In such cases, only partial removal of edema fluid should be attempted, and fluid should be mobilized slowly using a diuretic regimen that accomplishes the task with minimal perturbation of normal physiology. Brater (1998) provides a logically compelling algorithm for diuretic therapy (specific recommendations for drug, dose, route, and drug combinations) in patients with edema caused by renal, hepatic, or cardiac disorders. The basic features of “Brater’s algorithm” are summarized in Figure 25–15.

In many clinical situations, edema is not caused by abnormal Na+ intake or by an altered renal Na+ handling. Rather, edema is the result of altered Starling forces at the capillary beds—a “Starling trap.” Use of diuretics in these clinical settings represents a judicious compromise between the edematous state and the hypovolemic state. In such conditions, reducing total ECFV with diuretics will decrease edema but also will cause depletion of “sensed” ECFV, possibly leading to hypotension, malaise, and asthenia.

Diuretic resistance refers to edema that is or has become refractory to a given diuretic. If diuretic resistance develops against a less efficacious diuretic, a more efficacious diuretic should be substituted, such as a loop diuretic for a thiazide. However, resistance to loop diuretics is not uncommon and can be due to several causes.

NSAID co-administration is a common preventable cause of diuretic resistance. An estimated 10% of the elderly each year have periods when NSAID and diuretic prescriptions overlap. Prostaglandin production, especially PGE2, is an important counter-regulatory mechanism in states of reduced renal perfusion such as volume contraction, congestive heart failure, and cirrhosis characterized by activation of the renin-angiotensin-aldosterone (RAA) and sympathetic nervous systems. Prostaglandins reduce NaCl reabsorption in the distal nephron, antagonize effects of ADH, and redistribute blood flow from cortex to juxtamedullary regions in this setting. NSAID administration can block these prostaglandin-mediated effects that counterbalance the RAA and sympathetic nervous system, resulting in salt and water retention. Interaction between NSAIDs and diuretics can result in important clinical consequences such as development or exacerbation of congestive heart failure. NSAIDs can also increase blood pressure, especially in the elderly. In one study of patients over age 55, the relative risk of hospitalization for congestive heart failure (CHF) during periods of concomitant diuretic and NSAID use was increased 2.2-fold over that with diuretic use alone. The majority of these admissions occurred in the first month of simultaneous use, most in the first 20 days. After 40 days, risk was similar to that before simultaneous use. This appeared to be a class effect with no significant differences between individual NSAIDs. Diuretic resistance also occurs with COX-2-selective inhibitors.

In chronic renal failure, a reduction in RBF decreases delivery of diuretics to the kidney, and accumulation of endogenous organic acids competes with loop diuretics for transport at the proximal tubule. Consequently, diuretic concentration at the active site in the tubular lumen is diminished. In nephrotic syndrome, binding of diuretics to luminal albumin was postulated to limit response; however, the validity of this concept has been challenged (Agarwal et al., 2000). In hepatic cirrhosis, nephrotic syndrome, and heart failure,
nephrons may have diminished diuretic responsiveness because of increased proximal tubular Na⁺ reabsorption, leading to diminished Na⁺ delivery to distal nephron segments (Knauf and Mutschler, 1997).

Faced with resistance to loop diuretics, the clinician has several options:

1. Bed rest may restore drug responsiveness by improving the renal circulation.
2. An increase in dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (the ceiling dose) of the diuretic.
3. Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic (Ferguson et al., 1997) will increase the length of time that an effective diuretic concentration is at the active site.
4. Use of combination therapy to sequentially block more than one site in the nephron may result in a synergistic interaction between two diuretics. For instance, a combination of a loop diuretic with a K⁺-sparing or a thiazide diuretic may improve therapeutic response; however, nothing is gained by the administration of two drugs of the same type.

Thiazide diuretics with significant proximal tubular effects (e.g., metolazone) are particularly well suited for sequential blockade when co-administered with a loop diuretic. This combination should be used with caution and the patient followed closely in the first few weeks of therapy. Significant complications may ensue, including severe hyponatremia, hypokalemia, and volume depletion. The patient should be warned to stop both drugs and contact his or her physician if weight loss exceeds 5 pounds per week.

5. Reducing salt intake will diminish postdiuretic Na⁺ retention that can nullify previous increases in Na⁺ excretion.
6. Scheduling of diuretic administration shortly before food intake will provide effective diuretic concentration in the tubular lumen when salt load is highest.
All currently available diuretics perturb K+ homeostasis. However, studies in animals established that blockade of adenosine A1 receptors induces a brisk natriuresis without significantly increasing urinary K+ excretion (Kuan et al., 1993). Two clinical studies with FK453, a highly selective A1-receptor antagonist, confirm that blockade of A1 receptors induces natriuresis in humans with minimal effects on K+ excretion (van Buren et al., 1993). The natriuretic mechanism of this novel class of diuretics has been partially elucidated (Takeda et al., 1993). Elevated intracellular cyclic AMP reduces basolateral Na+-HCO3 symport in proximal tubular cells. Endogenous adenosine normally acts on A1 receptors in these cells to inhibit adenyl cyclase and reduce cyclic AMP accumulation. Blockade of A1 receptors removes this inhibition, permits cellular cyclic AMP to rise, and results in reduced activity of the Na+-HCO3 symporter. Because A1 receptors are involved in TGF, A1 receptor antagonists uncouple increased distal Na+ delivery from activation of TGF. Other mechanisms, including an effect in the collecting tubules, contribute to the natriuretic response to A1 receptor antagonists; however, it is not known why this class of diuretics has little effect on K+ excretion. In some patients, loop diuretics may compromise renal hemodynamics and actually reduce GFR, a phenomenon known as diuretic intolerance. Importantly, A1 receptor antagonists tend to improve GFR in the setting of diuretic intolerance. A1 receptor antagonists such as rolofylline are in clinical trials. However, the future utility of this class of diuretics is doubtful: the large PROTECT trial showed in 2009 that rolofylline was not superior to placebo in patients with acute heart failure; rolofylline also increased the incidence of seizures, an expected side-effect of A1 receptor antagonists.

WATER HOMEOSTASIS

Arginine vasopressin (the antidiuretic hormone in humans) is the main hormone that regulates body fluid osmolality. Many diseases of water homeostasis and many pharmacological strategies for correcting such disorders involve vasopressin. This section of the chapter focuses on vasopressin, including (1) chemistry of vasopressin agonists and vasopressin antagonists; (2) physiology (anatomical considerations; the synthesis, transport, and storage of vasopressin; and regulation of vasopressin secretion); (3) basic pharmacology (vasopressin receptors and their signal-transduction pathways, renal actions of vasopressin, pharmacological modification of the antidiuretic response to vasopressin, and nonrenal actions of vasopressin); (4) diseases affecting the vasopressin system (diabetes insipidus, syndrome of inappropriate secretion of antidiuretic hormone [SIADH], and other water-retaining states); and (5) clinical pharmacology of vasopressin peptides. A small number of other drugs can be used to treat abnormalities of water balance; a discussion of these agents is integrated into the section on diseases affecting the vasopressin system.
project to the external zone of the median eminence and release vasopressin directly into the pituitary portal circulation.

**Synthesis.** Vasopressin and oxytocin are synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN; the two hormones are synthesized predominantly in separate neurons. Parvicellular neurons in the PVN also synthesize vasopressin. Vasopressin synthesis appears to be regulated solely at the transcriptional level. In humans, a 168-amino acid preprohormone (Figure 25–16) is synthesized, and a signal peptide (residues –23 to –1) ensures incorporation of the nascent polypeptide into ribosomes. During synthesis, the signal peptide is removed to form vasopressin prohormone, which then is processed and incorporated into the Golgi compartment and then into membrane-associated granules. The prohormone contains three domains: vasopressin (residues 1-9), vasopressin (VP)-neurophysin (residues 13-105), and VP-glycopeptide (residues 107-145). The vasopressin domain is linked to the VP-neurophysin domain through a glycine-lysine-arginine-processing signal, and the VP-neurophysin is linked to the VP-glycopeptide domain by an arginine-processing signal. In secretory granules, an endopeptidase, exopeptidase, monoxygenase, and lyase act sequentially on the prohormone to produce vasopressin, VP-neurophysin (sometimes referred to as neurophysin II or MSEL-neurophysin), and VP-glycopeptide (sometimes called copeptin). The synthesis and transport of vasopressin depend on the preprohormone conformation. In particular, VP-neurophysin binds vasopressin and is critical to correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or VP-neurophysin give rise to central diabetes insipidus.

**Transport and Storage.** The process of axonal transport of vasopressin- and oxytocin-containing granules is rapid, and these hormone-laden granules arrive at their destinations within 30 minutes, ready for release by exocytosis when the magnocellular or parvicellular neurons are stimulated appropriately.

Maximal release of vasopressin occurs when impulse frequency is ~12 spikes per second for 20 seconds. Higher frequencies or longer periods of stimulation lead to diminished hormone release (fatigue). Appropriately, vasopressin-releasing cells demonstrate an atypical pattern of spike activity characterized by rapid phasic bursts (5-12 spikes per second for 15-60 seconds) separated by quiescent periods (15-60 seconds in duration). This pattern is orchestrated by activation and inactivation of ion channels in magnocellular neurons and provides for optimal vasopressin release.

**Vasopressin Synthesis Outside the CNS.** Vasopressin also is synthesized by heart and adrenal gland. In heart, elevated wall stress increases vasopressin synthesis severalfold. Cardiac synthesis of vasopressin is predominantly vascular and perivascular and may contribute to impaired ventricular relaxation and coronary vasoconstriction. Vasopressin synthesis in the adrenal medulla stimulates catecholamine secretion from chromaffin cells and may promote adrenal cortical growth and stimulate aldosterone synthesis.

![Figure 25–16. Processing of the 168–amino acid human 8-arginine vasopressin (AVP) preprohormone to AVP, vasopressin (VP)-neurophysin, and VP-glycopeptide. More than 40 mutations in the single gene on chromosome 20 that encodes AVP preprohormone give rise to central diabetes insipidus. *Boxes indicate mutations leading to central diabetes insipidus.](image-url)
Regulation of Vasopressin Secretion. An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary (Bankir, 2001). Severe hypovolemia/hypotension also is a powerful stimulus for vasopressin release. In addition, pain, nausea, and hypoxia can stimulate vasopressin secretion, and several endogenous hormones and pharmacological agents can modify vasopressin release.

Hyperosmolality. The relationship between plasma osmolality and plasma vasopressin concentration is shown in Figure 25–17A, and the relationship between plasma vasopressin levels and urine osmolality is illustrated in Figure 25–17B. The osmolality threshold for secretion is ~280 mOsm/kg. Below the threshold, vasopressin is barely detectable in plasma, and above the threshold, vasopressin levels are a steep and relatively linear function of plasma osmolality. A small increase in plasma osmolality leads to enhanced vasopressin secretion. Indeed, a 2% elevation in plasma osmolality causes a 2- to 3-fold increase in plasma vasopressin levels, which in turn causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality above 290 mOsm/kg lead to an intense desire for water (thirst). Thus, the vasopressin system affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. It is important to point out, however, that above a plasma osmolality of ~290 mOsm/kg, plasma vasopressin levels exceed 5 pM. Since urinary concentration is maximal (~1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends entirely on water intake rather than on decreases in water loss.

Several CNS structures are involved in osmotic stimulation of vasopressin release by the posterior pituitary; these structures are collectively referred to as the osmoreceptive complex. Although magnocellular neurons in SON and PVN are osmosensitive, afferent inputs from other components of the osmoreceptive complex are required for a normal vasopressin response. The SON and PVN receive projections from the subfornical organ (SFO) and the organum vasculosum of the lamina terminalis (OVLT) either directly or indirectly by means of the median preoptic nucleus (MnPO). Subgroups of neurons in the SFO, OVLT, and MnPO are either osmoreceptors or osmoresponders (i.e., are stimulated by osmoreceptive neurons located at other sites). Thus, a web of interconnecting neurons contributes to osmotically induced vasopressin secretion.

Aquaporin 4, a water-selective channel, is associated with CNS structures involved in osmoregulation and may confer osmosensitivity. In the CNS, aquaporin 4 resides on glial and ependymal cells rather than on neurons, suggesting that osmotic status may be communicated to the neuronal cell by a glial-neuron interaction (Wells, 1998).

Hepatic Portal Osmoreceptors. An oral salt load activates hepatic portal osmoreceptors leading to increased vasopressin release. This mechanism augments plasma vasopressin levels even before the oral salt load increases plasma osmolality.

Hypovolemia and Hypotension. Vasopressin secretion also is regulated hemodynamically by changes in effective blood volume and/or arterial blood pressure (Robertson, 1992). Regardless of the cause (e.g., hemorrhage, Na+ depletion, diuretics, heart failure, hepatic cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume and/or arterial blood pressure may be associated with high circulating vasopressin concentrations. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; i.e., small decreases (5%) in blood volume and/or pressure have little effect on vasopressin secretion, whereas larger decreases (20-30%) can increase vasopressin levels to 20-30 times normal (exceeding the vasopressin concentration required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors.

![Figure 25–17.](image-url)
known, and the vasopressin response to hypovolemia or hypoten-
sion serves as a mechanism to stave off cardiovascular collapse
during periods of severe blood loss and/or hypotension.

Hemodynamic regulation of vasopressin secretion does not dis-
rupt osmotic regulation; rather, hypovolemia/hypotension alters
the set point and slope of the plasma osmolality-plasma vaso-
pressin relationship (Figure 25–18).

Neuronal pathways that mediate hemodynamic regulation of
vasopressin release are different from those involved in osmoregu-
lation. Baroreceptors in left atrium, left ventricle, and pulmonary
veins sense blood volume (filling pressures), and baroreceptors in
carotid sinus and aorta monitor arterial blood pressure. Nerve
impulses reach brainstem nuclei predominantly through the vagal
trunk and glossopharyngeal nerve; these signals are relayed to the
solitary tract nucleus, then to the A1-noradrenergic cell group in the
caudal ventrolateral medulla, and finally to the SON and PVN.

Hormones and Neurotransmitters. Vasopressin-synthesizing mag-
nocellular neurons have a large array of receptors on both perikarya
and nerve terminals; therefore, vasopressin release can be accentu-
ated or attenuated by chemical agents acting at both ends of the mag-
nocellular neuron. Also, hormones and neurotransmitters can modu-
late vasopressin secretion by stimulating or inhibiting neurons
in nuclei that project, either directly or indirectly, to the SON and
PVN. Because of these complexities, results of any given investiga-
tion may depend critically on route of administration of the agent
and on the experimental paradigm. In many cases, the precise mecha-
nism by which a given agent modulates vasopressin secretion is
either unknown or controversial, and the physiological relevance of
the modulation of vasopressin secretion by most hormones and neu-
rotransmitters is unclear.

Nonetheless, several agents are known to stimulate vaso-
pressin secretion, including acetylcholine (by nicotinic receptors),
histamine (by H1 receptors), dopamine (by both D1 and D2 receptors),
glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P,
vasoactive intestinal polypeptide, prostaglandins, and angiotensin II
(AngII). Inhibitors of vasopressin secretion include atrial natriuretic
peptide, γ-aminobutyric acid, and opioids (particularly dynorphin
via κ receptors). The effects of AngII have received the most atten-
tion. AngII, applied directly to magnocellular neurons in the SON
and PVN, increases neuronal excitability; when applied to the
MnPO, AngII indirectly stimulates magnocellular neurons in the
SON and PVN. In addition, AngII stimulates angiotensin-sensitive neu-
rions in the OVLT and SFO (circumventricular nuclei lacking a
blood-brain barrier) that project to the SON/PVN. Thus, AngII syn-
thetized in the brain and circulating AngII may stimulate vasopressin
release. Inhibition of the conversion of AngII to AngIII blocks AngII-
induced vasopressin release, suggesting that AngIII is the main effec-
tor peptide of the brain renin-angiotensin system controlling
vasopressin release (Reaux et al., 2001).

Pharmacological Agents. A number of drugs alter urine osmolality
by stimulating or inhibiting vasopressin secretion. In some cases the
mechanism by which a drug alters vasopressin secretion involves
direct effects on one or more CNS structures that regulate vaso-
pressin secretion. In other cases vasopressin secretion is altered indi-
rectly by the effects of a drug on blood volume, arterial blood
pressure, pain, or nausea. In most cases the mechanism is not known.
Stimulatots of vasopressin secretion include vincristine, cyclophos-
phamide, tricyclic antidepressants, nicotine, epinephrine, and high
doses of morphine. Lithium, which inhibits the renal effects of vaso-
pressin, also enhances vasopressin secretion. Inhibitors of vaso-
pressin secretion include ethanol, phenytoin, low doses of morphine,
glucocorticoids, fluophenazine, haloperidol, promethazine, oxilor-
pham, and butorphanol. Carbamazepine has a renal action to produce
antidiuresis in patients with central diabetes insipidus but actually
inhibits vasopressin secretion by a central action.

**BASIC PHARMACOLOGY
OF VASOPRESSIN**

**Vasopressin Receptors.** Cellular vasopressin effects are
mediated mainly by interactions of the hormone with the
three types of receptors, V1a, V1b, and V2. The V1a receptor
is the most widespread subtype of vasopressin receptor;
it is found in vascular smooth muscle, adrenal gland,
myometrium, bladder, adipocytes, hepatocytes, platelets,
renal medullary interstitial cells, vasa recta in the renal
microcirculation, epithelial cells in the renal cortical col-
lecting-duct, spleen, testis, and many CNS structures. V1b
receptors have a more limited distribution and are found
in the anterior pituitary, several brain regions, pancreas,
and adrenal medulla. V2 receptors are located predomi-
nantly in principal cells of the renal collecting-duct sys-
tem but also are present on epithelial cells in thick
ascending limb and on vascular endothelial cells. Although
originally defined by pharmacological criteria,
vasopressin receptors now are defined by their primary
amino acid sequences. The cloned vasopressin receptors
are typical heptahelical GPCRs. Manning and co-workers (1999) synthesized novel hypotensive vasopressin peptide agonists that do not interact with V1a, V1b, or V2 receptors and may stimulate a putative vasopressin vasodilatory receptor.

Two additional putative receptors for vasopressin have been cloned. A vasopressin-activated Ca\(^{2+}\)-mobilizing receptor with one transmembrane domain binds vasopressin and increases intracellular Ca\(^{2+}\) (Serradeil-Le Gal et al., 2002). A dual AngII-vasopressin heptahelial receptor activates adenylyl cyclase in response to both AngII and vasopressin (Serradeil-Le Gal et al., 2002). The physiological roles of these putative vasopressin receptors are unclear.

**V1 Receptor-Effector Coupling.** Figure 25–19 summarizes the current model of V1 receptor-effector coupling. Vasopressin binding to V1 receptors activates the\(\text{G}_q\)-PLC-IP3 pathway, thereby mobilizing intracellular Ca\(^{2+}\) and activating PKC, ultimately causing biological effects that include immediate responses (e.g., vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth responses in smooth muscle cells. Other effects of V1-receptor activation may be mediated by stimulation of small G proteins, activation of PLD and PLA\(_2\), and activation of V1-sensitive Ca\(^{2+}\) influx. Some effects of V1-receptor activation are secondary to synthesis of prostaglandins and epoxyeicosatrienoic acids (Chapter 33).

**V2 Receptor-Effector Coupling.** Principal cells in renal collecting duct have V2 receptors on their basolateral membranes that couple to Gs to stimulate adenylyl cyclase activity (Figure 25–20) when vasopressin binds to V2 receptors. The resulting increase in cellular cyclic AMP and PKA activity triggers an increased rate of

---

**Figure 25–19. Mechanism of V1 receptor-effector coupling.** Binding of 8-arginine vasopressin (AVP) to V1 vasopressin receptors (V1) stimulates several membrane-bound phospholipases. Stimulation of the \(\text{G}_q\)-PLC\(_\beta\) pathway results in IP3 formation, mobilization of intracellular Ca\(^{2+}\), and activation of PKC. Activation of V1 receptors also causes influx of extracellular Ca\(^{2+}\) by an unknown mechanism. PKC and Ca\(^{2+}\)/calmodulin-activated protein kinases phosphorylate cell-type-specific proteins leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA\(_2\); the resulting mobilization of arachidonic acid (AA) provides substrate for eicosanoid synthesis by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways, leading to local production of prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT), which may activate a variety of signaling pathways, including those linked to Gs and Gi. Biological effects mediated by the V1 receptor include vasoconstriction, glycogenolysis, platelet aggregation, ACTH release, and growth of vascular smooth muscle cells. The effects of vasopressin on cell growth involve transcriptional regulation by the FOS/JUN AP-1 transcription complex.
insertion of water channel-containing vesicles (WCVs) into the apical membrane and a decreased rate of endocytosis of WCVs from the apical membrane (Snyder et al., 1992). Distribution of WCVs between the cytosolic compartment and apical membrane compartment is thus shifted in favor of the apical membrane compartment (Nielsen et al., 1999). Because WCVs contain preformed functional water channels (aquaporin 2), their net shift into apical membranes in response to V2-receptor stimulation greatly increases water permeability of the apical membrane (see Figures 25–20 and 25–21).

**Figure 25–20.** Mechanism of V2 receptor-effector coupling. Binding of vasopressin (AVP) to the V2 receptor activates the Gs-adenyl cyclase-cAMP-PKA pathway and shifts the balance of aquaporin 2 trafficking toward the apical membrane of the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of serine 256 of aquaporin 2 is involved in V2 receptor signaling, other proteins located both in the water channel-containing vesicles and the apical membrane of the cytoplasm also may be involved.

**Figure 25–21.** Structure of aquaporins. Aquaporins have six transmembrane domains, and the NH1 and COOH termini are intracellular. Loops B and E each contain an asparagine-proline-alanine (NPA) sequence. Aquaporins fold with transmembrane domains 1, 2, and 6 in close proximity and transmembrane domains 3, 4 and 5 in juxtaposition. The long B and E loops dip into the membrane, and the NPA sequences align to create a pore through which water can diffuse. Most likely aquaporins form a tetrameric oligomer. At least seven aquaporins are expressed at distinct sites in the kidney. Aquaporin 1, abundant in the proximal tubule and descending thin limb, is essential for concentration of urine. Aquaporin 2, exclusively expressed in the principal cells of the connecting tubule and collecting duct, is the major vasopressin-regulated water channel. Aquaporin 3 and aquaporin 4 are expressed in the basolateral membranes of collecting-duct principal cells and provide exit pathways for water reabsorbed apically by aquaporin 2. Aquaporin 7 is in the apical brush border of the straight proximal tubule. Aquaporins 6 to 8 are also expressed in kidney; their functions remain to be clarified. Vasopressin regulates water permeability of the collecting duct by influencing the trafficking of aquaporin 2 from intracellular vesicles to the apical plasma membrane (Figure 25–20). AVP-induced activation of the cAMP-PKA pathway also enhances expression of aquaporin 2 mRNA and protein; chronic dehydration thus causes up-regulation of aquaporin 2 and water transport in the collecting duct.
Renal Actions of Vasopressin. Several sites of vasopressin action in kidney involve both V$_1$ and V$_2$ receptors (Bankir, 2001). V$_1$ receptors mediate contraction of mesangial cells in the glomerulus and contraction of vascular smooth muscle cells in vasa recta and efferent arteriole. V$_1$-receptor-mediated reduction of inner medullary blood flow contributes to the maximum concentrating capacity of the kidney (Franchini and Cowley, 1996) (Figure 25–22). V$_2$ receptors also stimulate prostaglandin synthesis by medullary interstitial cells. Since PGE$_2$ inhibits adenylyl cyclase in collecting duct, stimulation of prostaglandin synthesis by V$_1$ receptors may counterbalance V$_2$-receptor-mediated antiuresis. V$_1$ receptors on principal cells in cortical collecting duct may inhibit V$_2$-receptor-mediated water flux by activation of PKC. V$_2$ receptors mediate the most prominent response to vasopressin, which is increased water permeability of the collecting duct. Indeed, vasopressin can increase water permeability in collecting duct at concentrations as low as 50 fM. Thus, V$_2$-receptor-mediated effects of vasopressin occur at concentrations far lower than are required to engage V$_1$-receptor-mediated actions. This differential sensitivity may not be due to differences in receptor affinities because cloned rat V$_1$ and V$_2$ receptors have similar affinities for vasopressin (K$_d$ = 0.7 and 0.4 nM, respectively) but rather may be due to differential amplification of their signal-transduction pathways.

The collecting-duct system is critical for water conservation. By the time tubular fluid arrives at the cortical collecting duct, it has been rendered hypotonic by the upstream diluting segments of the nephron that reabsorb NaCl without reabsorbing water. In the well-hydrated subject, plasma osmolality is in the normal range, concentrations of vasopressin are low, the entire collecting duct is relatively impermeable to water, and the urine is dilute. Under conditions of dehydration, plasma osmolality is increased, concentrations of vasopressin are elevated, and the collecting duct becomes permeable to water. The osmotic gradient between dilute tubular urine and hypertonic renal interstitial fluid (which becomes progressively more hypertonic in deeper regions of the renal medulla) provides for osmotic flux of water out of the collecting duct. The final osmolality of urine may be as high as 1200 mOsm/kg in humans, and a significant saving of solute-free water thus is possible.

Other renal actions mediated by V$_2$ receptors include increased urea transport in inner medullary collecting duct and increased Na$^+$ transport in thick ascending limb; both effects contribute to the urine-concentrating ability of the kidney (Figure 25–22). V$_2$ receptors also increase Na$^+$ transport in cortical collecting duct (Ecelbarger et al., 2001), and this may synergize with aldosterone to enhance Na$^+$ reabsorption during hypovolemia.

Pharmacological Modification of the Antidiuretic Response to Vasopressin. Nonsteroidal anti-inflammatory drugs (NSAIDs), particularly indomethacin, enhance the

![Figure 25–22. Mechanisms by which vasopressin increases the renal conservation of water.](image-url)
antidiuretic response to vasopressin. Since prostaglandins attenuate antidiuretic responses to vasopressin and NSAIDs inhibit prostaglandin synthesis, reduced prostaglandin production probably accounts for potentiation of vasopressin’s antidiuretic response. Carbamazepine and chlorpropamide also enhance antidiuretic effects of vasopressin by unknown mechanisms. In rare instances, chlorpropamide can induce water intoxication.

A number of drugs inhibit the antidiuretic actions of vasopressin. Lithium is of particular importance because of its use in the treatment of manic-depressive disorders. Acutely, Li⁺ appears to reduce V₂-receptor-mediated stimulation of adenyl cyclase. Also, Li⁺ increases plasma levels of parathyroid hormone, a partial antagonist to vasopressin. In most patients, the antibiotic demeclocycline attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP.

**Nonrenal Actions of Vasopressin.** Vasopressin and related peptides are ancient hormones in evolutionary terms, and they are found in species that do not concentrate urine. Thus, it is not surprising that vasopressin has nonrenal actions in mammals.

**Cardiovascular System.** The cardiovascular effects of vasopressin are complex, and vasopressin’s role in physiological situations is ill-defined. Vasopressin is a potent vasoconstrictor (V₁ receptors), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appear most sensitive, with significant vasoconstriction also occurring in GI tract, coronary vessels, and brain. Despite the potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses in vivo are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V₁ receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V₂ receptors cause vasodilation in some blood vessels.

A large body of data supports the conclusion that vasopressin helps to maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. At present, there is no convincing evidence for a role of vasopressin in essential hypertension in humans (Kawano et al., 1997).

The effects of vasopressin on heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. In humans, vasopressin effects on coronary blood flow can be demonstrated easily, especially if large doses are employed. The cardiac actions of the hormone are of more than academic interest. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control diabetes insipidus, and vasopressin-induced myocardial ischemia has led to severe reactions and even death.

**CNS.** It is likely that vasopressin plays a role as a neurotransmitter and/or neuromodulator. Vasopressin may participate in the acquisition of certain learned behaviors, in the development of some complex social processes, and in the pathogenesis of specific psychiatric diseases such as depression. However, the physiological/pathophysiological relevance of these findings is controversial, and some actions of vasopressin on memory and learned behavior may be due to visceral autonomic effects. Many studies support a physiological role for vasopressin as a naturally occurring antipyretic factor. Although vasopressin can modulate CNS autonomic systems controlling heart rate, arterial blood pressure, respiration rate, and sleep patterns, the physiological significance of these actions is unclear. Finally, ACTH secretion is enhanced by vasopressin released from parvicellular neurons in the PVN and secreted into pituitary portal capillaries from axon terminals in the median eminence. Although vasopressin is not the principal corticotropin-releasing factor, vasopressin may provide for sustained activation of the hypothalamic-pituitary-adrenal axis during chronic stress. CNS effects of vasopressin appear to be mediated predominantly by V₁ receptors.

**Blood Coagulation.** Activation of V₂ receptors by desmopressin or vasopressin increases circulating levels of procoagulant factor VIII and of von Willebrand factor. These effects are mediated by extrarenal V₂ receptors (Bernat et al., 1997). Presumably, vasopressin stimulates secretion of von Willebrand factor and of factor VIII from storage sites in vascular endothelium. However, since release of von Willebrand factor does not occur when desmopressin is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.

**Other Nonrenal Effects of Vasopressin.** At high concentrations, vasopressin stimulates smooth muscle contraction in uterus (by oxytocin receptors) and GI tract (by V₁ receptors). Vasopressin is stored in platelets, and activation of V₁ receptors stimulates platelet aggregation. Also, activation of V₁ receptors on hepatocytes stimulates glycogenolysis. The physiological significance of these effects of vasopressin in not known.

**VASOPRESSIN RECEPTOR AGONISTS AND ANTAGONISTS**

A number of vasopressin-like peptides occur naturally (Table 25–8). All are nonapeptides, contain cysteine residues in positions 1 and 6, have an intramolecular disulfide bridge between the two cysteine residues (essential for agonist activity), have additional conserved amino acids in positions 5, 7, and 9 (asparagine, proline, and glycine, respectively), contain a basic amino acid in position 8, and are amidated on the carboxyl terminus. In all mammals except swine, the neuropeptide sequence is 8-arginine vasopressin, and the terms vasopressin, arginine vasopressin (AVP), and antidiuretic hormone (ADH) are used interchangeably.

The chemical structure of oxytocin is closely related to that of vasopressin: oxytocin is [Ile³, Leu⁸]AVP. Oxytocin binds to specific oxytocin receptors on myoepithelial cells in mammary gland and on
smooth muscle cells in the uterus, causing milk ejection and uterine contraction, respectively. Inasmuch as vasopressin and oxytocin are structurally similar, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other’s receptors. Therefore, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin receptors; at high doses, they may block or mimic the effects of oxytocin.

Many vasopressin analogs were synthesized with the goal of increasing duration of action and selectivity for vasopressin receptor subtypes (V₁ versus V₂ vasopressin receptors, which mediate pressor responses and antidiuretic responses, respectively). Deamination at position 1 increases duration of action and increases

\(^a\)Available for clinical use.
antidiuretic activity without increasing vasopressor activity. Substitution of D-arginine for L-arginine greatly reduces vasopressor activity without reducing antidiuretic activity. Thus, the antidiuretic-to-vasopressor ratio for 1-deamino–8-D-arginine vasopressin (Table 25–8), also called desmopressin (DDAVP, MINIRIN, STIMATE, others), is ~3000 times greater than that for vasopressin, and desmopressin now is the preferred drug for the treatment of central diabetes insipidus. Substitution of valine for glutamine in position 4 further increases the antidiuretic selectivity, and the antidiuretic to vasopressor ratio for deamino [Val4, D-Arg8]AVP (Table 25–8) is ~11,000 times greater than that for vasopressin. Nakamura and colleagues (2000) synthesized a nonpeptide V2-receptor agonist (Table 25–8).

Increasing V1 selectivity has proved more difficult than increasing V2 selectivity, but a limited number of agonists with modest selectivity for V1 receptors have been developed (Table 25–8). Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical V1 nor V2 receptors. Since vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical V1 receptors, and since many vasopressin analogs with vasoconstrictr activity release ACTH, V1 receptors have been subclassified into V1a (vascular/hepatic) and V1b (pituitary) receptors. V1b receptors are also called V1 receptors. Vasopressin analogs that are agonists selective for V1a or V1b receptors have been described (Table 25–8).

Chemistry of Vasopressin Receptor Antagonists. The impetus for the development of specific vasopressin receptor antagonists is the belief that such drugs may be useful in a number of clinical settings. Based on receptor physiology, selective V1a antagonists may be beneficial when total peripheral resistance is increased (e.g., congestive heart failure and hypertension), whereas selective V1b antagonists could be useful whenever reabsorption of solute-free water is excessive (e.g., the syndrome of inappropriate secretion of antidiuretic hormone [SIADH] and hyponatremia associated with a reduced effective blood volume). Combined V1a/V1b receptor antagonists might be beneficial in diseases associated with a combination of increased peripheral resistance and dilutional hyponatremia (e.g., congestive heart failure).

Highly selective V1 and V2 peptide antagonists that are structural analogs of vasopressin have been synthesized (see Table 25–9 for examples), including both cyclic and linear peptides. 1-[(β-Mercapto-β, β-cyclopentamethylenepropionic acid), 2-O-methyltyrosine] arginine vasopressin, also known as d(CH2)8[Tyr(Me)2]AVP, has a greater affinity for V1a receptors than for either V1b or V2 receptors; this antagonist has been employed widely in physiological and pharmacological studies. Although 1-deamino[penicillamine, 2-O-methyltyrosine] arginine vasopressin, also called D[Pro[Tyr(Me)2]]AVP, is a potent V1b receptor antagonist with little affinity for the V2 receptor, it also blocks V1a receptors. No truly selective peptide V1b-receptor antagonist is available. Peptide antagonists have limited oral activity, and the potency of peptide V2 antagonists is species dependent.

**DISEASES AFFECTING THE VASOPRESSIN SYSTEM**

**Diabetes Insipidus (DI).** DI is a disease of impaired renal water conservation owing either to inadequate vasopressin secretion from the neurohypophysis (central DI) or to insufficient renal vasopressin response (nephrogenic DI). Very rarely, DI can be caused by an abnormally high degradation rate of vasopressin by circulating vasopressinases. Pregnancy may accentuate or reveal central and/or nephrogenic DI by increasing plasma levels of vasopressinase and by reducing renal sensitivity to vasopressin. Patients with DI excrete large volumes (>30 mL/kg per day) of dilute (<200 mOsm/kg) urine and, if their thirst mechanism is functioning normally, are polydipsic. In contrast to the sweet urine excreted by patients with diabetes mellitus, urine from patients with DI is tasteless, hence the name insipidus.

The urinary taste test for DI has been supplanted by the approach of observing whether the patient is able to reduce urine volume and increase urine osmolality after a period of carefully observed fluid deprivation. Central DI can be distinguished from nephrogenic DI by administration of desmopressin, which will increase urine osmolality in patients with central DI but have little or no effect in patients with nephrogenic DI. DI can be differentiated from primary polydipsia by measuring plasma osmolality, which will be low to low-normal in patients with primary polydipsia and high to high-normal in patients with DI. For a more complete discussion of diagnostic procedures, see Robertson (2001).

**Central DI.** Head injury, either surgical or traumatic, in the region of the pituitary and/or hypothalamus may cause central DI. Postoperative central DI may be transient, permanent, or triphasic (recovery followed by permanent relapse). Other causes include hypothalamic or pituitary tumors, cerebral aneurysms, CNS ischemia, and brain infiltrations and infections (Robertson, 2001). Central DI may also be idiopathic or familial. Familial central DI usually is autosomal dominant (chromosome 20), and vasopressin deficiency occurs several months or years after birth and worsens gradually. Autosomal dominant central DI is linked to mutations in the vasopressin preprohormone gene that cause the prohormone to misfold and oligomerize improperly. The long-term result is accumulation of the mutant vasopressin precursor in the affected neuron because the precursor cannot move from the endoplasmic reticulum into the secretory pathway. Accumulation of mutant vasopressin precursor causes neuronal death, hence the dominant mode of inheritance (Robertson, 2001). Rarely, familial central DI is autosomal recessive owing to a mutation in the vasopressin peptide itself that gives rise to an inactive vasopressin mutant.

Antidiuretic peptides are the primary treatment for central DI, with desmopressin being the peptide of choice. For patients with central DI who cannot tolerate antidiuretic peptides because of side effects or allergic reactions, other treatment options are available.
Chlorpropamide, an oral sulfonylurea, potentiates the action of small or residual amounts of circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. Doses of 125-500 mg daily appear effective in patients with partial central DI. If polyuria is not controlled satisfactorily with chlorpropamide alone, addition of a thiazide diuretic to the regimen usually results in an adequate reduction in urine volume. Carbamazepine (800-1000 mg daily in divided doses) also reduces urine volume in patients with central DI. Long-term use may induce serious adverse effects; therefore, carbamazepine is used rarely to treat central DI. The antidiuretic mechanisms of chlorpropamide, carbamazepine, and clofibrate (not available in the U.S.) are not clear. These agents are not effective in nephrogenic DI, which indicates that functional V₂ receptors are required for the antidiuretic effect. Since carbamazepine inhibits and chlorpropamide has little effect on vasopressin secretion, it is likely that carbamazepine and chlorpropamide act directly on the kidney to enhance V₂-receptor-mediated antidiuresis.

**Nephrogenic DI.** Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, Li⁺, foscarnet, clozapine, demeclocycline, and other drugs can induce nephrogenic DI. As many as one in three patients treated with Li⁺ may develop nephrogenic DI.

X-linked nephrogenic DI is caused by mutations in the gene encoding the V₂ receptor, which maps to Xq28. A number of missense, nonsense, and frame-shift mutations in the gene encoding the V₂ receptor were identified in patients with this disorder. Mutations in the V₂ receptor gene may cause impaired routing of the V₂ receptor to the cell surface, defective coupling of the receptor to G proteins, or decreased receptor affinity for vasopressin. The effects of these mutations range from a complete loss of responsiveness to vasopressin to a shift to the left of the concentration-response curve. Autosomal recessive and dominant nephrogenic DI result from inactivating mutations in aquaporin 2. These findings indicate that aquaporin 2 is essential for the antidiuretic effect of vasopressin in humans.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate water intake, drugs also can be used to reduce polyuria. Amiloride blocks Li⁺ uptake by the Na⁺ channel in the collecting-duct system and may be effective in patients with mild to moderate concentrating defects. Patients with severe disease often do not respond. Thiazide diuretics reduce the polyuria of patients with DI and often are used to treat nephrogenic DI. The use of thiazide diuretics in infants with nephrogenic DI may be crucially important because uncontrolled polyuria may exceed the child’s capacity to imbibe and absorb fluids. The antidiuretic mechanism of thiazides in DI is incompletely understood. It is possible that the natriuretic action of thiazides and resulting extracellular fluid volume depletion play an important role in thiazide-induced antidiuresis. In this regard, whenever extracellular fluid volume is reduced, compensatory mechanisms increase NaCl reabsorption in proximal tubule, reducing the volume delivered to the distal tubule. Consequently, less free water can be formed, which should diminish polyuria. However, studies in rats with vasopressin-deficient DI challenge this hypothesis. Nonetheless, the antidiuretic effects appear to parallel the thiazide’s ability to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of Na⁺ intake can enhance the antidiuretic effectiveness of thiazides.

A number of case reports describe the effectiveness of indomethacin in the treatment of nephrogenic DI; however, other prostaglandin synthase inhibitors (e.g., ibuprofen) appear to be less effective. The mechanism of the effect may involve a decrease in glomerular filtration rate, an increase in medullary solute concentration, and/or enhanced proximal fluid reabsorption. Also, since prostaglandins attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V₂-receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the prostaglandin effect and enhancement of vasopressin effects on the principal cells of collecting duct.

**Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH).** SIADH is a disease of impaired water excretion with accompanying hyponatremia and hyposmolality caused by the inappropriate secretion of vasopressin. Clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH (Robertson, 2001), including malignancies, pulmonary diseases, CNS injuries/diseases (e.g., head trauma, infections, and tumors), and general surgery.

The three drug classes most commonly implicated in drug-induced SIADH include psychotropic medications (e.g., selective serotonin reuptake inhibitors, haloperidol, and tricyclic antidepressants), sulfonylureas (e.g., chlorpropamide), and vinca alkaloids (e.g., vincristine and vinblastine). Other drugs strongly associated with SIADH include clonidine, cyclophosphamide, enalapril, felbamate, ifosfamide, and methyldopa, pentamidine, and vinorelbine. In a normal individual, an elevation in plasma vasopressin per se does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin. Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with kidney’s concentrating ability), and drugs that inhibit the effect of vasopressin to increase water permeability in collecting ducts. To inhibit vasopressin’s action in collecting ducts, demeclocycline, a tetracycline, has been the preferred drug, but tolvaptan and conivaptan, V₂ receptor antagonists, are now available (see next section and Table 25–9).

Although Li⁺ can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index.
Therefore, Li\(^+\) should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated (e.g., patients with liver disease). It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na\(^+\) stabilizes in the range of 125–132 m\(\text{M}\); such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na\(^+\) levels drop below 120 m\(\text{M}\), should therapy with demeclocycline be initiated. Since hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, is the cause of symptoms, the goal of therapy is simply to increase plasma osmolality toward normal. For a more complete description of the diagnosis and treatment of SIADH, see Robertson (2001).

Other Water-Retaining States. In patients with congestive heart failure, cirrhosis, or nephrotic syndrome, effective blood volume often is reduced, and hypovolemia frequently is exacerbated by the liberal use of diuretics. Since hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V\(_1\) receptor antagonists and specific inhibitors of water channels in the collecting duct has provided a new therapeutic strategy not only in patients with SIADH but also in the more common setting of hyponatremia in patients with heart failure, liver cirrhosis, and nephrotic syndrome, as discussed in the next section.

**CLINICAL PHARMACOLOGY OF VASOPRESSIN PEPTIDES**

**Agonists**

**Therapeutic Uses.** Two antidiuretic peptides are available for clinical use in the U.S.:

- Vasopressin (synthetic 8-L-arginine vasopressin; PITRESSIN, others) is available as a sterile aqueous solution; it may be administered subcutaneously, intramuscularly, or intranasally.
- Desmopressin acetate (synthetic 1-deamino-8-D-arginine vasopressin; DDAVP, others) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a solution for intranasal administration with either a nasal spray pump or nasal tube delivery system, and in tablets for oral administration.

The therapeutic uses of vasopressin and its congeners can be divided into two main categories according to the type of vasopressin receptor involved.

**\(V_1\) receptor-mediated** therapeutic applications are based on the rationale that \(V_1\) receptors cause GI and vascular smooth muscle contraction. \(V_1\) receptor-mediated GI smooth muscle contraction has been used to treat postoperative ileus and abdominal distension and to dispel intestinal gas before abdominal roentgenography to avoid interfering gas shadows. \(V_1\) receptor-mediated vasoconstriction of the splanchnic arterial vessels reduces blood flow to the portal system and, thereby, attenuates pressure and bleeding in esophageal varices (Burroughs, 1998). Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, \(V_1\) receptor agonists have been used in an emergency setting until endoscopy can be performed (Vlavianos and Westaby, 2001). Simultaneous administration of nitroglycerin with \(V_1\) receptor agonists may attenuate the cardiotoxic effects of \(V_1\) agonists while enhancing their beneficial splanchnic effects. Also, \(V_1\) receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. Finally, \(V_1\) receptor-mediated vasoconstriction has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, cesarean section, and uterine myoma resection.

The applications of \(V_1\) receptor agonists can be accomplished with vasopressin; however, the use of vasopressin for all these indications is no longer recommended because of significant adverse reactions. Terlipressin (LUCASSIN) is preferred for bleeding esophageal varices because of increased safety compared with vasopressin (Vlavianos and Westaby, 2001) and is designated as an orphan drug for this use. Moreover, terlipressin is effective in patients with hepatorenal syndrome, particularly when combined with albumin (Ortega et al., 2002). Terlipressin has been granted priority review, orphan drug status, and fast-track designation by the FDA for type I hepatorenal syndrome.

Vasopressin levels in patients with vasodilatory shock are inappropriately low, and such patients are extraordinarily sensitive to the pressor actions of vasopressin. The combination of vasopressin and norepinephrine is superior to norepinephrine alone in the management of catecholamine-resistant vasodilatory shock. However, recent clinical trials show that, in comparison to catecholamines alone, addition of vasopressin does not improve outcomes in either cardiac arrest or septic shock.

**\(V_2\) receptor-mediated** therapeutic applications are based on the rationale that \(V_2\) receptors cause water conservation and release of blood coagulation factors. Central but not nephrogenic DI can be treated with \(V_2\) receptor agonists, and polyuria and polydipsia usually are well controlled by these agents. Some patients experience transient DI (e.g., in head injury or surgery in the area of the pituitary); however, therapy for most patients with DI is lifelong. Desmopressin is the drug of choice for the vast majority of patients, and numerous clinical trials demonstrated the efficacy and tolerability of desmopressin in both adults and children.

The duration of effect from a single intranasal dose is from 6–20 hours; twice-daily administration is effective in most patients. There is considerable variability in the intranasal dose of desmopressin required to maintain normal urine volume, and the dosage must be tailored individually. The usual intranasal dosage in adults...
is 10-40 μg daily either as a single dose or divided into two or three doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. An initial dose of 2.5 μg can be used, with therapy first directed toward control of nocturia. An equivalent or higher morning dose controls daytime polyuria in most patients, although a third dose occasionally may be needed in the afternoon. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable peptide absorption following nasal administration. Oral administration of desmopressin in doses 10-20 times the intranasal dose provides adequate desmopressin blood levels to control polyuria. Subcutaneous administration of 1-2 μg daily of desmopressin also is effective in central DI.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V₁ receptor-mediated side effects. Vasopressin can be used as an alternative to desmopressin in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient, and long-acting agents may produce water intoxication.

An additional V₂ receptor-mediated therapeutic application is the use of desmopressin in bleeding disorders (Mannucci, 1997). In most patients with type I von Willebrand’s disease (vWD) and in some with type IIa vWD, desmopressin will elevate von Willebrand factor and shorten bleeding time. However, desmopressin generally is ineffective in patients with types IIa, IIb, and III vWD. Desmopressin may cause a marked transient thrombocytopenia in individuals with type III vWD and is contraindicated in such patients. Desmopressin also increases factor VIII levels in patients with mild to moderate hemophilia A. Desmopressin is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. Using a test dose of nasal spray, the response of any given patient with type I vWD or hemophilia A to desmopressin should be determined at the time of diagnosis or 1-2 weeks before elective surgery to assess the extent of increase in factor VIII or von Willebrand factor. Desmopressin is employed widely to treat the hemostatic abnormalities induced by uremia. In patients with renal insufficiency, desmopressin shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII-related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. Desmopressin is effective in some patients with liver cirrhosis-induced or drug-induced (e.g., heparin, hirudin, and antiplatelet agents) bleeding disorders. Desmopressin, given intravenously at a dose of 0.3 μg/kg, increases factor VIII and von Willebrand factor for > 6 hours. Desmopressin can be given at intervals of 12-24 hours depending on the clinical response and severity of bleeding. Tachyphylaxis to desmopressin usually occurs after several days (owing to depletion of factor VIII and von Willebrand factor storage sites) and limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another V₂ receptor-mediated therapeutic application is the use of desmopressin for primary nocturnal enuresis. Bedtime administration of desmopressin intranasal spray or tablets provides a high response rate that is sustained with long-term use, that is safe, and that accelerates the cure rate. Finally, desmopressin has been found to relieve post-lumbar puncture headache probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

**Pharmacokinetics.** When vasopressin and desmopressin are given orally, they are inactivated quickly by trypsin, which cleaves the peptide bond between amino acids 8 and 9.

Inactivation by peptidases in various tissues (particularly liver and kidney) results in a plasma t½ of vasopressin of 17-35 minutes. Following intramuscular or subcutaneous injection, antidiuretic effects of vasopressin last 2-8 hours. The plasma t½ of desmopressin has two components, a fast component (~8 min) and a slow component (30-117 min). Only 3% and 0.15%, respectively, of intranasally and orally administered desmopressin is absorbed.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions.** Most adverse effects are mediated through V₁ receptor activation on vascular and GI smooth muscle; consequently, such adverse effects are much less common and less severe with desmopressin than with vasopressin.

After injection of large doses of vasopressin, marked facial pallor owing to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. Most serious, however, is the effect on the coronary circulation. Vasopressin should be administered only at low doses and with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene were encountered in patients receiving large doses of vasopressin.

The major V₂ receptor-mediated adverse effect is water intoxication, which can occur with desmopressin or vasopressin. In this regard, many drugs, including carbamazepine, chlorpropamide, morphine, tricyclic antidepressants, and NSAIDs, can potentiate the antidiuretic effects of these peptides. Several drugs such as Li⁺, demeclocycline, and ethanol can attenuate the antidiuretic response to desmopressin. Desmopressin and vasopressin should be used cautiously in disease states in which a rapid increase in extracellular water may impose risks (e.g., in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving desmopressin to maintain hemostasis should be advised to reduce fluid intake. Also, it is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue.
Mild facial flushing and headache are the most common adverse effects associated with desmopressin. Allergic reactions ranging from urticaria to anaphylaxis may occur with desmopressin or vasopressin. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

**Vasopressin Receptor Antagonists**

Table 25–9 lists the structures and selectivity of receptor antagonists.

**Therapeutic Uses.** When the kidney perceives the arterial blood volume to be low (as in the disease states of CHF, cirrhosis, and nephrosis), AVP perpetuates a state of total body salt and water excess. V2 receptor (V2,R) antagonists or “aquaretics” may have a therapeutic role in these conditions, especially in patients with concomitant hyponatremia. They are also effective in hyponatremia associated with SIADH. Aquaretics increase renal free water excretion with little or no change in electrolyte excretion. Since they do not affect Na+ reabsorption they do not stimulate the TGF mechanism with its associated consequence of reducing GFR. Conivaptan, a V1aR/V2R antagonist, and tolvaptan, a selective V2,R antagonist, are FDA-approved for use in patients with euvolemic or hypervolemic hyponatremia associated with SIADH. The V2,R antagonist mozavaptan is approved in Japan for the treatment hyponatremia secondary to SIADH caused by malignancy. Although a large number of vasopressin receptor antagonists are in preclinical and clinical trials, we will discuss only the V2,R antagonists mozavaptan and tolvaptan, and the V1aR/V2R antagonist conivaptan (Costello-Boerrigter et al., 2009).

**Mozavaptan.** Mozavaptan was the first nonpeptide V2 receptor antagonist in clinical use. It was approved for treatment of SIADH secondary to cancer in Japan in 1996. Mozavaptan causes a dose-dependent increase in free water excretion with only slight increases in urinary Na+ and K+ excretion.

**Tolvaptan.** Tolvaptan (SAMSCA) is a selective oral V2,R antagonist developed through structural modifications of mozavaptan to create a more selective V2,R antagonist. In short-term clinical trials in patients with CHF and reduced ejection fraction, the drug decreased body weight and improved dyspnea. In long-term trials, there was no effect on all-cause mortality, cardiovascular death, or hospitalization for heart failure; losses in body weight and increases in Na+ concentration were sustained over the course of the studies. Tolvaptan is approved for clinically significant hypervolemic and euvolemic hyponatremia. The drug is labeled with a black box warning against too rapid correction of hyponatremia (can have serious and fatal consequences) and the recommendation to initiate therapy in a hospital setting capable of close monitoring of serum Na+. Tolvaptan is contraindicated in patients receiving drugs that inhibit CYP3A4.

**Conivaptan.** Conivaptan (VAPRISOL) is a nonselective V1aR/V2R antagonist that is FDA-approved for the treatment of hospitalized patients with euvolemic hyponatremia and hypervolemic hyponatremia. The drug is available only for intravenous infusion. In CHF patients, conivaptan increases renal free water excretion without a change in systemic vascular resistance. The manufacturer recommends starting administration with a 20 mg loading dose given over 30 minutes followed by a continuous infusion of an additional 20 mg over the first 24 hours. The infusion is then continued at 20 mg/day for a maximum of three additional days. The dose can be increased to 40 mg/day if there is no response to the 20 mg dose. Doses higher than 40 mg/day have no additional benefit. Serum Na+ concentration should not be increased >12 mEq/L in a 24-hour period.

**Pharmacokinetics**

**Mozavaptan.** Mozavaptan is available in 30-mg tablets. Few data are available regarding its pharmacokinetics. It binds to the V2,R with much higher affinity than V1a,R, Kd 9.42 ± 0.9 nM versus 150 ± 15 nM, respectively. Its peak effects occur 60-90 minutes after an oral dose.

**Tolvaptan.** Tolvaptan is available in 15 and 30 mg tablets and inhibits the V2,R with a Kd of 0.43 ± 0.06 nM and the V1a,R with a Kd of 12.3 ± 0.8 nM. Tolvaptan is 29 times more selective for the V2,R than the V1a,R. Most of its effects on renal free water excretion occur in the first 6-8 hours after administration. Tolvaptan has a t1/2 of 6-8 hours and <1% is excreted in the urine. The starting dose is 15 mg once daily, and this dose can be titrated up to a maximum of 60 mg daily. Tolvaptan is a substrate and inhibitor of P-glycoprotein and is eliminated entirely by CYP3A metabolism.

**Conivaptan.** Conivaptan inhibits the V1a,R with a Kd of 6.3 ± 1.8 nM and the V2,R with a Kd of 1.1 ± 0.2 nM. Total body clearance is 9.5-10.1 L/hr. It is highly protein bound and has a terminal elimination t1/2 of 5-12 hours. Conivaptan is metabolized via CYP3A4 and is partially excreted by the kidney. Caution should be exercised in those with hepatic and renal disease. At higher doses clearance may be reduced in the elderly.

**Toxicity, Adverse Effects, Contraindications, Drug Interactions**

**Mozavaptan.** Mozavaptan’s major side effects are dry mouth and abnormal liver function tests.

**Tolvaptan.** Tolvaptan is eliminated by CYP3A4. Plasma concentrations of the drug are increased by ketoconazole. There is no known affect on amiodarone, digoxin, or warfarin metabolism. Among the

- **OPC-31260 (mozavaptan)**
  - Available for clinical use.

- **OPC-41061 (tolvaptan)**
  - Also blocks \( V_{1a} \) receptor, rather than \( V_2 \) antagonistic activity in rats; however, antagonistic activity may be less or nonexistent in other species. Also, with prolonged infusion may exhibit significant agonist activity.

- **YM-087 (conivaptan)**

- **JTV-605**

- **CL-385004**

- **YM 087 (conivaptan)**

---

\(^a\) Also blocks \( V_{1a} \) receptor, rather than \( V_2 \) antagonistic activity in rats; however, antagonistic activity may be less or nonexistent in other species. Also, with prolonged infusion may exhibit significant agonist activity. \(^b\) Available for clinical use.
adverse effects listed for tolvaptan are GI effects, hyperglycemia, and pyrexia. Less common are cerebrovascular accident, deep vein thrombosis, disseminated intravascular coagulation, intracardiac thrombus, ventricular fibrillation, urethral hemorrhage, vaginal hemorrhage, pulmonary embolism, respiratory failure, diabetic ketoacidosis, ischemic colitis, increase in prothrombin time and rhabdomyolysis.

**Conivaptan.** Conivaptan is metabolized by CYP3A4 and as a result is associated with a variety of drug-drug interactions. It should not be administered in patients receiving ketoconazole, itraconazole, ritonavir, indinavir, clarithromycin, or other strong CYP3A4 inhibitors. Conivaptan increases levels of simvastatin, digoxin, amlodipine, and midazolam. It is not known to interact with warfarin or prolong the QTc interval. Due to multiple drug-drug interactions conivaptan is no longer being developed for chronic long-term oral use. The most common adverse effect of conivaptan is an infusion site reaction. The manufacturer recommends that the drug only be infused into large veins and that infusion sites be changed daily. Other adverse effects have included headache, hypertension, hypotension, hypokalemia, and pyrexia.

**Future Directions in Vasopressin Analog Analogs**

Nonpeptide vasopressin receptor antagonists and agonists are being developed for a wide range of clinical indications, including for $V_{1a}$-selective antagonists: dysmenorrhea, preterm labor, and Raynaud’s syndrome; for $V_{1b}$-selective antagonists: stress-related disorders, anxiety, depression, ACTH-secreting tumors, and Cushing’s syndrome; for $V_2$-selective and $V_1a/V_2$-selective antagonists: heart failure, SIADH, cirrhosis, hyponatremia, brain edema, nephrotic syndrome, diabetic nephropathy, and glaucoma; and for $V_2$-selective agonists: central DI, nocturnal enuresis, nocturnal polyuria, and urinary incontinence (Wong and Verbalis, 2001).

Preliminary data support several of the indications mentioned earlier for vasopressin receptor antagonists and agonists. Relcovaptan (SR 49059) is a $V_{1a}$-selective antagonist that has efficacy in primary dysmenorrhea (Brouard et al., 2000), and nelivaptan (SSR 149415) is a $V_{1b}$-selective antagonist that demonstrates anxiolytic activity in animal models of stress (Griebel et al., 2002). Aquaretics are drugs that increase free-water clearance with minimal effects on electrolyte excretion. The $V_2$-selective antagonist lixivaptan (VPA-985) is an effective aquaretic in patients with hyponatremia of various etiologies (Wong et al., 2003). In contrast, the $V_2$-selective agonist OPC-51803 has strong antidiuretic effects in animals and is being developed for central DI, nocturnal enuresis, and urinary incontinence (Nakamura et al., 2003). It is likely that more nonpeptide vasopressin receptor antagonists and agonists will become available clinically in the near future.

**BIBLIOGRAPHY**

The renin–angiotensin system (RAS) participates significantly in the pathophysiology of hypertension, congestive heart failure, myocardial infarction, and diabetic nephropathy. This realization has led to a thorough exploration of the RAS and the development of new approaches for inhibiting its actions. This chapter discusses the biochemistry, molecular and cellular biology, and physiology of the RAS; the pharmacology of drugs that interrupt the RAS; and the clinical utility of inhibitors of the RAS. Therapeutic applications of drugs covered in this chapter are also discussed in Chapters 27 and 28.

THE RENIN–ANGIOTENSIN SYSTEM

History. In 1898, Tiegerstedt and Bergman found that crude saline extracts of the kidney contained a pressor substance that they named renin. In 1934, Goldblatt and his colleagues demonstrated that constriction of the renal arteries produced persistent hypertension in dogs. In 1940, Braun-Menéndez and his colleagues in Argentina and Page and Helmer in the U.S. reported that renin was an enzyme that acted on a plasma protein substrate to catalyze the formation of the actual pressor material, a peptide, that was named hypertensin by the former group and angiotonin by the latter. These two terms persisted for nearly 20 years until it was agreed to rename the pressor substance angiotensin and to call the plasma substrate angiotensinogen. In the mid-1950s, two forms of angiotensin were recognized, a decapeptide (angiotensin I [AngI]) and an octapeptide (angiotensin II [AngII]) formed by proteolytic cleavage of AngI by an enzyme termed angiotensin-converting enzyme (ACE). The octapeptide was shown to be the more active form, and its synthesis in 1957 by Schwzyer and by Bumpus made the material available for intensive study.

It was later shown that the kidneys are important for aldosterone regulation and that angiotensin potently stimulates the production of aldosterone in humans. Moreover, renin secretion increased with depletion of Na+. Thus, the RAS came to be recognized as a mechanism to stimulate aldosterone synthesis and secretion and an important homeostatic mechanism in the regulation of blood pressure and electrolyte composition.

In the early 1970s, polypeptides were discovered that either inhibited the formation of AngII or blocked AngII receptors. These inhibitors revealed important physiological and pathophysiological roles for the RAS and inspired the development of a new and broadly efficacious class of antihypertensive drugs: the orally active ACE inhibitors. Studies with ACE inhibitors uncovered roles for the RAS in the pathophysiology of hypertension, heart failure, vascular disease, and renal failure. Selective and competitive antagonists of AngII receptors were developed that yielded losartan, the first orally active, highly selective, and potent nonpeptide AngII receptor antagonist. Subsequently, many other AngII receptor antagonists have been developed. Recently aliskiren, a direct renin inhibitor, was approved for antihypertensive therapy (see Chapter 27).

Components of the Renin–Angiotensin System

Overview. AngII, the most active angiotensin peptide, is derived from angiotensinogen in two proteolytic steps. First, renin, an enzyme released from the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate). Then, ACE removes the carboxy-terminal dipeptide of AngI to produce the octapeptide AngII. These enzymatic steps are summarized in Figure 26–1. AngII acts by binding to two heptahelical GPCRs, AT₁ and AT₂.

The understanding of the RAS has expanded in recent years. The current view of the RAS also includes a local (tissue) RAS, alternative pathways for AngII synthesis (ACE independent), formation of other biologically active angiotensin peptides (AngIII, AngIV, Ang[1–7]), and additional angiotensin binding receptors (angiotensin subtypes 1, 2, and 4 [AT₁, AT₂, AT₄]; Mas) that participate in cell growth differentiation, hypertrophy, inflammation, fibrosis, and apoptosis. All components of the RAS are described in detail in a later section.

Renin. Renin is the major determinant of the rate of AngII production. It is synthesized, stored, and secreted by exocytosis into the
renal arterial circulation by the granular juxtaglomerular cells (Figure 26–2) located in the walls of the afferent arterioles that enter the glomeruli. Renin is an aspartyl protease that cleaves the bond between residues 10 and 11 at the amino terminus of angiotensinogen to generate AngI. The active form of renin is a glycoprotein that contains 340 amino acids. It is synthesized as a preproenzyme of 406 amino acid residues that is processed to prorenin. Prorenin is proteolytically activated by proconvertase 1 or cathepsin B enzymes that remove 43 amino acids (propeptide) from its amino terminus to uncover the active site of renin (Figure 26–3). The active site of renin is located in a cleft between the two homologous lobes of the enzyme. Nonproteolytic activation of prorenin, central to the activation of local (tissue) RAS, occurs when prorenin binds to the prorenin/renin ((pro)renin) receptor, resulting in conformational changes that unfold the propeptide and expose the active catalytic site of the enzyme. (Danser et al., 2005). Both renin and prorenin are stored in the juxtaglomerular cells and, when released, circulate in the blood. The concentration of prorenin in the circulation is ~10-fold greater than that of the active enzyme. The t 1/2 of circulating renin is ~15 minutes.

**Control of Renin Secretion.** The secretion of renin from juxtaglomerular cells is controlled predominantly by three pathways (Figure 26–2):

- the macula densa pathway
- the intrarenal baroreceptor pathway
- the β1 adrenergic receptor pathway

The first mechanism is the **macula densa pathway.** The macula densa lies adjacent to the juxtaglomerular cells and is composed of specialized columnar epithelial cells in the wall of that portion of the cortical thick ascending limb that passes between the afferent and efferent arterioles of the glomerulus. A change in NaCl reabsorption by the macula densa results in the transmission to nearby juxtaglomerular cells of chemical signals that modify renin release. Increases in NaCl flux across the macula densa inhibit renin release, whereas decreases in NaCl flux stimulate renin release. ATP, adenosine, and prostaglandins modulate the macula densa pathway. ATP and adenosine are released when NaCl transport increases ATP acts on P2Y receptors to inhibit renin release. Adenosine acts via the A1 adenosine receptor to inhibit renin release. Prostaglandins (PGE2, PGI2) are released when NaCl transport decreases and stimulate renin release through enhancing cyclic AMP formation. Prostaglandin production is stimulated by inducible cyclooxygenase-2 (COX-2). COX-2 and neuronal nitric oxide synthase (nNOS) participate in the mechanism of macula densa–stimulated renin release. The expression of COX-2 and nNOS is upregulated by chronic dietary Na+ restriction; selective inhibition of either COX-2 or nNOS inhibits renin release. The nNOS/NO pathway, in part, may mediate increases in COX-2 expression induced by a low-Na+ diet; however, COX-2 expression in the macula densa is not attenuated in nNOS knockout mice, which suggests that other mechanisms can compensate for nNOS in the regulation of COX-2.

Regulation of the macula densa pathway is more dependent on the luminal concentration of Cl− than Na+. NaCl transport into the macula densa is mediated by the Na+-K+-2Cl− symporter (Figure 26–2B), and the half-maximal concentrations of Na+ and Cl− required for transport via this symporter are 2-3 and 40 mEq/L, respectively. Because the luminal concentration of Na+ at the macula densa usually is much greater than the level required for half-maximal transport, physiological variations in luminal Na+ concentrations at the macula densa have little effect on renin release (i.e., the symporter remains saturated with respect to Na+). On the other hand, physiological changes in Cl− concentrations (20-60 mEq/L) at the macula densa profoundly affect macula densa–mediated renin release.
Figure 26–2. A. Schematic portrayal of the three major physiological pathways regulating renin release. See text for details. MD, macula densa; PGI₂/PGE₂ prostaglandins I₂ and E₂; NSAIDs, nonsteroidal antiinflammatory drugs; Ang II, angiotensin II; ACE, angiotensin-converting enzyme. AT₁ R, angiotensin subtype 1 receptor; NE/Epi, norepinephrine/epinephrine; JGCs, juxtaglomerular cells. B. Mechanisms by which the macula densa regulates renin release. Changes in tubular delivery of NaCl to the macula densa cause appropriate signals to be conveyed to the juxtaglomerular cells. Sodium depletion upregulates nNOS and COX-2 in the macula densa to enhance production of prostaglandins (PGs). PGs and catecholamines stimulate cyclic AMP production and thence renin release from the juxtaglomerular cells. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels. Adenosine diffuses to the juxtaglomerular cells and inhibits cyclic AMP production and renin release via G₁ coupled A₁ receptors. Increased NaCl transport in the macula densa augments the efflux of ATP, which may inhibit renin release directly by binding to P2Y receptors and activating the G₁-PLC-IP₃-Ca²⁺ pathway in juxtaglomerular cells. Circulating Ang II also inhibits renin release on juxtaglomerular cells via G₉ coupled AT₁ receptors.
The second mechanism controlling renin release is the intrarenal baroreceptor pathway. Increases and decreases in blood pressure or renal perfusion pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus to secretion is believed to be reduced tension within the wall of the afferent arteriole. The release of renal prostaglandins and biomechanical coupling via stretch-activated ion channels may mediate in part the intrarenal baroreceptor pathway (Wang et al., 1999).

The third mechanism, the β adrenergic receptor pathway, is mediated by the release of norepinephrine from postganglionic sympathetic nerves; activation of β1 receptors on juxtaglomerular cells enhances renin secretion.

The three mechanisms regulating renin release are embedded in a feedback regulation (Figure 26–2A). Increased renin secretion enhances the formation of AngII, which stimulates AT1 receptors on juxtaglomerular cells to inhibit renin release, an effect termed short-loop negative feedback. AngII increases arterial blood via AT1 receptors; this effect inhibits renin release by:

- activating high-pressure baroreceptors, thereby reducing renal sympathetic tone
- increasing pressure in the preglomerular vessels
- reducing NaCl reabsorption in the proximal tubule (pressure natriuresis), which increases tubular delivery of NaCl to the macula densa

The inhibition of renin release owing to AngII-induced increases in blood pressure has been termed long-loop negative feedback.

The physiological pathways regulating renin release are influenced by arterial blood pressure, dietary salt intake, and a number of pharmacological agents (Figure 26–2A). Loop diuretics stimulate renin release by decreasing arterial blood pressure and by blocking the reabsorption of NaCl at the macula densa. Nonsteroidal anti-inflammatory drugs (NSAIDs; see Chapter 34) inhibit prostaglandin synthesis and thereby decrease renin release. ACE inhibitors, angiotensin receptor blockers (ARBs), and renin inhibitors interrupt both the short- and long-loop negative feedback mechanisms and therefore increase renin release. Increasing cyclic AMP in the juxtaglomerular cells stimulates renin. Centrally acting sympatholytic drugs (see Chapter 12), as well as β adrenergic receptor antagonists, decrease renin secretion by reducing activation of β adrenergic receptors on juxtaglomerular cells.

**Angiotensinogen.** The substrate for renin is angiotensinogen, an abundant globular glycoprotein (MW = 55,000-60,000). AngI is cleaved from the amino terminus of angiotensinogen. The human angiotensinogen contains 452 amino acids and is synthesized as pre-angiotensinogen, which has a 24– or 33–amino acid signal peptide. Angiotensinogen is synthesized and secreted primarily by the liver, although angiotensinogen transcripts also are abundant in fat, certain regions of the central nervous system (CNS), and the kidneys. Angiotensinogen synthesis is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and AngII. During pregnancy, plasma levels of angiotensinogen increase several-fold owing to increased estrogen.

Circulating levels of angiotensinogen are approximately equal to the $K_m$ of renin for its substrate (~1 μM). Consequently, the rate of AngII synthesis, and therefore blood pressure, can be influenced by changes in angiotensinogen levels. For instance, knockout mice lacking angiotensinogen are hypotensive, and there is a progressive relationship among the number of copies of the angiotensinogen gene, plasma levels of angiotensinogen, and arterial blood pressure. Oral contraceptives containing estrogen increase circulating levels of angiotensinogen and can induce hypertension. A missense mutation in the angiotensinogen gene (a methionine to threonine at position 235 of angiotensinogen) that increases plasma levels of angiotensinogen is associated with essential and pregnancy-induced hypertension (Sethi et al., 2003). Angiotensinogen shares sequence homologies that have anti-angiogenic properties with the serpin protein family (Céleri et al., 2002).

**Angiotensin-Converting Enzyme (ACE, Kininase II, Dipeptidyl Carboxypeptidase).** ACE is an ectoenzyme and glycoprotein with
an apparent molecular weight of 170,000. Human ACE contains 1277 amino acid residues and has two homologous domains, each with a catalytic site and a Zn$^{2+}$-binding region. ACE has a large amino-terminal extracellular domain, a short carboxyl-terminal intracellular domain, and a 17–amino acid hydrophobic region that anchors the ectoenzyme to the cell membrane. ACE is rather nonspecific and cleaves dipeptide units from substrates with diverse amino acid sequences. Preferred substrates have only one free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus, the enzyme does not degrade AngII. ACE is identical to kininase II, the enzyme that inactivates bradykinin and other potent vasodilator peptides. Although slow conversion of AngI to AngII occurs in plasma, the very rapid metabolism that occurs in vivo is due largely to the activity of membrane-bound ACE present on the luminal surface of endothelial cells throughout the vascular system.

The ACE gene contains an insertion/deletion polymorphism in intron 16 that explains 47% of the phenotypic variation in serum ACE levels. The deletion allele, associated with higher levels of serum ACE and increased metabolism of bradykinin, may confer an increased risk of hypertension, cardiac hypertrophy, atherosclerosis, and diabetic nephropathy (Hadjadj et al., 2001) but may be protective against Alzheimer’s disease (Sayed-Tabatabaei et al., 2006; Castrop et al., 2010).

Angiotensin-Converting Enzyme 2. Two groups independently discovered a novel ACE-related carboxypeptidase, now termed ACE2 (Donoghue et al., 2000; Tipnis et al., 2000). Human ACE2 is 805 amino acids in length with a short putative signal sequence. ACE2 contains a single catalytic domain that is 42% identical to the two catalytic domains of ACE. ACE2 cleaves one amino acid from the carboxyl terminal to convert AngI to Ang(1–9) and AngII to Ang(1–7). AngII is the preferred substrate for ACE2 with 400-fold higher affinity than AngI. The physiological significance of ACE2 is still uncertain; it may serve as a counter-regulatory mechanism to oppose the effects of ACE. ACE2 regulates the levels of AngII and limits its effects by converting it to Ang(1–7), which binds to Mas receptors and elicits vasodilator and anti-proliferative responses (Varagic et al., 2008). ACE2 is not inhibited by the standard ACE inhibitors and has no effect on bradykinin. In animals, reduced expression of ACE2 is associated with hypertension, defects in cardiac contractility, and elevated levels of AngII (Crackower et al., 2002). Overexpression of the ACE2 gene prevents AngII-induced cardiac hypertrophy in hypertensive rats (Huentelman et al., 2005). ACE2 also serves as a receptor for the SARS coronavirus (Li et al., 2003).

Angiotensin Peptides. When given intravenously, AngI is rapidly converted to AngII. However, AngI per se is less than 1% as potent as AngII on smooth muscle, the heart, and the adrenal cortex. Angiotensin III (AngIII), also called Ang(2–8), can be formed either by the action of aminopeptidase on AngII or by the action of ACE on Ang(2–10). AngII and AngIII cause qualitatively similar effects. AngII and AngIII stimulate aldosterone secretion with equal potency; however, AngIII is only 25% and 10% as potent as AngII in elevating blood pressure and stimulating the adrenal medulla, respectively.

Ang(1–7) is formed by multiple pathways (Figure 26–1). AngI can be converted to Ang(1–7) by endopeptidases. AngII can be converted to Ang(1–7) by prolylcarboxypeptidase (Ferrario et al., 1997). ACE2 converts AngI to Ang(1–9) and AngII to Ang(1–7); ACE metabolizes Ang(1–9) to Ang(1–7). In animal models, Ang(1–7) opposes many of the effects of AngII; it induces vasodilation, promotes NO production, potentiates the vasodilatory effects of bradykinin, and inhibits AngII-induced activation of ERK1/2; it has anti-angiogenic, anti-proliferative, and anti-thrombotic effects; and is cardioprotective in cardiac ischemia and heart failure. The effects of Ang(1–7) are mediated by a specific Mas receptor. The Mas proto-oncogene encodes an orphan G protein–coupled receptor (Santos et al., 2008; Varagic et al., 2008). Ferrario and colleagues (1997) proposed that Ang(1–7) serves to counterbalance the actions of AngII, which may depend on ACE-AngII/ACE2-Ang(1–7) activity ratio (Santos et al., 2008). ACE inhibitors increase tissue and plasma levels of Ang(1–7), both because AngI levels are increased and diverted away from AngII formation (Figure 26–1) and because ACE contributes to the plasma clearance of Ang(1–7). AT$_1$ receptor blockade boosts the levels of AngII that is converted to Ang(1–7) by ACE2.

Angiotensin IV (AngIV), also called Ang(3–8), is formed from AngIII through the catalytic action of aminopeptidase M and has potent effects on memory and cognition. Central and peripheral actions of AngIV are mediated through specific AT$_4$ receptors identified as insulin-regulated amino pepitides (IRAPs). AngIV binding to AT$_3$ receptors inhibits the catalytic activity of IRAPs and enables accumulation of various neuropeptides linked to memory potentiation. Other actions include renal vasodilation, natriuresis, neuronal differentiation, hypertrophy, inflammation, and extracellular matrix remodeling (Ruiz-Ortega et al., 2007). Analogs of angiotensin IV are being developed for their therapeutic potential in cognition in Alzheimer disease or head injury (Albiston et al., 2007).

Angiotensinases. These include aminopeptidases, endopeptidases, carboxypeptidases, and other peptidases that degrade and inactivate angiotensin peptides; none is specific.

Local (Tissue) Renin–Angiotensin Systems. The traditional view of the RAS as classical endocrine system is oversimplified. The modern view of the RAS also includes the local (tissue) RAS. Local (tissue) RAS is an AngII-producing system that is being recognized for its role in hypertension, inflammation, remodeling, and apoptosis. Activation of (tissue) RAS and local AngII production require the binding of renin or prorenin to the specific (pro)renin receptor (PRR), located on cell surfaces. In this regard, it is important to distinguish between extrinsic and intrinsic local RAS:

Extrinsic Local RAS. ACE is present on the luminal face of vascular endothelial cells throughout the circulation, and circulating renin of renal origin can be taken up by the arterial wall and by other tissues (Danser et al., 1994).

Intrinsic Local RAS. Many tissues—including the brain, pituitary, blood vessels, heart, kidney, and adrenal gland—express mRNAs for renin, angiotensinogen, and/or ACE, and various cells cultured from these tissues produce renin, angiotensinogen, ACE, and angiotensins I, II, and III. Thus, it appears that local RASs exist independently of the renal/hepatic-based system and may influence vascular, cardiac, and renal function and structure (Paul et al., 2006).

The (Pro)Renin Receptor. The PRR is the functional receptor, located on the cell surface, that binds prorenin and renin with high affinity (K$_D$ ~6 and 20 nM, respectively) and specificity (Batenburg and Danser, 2008). Human PRR is a 350–amino acid protein that shares no homology with any membrane protein. The PRR gene is located
in the locus p11.4 of the X chromosome and is named ATP6ap2 (ATPase-associated protein). Knockout of the PRR gene is lethal. In humans, mutations in the PRR gene are associated with mental retardation and epilepsy, suggesting an important role in cognition, brain development, and survival (Nguyen and Danser, 2008; Ramser et al., 2005). Prorenin and renin also bind to mannose-6-phosphate receptor (M6P), an insulin-like growth factor II receptor that functions as a clearance receptor.

Binding of (pro)renin to PRR enhances the catalytic activity of renin by 4-5 fold and induces non-proteolytic activation of prorenin (Figure 26-3). Bound, activated (pro)renin catalyzes the conversion of angiotensinogen to AngI, which is subsequently converted to AngII by ACE located on the cell surface. Locally produced AngII binds to AT$_1$ receptors and activates intracellular signaling events that regulate cell growth, collagen deposition, fibrosis, inflammation, and apoptosis (Nguyen and Danser, 2008).

The binding of (pro)renin to PRR also induces AngII-independent signaling events that include activation of ERK1/2, p38, tyrosine kinases, TGF-β gene expression, and plasminogen activator inhibitor type 1 (PAI-1). These signaling pathways are not blocked by ACE inhibitors or AT$_1$ receptor antagonists and are reported to contribute to fibrosis, nephrosis, and organ damage (Kaneshiro et al., 2007; Nguyen and Danser, 2008; see Figure 26-4). PRR is abundant in the heart, brain, eye, adrenals, placenta, adipose tissue, liver, and kidneys. Overexpression of the human PRR in transgenic animals increases plasma aldosterone levels in the absence of changes in plasma renin levels and induces hypertension and nephropathy. Rats overexpressing PRR exhibit increased expression of COX-2 in the macula densa and develop proteinuria and glomerulosclerosis that increase with aging (Kaneshiro et al., 2006; Kaneshiro et al., 2007).

Prorenin is no longer considered the inactive precursor of renin. Prorenin is capable of activating local (tissue) RAS and AngII-dependent and independent events that may contribute to organ damage. Circulating plasma concentrations of prorenin are 10-fold higher than renin in healthy subjects but are elevated to 100-fold in diabetic patients and are associated with increased risk of nephropathy, renal fibrosis, and retinopathy (Danser and Deinum, 2005; Nguyen and Danser, 2008). The interaction of prorenin with PRR has become a target for therapeutic interventions.

**Alternative Pathways for Angiotensin Biosynthesis.** Angiotensinogen may be converted to AngI or directly to AngII by cathepsin G and tonin. Other enzymes that convert AngI to AngII include cathepsin G, chymostatin-sensitive AngII-generating enzyme, and heart chymase. Chymase contributes to the local tissue conversion of AngI to AngII, particularly in the heart and kidneys (Paul et al., 2006).

**Angiotensin Receptors.** AngII and AngIII couple to specific GPCRs designated AT$_1$ and AT$_2$ (de Gasparo et al., 2000). The AT$_1$ receptor has a 10,000-fold higher affinity for losartan (and related biphenyl tetrazole derivatives) than the AT$_2$ receptor. The AT$_1$ receptor (359 amino acids) and the AT$_2$ receptor (363 amino acids) share 34% sequence homology.

Most of the known biological effects of AngII are mediated by the AT$_1$ receptor. The AT$_1$ receptor gene contains a polymorphism (A-to-C transversion in position 1166) associated with hypertension, hypertrophic cardiomyopathy, and coronary artery vasocostriction. Moreover, the C allele synergizes with the ACE deletion allele with regard to increased risk of coronary artery disease (Álvarez et al., 1998). Preeclampsia is associated with the development of agonistic auto-antibodies against the AT$_1$ receptor (Wallukat et al., 1999).

Functional roles for the AT$_2$ receptors are less well defined, but they may counterbalance many of the effects of the AT$_1$ receptors by having antiproliferative, proapoptotic, vasodilatory, natriuretic, and antihypertensive effects (Jones et al., 2008; Carey et al., 2001). The AT$_2$ receptor is distributed widely in fetal tissues, but its distribution is more restricted in adults. Although the AT$_2$ receptor generally is conceptualized as a cardiovascular protective receptor, its overexpression and activation may contribute to myocyte hypertrophy and cardiac fibrosis (D’Amore et al., 2005; Ichihara et al., 2001). Expression of AT$_2$ receptors is upregulated in cardiovascular diseases, including heart failure, cardiac fibrosis, and ischemic heart disease; however, the significance of increased AT$_2$ receptor expression is unclear (Jones et al., 2008).

**Figure 26-4. Ang II-dependent and Ang II-independent actions of prorenin.** See text for details.
The Mas receptor mediates the effects of Ang(1–7), which include vasodilation and anti-proliferation. Deletion of the Mas gene in transgenic mice reveals cardiac dysfunction (Santos et al., 2008).

The AT₂ receptor (IRAP; see Figure 26-2) mediates the effects of AngIV. This receptor is a single transmembrane protein (1025 amino acids) that co-localizes with the glucose transporter GLUT4. AT₂ receptors are detectable in a number of tissues, such as heart, vasculature, adrenal cortex, and brain regions processing sensory and motor functions (Chai et al., 2004).

**Angiotensin Receptor–Effector Coupling.** AT₁ receptors activate a large array of signal-transduction systems to produce effects that vary with cell type and that are a combination of primary and secondary responses. AT₁ receptors couple to several heterotrimeric G proteins, including Gq, G₁₂/₁₃, and Gi. In most cell types, AT₁ receptors couple to Gq to activate the PLCβ–IP₃–Ca²⁺/CaM pathway. Secondary to Gq activation, activation of PKC, PLA₂, and PLD and eicosanoid production, as well as activation of Ca²⁺–calmodulin–dependent MAP kinases and the Ca²⁺–calmodulin–dependent activation of NOS may occur. Activation of Gi may occur and will reduce the activity of adenyl cyclase, lowering cellular cyclic AMP content; however, there also is evidence for Gq → Gi cross-talk such that activation of the AT₁–Gq–PLC pathway enhances cyclic AMP production (Meszaros et al., 2000; Epperson et al., 2004). The βγ subunits of Gi and activation of G₁₂/₁₃ lead to activation of tyrosine kinases and small G proteins such as Rho. Ultimately, the JAK/STAT pathway may be activated and a variety of transcriptional regulatory factors induced. By these mechanisms, angiotensins influence the expression of a host of gene products relating to cell growth and the production of components of the extracellular matrix. AT₁ receptors also stimulate the activity of a membrane-bound NADH/NADPH oxidase that generates reactive oxygen species (ROS). ROS may contribute to biochemical effects (activation of MAP kinase, tyrosine kinase, and phosphatases; inactivation of NO; and expression of monocyte chemoattractant protein-1) and physiological effects (acute effects on renal function, chronic effects on blood pressure, and vascular hypertrophy and inflammation) (Mehta and Griendling, 2007; Higuchi et al., 2007). The relative importance of these myriad signal-transduction pathways in mediating biological responses to AngII is tissue specific. The presence of other receptors may alter the response to AT₁ receptor activation. For example, AT₁ receptors heterodimerize with bradykinin B₂ receptors, a process that enhances AngII sensitivity in preeclampsia (AbdAlla et al., 2002).

Less is known about AT₂ receptor–effector coupling. Signaling from AT₂ receptors is mediated by G protein-dependent and independent pathways. Consequences of AT₂ receptor activation include activation of phosphoprotein phosphatases, K⁺ channels, synthesis of NO and cyclic GMP, bradykinin production, and inhibition of Ca²⁺ channel functions (Jones et al., 2008). AT₂ receptors may possess constitutive activity. Overexpression of AT₂ receptors has been reported to induce NO production in vascular smooth muscle cells and hypertrophy in cardiac myocytes through an intrinsic activity of the AT₂ receptor independent of angiotensin binding (D’Amore et al., 2005; Jones et al., 2008). Homo-oligomerization of AT₂ receptors also has been reported to induce apoptosis (Miura et al., 2005). The AT₂ receptor may bind directly to and antagonize the AT₁ receptor (AbdAlla et al., 2001) and can form heterodimers with the bradykinin B₂ receptor to enhance NO production (Abadir, 2006).

Functions and Effects of the Renin–Angiotensin System

The main effects of AngII on the cardiovascular system include:

- rapid pressor response
- slow pressor response
- vascular and cardiac hypertrophy and remodeling

Modest increases in plasma concentrations of AngII acutely raise blood pressure; on a molar basis, AngII is ~40 times more potent than NE (see Chapter 12); the EC₅₀ of AngII for acutely raising arterial blood pressure is ~0.3 nM. When a single moderate dose of AngII is injected intravenously, systemic blood pressure begins to rise within seconds, peaks rapidly, and returns to normal within minutes (Figure 26–5). This rapid pressor response to AngII is due to a swift increase in total peripheral resistance—a response that helps to maintain arterial blood pressure in the face of an acute hypotensive challenge (e.g., blood loss or vasodilation). Although AngII increases cardiac contractility directly (via opening voltage-gated Ca²⁺ channels in cardiac myocytes) and increases heart rate indirectly (via facilitation of sympathetic tone, enhanced adrenergic neurotransmission, and adrenal catecholamine release), the rapid increase in arterial blood pressure activates a baroreceptor reflex that decreases sympathetic tone and increases vagal tone. Thus, depending on the physiological

![Figure 26–5. Effect of a bolus intravenous injection of AngII (0.05 μg/kg) on arterial blood pressure (BP) and renal blood flow (RBF) in a conscious dog. (Reproduced with permission, from Zimmerman BG. Absence of adrenergic mediation of agonist response to [Sar¹,Ala⁸]angiotensin II in conscious normotensive and hypertensive dogs. Clin Sci, 1979, 57:71–81. © the Biochemical Society.)](image-url)
state, AngII may increase, decrease, or not change cardiac contractility, heart rate, and cardiac output. Changes in cardiac output therefore contribute little, if at all, to the rapid pressor response induced by AngII.

AngII also causes a slow pressor response that helps to stabilize arterial blood pressure over the long term. A continuous infusion of initially subpressor doses of AngII gradually increases arterial blood pressure, with the maximum effect requiring days to achieve. This slow pressor response probably is mediated by a decrement in renal excretory function that shifts the renal pressure–natriuresis curve to the right (see the next section). AngII stimulates the synthesis of endothelin-1 and superoxide anion, which may contribute to the slow pressor response.

In addition to its effects on arterial blood pressure, AngII stimulates remodeling of the cardiovascular system, causing hypertrophy of vascular and cardiac cells and increased synthesis and deposition of collagen by cardiac fibroblasts.

Mechanisms by Which Angiotensin II Increases Total Peripheral Resistance. AngII increases total peripheral resistance (TPR) via direct and indirect effects on blood vessels (Figure 26–6).

Rapid Pressor Response

Direct Vasoconstriction. AngII constricts precapillary arterioles and, to a lesser extent, postcapillary venules by activating AT1 receptors located on vascular smooth muscle cells and stimulating the Gq–PLC–IP3–Ca2+ pathway. AngII has differential effects on vascular beds. Direct vasoconstriction is strongest in the kidneys (Figure 26–5) and somewhat less in the splanchnic vascular bed; blood flow in these regions falls sharply when AngII is infused. AngII-induced vasoconstriction is much less in vessels of the brain and still weaker in...
those of the lung and skeletal muscle. Nevertheless, high circulating concentrations of AngII may decrease cerebral and coronary blood flow.

**Enhancement of Peripheral Noradrenergic Neurotransmission.** AngII augments norepinephrine release from sympathetic nerve terminals by inhibiting the reuptake of norepinephrine into nerve terminals and by enhancing the vascular response to NE (see Chapter 12). High concentrations of the peptide stimulate ganglion cells directly.

**Effects on the CNS.** Small amounts of AngII infused into the vertebral arteries cause an increase in arterial blood pressure. This response—mediated by increased sympathetic outflow—reflects effects of the hormone on circumventricular nuclei that are not protected by a blood-brain barrier (e.g., area postrema, subfornical organ, organum vasculosum of the lamina terminalis). Circulating AngII also attenuates baroreceptor-mediated reductions in sympathetic discharge, thereby increasing arterial pressure. The CNS is affected both by bloodborne AngII and by AngII formed within the brain, where it may serve as a neurotransmitter. The brain contains all components of the RAS. In addition to increasing sympathetic tone, AngII also causes a centrally mediated dipsogenic (thirst) effect and enhances the release of vasopressin from the neurohypophysis.

**Release of Catecholamines from the Adrenal Medulla.** AngII stimulates the release of catecholamines from the adrenal medulla by depolarizing chromaffin cells.

**Slow Pressor Response**

**Alteration of Renal Function.** AngII has pronounced effects on renal function, reducing the urinary excretion of Na⁺ and water while increasing the excretion of K⁺. The overall effect of AngII on the kidneys is to shift the renal pressure–natriuresis curve to the right (Figure 26–7).

**Direct Effects of Angiotensin II on Na⁺ Reabsorption in the Renal Tubules.** Very low concentrations of AngII stimulate Na⁺/H⁺ exchange in the proximal tubule—an effect that increases Na⁺, Cl⁻, and bicarbonate reabsorption. Approximately 20-30% of the bicarbonate handled by the nephron may be affected by this mechanism. AngII also increases the expression of the Na⁺–glucose symporter in the proximal tubule (Bautista et al., 2004). Paradoxically, at high concentrations, AngII may inhibit Na⁺ transport in the proximal tubule. AngII also directly stimulates the Na⁺–K⁺–2Cl⁻ symporter in the thick ascending limb. The proximal tubule secretes angiotensinogen, and the connecting tubule releases renin, so a paracrine tubular RAS may contribute to Na⁺ reabsorption.

**Release of Aldosterone from the Adrenal Cortex.** AngII stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone, and augments responses to other stimuli (e.g., ACTH, K⁺). Increased output of aldosterone is elicited by concentrations of AngII that have little or no acute effect on blood pressure. Aldosterone acts on the distal and collecting tubules to cause retention of Na⁺ and excretion of K⁺ and H⁺. The stimulant effect of AngII on aldosterone synthesis and release is enhanced under conditions of hyponatremia or hyperkalemia and is reduced when concentrations of Na⁺ and K⁺ in plasma are altered in the opposite directions.

**Altered Renal Hemodynamics.** AngII reduces renal blood flow and renal excretory function by directly constricting the renal vascular smooth muscle, by enhancing renal sympathetic tone (a CNS effect), and by facilitating renal adrenergic transmission (an intrarenal effect). AngII-induced vasoconstriction of preglomerular microvessels is enhanced by endogenous adenosine owing to signal-transduction systems activated by AT₁ and the adenosine A₁ receptor (Hansen et al., 2003).

AngII influences glomerular filtration rate (GFR) by means of several mechanisms:

- constriction of the afferent arterioles, which reduces intraglomerular pressure and tends to reduce GFR
- constriction of mesangial cells, which decreases the capillary surface area within the glomerulus available for filtration and also tends to decrease GFR
- constriction of efferent arterioles, which increases intraglomerular pressure and tends to increase GFR

![Figure 26–7. Pressure-natriuresis curve: effects of Na⁺ intake on renin release (AngII formation) and arterial blood pressure.](http://lww.com/)

Normally, GFR is slightly reduced by AngII; however, during renal artery hypotension, the effects of AngII on the efferent arteriole predominate so that AngII increases GFR. Thus, blockade of the RAS may cause acute renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

**Vascular and Cardiac Hypertrophy and Remodeling.** Pathological alterations involving cardiac hypertrophy and remodeling increase morbidity and mortality. These morbid changes in cardiovascular structure are due to increased migration, proliferation (hyperplasia), and hypertrophy of cells, as well as to increased extracellular matrix. The cells involved include vascular smooth muscle cells, cardiac myocytes, and fibroblasts. In this regard, AngII:

- stimulates the migration, proliferation, and hypertrophy of vascular smooth muscle cells
- increases extracellular matrix production by vascular smooth muscle cells
- causes hypertrophy of cardiac myocytes
- increases extracellular matrix production by cardiac fibroblasts

These effects of AngII are mediated by acting directly on cells to induce the expression of specific proto-oncogenes (c-fos, c-jun, c-myc, and egr-1) that alter the expression of growth factors such as basic FGF, PDGF, and TGF-β. In addition, AngII alters extracellular matrix formation and degradation indirectly by increasing aldosterone.

**Hemodynamically Mediated Effects of Angiotensin II on Cardiovascular Structure.** In addition to the direct cellular effects of AngII on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na+ retention) and afterload (increased arterial blood pressure) probably contribute to cardiac hypertrophy and remodeling. Arterial hypertension also contributes to hypertrophy and remodeling of blood vessels.

**Role of the RAS in Long-Term Maintenance of Arterial Blood Pressure Despite Extremes in Dietary Na+ Intake.** Arterial blood pressure is a major determinant of Na+ excretion. This is illustrated graphically by plotting urinary Na+ excretion versus mean arterial blood pressure (Figure 26–7), a plot known as the renal pressure–natriuresis curve. Over the long term, Na+ excretion must equal Na+ intake; therefore, the set point for long-term levels of arterial blood pressure can be obtained as the intersection of a horizontal line representing Na+ intake with the renal pressure–natriuresis curve. As illustrated in Figure 26–7, the RAS plays a major role in maintaining a constant set point for long-term levels of arterial blood pressure despite extreme changes in dietary Na+ intake. When dietary Na+ intake is low, renin release is stimulated, and AngII acts on the kidneys to shift the renal pressure–natriuresis curve to the right. Conversely, when dietary Na+ is high, renin release is inhibited, and the withdrawal of AngII shifts the renal pressure–natriuresis curve to the left. When modulation of the RAS is blocked by drugs, changes in salt intake markedly affect long-term levels of arterial blood pressure.

**Other Effects of the RAS.** Expression of the RAS is required for the development of normal kidney morphology, particularly the maturational growth of the renal papilla (Niimura et al., 1995). AngII causes a marked anorexigenic effect and weight loss, and high circulating levels of AngII may contribute to the anorexia, wasting, and cachexia of heart failure (Brink et al., 1996).

**Angiotensin and Vascular Disease**

The RAS induces vascular disease by multiple mechanisms, including directly and indirectly (via aldosterone): stimulating vascular smooth muscle cell migration, proliferation, and extracellular matrix production; increasing the release of plasminogen activator inhibitor type 1 and enhancing the expression of monocyte chemoattractant protein 1; augmenting the expression of adhesion proteins (e.g., ICAM-1, integrins, and osteopontin) in vascular cells; and stimulating the production of inflammatory chemokines and cytokines that enhance the migration of inflammatory cells (Schmieder et al., 2007). AngII markedly accelerates the development of atherosclerosis in apolipoprotein E–deficient mice (Weiss et al., 2001), an animal model of atherosclerosis.

**INHIBITORS OF THE RENIN–ANGIOTENSIN SYSTEM**

Clinical interest focuses on developing inhibitors of the RAS. Three types of inhibitors are utilized therapeutically (Figure 26–8):

- ACE inhibitors (ACEIs)
- angiotensin receptor blockers (ARBs)
- direct renin inhibitors (DRIs)
Angiotensin-Converting Enzyme Inhibitors

**History.** In the 1960s, Ferreira and colleagues found that the venoms of pit vipers contain factors that intensify vasodilator responses to bradykinin. These bradykinin-potentiating factors are a family of peptides that inhibit kininase II, an enzyme that inactivates bradykinin. Erdös and coworkers established that ACE and kininase II are the same enzyme, which catalyzes both the synthesis of AngII and the destruction of bradykinin. Based on these findings, the nonapeptide teprotide (snake venom peptide that inhibits kininase II and ACE) was later synthesized and tested in human subjects. It lowered blood pressure in many patients with essential hypertension and exerted beneficial effects in patients with heart failure.

The orally effective ACE inhibitor captopril was developed by a rational approach that involved analysis of the inhibitory action of teprotide, inference about the action of ACE on its substrates, and analogy with carboxypeptidase A, which was known to be inhibited by D-benzylsuccinic acid. Ondetti, Cushman, and colleagues argued that inhibition of ACE might be produced by succinyl amino acids that corresponded in length to the dipeptide cleaved by ACE. This led to the synthesis of a series of carboxy alkanoyl and mercapto alkanoyl derivatives that are potent competitive inhibitors of ACE. Most active was captopril (Vane, 1999).

**Pharmacological Effects in Normal Laboratory Animals and Humans.** The effect of ACE inhibitors on the RAS is to inhibit the conversion of AngI to the active AngII. Inhibition of AngII production will lower blood pressure and enhance natriuresis. ACE is an enzyme with many substrates, and inhibition of ACE may also induce effects unrelated to reducing the levels of AngII. ACE inhibitors increase bradykinin levels and bradykinin stimulates prostaglandin biosynthesis; both may contribute to the pharmacological effects of ACE inhibitors. ACE inhibitors increase by 5-fold the circulating levels of the natural stem cell regulator N-acetyl-seryl-aspartyl-lysyl-proline, which may contribute to the cardioprotective effects of ACE inhibitors (Rhaleb et al., 2001). In addition, ACE inhibitors will increase renin release and the rate of formation of AngI by interfering with both short- and long-loop negative feedbacks on renin release (Figure 26–2A). Accumulating AngI is directed down alternative metabolic routes, resulting in the increased production of vasodilator peptides such as Ang(1–7). In healthy, Na+-replete animals and humans, a single oral dose of an ACE inhibitor has little effect on systemic blood pressure, but repeated doses over several days cause a small reduction in blood pressure. By contrast, even a single dose of these inhibitors lowers blood pressure substantially in normal subjects depleted of Na+ (Figure 26-7).

**Clinical Pharmacology.** ACE inhibitors can be classified into three broad groups based on chemical structure: (1) sulfhydryl-containing ACE inhibitors structurally related to captopril; (2) dicarboxyl-containing ACE inhibitors structurally related to enalapril (e.g., lisinopril, benazepril, quinapril, moexipril, ramipril, trandolapril, perindopril); and (3) phosphorus-containing ACE inhibitors structurally related to fosinopril. Many ACE inhibitors are ester-containing prodrugs that are 100-1000 times less potent but have a better oral bioavailability than the active molecules. Currently, 11 ACE inhibitors are available for clinical use in the U.S. (Figure 26–9). They differ with regard to potency, whether ACE inhibition is primarily a direct effect of the drug itself or the effect of an active metabolite, and pharmacokinetics.

With the exceptions of fosinopril and spirapril (which display balanced elimination by the liver and kidneys), ACE inhibitors are cleared predominantly by the kidneys. Impaired renal function significantly diminishes the plasma clearance of most ACE inhibitors, and dosages of these drugs should be reduced in patients with renal impairment. Elevated plasma renin activity renders patients hyperresponsive to ACE inhibitor–induced hypotension, and initial dosages of all ACE inhibitors should be reduced in patients with high plasma levels of renin (e.g., patients with heart failure and salt-depleted patients).
All ACE inhibitors block the conversion of AngI to AngII and have similar therapeutic indications, adverse-effect profiles, and contraindications. Although captopril and enalapril are indistinguishable with regard to antihypertensive efficacy and safety, the Quality-of-Life Hypertension Study Group reported that captopril may have a more favorable effect on quality of life (Testa et al., 1993). Because hypertension usually requires lifelong treatment, quality-of-life issues are an important consideration in comparing antihypertensive drugs. ACE inhibitors differ markedly in tissue distribution, and it is possible that this difference could be exploited to inhibit some local (tissue) RAS while leaving others relatively intact.

captopril (CAPOTEN, others). Captopril, the first ACE inhibitor to be marketed, is a potent ACE inhibitor with a $K_i$ of 1.7 nM. It is the only ACE inhibitor approved for use in the U.S. that contains a sulfhydryl moiety. Given orally, captopril is absorbed rapidly and has a bioavailability ~75%. Bioavailability is reduced by 25-30% with food, so captopril should be given 1 hour before meals. Peak concentrations in plasma occur within an hour, and the drug is cleared rapidly with a $t_{1/2}$ ~2 hours. Most of the drug is eliminated in urine, 40-50% as captopril and the rest as captopril disulfide dimers and captopril–cysteine disulfide. The oral dose of captopril ranges from 6.25-150 mg two to three times daily, with 6.25 mg
ACE with a hydrolyzed by esterases in the liver to produce the active dicarboxylic acid, enalaprilat. Enalaprilat is a highly potent inhibitor of ACE with a $K_i$ of 0.2 nM. Although it also contains a “proline surrogate,” enalapril differs from captopril in that it is an analog of a tripeptide rather than of a dipeptide. Enalapril is absorbed rapidly when given orally and has an oral bioavailability of ~60% (not reduced by food). Although peak concentrations of enalaprilat in plasma occur within an hour, enalaprilat concentrations peak only after 3-4 hours. Enalapril has a $t_{1/2}$ of ~1.3 hours, but enalaprilat, because of tight binding to ACE, has a plasma $t_{1/2}$ of ~11 hours. Nearly all the drug is eliminated by the kidneys as either intact enalapril or enalaprilat. The oral dosage of enalapril ranges from 2.5-40 mg daily (single or divided dose), with 2.5 and 5 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively.

**Enalaprilat** (Vasotec Injection, others). Enalaprilat is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate. For hypertensive patients, the dosage is 0.625-1.25 mg given intravenously over 5 minutes. This dosage may be repeated every 6 hours.

**Lisinopril** (Prinivil, Zestril, others). Lisinopril is the lysine analog of enalaprilat; unlike enalapril, lisinopril itself is active. In *vitro*, lisinopril is a slightly more potent ACE inhibitor than is enalaprilat. Lisinopril is absorbed slowly, variably, and incompletely (~30%) after oral administration (not reduced by food); peak concentrations in plasma are achieved in ~7 hours. It is cleared as the intact compound by the kidney, and its $t_{1/2}$ in plasma is ~12 hours. Lisinopril does not accumulate in tissues. The oral dosage of lisinopril ranges from 5-40 mg daily (single or divided dose), with 5 and 10 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg and close medical supervision is recommended for patients with heart failure who are hyponatremic or have renal impairment.

**Benazepril** (Lotensin, others). Cleavage of the ester moiety by hepatic esterases transforms benazepril, a prodrug, into benazeprilat, an ACE inhibitor that *in vitro* is more potent than captopril, enalaprilat, or lisinopril. Benazepril is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). Benazepril is nearly completely metabolized to benazeprilat and to the glucuronide conjugates of benazepril and benazeprilat, which are excreted into both the urine and bile; peak concentrations of benazepril and benazeprilat in plasma are achieved in 0.5-1 hour and 1-2 hours, respectively. Benazeprilat has an effective plasma $t_{1/2}$ of 10-11 hours. With the exception of the lungs, benazeprilat does not accumulate in tissues. The oral dosage of benazepril ranges from 5-80 mg daily (single or divided dose).

**Fosinopril** (Monopril, others). Fosinopril is the only ACE inhibitor approved for use in the U.S. that contains a phosphate group that binds to the active site of ACE. Cleavage of the ester moiety by hepatic esterases transforms fosinopril, a prodrug, into fosinoprilat, an ACE inhibitor that *in vitro* is more potent than captopril yet less potent than enalaprilat. Fosinopril is absorbed slowly and incompletely (36%) after oral administration (rate but not extent reduced by food). Fosinopril is largely metabolized to fosinoprilat (75%) and to the glucuronide conjugate of fosinoprilat. These are excreted in both the urine and bile; peak concentrations of fosinoprilat in plasma are achieved in ~3 hours. Fosinoprilat has an effective plasma $t_{1/2}$ of ~11.5 hours; its clearance is not significantly altered by renal impairment. The oral dosage of fosinopril ranges from 10-80 mg daily (single or divided dose). The initial dose is reduced to 5 mg daily in patients with Na+ or water depletion or renal failure.

**Trandolapril** (Mavik, others). An oral dose of trandolapril is absorbed without reduction by food and produces plasma levels of trandolapril (70% bioavailability). Trandolaprilat is ~8 times more potent than trandolapril as an ACE inhibitor. Trandolapril is metabolized to trandolaprilat and to inactive metabolites (mostly glucuronides of trandolapril and deesterification products), and these are recovered in the urine (33%, mostly trandolaprilat) and faeces (66%). Peak concentrations of trandolaprilat in plasma are achieved in 4-10 hours. Trandolapril displays biphasic elimination kinetics with an initial $t_{1/2}$ of ~10 hours (the major component of elimination), followed by a more prolonged $t_{1/2}$ (owing to slow dissociation of trandolaprilat from tissue ACE). Plasma clearance of trandolaprilat is reduced by both renal and hepatic insufficiency. The oral dosage ranges from 1-8 mg daily (single or divided dose). The initial dose is 0.5 mg in patients who are taking a diuretic or who have renal impairment, and 2 mg for African-Americans.

**Quinapril** (Accupril, others). Cleavage of the ester moiety by hepatic esterases transforms quinapril, a prodrug, into quinaprilat, an ACE inhibitor that *in vitro* is about as potent as benazeprilat. Quinapril is absorbed rapidly (peak concentrations are achieved in 1 hour), and the rate, but not extent, of oral absorption (60%) may be reduced by food (delayed peak). Quinaprilat and other minor metabolites of quinapril are excreted in the urine (61%) and faeces (37%). Peak concentrations of quinaprilat in plasma are achieved in ~2 hours. Conversion of quinapril to quinaprilat is reduced in patients with diminished liver function. The initial $t_{1/2}$ of quinaprilat is ~2 hours; a prolonged terminal $t_{1/2}$ ~25 hours may be due to high-affinity binding of the drug to tissue ACE. The oral dosage of quinapril ranges from 5-80 mg daily (single or divided dose).

**Ramipril** (Altace, others). Cleavage of the ester moiety by hepatic esterases transforms ramipril into ramiprilat, an ACE inhibitor that *in vitro* is about as potent as benazeprilat and quinaprilat. Ramipril is absorbed rapidly (peak concentrations are achieved in 1 hour), and the rate but not extent of its oral absorption (50-60%) is reduced by food. Ramipril is metabolized to ramiprilat and to inactive metabolites (glucuronides of ramipril and ramiprilat and the diketopiperazine ester and acid) that are excreted predominantly by the kidneys. Peak concentrations of ramiprilat in plasma are achieved in ~3 hours. Ramiprilat displays triphasic elimination kinetics with half-lives of 2-4 hours, 9-18 hours, and >50 hours. This triphasic elimination is due to extensive distribution to all tissues (initial $t_{1/2}$), clearance of free ramiprilat from plasma (intermediate $t_{1/2}$), and dissociation of ramiprilat from tissue ACE (long terminal $t_{1/2}$). The oral dosage of ramipril ranges from 1.25-20 mg daily (single or divided dose).

**Moexipril** (Univasc, others). Moexipril is another prodrug whose antihypertensive activity is almost entirely due to its deesterified
metabolite, moexiprilat. Moexipril is absorbed incompletely, with bioavailability as moexiprilat of ~13%. Bioavailability is markedly decreased by food. The time to peak plasma concentration of moexiprilat is almost 1.5 hours; the elimination t1/2 varies between 2 and 12 hours. The recommended dosage range is 7.5-30 mg daily (single or divided doses). The dosage range is halved in patients who are taking diuretics or who have renal impairment.

Perindopril (ACEON). Perindopril erbumine is a prodrug, and 30-50% of systemically available perindopril is transformed to perindopril by hepatic esterases. Although the oral bioavailability of perindopril (75%) is not affected by food, the bioavailability of perindoprilat is reduced by ~35%. Perindopril is metabolized to perindoprilat and to inactive metabolites (glucuronides of perindopril and perindoprilat, dehydrated perindopril, and diastereomers of dehydrated perindoprilat) that are excreted predominantly by the kidneys. Peak concentrations of perindoprilat in plasma are achieved in 3-7 hours. Perindoprilat displays biphasic elimination kinetics with half-lives of 3-10 hours (the major component of elimination) and 30-120 hours (owing to slow dissociation of perindoprilat from tissue ACE). The oral dosage ranges from 2-16 mg daily (single or divided dose).

Therapeutic Uses of ACE Inhibitors and Clinical Summary. Drugs that interfere with the RAS play a prominent role in the treatment of cardiovascular disease, the major cause of mortality in modern Western societies.

ACE Inhibitors in Hypertension. Inhibition of ACE lowers systemic vascular resistance and mean, diastolic, and systolic blood pressures in various hypertensive states except when high blood pressure is due to primary aldosteronism (see Chapter 27). The initial change in blood pressure tends to be positively correlated with plasma renin activity (PRA) and AngII plasma levels prior to treatment. Some patients may show a sizable reduction in blood pressure that correlates poorly with pretreatment values of PRA. It is possible that increased local (tissue) production of AngII or increased responsiveness of tissues to normal levels of AngII makes some hypertensive patients sensitive to ACE inhibitors despite normal PRA.

The long-term fall in systemic blood pressure observed in hypertensive individuals treated with ACE inhibitors is accompanied by a leftward shift in the renal pressure–natriuresis curve (Figure 26–7) and a reduction in total peripheral resistance in which there is variable participation by different vascular beds. The kidney is a notable exception: because the renal vessels are extremely sensitive to the vasoconstrictor actions of AngII, ACE inhibitors increase renal blood flow via vasodilation of the afferent and efferent arterioles. Increased renal blood flow occurs without an increase in GFR; thus, the filtration fraction is reduced.

ACE inhibitors cause systemic arteriolar dilation and increase the compliance of large arteries, which contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed, although stroke volume and cardiac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised, and responses to postural changes and exercise are little impaired. Even when a substantial lowering of blood pressure is achieved, heart rate and concentrations of catecholamines in plasma generally increase only slightly, if at all. This perhaps reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of AngII on the sympathetic nervous system.

Aldosterone secretion is reduced, but not seriously impaired, by ACE inhibitors. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as ACTH and K+. The activity of these secretogogues on the zona glomerulosa of the adrenal cortex requires very small trophic or permissive amounts of AngII, which always are present because ACE inhibition never is complete. Excessive retention of K+ is encountered in patients taking supplemental K+, in patients with renal impairment, or in patients taking other medications that reduce K+ excretion.

ACE inhibitors alone normalize blood pressure in ~50% of patients with mild to moderate hypertension. Ninety percent of patients with mild to moderate hypertension will be controlled by the combination of an ACE inhibitor and either a Ca2+ channel blocker, a β adrenergic receptor blocker, or a diuretic. Diuretics augment the antihypertensive response to ACE inhibitors by rendering the patient’s blood pressure renin dependent. Several ACE inhibitors are marketed in fixed-dose combinations with a thiazide diuretic or Ca2+ channel blocker for the management of hypertension.

ACE Inhibitors in Left Ventricular Systolic Dysfunction. Unless contraindicated, ACE inhibitors should be given to all patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure (see Chapter 28). Several large, randomized, placebo-controlled clinical studies demonstrate that inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and myocardial infarction, decreases hospitalization, and improves quality of life. The more severe the ventricular dysfunction, the greater the benefit from ACE inhibition.

Inhibition of ACE commonly reduces afterload and systolic wall stress, and both cardiac output and
cardiac index increase, as do indices of stroke work and stroke volume. In systolic dysfunction, AngII decreases arterial compliance, and this is reversed by ACE inhibition (Lage et al., 2002). Heart rate generally is reduced. Systemic blood pressure falls, sometimes steeply at the outset, but tends to return toward initial levels. Renovascular resistance falls sharply, and renal blood flow increases. Natriuresis occurs as a result of the improved renal hemodynamics, the reduced stimulus to the secretion of aldosterone by AngII, and the diminished direct effects of AngII on the kidney. The excess volume of body fluids contracts, which reduces venous return to the right side of the heart. A further reduction results from venodilation and an increased capacity of the venous bed.

Although AngII has little acute venoconstrictor activity, long-term infusion of AngII increases venous tone, perhaps by central or peripheral interactions with the sympathetic nervous system. The response to ACE inhibitors also involves reductions of pulmonary arterial pressure, pulmonary capillary wedge pressure, and left atrial and left ventricular filling volumes and pressures. Consequently, preload and diastolic wall stress are diminished. The better hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system. Cerebral and coronary blood flows usually are well maintained, even when systemic blood pressure is reduced.

In heart failure, ACE inhibitors reduce ventricular dilation and tend to restore the heart to its normal elliptical shape. ACE inhibitors may reverse ventricular remodeling via changes in preload/afterload, by preventing the growth effects of AngII on myocytes, and by attenuating cardiac fibrosis induced by AngII and aldosterone.

**ACE Inhibitors in Acute Myocardial Infarction.** The beneficial effects of ACE inhibitors in acute myocardial infarction are particularly large in hypertensive (Borghi et al., 1999) and diabetic (Zuanetti et al., 1997) patients (Chapter 27). Unless contraindicated (e.g., cardiogenic shock or severe hypotension), ACE inhibitors should be started immediately during the acute phase of myocardial infarction and can be administered along with thrombolytics, aspirin, and β-adrenergic receptor antagonists (ACE Inhibitor Myocardial Infarction Collaborative Group, 1998). In high-risk patients (e.g., large infarct, systolic ventricular dysfunction), ACE inhibition should be continued long term.

**ACE Inhibitors in Patients Who Are at High Risk of Cardiovascular Events.** The HOPE study demonstrated that patients at high risk of cardiovascular events benefited considerably from treatment with ACE inhibitors (Heart Outcomes Prevention Study Investigators, 2000). ACE inhibition significantly decreased the rate of myocardial infarction, stroke, and death in patients who did not have left ventricular dysfunction but had evidence of vascular disease or diabetes and one other risk factor for cardiovascular disease. The EUROPA trial demonstrated that in patients with coronary artery disease but without heart failure, ACE inhibition reduced cardiovascular disease death and myocardial infarction (European Trial, 2003).

**ACE Inhibitors in Diabetes Mellitus and Renal Failure.** Diabetes mellitus is the leading cause of renal disease. In patients with type 1 diabetes mellitus and diabetic nephropathy, captopril prevents or delays the progression of renal disease. Renoprotection in type 1 diabetes, as defined by changes in albumin excretion, also is observed with lisinopril. The renoprotective effects of ACE inhibitors in type 1 diabetes are in part independent of blood pressure reduction. In addition, ACE inhibitors may decrease retinopathy progression in type 1 diabetics and attenuate the progression of renal insufficiency in patients with a variety of nondiabetic nephropathies (Ruggenenti et al., 2010).

Several mechanisms participate in the renal protection afforded by ACE inhibitors. Increased glomerular capillary pressure induces glomerular injury, and ACE inhibitors reduce this parameter both by decreasing arterial blood pressure and by dilating renal efferent arterioles. ACE inhibitors increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to proteinaceous factors that may stimulate mesangial cell proliferation and matrix production, two processes that contribute to expansion of the mesangium in diabetic nephropathy. Because AngII is a growth factor, reductions in the intrarenal levels of AngII may further attenuate mesangial cell growth and matrix production.

**ACE Inhibitors in Scleroderma Renal Crisis.** The use of ACE inhibitors considerably improves survival of patients with scleroderma renal crisis (Steen and Medsger, 1990).

**Adverse Effects of ACE Inhibitors.** In general, ACE inhibitors are well tolerated. Metabolic side effects are rare during long-term therapy with ACE inhibitors. The drugs do not alter plasma concentrations of uric acid or Ca²⁺ and may improve insulin sensitivity in patients with insulin resistance and decrease cholesterol and lipoprotein (a) levels in proteinuric renal disease.

**Hypotension.** A steep fall in blood pressure may occur following the first dose of an ACE inhibitor in patients with elevated PRA. Care should be exercised in patients who are salt depleted, are on multiple antihypertensive drugs, or who have congestive heart failure.

**Cough.** In 5-20% of patients, ACE inhibitors induce a bothersome, dry cough mediated by the accumulation in the lungs of bradykinin, substance P, and/or prostaglandins. Thromboxane antagonism, aspirin, and iron supplementation reduce cough induced by ACE inhibitors. ACE dose reduction or switching to an ARB is sometimes
effective. Once ACE inhibitors are stopped, the cough disappears, usually within 4 days.

**Hyperkalemia.** Significant K⁺ retention is rarely encountered in patients with normal renal function. However, ACE inhibitors may cause hyperkalemia in patients with renal insufficiency or diabetes or in patients taking K⁺-sparing diuretics, K⁺ supplements, β receptor blockers, or NSAIDs.

**Acute Renal Failure.** AngII, by constricting the efferent arteriole, helps to maintain adequate glomerular filtration when renal perfusion pressure is low. Inhibition of ACE can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or diuretics.

**Fetopathic Potential.** The fetopathic effects may be due in part to fetal hypotension. Once pregnancy is diagnosed, it is imperative that ACE inhibitors be discontinued as soon as possible.

**Skin Rash.** ACE inhibitors occasionally cause a maculopapular rash that may itch, but that may resolve spontaneously or with antihistamines. Although initially attributed to the presence of the sulfhydryl group in captopril, a rash also may occur with other ACE inhibitors, albeit less frequently.

**Angioedema.** In 0.1-0.5% of patients, ACE inhibitors induce a rapid swelling in the nose, throat, mouth, glottis, larynx, lips, and/or tongue. Once ACE inhibitors are stopped, angioedema disappears within hours; meanwhile, the patient’s airway should be protected, and if necessary, epinephrine, an antihistamine, and/or a glucocorticoid should be administered. African-Americans have a 4.5 times greater risk of ACE inhibitor–induced angioedema than Caucasians (Brown et al., 1996). Although rare, angioedema of the intestine (visceral angioedema) characterized by emesis, watery diarrhea, and abdominal pain also has been reported.

**Other Side Effects.** Extremely rare but reversible side effects include dysgeusia (an alteration in or loss of taste), neutropenia (symptoms include sore throat and fever), glycosuria (spillage of glucose into the urine in the absence of hyperglycemia), and hepatotoxicity.

**Drug Interactions.** Antacids may reduce the bioavailability of ACE inhibitors; capsaicin may worsen ACE inhibitor–induced cough; NSAIDs, including aspirin, may reduce the antihypertensive response to ACE inhibitors; and K⁺-sparing diuretics and K⁺ supplements may exacerbate ACE inhibitor–induced hyperkalemia. ACE inhibitors may increase plasma levels of digoxin and lithium and may increase hypersensitivity reactions to allopurinol.

---

**NON-PEPTIDE ANGIOTENSIN II RECEPTOR ANTAGONISTS**

**History.** Attempts to develop therapeutically useful AngII receptor antagonists date to the early 1970s, and these initial endeavors concentrated on angiotensin peptide analog. Saralasin, 1-sarcosine, 8-isoleucine AngII, and other 8-substituted angiotensins were potent AngII receptor antagonists but were of no clinical value because of lack of oral bioavailability and unacceptable partial agonist activity.

A breakthrough came in the early 1980s with the synthesis and testing of a series of imidazole-5-acetic acid derivatives that attenuated pressor responses to AngII in rats. Two compounds, S-8307 and S-8308, were found to be highly specific, albeit very weak, non-peptide AngII receptor antagonists that were devoid of partial agonist activity. Through a series of stepwise modifications, the orally active, potent, and selective non-peptide AT₁ receptor antagonist losartan was developed (Timmermans et al., 1993) and approved for clinical use in the U.S. in 1995. Since then, six additional AT₁ receptor antagonists (Figure 26–10) have been approved. Although these AT₁ receptor antagonists are devoid of partial agonist activity, structural modifications as minor as a methyl group can transform a potent antagonist into an agonist (Perlman et al., 1997).

**Pharmacological Effects.** The AngII receptor blockers bind to the AT₁ receptor with high affinity and are more than 10,000-fold selective for the AT₁ receptor over the AT₂ receptor. The rank-order affinity of the AT₁ receptor for ARBs is candesartan > olmesartan > irbesartan = eprosartan > telmisartan = valsartan = EXP 3174 (the active metabolite of losartan) > losartan. Although binding of ARBs to the AT₁ receptor is competitive, the inhibition by ARBs of biological responses to AngII often is insurmountable (the maximal response to AngII cannot be restored in the presence of the ARB regardless of the concentration of AngII added to the experimental preparation).

The mechanism of insurmountable antagonism by ARBs may be due to slow dissociation kinetics of the compounds from the AT₁ receptor; however, a number of other factors may contribute, such as ARB-induced receptor internalization and alternative binding sites for ARBs on the AT₁ receptor (McConnaughey et al., 1999). Insurmountable antagonism has the theoretical advantage of sustained receptor blockade even with increased levels of endogenous ligand and with missed doses of drug. Whether this advantage translates into an enhanced clinical performance remains to be determined.

ARBs potently and selectively inhibit most of the biological effects of AngII (Timmermans et al., 1993; Csajka et al., 1997), including AngII–induced (1) contraction of vascular smooth muscle, (2) rapid pressor responses, (3) slow pressor responses, (4) thirst, (5) vasopressin release, (6) aldosterone secretion, (7) release of adrenal catecholamines, (8) enhancement of noradrenergic neurotransmission, (9) increases in sympathetic tone, (10) changes in renal function, and (11) cellular hypertrophy and hyperplasia. ARBs reduce arterial blood pressure in animals with renovascular and genetic hypertension, as well as in transgenic animals overexpressing the renin gene. ARBs, however, have little effect on arterial blood pressure in animals with low-renin hypertension (e.g., rats with hypertension induced by NaCl and deoxycorticosterone).

Do ARBs have therapeutic efficacy equivalent to that of ACE inhibitors? Although both classes of drugs block the RAS, they differ in several important aspects:
ARBs reduce activation of AT\(_1\) receptors more effectively than do ACE inhibitors. ACE inhibitors reduce the biosynthesis of AngII by the action of ACE, but do not inhibit alternative non-ACE AngII-generating pathways. ARBs block the actions of AngII via the AT\(_1\) receptor regardless of the biochemical pathway leading to AngII formation.

In contrast to ACE inhibitors, ARBs permit activation of AT\(_2\) receptors. ACE inhibitors increase renin release, but block the conversion of AngI to AngII. ARBs also stimulate renin release; however, with ARBs, this translates into a several-fold increase in circulating levels of AngII. Because ARBs block AT\(_1\) receptors, this increased level of AngII is available to activate AT\(_2\) receptors.

Figure 26–10. AngII receptor antagonists. Structures within red boxes are removed by esterases and replaced with a hydrogen atom to form the active molecule \textit{in vivo}. “~” indicates point of attachment to biphenyl core.
• **ACE inhibitors may increase Ang(1–7) levels more than do ARBs.** ACE is involved in the clearance of Ang(1–7), so inhibition of ACE may increase Ang(1–7) levels more so than do ARBs.

• **ACE inhibitors increase the levels of a number of ACE substrates, including bradykinin and Ac-SDKP.**

Whether the pharmacological differences between ARBs and ACE inhibitors result in significant differences in therapeutic outcomes is an open question.

**Clinical Pharmacology.** Oral bioavailability of ARBs generally is low (<50%, except for irbesartan, with 70% available), and protein binding is high (>90%).

**Candesartan Cilexetil (ATACAND).** Candesartan cilexetil is an inactive ester prodrug that is completely hydrolyzed to the active form, candesartan, during absorption from the gastrointestinal tract. Peak plasma levels are obtained 3-4 hours after oral administration, and the plasma t<sub>1/2</sub> is ~9 hours. Plasma clearance of candesartan is due to renal elimination (33%) and biliary excretion (67%). The plasma clearance of candesartan is affected by renal insufficiency but not by mild-to-moderate hepatic insufficiency. Candesartan cilexetil should be administered orally once or twice daily for a total daily dose of 4-32 mg.

**Eprosartan (TEVETEN).** Peak plasma levels are obtained 1-2 hours after oral administration, and the plasma t<sub>1/2</sub> is 5-9 hours. Eprosartan is metabolized in part to the glucuronide conjugate. Clearance is by renal elimination and biliary excretion. The plasma clearance of eprosartan is affected by both renal insufficiency and hepatic insufficiency. The recommended dosage of eprosartan is 400-800 mg/day in one or two doses.

**Irbesartan (AVAPRO).** Peak plasma levels are obtained ~1.5-2 hours after oral administration, and the plasma t<sub>1/2</sub> is 11-15 hours. Irbesartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of irbesartan is unaffected by either renal or mild-to-moderate hepatic insufficiency. The oral dosage of irbesartan is 150-300 mg once daily.

**Losartan (COZAAR).** Approximately 14% of an oral dose of losartan is converted to the 5-carboxylic acid metabolite EXP 3174, which is more potent than losartan as an AT<sub>1</sub> receptor antagonist. The metabolism of losartan to EXP 3174 and to inactive metabolites is mediated by CYP2C9 and CYP3A4. Peak plasma levels of losartan and EXP 3174 occur ~1-3 hours after oral administration, respectively, and the plasma half-lives are 2.5 and 6-9 hours, respectively. The plasma clearances of losartan and EXP 3174 are due to renal clearance and hepatic clearance (metabolism and biliary excretion). The plasma clearance of losartan and EXP 3174 is affected by hepatic but not renal insufficiency. Losartan should be administered orally once or twice daily for a total daily dose of 25-100 mg. In addition to being an ARB, losartan is a competitive antagonist of the thromboxane A<sub>2</sub> receptor and attenuates platelet aggregation (Levy et al., 2000). Also, EXP 3179, a metabolite of losartan without angiotensin receptor effects, reduces COX-2 mRNA upregulation and COX-dependent prostaglandin generation (Krämer et al., 2002).

**Olmesartan Medoxomil (BENICAR).** Olmesartan medoxomil is an inactive ester prodrug that is completely hydrolyzed to the active form, olmesartan, during absorption from the gastrointestinal tract. Peak plasma levels are obtained 1.4-2.8 hours after oral administration, and the plasma t<sub>1/2</sub> is between 10 and 15 hours. Plasma clearance of olmesartan is due to both renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of olmesartan, no dose adjustment is required in patients with mild-to-moderate renal or hepatic impairment. The oral dosage of olmesartan medoxomil is 20-40 mg once daily.

**Telmisartan (MICARDIS).** Peak plasma levels are obtained 0.5-1 hour after oral administration, and the plasma t<sub>1/2</sub> is ~24 hours. Telmisartan is cleared from the circulation mainly by biliary secretion of intact drug. The plasma clearance of telmisartan is affected by hepatic but not renal insufficiency. The recommended oral dosage of telmisartan is 40-80 mg once daily.

**Valsartan (DUVAAN).** Peak plasma levels occur 2-4 hours after oral administration, and the plasma t<sub>1/2</sub> is ~9 hours. Food markedly decreases absorption. Valsartan is cleared from the circulation by the liver (~70% of total clearance). The plasma clearance of valsartan is affected by hepatic but not renal insufficiency. The oral dosage of valsartan is 80-320 mg once daily.

**Therapeutic Uses of AngII Receptor Antagonists.** All ARBs are approved for the treatment of hypertension. In addition, irbesartan and losartan are approved for diabetic nephropathy, losartan is approved for stroke prophylaxis, and valsartan is approved for heart failure and to reduce cardiovascular mortality in clinically stable patients with left ventricular failure or left ventricular dysfunction following myocardial infarction. The efficacy of ARBs in lowering blood pressure is comparable with that of ACE inhibitors and other established antihypertensive drugs, with a favorable adverse-effect profile. ARBs also are available as fixed-dose combinations with hydrochlorothiazide or amlodipine (Chapters 27 and 28).

Losartan is well tolerated in patients with heart failure and is comparable to enalapril with regard to improving exercise tolerance (Lang et al., 1997). The Evaluation of Losartan in the Elderly (ELITE) study reported that in elderly patients with heart failure, losartan was as effective as captopril in improving symptoms and better in reducing mortality (Pitt et al., 1997). However, the greater reduction in mortality by losartan was not confirmed in the larger Losartan Heart Failure Survival Study (ELITE II) trial (Pitt et al., 2000). The Valsartan in Acute Myocardial Infarction (VALIANT) trial demonstrated that valsartan is as effective as captopril in patients with myocardial infarction complicated by left ventricular systolic dysfunction with regard to all-cause-mortality (Pfeffer et al., 2003). Both valsartan and candesartan reduce mortality and morbidity in heart failure patients (Maggioni et al., 2002; Granger et al., 2003). Current recommendations are to use ACE inhibitors as first-line agents for the treatment of heart failure and to reserve ARBs for treatment of heart failure in patients who cannot tolerate or have an unsatisfactory response to ACE inhibitors.

At present, there is conflicting evidence regarding the advisability of combining an ARB and an ACE inhibitor in heart failure patients. The Candesartan in Heart Failure Assessment of Reduction in Mortality (CHARM-additive) and the Valsartan in Heart Failure (ValHeFt) studies indicate that a combination of ARB and ACE inhibitors decrease morbidity and mortality in patients with heart
failure (McMurray et al., 2003; Cohn and Tognoni, 2001). In contrast, the VALIANT and ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint) findings show no added benefits with combination therapy, which was associated with more adverse effects (Pfeffer et al., 2003; ONTARGET Investigators, 2008).

ARBs are renoprotective in type 2 diabetes mellitus, in part via blood pressure-independent mechanisms (Viberti et al., 2002). Based on these results, many experts now consider them the drugs of choice for renoprotection in diabetic patients. The Losartan Intervention For Endpoint (LIFE) Reduction in Hypertension Study demonstrated the superiority of an ARB compared with a β1 adrenergic receptor antagonist with regard to reducing stroke in hypertensive patients with left ventricular hypertrophy (Dahlöf et al., 2002). Also, irebesartan appears to maintain sinus rhythm in patients with persistent, long-standing atrial fibrillation (Madrid et al., 2002). Losartan is reported to be safe and highly effective in patients with persistent, long-standing atrial fibrillation (Madrid et al., 2002). Losartan is reported to be safe and highly effective in the treatment of portal hypertension in patients with cirrhosis and portal hypertension (Schneider et al., 1999) without compromising renal function.

Adverse Effects. ARBs are generally well tolerated. The incidence of angioedema and cough with ARBs is less than that with ACE inhibitors. As with ACE inhibitors, ARBs have teratogenic potential and should be discontinued in pregnancy. In patients whose arterial blood pressure or renal function is highly dependent on the RAS (e.g., renal artery stenosis), ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure. ARBs may cause hyperkalemia in patients with renal disease or in patients taking K+ supplements or K+-sparing diuretics. ARBs enhance the blood pressure-lowering effect of other antihypertensive drugs, a desirable effect but one that may necessitate dosage adjustment. There are rare postmarketing reports of anaphylaxis, abnormal hepatic function, hepatitis, neutropenia, leukopenia, agranulocytosis, pruritus, urticaria, hypotension, alopecia, and vasculitis, including Henoch-Schönlein purpura.

DIRECT RENIN INHIBITORS

DRIs are a novel class of antihypertensive drugs that inhibit the RAS at its origin. Angiotensinogen is the only specific substrate for renin, and its conversion to AngI presents a rate-limiting step for the generation of downstream components of the RAS.

Aliskiren (TEKTURNA) is the only DRI approved for clinical use.

History. The earlier renin inhibitors were orally inactive peptide analogs of the prorenin propeptide or analogs of renin-substrate cleavage site. Orally active, first-generation renin inhibitors (enalikiren, zankiren, CGP38560A, and remikiren) were effective in reducing AngII levels, but none of them made it past clinical trials due to their low potency, poor bioavailability, and short $t_{1/2}$. Low-molecular-weight renin inhibitors were designed based on molecular modeling and crystallographic structural information of renin-substrate interaction (Wood et al., 2003; Staessen et al., 2006). This led to the development of aliskiren, a second-generation renin inhibitor that was approved by the U.S. FDA in 2007 for the treatment of hypertension. Aliskiren has blood pressure-lowering effects similar to those of ACE inhibitors and ARBs.

Pharmacological Effects. Aliskiren is a low-molecular-weight non-peptide that is a potent competitive inhibitor of renin. It binds the active site of renin to block conversion of angiotensinogen to AngI, thus reducing the consequent production of AngII. Aliskiren has a 10,000-fold higher affinity to renin ($IC_{50} \approx 0.6 \text{nM}$) than to any other aspartic peptidases.

In healthy volunteers, aliskiren (40-640 mg/day) induces a dose-dependent decrease in blood pressure, reduces PRA and AngI and AngII levels, but increases plasma renin concentration by 16-34-fold due to the loss of the short-loop negative feedback by AngII. Aliskiren also decreases plasma and urinary aldosterone levels and enhances natriuresis (Nussberger et al., 2002).

Aliskiren binds with great specificity to human and primate renin, but is less specific for non-primate renins (e.g., dog, cat, rat, pig) and induces a dose-dependent reduction in blood pressure in Na+-depleted marmosets, equivalent to valsartan or benazepril (Wood et al., 2003; Wood et al., 2005). In double transgenic rats expressing human renin and human angiotensinogen genes, aliskiren is similar to the high dose of valsartan in lowering blood pressure, reducing albuminuria, normalizing serum creatinine, and protecting against end-organ damage (Pilz et al., 2005).

Clinical Pharmacology. Aliskiren is recommended as a single oral dose of 150 or 300 mg/day. Bioavailability of aliskiren is low (~2.5%), but its high affinity and potency compensate for the low bioavailability. Peak plasma concentrations are reached within 3-6 hours. The $t_{1/2}$ is 20-45 hours. Steady state in plasma is achieved in 5-8 days. Plasma protein binding is 50% and is independent of concentration. Aliskiren is a substrate for P-glycoprotein (Pgp), which accounts for low absorption. Fatty meals significantly decrease the absorption of aliskiren. Hepatic metabolism by CYP3A4 is minimal. Elimination is mostly as unchanged drug in feces. About 25% of the absorbed dose appears in the urine as parent drug. Aliskiren is well tolerated in the elderly population, in patients with hepatic disease and renal insufficiency, and in patients with type 2 diabetes (Vaidyanathan et al., 2008).

Therapeutic Uses of Aliskiren in Hypertension. Clinical studies confirm aliskiren as an effective antihypertensive agent that induces significant dose-dependent
(75-300 mg) reductions in blood pressure. Aliskiren is as effective as ACE inhibitors (ramipril), ARBs (losartan, irbesartan, valsartan), and hydrochlorothiazide (HCTZ) in lowering blood pressure in patients with mild-to-moderate hypertension (Oparil et al., 2007; Sanoski, 2009). Aliskiren also is as effective as lisinopril in lowering blood pressure in patients with severe hypertension (Strasser et al., 2007). The long t½ of aliskiren allows its antihypertensive effects to be sustained for several days following termination of therapy (Oh et al., 2007).

Many short-term studies indicate that the effect of aliskiren in combination with ACE inhibitors, ARBs, and HCTZ is additive in lowering blood pressure. The antihypertensive effects of aliskiren in monotherapy and in combination therapy were evaluated in patients with mild-to-moderate hypertension. In these studies, supplementing aliskiren to ramipril, irbesartan, valsartan, or HCTZ induced additional decreases in systolic and diastolic blood pressure that were larger than that induced by any of the drugs alone. PRA is inhibited by aliskiren but significantly elevated with ramipril, irbesartan, and HCTZ (Table 26-1). Co-administration of aliskiren with ramipril, irbesartan, or HCTZ neutralized the increase in plasma renin activity to baseline levels (Staessen, 2006; Sanoski, 2009). Because plasma renin levels correlate with the capacity to generate AngII, the ability of aliskiren to neutralize plasma renin in combination therapy may contribute to better control of blood pressure than monotherapy.

The antihypertensive effect of aliskiren is significantly augmented in combination with HCTZ (Oparil et al., 2007). Fixed-dose combinations of aliskiren/HCTZ are marketed for antihypertensive therapy (Baldwin and Plosker, 2009).

Therapeutic Uses of Aliskiren in End-Organ Damage. The ability of aliskiren to inhibit the increased PRA caused by ACE inhibitors and ARBs theoretically provides a more comprehensive blockade of the RAS and may limit activation of the local (tissue) RAS (Table 26-1). Studies are ongoing to address whether aliskiren provides better protection against end-organ damage in cardiovascular and renal diseases.

The ALLAY trial (Aliskiren in Left Ventricular Hypertrophy trial) compared the effect of aliskiren with losartan on left ventricular hypertrophy as a marker of end-organ damage. Both aliskiren and losartan were equivalent in reducing blood pressure and decreasing left ventricular mass, but there was no additional reduction in left ventricular mass with combination therapy (Solomon et al., 2009).

The ALOFT trial (Aliskiren Observation of Heart Failure Treatment) indicated that aliskiren was beneficial when added to ACE inhibitors in heart failure treatment (McMurray et al., 2008). Patients received aliskiren or placebo in addition to standard heart failure treatment (ACE inhibitors, ARBs, β blockers), and the primary outcome measured was changes in N-terminal proB type natriuretic peptide (BNP). Aliskiren caused a significant decrease in plasma BNP levels, urinary BNP, and aldosterone levels, indicating favorable neurohormonal effects of aliskiren in heart failure when added to standard therapy. A follow-up SPHERE trial (Aliskiren Trial to Mediate Outcome Prevention in Heart Failure) will address long-term outcome in heart failure patients.

The AVOID trial (Aliskiren in Evaluation of Proteinuria I Diabetes Trial) reported aliskiren to be renoprotective in patients with hypertension and type 2 diabetes. Patients were on the maximal dose of losartan for 3 months before adding aliskiren or placebo for 6 months. At the end of the study period, patients taking aliskiren had their mean urinary albumin-to-creatinine ratio significantly decreased by 20%, and the decrease was 50% or more in 24.7% of patients compared with placebo. The renoprotective effects of aliskiren were independent of blood pressure–lowering effects.

Aliskiren is an effective antihypertensive agent that is well tolerated in monotherapy and combination therapy. It has cardioprotective and renoprotective effects in combination therapy; however, long-term advantages still need to be established. Aliskiren is recommended in patients who are intolerant to other antihypertensive therapies or for use in combination with other drugs for further blood pressure control.

**Adverse Events.** Aliskiren is well tolerated, and adverse events are mild or comparable to placebo with no gender difference. Adverse effects include mild gastrointestinal symptoms such as diarrhea observed at high doses (600 mg daily), abdominal pain, dyspepsia, and gastroesophageal reflux; headache; nasopharyngitis; dizziness; fatigue; upper-respiratory tract infection; back pain; angioedema; and cough (cough was much less common than with ACE inhibitors). Other adverse effects reported for aliskiren that were slightly increased compared with placebo include rash, hypotension, hyperkalemia in diabetics on combination therapy, elevated uric acid, renal stones, and gout. Like other RAS inhibitors, aliskiren is not recommended in pregnancy.

**Drug Interactions.** Aliskiren does not interact with drugs that interact with CYPs. Aliskiren reduces absorption of furosemide by 50%. Irbesartan reduces the $C_{\text{max}}$ of aliskiren by 50%. Aliskiren plasma levels are increased by drugs, such as ketoconazole, atorvastatin, and cyclosporine, that inhibit P-glycoprotein.

**Pharmacological Lowering of Blood Pressures Alters Components of the RAS**

The renin-angiotensin system responds to alterations in blood pressure with compensatory changes (Figure 26-2). Thus, pharmacological agents that lower blood pressure will alter the feedback loops that regulate the RAS and cause changes in the levels and activities of the system’s components. These changes are summarized in Table 26-1.

**BIBLIOGRAPHY**

Dahlof B, Devereux RB, Kjeldsen SE, et al., for the LIFE Study Group. Cardiovascular morbidity and mortality in the Losartan Intervention For Endpoint reduction in hypertension study (Parving et al., 2008). The long-term ALTITUDE study (Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints) is in progress to assess if aliskiren will reduce cardiovascular and renal morbidity and mortality when added to ACE inhibitors and ARBs. The study is expected to end in 2011 (Parving et al., 2009).

PATHOPHYSIOLOGY OF ISCHEMIC HEART DISEASE

Angina pectoris, the primary symptom of ischemic heart disease, is caused by transient episodes of myocardial ischemia that are due to an imbalance in the myocardial oxygen supply–demand relationship. This imbalance may be caused by an increase in myocardial oxygen demand (which is determined by heart rate, ventricular contractility, and ventricular wall tension) or by a decrease in myocardial oxygen supply (primarily determined by coronary blood flow, but occasionally modified by the oxygen-carrying capacity of the blood) or sometimes by both (Figure 27–1). Because blood flow is inversely proportional to the fourth power of the artery’s luminal radius, the progressive decrease in vessel radius that characterizes coronary atherosclerosis can impair coronary blood flow and lead to symptoms of angina when myocardial \( O_2 \) demand increases, as with exertion (so-called typical angina pectoris). In some patients, anginal symptoms may occur without any increase in myocardial \( O_2 \) demand, but rather as a consequence of an abrupt reduction in blood flow, as might result from coronary thrombosis (unstable angina) or localized vasospasm (variant or Prinzmetal angina). Regardless of the precipitating factors, the sensation of angina is similar in most patients. Typical angina is experienced as a heavy, pressing substernal discomfort (rarely described as a “pain”), often radiating to the left shoulder, flexor aspect of the left arm, jaw, or epigastrum. However, a significant minority of patients note discomfort in a different location or of a different character. Women, the elderly, and diabetics are more likely to experience myocardial ischemia with atypical symptoms. In most patients with typical angina, whose symptoms are provoked by exertion, the symptoms are relieved by rest or by administration of sublingual nitroglycerin.

Angina pectoris is a common symptom, affecting more than 9 million Americans (Rosamond et al., 2008). Angina pectoris may occur in a stable pattern over many years or may become unstable, increasing in frequency or severity and even occurring at rest. In typical stable angina, the pathological substrate is usually fixed atherosclerotic narrowing of an epicardial coronary artery, on which exertion or emotional stress superimposes an increase in myocardial \( O_2 \) demand. In variant angina, focal or diffuse coronary vasospasm episodically reduces coronary flow. Patients also may display a mixed pattern of angina with the addition of altered vessel tone on a background of atherosclerotic narrowing. In most patients with unstable angina, rupture of an atherosclerotic plaque, with consequent platelet adhesion and aggregation, decreases coronary blood flow. Superimposed thrombosis may lead to the complete abrogation of blood flow. Atherosclerotic plaques with thinner fibrous caps appear to be more “vulnerable” to rupture.

Myocardial ischemia also may be silent, with electrocardiographic, echocardiographic, or radionuclide evidence of ischemia appearing in the absence of symptoms. While some patients have only silent ischemia, most patients who have silent ischemia have symptomatic episodes as well. The precipitants of silent ischemia appear to be the same as those of symptomatic ischemia. We now know that the ischemic burden (i.e., the total time a patient is ischemic each day) is greater in many patients than was recognized previously. In most trials, the agents that are efficacious in typical angina also are efficacious in reducing silent ischemia.
receptor antagonists appear to be more effective than the Ca\textsuperscript{2+} channel blockers in the prevention of episodes. Therapy directed at abolishing all silent ischemia has not been shown to be of additional benefit over conventional therapy.

This section describes the principal pharmacological agents used in the treatment of angina. The major drugs are nitrovasodilators, β adrenergic receptor antagonists (see Chapter 12), and Ca\textsuperscript{2+} channel antagonists. These anti-anginal agents improve the balance of myocardial O\textsubscript{2} supply and O\textsubscript{2} demand, increasing supply by dilating the coronary vasculature and/or decreasing demand by reducing cardiac work (Figure 27–1).

Other drugs also have efficacy in treatment of both stable and unstable angina, including antiplatelet agents (see Chapters 30) as well as statins (HMG CoA-reductase inhibitors) (see Chapter 31), which may have a role in stabilizing the vulnerable plaque. A new class of medications that appears to be effective in treatment of angina is exemplified by ranolazine (RANEXA) (Wilson et al., 2009), which has been approved for treatment of chronic angina. The mechanisms whereby ranolazine exerts its anti-anginal effect are incompletely understood, but the drug appears to exert direct effects on cardiac myocyte Na\textsuperscript{+} channels (Hasenfuss and Maier 2008; Nash and Nash 2008).

Increasing the cardiac extraction of O\textsubscript{2} from the blood has not been a practical therapeutic goal. Drugs used in typical angina function principally by reducing myocardial O\textsubscript{2} demand by decreasing heart rate, myocardial contractility, and/or ventricular wall stress. By contrast, the principal therapeutic goal in unstable angina is to increase myocardial blood flow; strategies include the use of antiplatelet agents and heparin to reduce intracoronary thrombosis, often accompanied by efforts to restore flow by mechanical means, including percutaneous coronary interventions using coronary stents, or (less commonly) emergency coronary bypass surgery. The principal therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

Anti-anginal agents may provide prophylactic or symptomatic treatment, but β adrenergic receptor antagonists also reduce mortality apparently by decreasing the incidence of sudden cardiac death associated with myocardial ischemia and infarction. The chronic use of organic nitrate vasodilators, which are highly efficacious in treatment of angina, is not associated with improvements in cardiac mortality, and some investigators have suggested that chronic use of nitroglycerin may have adverse cardiovascular effects (Parker, 2004). It is unclear whether the new anti-anginal agent ranolazine may have beneficial effects on cardiovascular mortality, but this drug does appear to have salutary effects on glucose metabolism (Morrow et al., 2009).

The treatment of cardiac risk factors can reduce the progression or even lead to the regression of atherosclerosis. Aspirin is used routinely in patients with myocardial ischemia, and daily aspirin use reduces the incidence of clinical events (Gibbons et al., 2003). Other antiplatelet agents such as oral clopidogrel and intravenous anti-integrin drugs such as abciximab, tirofiban, and eptifibatide have been shown to reduce morbidity in patients with angina who undergo coronary artery stenting (Yehgizarians et al., 2000). Lipid-lowering drugs such as the statins, reduce mortality in patients with hypercholesterolemia with or without known coronary artery disease (Libby et al., 2002). Angiotensin-converting enzyme

**Figure 27–1. Pharmacological modification of the major determinants of myocardial O\textsubscript{2} supply.** When myocardial O\textsubscript{2} requirements exceed O\textsubscript{2} supply, an ischemic episode results. This figure shows the primary hemodynamic sites of actions of pharmacological agents that can reduce O\textsubscript{2} demand (left side) or enhance O\textsubscript{2} supply (right side). Some classes of agents have multiple effects. Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O\textsubscript{2} supply. Both pharmacotherapy and mecanotherapy attempt to restore a dynamic balance between O\textsubscript{2} demand and O\textsubscript{2} supply.
(ACE) inhibitors (see Chapter 26) also reduce mortality in patients with coronary disease (Yusuf et al., 2000) and are particularly recommended for patients when there is concomitant impairment of cardiac systolic function (Gibbons et al., 2003).

Coronary artery bypass surgery and percutaneous coronary interventions such as angioplasty and coronary artery stent deployment can complement pharmacological treatment. In some subsets of patients, percutaneous or surgical revascularization may have a survival advantage over medical treatment alone. Intracoronary drug delivery using drug-eluting coronary stents represents an intersection of mechanical and pharmacological approaches in the treatment of coronary artery disease. Novel therapies that modify the expression of vascular or myocardial cell genes eventually may become an important part of the therapy of ischemic heart disease.

ORGANIC NITRATES

These agents are prodrugs that are sources of nitric oxide (NO). NO activates the soluble isof orm of guanyl cyclase, thereby increasing intracellular levels of cyclic GMP. In turn, cyclic GMP promotes the dephosphorylation of the myosin light chain and the reduction of cytosolic Ca\(^{2+}\) and leads to the relaxation of smooth muscle cells in a broad range of tissues. The NO-dependent relaxation of vascular smooth muscle leads to vasodilation; NO-mediated guanyl cyclase activation inhibits platelet aggregation and relaxes smooth muscle in the bronchi and GI tract (Murad, 1996).

The broad biological response to nitrovasodilators reflects the existence of endogenous NO-modulated regulatory pathways. The endogenous synthesis of NO in humans is catalyzed by a family of NO synthases that oxidize the amino acid L-arginine to form NO, plus L-citrulline as a co-product. There are three distinct mammalian NO synthase isoforms termed nNOS, eNOS, and iNOS (see Chapter 3), and they are involved in processes as diverse as neurotransmission, vasomotion, and immunomodulation. In several vascular disease states, pathways of endogenous NO-dependent regulation appear to be deranged (reviewed in Dudzinski et al., 2006).

History. Nitroglycerin was first synthesized in 1846 by Sobrero, who observed that a small quantity placed on the tongue elicited a severe headache. The explosive properties of nitroglycerin also were soon noted, and control of this unstable compound for military and industrial use was not realized until Alfred Nobel devised a process to stabilize the nitroglycerin and patented a specialized detonator in 1863. The vast fortune that Nobel accrued from the nitroglycerin detonator patent provided the funds later used to establish the Nobel prizes. In 1857, T. Lauder Brunton of Edinburgh administered amyl nitrite, a known vasodepressor, by inhalation and noted that anginal pain was relieved within 30-60 seconds. The action of amyl nitrite was transitory, however, and the dosage was difficult to adjust. Subsequently, William Murrell surmised that the action of nitroglycerin mimicked that of amyl nitrite and established the use of sublingual nitroglycerin for relief of the acute anginal attack and as a prophylactic agent to be taken prior to exertion. The empirical observation that organic nitrates could dramatically and safely alleviate the symptoms of angina pectoris led to their widespread acceptance by the medical profession. Indeed, Alfred Nobel himself was prescribed nitroglycerin by his physicians when he developed angina in 1890. Basic investigations defined the role of NO in both the vasodilation produced by nitrates and endogenous vasodilation. The importance of NO as a signaling molecule in the cardiovascular system and elsewhere was recognized by the awarding of the 1998 Nobel Prize in medicine/physiology to the pharmacologists Robert Furchgott, Louis Ignarro, and Ferid Murad.

Chemistry. Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid (Table 27–1). Nitrate esters (—C—O—NO\(_2\)) and nitrite esters (—C—O—NO\(_2\)) are characterized by a sequence of carbon–oxygen–nitrogen, whereas nitro compounds possess carbon–nitrogen bonds (C—NO\(_2\)). Thus glyceryl trinitrate is not a nitro compound, and it is erroneously called nitroglycerin; however, this nomenclature is both widespread and official. Amyl nitrite is a highly volatile liquid that must be administered by inhalation and is of limited therapeutic utility. Organic nitrates of low molecular mass (such as nitroglycerin) are moderately volatile, oily liquids, whereas the high-molecular-mass nitrate esters (e.g., erythrityl tetrinitrate,isosorbide dinitrate, and isosorbide mononitrate) are solids. In the pure form (without an inert carrier such as lactose), nitroglycerin is explosive. The organic nitrates and nitrites, collectively termed nitrovasodilators, must be metabolized (reduced) to produce gaseous NO, which appears to be the active principle of this class of compounds. Nitric oxide gas also can be directly administered by inhalation (Bloch et al., 2007).

Pharmacological Properties

Mechanism of Action. Nitrites, organic nitrates, nitroso compounds, and a variety of nitrogen oxide–containing substances (including nitroprusside; see later in the chapter) lead to the formation of the reactive gaseous free radical NO and related NO-containing compounds. Nitric oxide gas also may be administered by inhalation. The exact mechanism(s) of denitration of the organic nitrates to liberate NO remains an active area of investigation (Chen et al., 2002).

Phosphorylation of the myosin light chain regulates the maintenance of the contractile state in smooth muscle. NO can activate guanylyl cyclase, increase the cellular level of cyclic GMP, activate PKG, and modulate the activities of cyclic nucleotide phosphodiesterases (PDEs 2, 3, and 5) in a variety of cell types. In smooth muscle, the net result is reduced phosphorylation of myosin light chain, reduced Ca\(^{2+}\) concentration in the cytosol, and relaxation. One important
consequence of the NO-mediated increase in intracellular cyclic GMP is the activation of PKG, which catalyzes the phosphorylation of various proteins in smooth muscle. Another important target of this kinase is the myosin light-chain phosphatase, which is activated on binding PKG and leads to dephosphorylation of the myosin light chain and thereby promotes vasorelaxation and smooth muscle relaxation in many other tissues.

The pharmacological and biochemical effects of the nitrovasodilators appear to be identical to those of an endothelium-derived relaxing factor now known to be NO. Although the soluble isoform of guanylyl cyclase remains the most extensively characterized molecular “receptor” for NO, it is increasingly clear that NO also forms specific adducts with thiol groups in proteins and with reduced glutathione to form nitrosothiol compounds with distinctive biological properties (Stamler et al., 2001). Mitochondrial aldehyde dehydrogenase has been shown to catalyze the reduction of nitroglycerin to yield bioactive NO metabolites (Chen et al., 2002), providing a potentially important clue to the biotransformation of organic nitrates in intact tissues. The regulation and pharmacology of eNOS have been reviewed (Dudzinski et al., 2006).

Cardiovascular Effects Hemodynamic Effects. The nitrovasodilators promote relaxation of vascular smooth muscle. Low concentrations of nitroglycerin preferentially dilate veins more than arterioles. This venodilation decreases venous return, leading to a fall in left and right ventricular chamber size and end-diastolic pressures, but usually results in little change in systemic vascular resistance. Systemic arterial pressure may fall slightly, and heart rate is unchanged or may increase slightly in response to a

decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of nitroglycerin that do not alter systemic arterial pressure may still produce arteriolar dilatation in the face and neck, resulting in a facial flush, or dilation of meningeal arterial vessels, causing headache. The molecular basis for the differential response of arterial versus venous tissues to nitroglycerin remains incompletely understood.

Higher doses of organic nitrates cause further venous pooling and may decrease arteriolar resistance as well, thereby decreasing systolic and diastolic blood pressure and cardiac output and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. The reflex tachycardia and peripheral arteriolar vasoconstriction tend to restore systemic vascular resistance; this is superimposed on sustained venous pooling. Coronary blood flow may increase transiently as a result of coronary vasodilation but may decrease subsequently if cardiac output and blood pressure decrease sufficiently.

In patients with autonomic dysfunction and an inability to increase sympathetic outflow (multiple-system atrophy and pure autonomic failure are the most common forms, much less commonly seen in the autonomic dysfunction associated with diabetes), the fall in blood pressure consequent to the venodilation produced by nitrates cannot be compensated. In these clinical contexts, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension and even aggravating angina. The appropriate therapy in patients with orthostatic angina and normal coronary arteries is to correct the orthostatic hypotension by expanding volume (fludrocortisone and a high-sodium diet), to prevent venous pooling with fitted support garments, and to carefully titrate use of oral vasopressors. Because patients with autonomic dysfunction occasionally may have coexisting coronary artery disease, the coronary anatomy should be defined before therapy is undertaken.

**Effects on Total and Regional Coronary Blood Flow.** Myocardial ischemia is a powerful stimulus to coronary vasodilation, and regional blood flow is adjusted by autoregulatory mechanisms. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation; if the stenosis is severe, much of the capacity to dilate is used to maintain resting blood flow. When demand increases, further dilation may not be possible. After demonstration of direct coronary artery vasodilation in experimental animals, it became generally accepted that nitrates relieved anginal pain by dilating coronary arteries and thereby increasing coronary blood flow. In the presence of significant coronary stenoses, there is a disproportionate reduction in blood flow to the subendocardial regions of the heart, which are subjected to the greatest extravascular compression during systole. Organic nitrates tend to restore blood flow in these regions toward normal.

The hemodynamic mechanisms responsible for these effects are not entirely clear. Most hypotheses have focused on the ability of organic nitrates to cause dilation and prevent vasoconstriction of large epicardial vessels without impairing autoregulation in the small vessels, which are responsible for ~90% of the overall coronary vascular resistance. The vessel diameter is an important determinant of the response to nitroglycerin; vessels >200 μm in diameter are highly responsive, whereas those >100 μm respond minimally. Experimental evidence in patients undergoing coronary bypass surgery indicates that nitrates do have a relaxant effect on large coronary vessels. Collateral flow to ischemic regions also is increased. Moreover, analyses of coronary angiograms in humans have shown that sublingual nitroglycerin can dilate epicardial stenoses and reduce the resistance to flow through such areas (Brown et al., 1981; Feldman et al., 1981). The resulting increase in blood flow would be distributed preferentially to ischemic myocardial regions as a consequence of vasodilation induced by autoregulation. An important indirect mechanism for a preferential increase in subendocardial blood flow is the nitroglycerin-induced reduction in intracavitary systolic and diastolic pressures that oppose blood flow to the subendocardium (see below). To the extent that organic nitrates decrease myocardial requirements for O₂ (see the next section), the increased blood flow in ischemic regions could be balanced by decreased flow in nonischemic areas, and an overall increase in coronary artery blood flow need not occur. Dilation of cardiac veins may improve the perfusion of the coronary microcirculation. Such redistribution of blood flow to subendocardial tissue is not typical of all vasodilators. Dipyridamole, e.g., dilates resistance vessels nonselectively by distorting autoregulation and is ineffective in patients with typical angina.

In patients with angina owing to coronary artery spasm, the ability of organic nitrates to dilate epicardial coronary arteries, and particularly regions affected by spasm, may be the primary mechanism by which they are of benefit.

**Effects on Myocardial O₂ Requirements.** By their effects on the systemic circulation, the organic nitrates also can reduce myocardial O₂ demand. The major determinants of myocardial O₂ consumption include left ventricular wall tension, heart rate, and myocardial contractility. Ventricular wall tension is affected by a number of factors that may be considered under the categories of preload and afterload. Preload is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Increasing end-diastolic volume augments the ventricular wall tension (by the law of Laplace, tension is proportional to pressure times radius). Increasing venous capacitance with nitrates decreases venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases O₂.
consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. Afterload is the impedance against which the ventricle must eject. In the absence of aortic valvular disease, afterload is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and \( O_2 \) consumption.

Organic nitrates decrease both preload and afterload as a result of respective dilation of venous capacitance and arteriolar resistance vessels. Organic nitrates do not appear to significantly alter the inotropic or chronotropic state of the heart, although NO synthesized by cardiac myocytes and fibroblasts may play a role in the modulation of cyclic nucleotide metabolism and may thereby alter autonomic responses (Gustafsson and Brunton, 2002). Because nitrates affect several of the primary determinants of myocardial \( O_2 \) demand, their net effect usually is to decrease myocardial \( O_2 \) consumption. In addition, an improvement in the lusitropic state of the heart may be seen with more rapid early diastolic filling. This may be secondary to the relief of ischemia rather than primary, or it may be due to a reflex increase in sympathetic activity. Nitrovasodilators also increase cyclic GMP in platelets, with consequent inhibition of platelet function (Loscalzo, 2001) and decreased deposition of platelets in animal models of arterial wall injury (Lam et al., 1988). While this may contribute to their anti-anginal efficacy, the effect appears to be modest and in some settings may be confounded by the potential of nitrates to alter the pharmacokinetics of heparin, reducing its anti-thrombotic effect.

When nitroglycerin is injected or infused directly into the coronary circulation of patients with coronary artery disease, anginal attacks (induced by electrical pacing) are not aborted even when coronary blood flow is increased. However, sublingual administration of nitroglycerin does relieve anginal pain in the same patients. Furthermore, venous phlebotomy that is sufficient to reduce left ventricular end-diastolic pressure can mimic the beneficial effect of nitroglycerin.

Patients can exercise for considerably longer periods after the administration of nitroglycerin. Nevertheless, with or without nitroglycerin, angina occurs at the same value of the triple product (aortic pressure \( \times \) heart rate \( \times \) ejection time, which is roughly proportional to myocardial consumption of \( O_2 \)). The observation that angina occurs at the same level of myocardial \( O_2 \) consumption suggests that the beneficial effects of nitroglycerin result from reduced cardiac \( O_2 \) demand rather than an increase in the delivery of \( O_2 \) to ischemic regions of myocardium. However, these results do not preclude the possibility that a favorable redistribution of blood flow to ischemic subendocardial myocardium may contribute to relief of pain in a typical anginal attack, nor do they preclude the possibility that direct coronary vasodilation may be the major effect of nitroglycerin in situations where vasospasm compromises myocardial blood flow.

**Mechanism of Relief of Symptoms of Angina Pectoris.** The ability of nitrates to dilate epicardial coronary arteries, even in areas of atherosclerotic stenosis, is modest, and the preponderance of evidence continues to favor a reduction in myocardial work, and thus in myocardial \( O_2 \) demand, as their primary effect in chronic stable angina.

Paradoxically, high doses of organic nitrates may reduce blood pressure to such an extent that coronary flow is compromised; reflex tachycardia and adrenergic enhancement of contractility also occur. These effects may override the beneficial action of the drugs on myocardial \( O_2 \) demand and can aggravate ischemia.

Additionally, sublingual nitroglycerin administration may produce bradycardia and hypotension, probably owing to activation of the Bezold-Jarisch reflex.

**Other Effects.** The nitrovasodilators act on almost all smooth muscle tissues. Bronchial smooth muscle is relaxed irrespective of the preexisting tone. The muscles of the biliary tract, including those of the gallbladder, biliary ducts, and sphincter of Oddi, are effectively relaxed. Smooth muscle of the GI tract, including that of the esophagus, can be relaxed and its spontaneous motility decreased by nitrates both in vivo and in vitro. The effect may be transient and incomplete in vivo, but abnormal “spasms” frequently is reduced. Indeed, many incidences of atypical chest pain and “angina” are due to biliary or esophageal spasm, and these too can be relieved by nitrates. Similarly, nitrates can relax ureteral and uterine smooth muscle, but these responses are of uncertain clinical significance.

**Absorption, Fate, and Excretion.** More than a century after the first use of organic nitrates to treat angina pectoris, their biotransformation remains the subject of active investigation. Studies in the 1970s suggested that nitroglycerin is reductively hydrolyzed by hepatic glutathione–organic nitrate reductase. More recent studies have implicated a mitochondrial aldehyde dehydrogenase enzyme in the biotransformation of nitroglycerin (Chen et al., 2002). Other enzymatic and nonenzymatic pathways also may contribute to the biotransformation of nitrovasodilators. Despite uncertainties about the quantitative importance of the various pathways involved in nitrovasodilator metabolism, the pharmacokinetic properties of nitroglycerin and isosorbide dinitrate have been studied in some detail (Parker and Parker, 1998).

**Preparations**

**Nitroglycerin.** In humans, peak concentrations of nitroglycerin are found in plasma within 4 minutes of sublingual administration; the
drug has a $t_{1/2}$ of 1-3 minutes. The onset of action of nitroglycerin may be even more rapid if it is delivered as a sublingual spray rather than as a sublingual tablet. Glyceryl dinitrate metabolites, which have about one-tenth the vasodilator potency, appear to have half-lives of ~40 minutes.

**Isosorbide Dinitrate.** The major route of metabolism of isosorbide dinitrate in humans appears to be by enzymatic denitration followed by glucuronide conjugation. Sublingual administration produces maximal plasma concentrations of the drug by 6 minutes, and the fall in concentration is rapid ($t_{1/2}$ of ~45 minutes). The primary initial metabolites, isosorbide-2-mononitrate and isosorbide-5-mononitrate, have longer half-lives (3-6 hours) and are presumed to contribute to the therapeutic efficacy of the drug.

**Isosorbide-5-Mononitrate.** This agent is available in tablet form. It does not undergo significant first-pass metabolism and so has excellent bioavailability after oral administration. The mononitrate has a significantly longer $t_{1/2}$ than does isosorbide dinitrate and has been formulated as a plain tablet and as a sustained-release preparation; both have longer durations of action than the corresponding dosage forms of isosorbide dinitrate.

**Inhaled NO.** Nitric oxide gas administered by inhalation appears to exert most of its therapeutic effects on the pulmonary vasculature because of the rapid inactivation of NO by hemoglobin in the blood. The selective pulmonary vasodilation observed when NO is administered by inhalation has formed the basis for the widespread use of inhaled NO to treat pulmonary hypertension in hypoxic neonates, where inhaled NO has been shown to significantly reduce morbidity and mortality (Bloch et al., 2007). The efficacy of inhaled NO in adults for other clinical situations that are characterized by elevated pulmonary vascular pressures (acute lung injury and primary pulmonary hypertension, among other disease states) has not yet been established, and therapies using inhaled NO remain under active investigation.

**Correlation of Plasma Concentrations of Drug and Biological Activity.** Intravenous administration of nitroglycerin or long-acting organic nitrates in anesthetized animals produces the same transient (1-4 minutes) decrease in blood pressure. Because denitration markedly reduces the activity of the organic nitrates, their rapid clearance from blood indicates that the transient duration of action under these conditions correlates with the concentrations of the parent compounds. The rate of hepatic denitration is characteristic of each nitrate and is influenced by hepatic blood flow or the presence of hepatic disease. In experimental animals, injection of moderate amounts of organic nitrates into the portal vein results in little or no vasodilator activity, indicating that a substantial fraction of drug can be inactivated by first-pass metabolism in the liver (isosorbide mononitrate is an exception).

**Tolerance**

Sublingual organic nitrates should be taken at the time of an anginal attack or in anticipation of exercise or stress. Such intermittent treatment provides reproducible cardiovascular effects. However, frequently repeated or continuous exposure to high doses of organic nitrates leads to a marked attenuation in the magnitude of most of their pharmacological effects. The magnitude of tolerance is a function of dosage and frequency of use.

Tolerance may result from a reduced capacity of the vascular smooth muscle to convert nitroglycerin to NO, _true vascular tolerance_, or to the activation of mechanisms extraneous to the vessel wall, _pseudotolerance_ (Münzel et al., 1995). Multiple mechanisms have been proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulfhydryl groups, and the generation of free radicals (Parker and Parker, 1998). Inactivation of mitochondrial aldehyde dehydrogenase, an enzyme implicated in biotransformation of nitroglycerin, is seen in models of nitrate tolerance (Sydow et al., 2004), potentially associated with oxidative stress (Parker, 2004). A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and deactivate the enzymes of the activation pathway; tolerance could involve endothelium-derived reactive oxygen species (Münzel et al., 1995; Parker 2004). Clinical data relating to the ability of agents that modify the renin–angiotensin–aldosterone system to prevent nitrate tolerance are contradictory (Parker and Parker, 1998). Important to the interpretation of clinical trials, factors that may influence the ability of such modification to prevent nitrate tolerance include the dose, whether the ACE inhibitors or angiotensin receptor antagonists were administered prior to the initiation of nitrates, and the tissue specificity of the agent. Despite experimental evidence that depletion of sulfhydryl groups may lead to impaired biotransformation of nitrates to NO and thereby result in nitrate tolerance, experimental results to date with sulfhydryl donors have been disappointing. Other changes that are observed in the setting of nitroglycerin tolerance include an enhanced response to vasoconstrictors such as angiotensin II (AngII), serotonin, and phenylephrine. Administration of nitroglycerin is associated with plasma volume expansion, which may be reflected by a decrease in hematocrit. Although diuretic therapy with hydrochlorothiazide can improve a patient’s exercise duration, appropriately designed crossover trials have failed to demonstrate an effect of diuretics on nitrate tolerance (Parker et al., 1996).

A more effective approach to restoring responsiveness is to interrupt therapy for 8-12 hours each day, which allows the return of efficacy. It is usually most convenient to omit dosing at night in patients with exertional angina either by adjusting dosing intervals of oral or buccal preparations or by removing cutaneous nitroglycerin. However, patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (i.e., occurring in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Tolerance also has been seen with isosorbide-5-mononitrate; an eccentric twice-daily dosing schedule appears to maintain efficacy (Parker and Parker, 1998).

While these approaches appear to be effective, some patients develop an increased frequency of nocturnal
angina when a nitrate-free interval is employed using nitroglycerin patches; such patients may require another class of anti-anginal agent during this period. Tolerance is not universal, and some patients develop only partial tolerance. The problem of anginal rebound during nitrate-free intervals is especially problematic in the treatment of unstable angina with intravenous nitroglycerin. As tolerance develops, increasing doses are required to achieve the same therapeutic effects; eventually, despite dose escalation, the drug loses efficacy.

A special form of nitroglycerin tolerance is observed in individuals exposed to nitroglycerin in the manufacture of explosives. If protection is inadequate, workers may experience severe headaches, dizziness, and postural weakness during the first several days of employment. Tolerance then develops, but headache and other symptoms may reappear after a few days away from the job—the “Monday disease.” The most serious effect of chronic exposure is a form of organic nitrate dependence. Workers without demonstrable organic vascular disease have been reported to have an increase in the incidence of acute coronary syndromes during the 24-72-hour periods away from the work environment (Parker et al., 1995). Coronary and digital arteriospasm during withdrawal and its relaxation by nitroglycerin also have been demonstrated radiographically.

Because of the potential problem of nitrate dependence, it seems prudent not to withdraw nitrates abruptly from a patient who has received such therapy chronically.

Toxicity and Untoward Responses

Untoward responses to the therapeutic use of organic nitrates are almost all secondary to actions on the cardiovascular system. Headache is common and can be severe. It usually decreases over a few days if treatment is continued and often can be controlled by decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and may progress occasionally to loss of consciousness, a reaction that appears to be accentuated by alcohol. It also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All the organic nitrates occasionally can produce drug rash.

Interaction of Nitrates with PDE5 Inhibitors. Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of coronary artery disease. Thus many men desiring therapy for erectile dysfunction already may be receiving (or may require, especially if they increase physical activity) anti-anginal therapy. The combination of sildenafil and other phosphodiesterase 5 (PDE5) inhibitors with organic nitrate vasodilators can cause extreme hypotension.

Cells in the corpus cavernosum produce NO during sexual arousal in response to nonadrenergic, noncholinergic neurotransmission (Burnett et al., 1992). NO stimulates the formation of cyclic GMP, which leads to relaxation of smooth muscle of the corpus cavernosum and penile arteries, engorgement of the corpus cavernosum, and erection. The accumulation of cyclic GMP can be enhanced by inhibition of the cyclic GMP–specific PDE5 family. Sildenafil (VIAGRA, REVATIO) and congener inhibitors PDE5 and have been demonstrated to improve erectile function in patients with erectile dysfunction. Not surprisingly, PDE5 inhibitors have assumed the status of widely used recreational drugs. Since the introduction of sildenafil, two additional PDE5 inhibitors have been developed for use in therapy of erectile dysfunction. Tadalafil (CIALIS, ADORICA) and vardenafil (LEVTIRA) share similar therapeutic efficacy and side-effect profiles with sildenafil; tadalafl has a longer time to onset of action and a longer therapeutic t1/2, than the other PDE5 inhibitors. Sildenafil has been the most thoroughly characterized of these compounds, but all three PDE5 inhibitors are contraindicated for patients taking organic nitrate vasodilators, and the PDE5 inhibitors should be used with caution in patients taking α or β adrenergic receptor antagonists (see Chapter 12).

The side effects of sildenafil and other PDE5 inhibitors are largely predictable on the basis of their effects on PDE5. Headache, flushing, and rhinitis may be observed, as well as dyspepsia owing to relaxation of the lower esophageal sphincter. Sildenafil and varde

nenafil also weakly inhibit PDE6, the enzyme involved in photoreceptor signal transduction (Chapters 3 and 64), and can produce visual disturbances, most notably changes in the perception of color hue or brightness. In addition to visual disturbances, sudden one-sided hearing loss has also been reported. Tadalafil inhibits PDE11, a widely distributed PDE isoform, but the clinical importance of this effect is not clear. The most important toxicity of all these PDE5 inhibitors is hemodynamic. When given alone to men with severe coronary artery disease, these drugs have modest effects on blood pressure, producing >10% fall in systolic, diastolic, and mean systemic pressures and in pulmonary artery systolic and mean pressures (Herrmann et al., 2000). However, sildenafil, tadalafil, and vardenafil all have a significant and potentially dangerous interaction with organic nitrates, the therapeutic actions of which are mediated via their conversion to NO with resulting increases in cyclic GMP. In the presence of a PDE5 inhibitor, nitrates cause profound increases in cyclic GMP and can produce dramatic reductions in blood pressure. Compared with controls, healthy male subjects pretreated with sildenafil or the other PDE5 inhibitors exhibit a much greater decrease in systolic blood pressure when treated with sublingual glyceryl trinitrate, and in many subjects a fall of more than 25 mm Hg was detected. This drug class toxicity is the basis for the warning that PDE5 inhibitors should not be prescribed to patients receiving any form of nitrate (Cheitlin et al., 1999) and dictates that patients should be questioned about the use of PDE5 inhibitors within 24 hours before nitrates are administered. A period of longer than 24 hours may be needed following administration of a PDE5 inhibitor for safe use of nitrates, especially with tadalafil because of its prolonged t1/2. In the event that patients develop significant hypotension following combined administration of sildenafil and
a nitrate, fluids and α-adrenergic receptor agonists, if needed, should be used for support (Cheitlin et al., 1999). These same hemodynamic responses to PDE5 inhibition also may underlie the efficacy of sildenafil in the treatment of patients with primary pulmonary hypertension, in whom chronic treatment with the drug appears to result in enhanced exercise capacity associated with a decrease in pulmonary vascular resistance (Tsai and Kass, 2009). PDE5 inhibitors also are being studied in patients with congestive heart failure and cardiac hypertrophy (see Chapter 28).

Sildenafil, tadalafil, and vardenafil are metabolized via CYP3A4, and their toxicity may be enhanced in patients who receive other substrates of this enzyme, including macrolide and imidazole antibiotics, some statins, and antiretroviral agents (see individual chapters and Chapter 6). PDE5 inhibitors also may prolong cardiac repolarization by blocking the I\textsubscript{Kr}. Although these interactions and effects are important clinically, the overall incidence and profile of adverse events observed with PDE5 inhibitors, when used without nitrates, are consistent with the expected background frequency of the same events in the treated population. In patients with coronary artery disease whose exercise capacity indicates that sexual activity is unlikely to precipitate angina and who are not currently taking nitrates, the use of PDE5 inhibitors can be considered. Such therapy needs to be individualized, and appropriate warnings must be given about the risk of toxicity if nitrates are taken subsequently for angina; this drug interaction may persist for approximately 24 hours for sildenafil and vardenafil and for considerably longer with tadalafil. Alternative non-nitrate anti-anginal therapy, such as β-adrenergic receptor antagonists, should be used during these time periods (Cheitlin et al., 1999).

**Therapeutic Uses**

**Angina.** Diseases that predispose to angina should be treated as part of a comprehensive therapeutic program with the primary goal being to prolong life. Conditions such as hypertension, anemia, thyrotoxicosis, obesity, heart failure, cardiac arrhythmias, and acute anxiety can precipitate anginal symptoms in many patients. Patients should be counseled to stop smoking, lose weight, and maintain a low-fat, high-fiber diet; hypertension and hyperlipidemia should be corrected; and daily aspirin (or clopidogrel if aspirin is not tolerated) (see Chapter 30) should be prescribed. Exposure to sympathomimetic agents (e.g., those in nasal decongestants and other sources) probably should be avoided. The use of drugs that modify the perception of pain is a poor approach to the treatment of angina because the underlying myocardial ischemia is not relieved.

Table 27–1 lists the preparations and dosages of the nitrates and organic nitrates. The rapidity of onset, the duration of action, and the likelihood of developing tolerance are related to the method of administration.

**Sublingual Administration.** Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug of the organic nitrates given sublingually. The onset of action is within 1-2 minutes, but the effects are undetectable by 1 hour after administration. An initial dose of 0.3 mg nitroglycerin often relieves pain within 3 minutes. Absorption may be limited in patients with dentures or with dry mouths. Nitroglycerin tablets are stable but should be dispensed in glass containers and protected from moisture, light, and extremes of temperature. Active tablets usually produce a burning sensation under the tongue, but the absence of this sensation does not reliably predict loss of activity; elderly patients especially may be unable to detect the burning sensation. Anginal pain may be prevented when the drug is used prophylactically immediately prior to exercise or stress. The smallest effective dose should be prescribed. Patients should be instructed to seek medical attention immediately if three tablets taken over a 15-minute period do not relieve a sustained attack because this situation may be indicative of myocardial infarction (MI), unstable angina, or another cause of the pain. Patients also should be advised that there is no virtue in trying to avoid taking sublingual nitroglycerin for anginal pain. Other nitrates that can be taken sublingually do not appear to be longer acting than nitroglycerin because their half-lives depend only on the rate at which they are delivered to the liver. They are no more effective than nitroglycerin and often are more expensive.

**Oral Administration.** Oral nitrates often are used to provide prophylaxis against anginal episodes in patients who have more than occasional angina. They must be given in sufficient dosage to provide effective plasma levels after first-pass hepatic degradation. Low doses (e.g., 5-10 mg isosorbide dinitrate) are no more effective than placebo in decreasing the frequency of anginal attacks or increasing exercise tolerance. Higher doses of either isosorbide dinitrate (e.g., 20 mg or more orally every 4 hours) or sustained-release preparations of nitroglycerin decrease the frequency of anginal attacks and improve exercise tolerance. Effects peak at 60-90 minutes and last for 3-6 hours. Under these circumstances, the activities of less potent metabolites also may contribute to the therapeutic effect. Chronic oral administration of isosorbide dinitrate (120-720 mg daily) results in persistence of the parent compound and higher plasma concentrations of metabolites. However, these doses are more likely to cause troublesome side effects and lead to tolerance. Administration of isosorbide mononitrate (typically starting at 20 mg) once or twice daily (in the latter case, with the doses administered 7 hours apart) is efficacious in the treatment of chronic angina, and once-daily dosing or an eccentric twice-daily dosing schedule can minimize the development of tolerance.

**Cutaneous Administration.** Application of nitroglycerin ointment can relieve angina, prolong exercise capacity, and reduce ischemic ST-segment depression with exercise for 4 hours or more. Nitroglycerin ointment (2%) is applied to the skin (2.5-5 cm) as it is squeezed from the tube and then spread in a uniform layer; the dosage must be adjusted for each patient. Effects are apparent within 30-60 minutes (although absorption is variable) and last for 4-6 hours. The ointment is particularly useful for controlling nocturnal angina, which commonly develops within 3 hours after the patient goes to sleep. Transdermal nitroglycerin disks use a nitroglycerin-impregnated polymer (bonded to an adhesive bandage) that permits gradual absorption and a continuous plasma nitrate concentration over 24 hours. The onset of action is slow, with peak effects occurring at 1-2 hours. To avoid tolerance, therapy should be interrupted for at least 8 hours each day. With this regimen, long-term prophylaxis of ischemic episodes often can be attained.
Transmucosal or Buccal Nitroglycerin. This formulation is inserted under the upper lip above the incisors, where it adheres to the gingiva and dissolves gradually in a uniform manner. Hemodynamic effects are seen within 2-5 minutes, and it is therefore useful for short-term prophylaxis of angina. Nitroglycerin continues to be released into the circulation for a prolonged period, and exercise tolerance may be enhanced for up to 5 hours.

Congestive Heart Failure. The utility of nitrovasodilators to relieve pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 28.

Unstable Angina Pectoris and Non-ST-Segment–Elevation Myocardial Infarction. The term unstable angina pectoris has been used to describe a broad spectrum of clinical entities characterized by an acute or subacute worsening in a patient’s anginal symptoms. The variable prognosis of unstable angina no doubt reflects the broad range of clinical entities subsumed by the term. More recently, efforts have been directed toward identifying patients with unstable angina on the basis of their risks for subsequent adverse outcomes such as MI or death. The term acute coronary syndrome has been useful in this context: Common to most clinical presentations of acute coronary syndrome is disruption of a coronary plaque, leading to local platelet aggregation and thrombosis at the arterial wall, with subsequent partial or total occlusion of the vessel. There is some variability in the pathogenesis of unstable angina, with gradually progressive atherosclerosis accounting for some cases of new-onset exertional angina. Less commonly, vasospasm in minimally atherosclerotic coronary vessels may account for some cases where rest angina has not been preceded by symptoms of exertional angina. For the most part, the pathophysiological principles that underlie therapy for exertional angina—which are directed at decreasing myocardial oxygen demand—have limited efficacy in the treatment of acute coronary syndromes characterized by an insufficiency of myocardial oxygen (blood) supply.

Notably, the degree of coronary stenosis correlates poorly with the likelihood of plaque rupture. Drugs that reduce myocardial O₂ consumption by reducing ventricular preload (nitrates) or by reducing heart rate and ventricular contractility (using β adrenergic receptor antagonists) are efficacious, but additional therapies are directed at the atherosclerotic plaque itself and the consequences (or prevention) of its rupture. As discussed later, these therapies include combinations of:

- anti-platelet agents, including aspirin and thienopyridines such as clopidogrel or prasugrel
- anti-thrombin agents such as heparin and the thrombolytics
- anti-integrin therapies that directly inhibit platelet aggregation mediated by glycoprotein (GP)IIb/IIIa
- mechano-pharmacological approaches with percutaneously deployed intracoronary stents
- coronary bypass surgery for selected patients

Along with nitrates and β adrenergic receptor antagonists, antiplatelet agents represent the cornerstone of therapy for acute coronary syndrome (Hillis and Lange, 2009). Aspirin (see later in the chapter) inhibits platelet aggregation and improves survival (Yeghiazarians et al., 2000). Heparin (either unfractionated or low-molecular-weight) also appears to reduce angina and prevent infarction. These and related agents are discussed in detail in Chapters 34 and 30. Anti-integrin agents directed against the platelet integrin GPIIb/IIIa (including abciximab, tirofiban, and eptifibatide) are effective in combination with heparin, as discussed later. Nitrates are useful both in reducing vasospasm and in reducing myocardial O₂ consumption by decreasing ventricular wall stress. Intravenous administration of nitroglycerin allows high concentrations of drug to be attained rapidly. Because nitroglycerin is degraded rapidly, the dose can be titrated quickly and safely using intravenous administration. If coronary vasospasm is present, intravenous nitroglycerin is likely to be effective, although the addition of a Ca²⁺ channel blocker may be required to achieve complete control in some patients. Because of the potential risk of profound hypotension, nitrates should be withheld and alternate anti-anginal therapy administered if patients have consumed a PDE5 inhibitor within 24 hours (discussed earlier).

Acute Myocardial Infarction. Therapeutic maneuvers in MI are directed at reducing the size of the infarct, preserving or retrieving viable tissue by reducing the O₂ demand of the myocardium, and preventing ventricular remodeling that could lead to heart failure.

Nitroglycerin is commonly administered to relieve ischemic pain in patients presenting with MI, but evidence that nitrates improve mortality in MI is sparse. Because they reduce ventricular preload through vasodilation, nitrates are effective in relief of pulmonary congestion. A decreased ventricular preload should be avoided in patients with right ventricular infarction because higher right-sided heart filling pressures are needed in this clinical context. Nitrates are relatively contraindicated in patients with systemic hypotension. According to the American Heart Association/American College of Cardiology (AHA/ACC) guidelines, “nitrates should not be used if hypotension limits the administration of β blockers, which have more powerful salutary effects” (Antman et al., 2004).

Because the proximate cause of MI is intracoronary thrombosis, reperfusion therapies are critically important, employing, when possible, direct percutaneous coronary interventions (PCIs) for acute MI, usually using drug-eluting intracoronary stents (Antman et al., 2004). Thrombolytic agents are administered at
hospitals where emergency PCI is not performed, but outcomes are better with direct PCI than with thrombolytic therapy (Antman et al., 2004) (see discussion of thrombolytic and antiplatelet therapies in Chapter 30).

**Variant (Prinzmetal) Angina.** The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary constriction results in reduced blood flow and ischemic pain. Multiple mechanisms have been proposed to initiate vasospasm, including endothelial cell injury. Whereas long-acting nitrates alone are occasionally efficacious in abolishing episodes of variant angina, additional therapy with Ca<sup>2+</sup> channel blockers usually is required. Ca<sup>2+</sup> channel blockers, but not nitrates, have been shown to influence mortality and the incidence of MI favorably in variant angina; they should generally be included in therapy.

**Ca<sup>2+</sup> CHANNEL ANTAGONISTS**

Voltage-sensitive Ca<sup>2+</sup> channels (L-type or slow channels) mediate the entry of extracellular Ca<sup>2+</sup> into smooth muscle and cardiac myocytes and sinoatrial (SA) and atrioventricular (AV) nodal cells in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca<sup>2+</sup> is a trigger for contraction, albeit by different mechanisms. Ca<sup>2+</sup> channel antagonists, also called Ca<sup>2+</sup> entry blockers, inhibit Ca<sup>2+</sup> channel function. In vascular smooth muscle, this leads to relaxation, especially in arterial beds. These drugs also may produce negative inotropic and chronotropic effects in the heart.

**History.** The work in the 1960s of Fleckenstein, Godfraind, and their colleagues led to the concept that drugs can alter cardiac and smooth muscle contraction by blocking the entry of Ca<sup>2+</sup> into myocytes. Godfraind and associates showed that the effect of the diphenylpiperazine analogues in preventing agonist-induced vascular smooth muscle contraction could be overcome by raising the concentration of Ca<sup>2+</sup> in the extracellular medium (Godfraind et al., 1986).

Hass and Hartfelder reported in 1962 that verapamil, a coronary vasodilator, possessed negative inotropic and chronotropic effects that were not seen with other vasodilatory agents, such as nitroglycerin. In 1967, Fleckenstein suggested that the negative inotropic effect resulted from inhibition of excitation–contraction coupling and that the mechanism involved reduced movement of Ca<sup>2+</sup> into cardiac myocytes. Verapamil was the first clinically available calcium-channel blocker; it is a congener of papaverine. Many other calcium entry blockers with a wide range of structures are now available. Other compounds, such as nifedipine and diltiazem, also were shown to block the movement of Ca<sup>2+</sup> through the cardiac myocyte Ca<sup>2+</sup> channel, or the slow channel (see Chapter 29), and thereby alter the plateau phase of the cardiac action potential. Subsequently, drugs in several chemical classes have been shown to alter cardiac and smooth muscle contraction by blocking or “antagonizing” the entry of Ca<sup>2+</sup> through channels in the myocyte membrane.

**Chemistry.** The multiple Ca<sup>2+</sup> channel antagonists that are approved for clinical use in the U.S. have diverse chemical structures. Clinically used Ca<sup>2+</sup> channel antagonists include the phenylalkylamine compound verapamil, the benzothiazepine diltiazem, and numerous dihydropyridines, including nifedipine, amlodipine, felodipine, isradipine, nicardipine, nisoldipine, and nimodipine. The structures and specificities of several of these drugs are shown in Table 27–2. Although these drugs are commonly grouped together as “calcium channel blockers,” there are fundamental differences among verapamil, diltiazem, and the dihydropyridines, especially with respect to pharmacological characteristics, drug interactions, and toxicities.

**Mechanisms of Action.** An increased concentration of cytosolic Ca<sup>2+</sup> causes increased contraction in both cardiac and vascular smooth muscle cells. The entry of extracellular Ca<sup>2+</sup> is more important in initiating the contraction of cardiac myocytes (Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release). The release of Ca<sup>2+</sup> from intracellular storage sites also contributes to contraction of vascular smooth muscle, particularly in some vascular beds. Cytosolic Ca<sup>2+</sup> concentrations can be increased by diverse contractile stimuli in vascular smooth muscle cells. Many hormones and autacoids increase Ca<sup>2+</sup> influx through so-called receptor-operated channels, whereas increases in external concentrations of K<sup>+</sup> and depolarizing electrical stimuli increase Ca<sup>2+</sup> influx through voltage-sensitive, or “potential operated,” channels. The Ca<sup>2+</sup> channel antagonists produce their effects by binding to the α subunit of the L-type Ca<sup>2+</sup> channels and reducing Ca<sup>2+</sup> flux through the channel. The vascular and cardiac effects of some of the Ca<sup>2+</sup> channel blockers are summarized in the next section and in Table 27–2.

Voltage-sensitive channels contain domains of homologous sequence that are arranged in tandem within a single large subunit. In addition to the major channel-forming subunit (termed α<sub>1</sub>), Ca<sup>2+</sup> channels contain several other associated subunits (termed α<sub>2</sub>, β, γ, and δ) (Schwartz, 1999). Voltage-sensitive Ca<sup>2+</sup> channels have been divided into at least three subtypes based on their conductances and sensitivities to voltage (Schwartz, 1999; Tsien et al., 1988). The channels best characterized to date are the L, N, and T subtypes. Only the L-type channel is sensitive to the dihydropyridine Ca<sup>2+</sup> channel blockers. All approved Ca<sup>2+</sup> channel blockers bind to the α<sub>1</sub> subunit of the L-type Ca<sup>2+</sup> channel, which is the main pore-forming unit of the channel. This ~250,000–Da subunit is associated with a disulfide-linked α<sub>δ</sub> subunit of ~140,000 Da and a smaller intracellular β subunit. The α<sub>1</sub> subunits share a common topology of four homologous domains, each of which is composed of six putative transmembrane segments (S1–S6). The α<sub>2</sub>, δ, and β subunits modulate the α<sub>1</sub> subunit (see Figure 14–2). The phenylalkylamine Ca<sup>2+</sup> channel blocker verapamil binds to transmembrane segment 6 of domain IV (IVS6), the benzothiazepine Ca<sup>2+</sup> channel blocker diltiazem

*Relative effects are ranked from no effect (0) to prominent (5). NR, not ranked. (Modified from Julian, 1987; Taira, 1987.)*
bonds to the cytoplasmic bridge between domain III (IIIS) and domain IV (IVS), and the dihydropyridine Ca\(^{2+}\) channel blockers (nifedipine and several others) bind to transmembrane segments of both domains III and IV. These three separate receptor sites are linked allosterically.

Pharmacological Properties

**Cardiovascular Effects. Actions in Vascular Tissue.** Although there is some involvement of Na\(^+\) currents, depolarization of vascular smooth muscle cells depends primarily on the influx of Ca\(^{2+}\). At least three distinct mechanisms may be responsible for contraction of vascular smooth muscle cells. First, voltage-sensitive Ca\(^{2+}\) channels open in response to depolarization of the membrane, and extracellular Ca\(^{2+}\) moves down its electrochemical gradient into the cell. After closure of Ca\(^{2+}\) channels, a finite period of time is required before the channels can open again in response to a stimulus. Second, agonist-induced contractions that occur without depolarization of the membrane result from stimulation of the G\(_q\)–PLC–IP\(_3\) pathway, resulting in the release of intracellular Ca\(^{2+}\) from the sarcoplasmic reticulum (Chapter 3). This receptor-mediated release of intracellular Ca\(^{2+}\) may trigger further influx of extracellular Ca\(^{2+}\). Third, receptor-operated Ca\(^{2+}\) channels allow the entry of extracellular Ca\(^{2+}\) in response to receptor occupancy.

An increase in cytosolic Ca\(^{2+}\) results in enhanced binding of Ca\(^{2+}\) to calmodulin. The Ca\(^{2+}\)–calmodulin complex in turn activates myosin light-chain kinase, with resulting phosphorylation of the myosin light chain. Such phosphorylation promotes interaction between actin and myosin and leads to contraction of smooth muscle. Ca\(^{2+}\) channel antagonists inhibit the voltage-dependent Ca\(^{2+}\) channels in vascular smooth muscle at significantly lower concentrations than are required to interfere with the release of intracellular Ca\(^{2+}\) or to block receptor-operated Ca\(^{2+}\) channels. All Ca\(^{2+}\) channel blockers relax arterial smooth muscle, but they have a less pronounced effect on most venous beds and hence do not affect cardiac preload significantly.

**Actions in Cardiac Cells.** The mechanisms involved in excitation–contraction coupling in the cardiac muscle differ from those in vascular smooth muscle in that a portion of the two inward currents is carried by Na\(^+\) through the fast channel in addition to that carried by Ca\(^{2+}\) through the slow channel. Within the cardiac myocyte, Ca\(^{2+}\) binds to troponin, relieving the inhibitory effect of troponin on the contractile apparatus and permitting a productive interaction of actin and myosin, leading to contraction. Thus, Ca\(^{2+}\) channel blockers can produce a negative inotropic effect. Although this is true of all classes of Ca\(^{2+}\) channel blockers, the greater degree of peripheral vasodilation seen with the dihydropyridines is accompanied by a sufficient baroreflex-mediated increase in sympathetic tone to overcome the negative inotropic effect. Diltiazem also may inhibit mitochondrial Na\(^+\)–Ca\(^{2+}\) exchange (Schwartz, 1992).

In the SA and AV nodes, depolarization largely depends on the movement of Ca\(^{2+}\) through the slow channel. The effect of a Ca\(^{2+}\) channel blocker on AV conduction and on the rate of the sinus node pacemaker depends on whether or not the agent delays the recovery of the slow channel (Schwarz, 1992). Although nifedipine reduces the slow inward current in a dose-dependent manner, it does not affect the rate of recovery of the slow Ca\(^{2+}\) channel. The channel blockade caused by nifedipine and related dihydropyridines also shows little dependence on the frequency of stimulation. At doses used clinically, nifedipine does not affect conduction through the AV node. In contrast, verapamil not only reduces the magnitude of the Ca\(^{2+}\) current through the slow channel but also decreases the rate of recovery of the channel. In addition, channel blockade caused by verapamil (and to a lesser extent by diltiazem) is enhanced as the frequency of stimulation increases, a phenomenon known as frequency dependence or use dependence. Verapamil and diltiazem depress the rate of the sinus node pacemaker and slow AV conduction; the latter effect is the basis for their use in the treatment of supraventricular tachyarrhythmias (see Chapter 29). Bepridil, like verapamil, inhibits both slow inward Ca\(^{2+}\) current and fast inward Na\(^+\) current. It has a direct negative inotropic effect. Its electrophysiological properties lead to slowing of the heart rate, prolongation of the AV nodal effective refractory period, and importantly, prolongation of the QTc interval. Particularly in the setting of hypokalemia, the last effect can be associated with torsades de pointes, a potentially lethal ventricular arrhythmia (see Chapter 29).

**Hemodynamic Effects.** All the Ca\(^{2+}\) channel blockers approved for clinical use decrease coronary vascular resistance and can lead to an increase in coronary blood flow. The dihydropyridines are more potent vasodilators in vivo and in vitro than verapamil, which is more potent than diltiazem. The hemodynamic effects of these agents vary depending on the route of administration and the extent of left ventricular dysfunction.

Nifedipine given intravenously increases forearm blood flow with little effect on venous pooling; this indicates a selective dilation of arterial resistance vessels. The decrease in arterial blood pressure elicits sympathetic reflexes, with resulting tachycardia and positive inotropy. Nifedipine also has direct negative inotropic effects in vitro. However, nifedipine relaxes vascular smooth muscle at significantly lower concentrations than those required for prominent direct effects on the heart. Thus, arteriolar resistance and blood pressure are lowered, contractility and segmental ventricular function are improved, and heart rate and cardiac output are
increased modestly. After oral administration of nifedipine, arterial dilation increases peripheral blood flow; venous tone does not change.

The other dihydropyridines—amlodipine, felodipine, isradipine, nicardipine, nisoldipine, nimodipine, and clevidipine—share many of the cardiovascular effects of nifedipine.

Amlodipine is a dihydropyridine that has a slow absorption and a prolonged effect. With a plasma t1/2 of 35-50 hours, plasma levels and effect increase over 7-10 days of daily administration of a constant dose. Amlodipine produces both peripheral arterial vasodilation and coronary dilation, with a hemodynamic profile similar to that of nifedipine. However, there is less reflex tachycardia with amlodipine, possibly because the long t1/2 produces minimal peaks that of nifedipine. However, there is less reflex tachycardia with amlodipine, possibly because the long t1/2 produces minimal peaks that of nifedipine. Felodipine may have even greater vascular specificity than does nifedipine or amlodipine. At concentrations producing vasodilation, there is no negative inotropic effect. Like nifedipine, felodipine indirectly activates the sympathetic nervous system, leading to an increase in heart rate. Nicardipine has anti-anginal properties similar to those of nifedipine and may have selectivity for coronary vessels. Isradipine also produces the typical peripheral vasodilation seen with other dihydropyridines, but because of its inhibitory effect on the SA node, little or no rise in heart rate is seen. This inhibitory effect does not extend to the cardiac myocytes, however, because no cardiodepressant effect is seen.

Despite the negative chronotropic effect, isradipine appears to have little effect on the AV node, so it may be used in patients with AV block or combined with a β adrenergic receptor antagonist. In general, because of their lack of myocardial depression and, to a greater or lesser extent, lack of negative chronotropic effect, dihydropyridines are less effective as monotherapy in stable angina than does nifedipine or amlodipine. At concentrations producing vasodilation, there is no negative inotropic effect. Like nifedipine, felodipine indirectly activates the sympathetic nervous system, leading to an increase in heart rate. Nicardipine has anti-anginal properties similar to those of nifedipine and may have selectivity for coronary vessels. Isradipine also produces the typical peripheral vasodilation seen with other dihydropyridines, but because of its inhibitory effect on the SA node, little or no rise in heart rate is seen. This inhibitory effect does not extend to the cardiac myocytes, however, because no cardiodepressant effect is seen.

Verapamil is a less potent vasodilator in vivo than are the dihydropyridines. Like dihydropyridines, verapamil causes little effect on venous resistance vessels at concentrations that produce arteriolar dilation. With doses of verapamil sufficient to produce peripheral arterial vasodilation, there are more direct negative chronotropic, dromotropic, and inotropic effects than with the dihydropyridines. Intravenous verapamil causes a decrease in arterial blood pressure owing to a decrease in vascular resistance, but the reflex tachycardia is blunted or abolished by the direct negative chronotropic effect of the drug. This intrinsic negative inotropic effect is partially offset by both a decrease in afterload and the reflex increase in adrenergic tone. Thus, in patients without congestive heart failure, ventricular performance is not impaired and actually may improve, especially if ischemia limits performance. In contrast, in patients with congestive heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function. Oral administration of verapamil reduces peripheral vascular resistance and blood pressure, often with minimal changes in heart rate. The relief of pacing-induced angina seen with verapamil is due primarily to a reduction in myocardial oxygen demand.

Intravenous administration of diltiazem can result initially in a marked decrease in peripheral vascular resistance and arterial blood pressure, which elicits a reflex increase in heart rate and cardiac output. Heart rate then falls below initial levels because of the direct negative chronotropic effect of the agent. Oral administration of diltiazem decreases both heart rate and mean arterial blood pressure. While diltiazem and verapamil produce similar effects on the SA and AV nodes, the negative inotropic effect of diltiazem is more modest.

The effects of Ca2+ channel blockers on diastolic ventricular relaxation (the lusitropic state of the ventricle) are complex. The direct effect of several of these agents, especially when given into the coronary arteries, is to impair relaxation (Walsh and O’Rourke, 1985). Clinical studies suggest an improvement in peak left ventricular filling rates when verapamil, nifedipine, nisoldipine, or nicardipine are given systemically, but one must be cautious in extrapolating this change in filling rates to enhancement of relaxation. Because ventricular relaxation is so complex, the effect of even a single agent may be pleiotropic. If reflex stimulation of sympathetic tone increases cyclic AMP levels in myocytes, increased lusitropy will result that may outweigh a direct negative lusitropic effect. Likewise, a reduction in afterload will improve the lusitropic state. In addition, if ischemia is improved, the negative lusitropic effect of asymmetrical left ventricular contraction will be reduced. The sum total of these effects in any given patient cannot be determined a priori. Thus, caution should be exercised in the use of Ca2+ channel blockers for this purpose; the ideal is to determine the end result objectively before committing the patient to therapy.
Absorption, Fate, and Excretion. Although the absorption of these agents is nearly complete after oral administration, their bioavailability is reduced, in some cases markedly, by first-pass hepatic metabolism. The effects of these drugs are evident within 30-60 minutes of an oral dose, with the exception of the more slowly absorbed and longer-acting agents amiodipine, isradipine, and felodipine. Sustained-release forms of the Ca²⁺ channel blockers are used clinically to reduce the number of daily doses needed to maintain therapeutic drug levels, and in the case of nifedipine, sustained-release forms of the drug appear to mitigate the reflex tachycardia sometimes seen following oral administration. Intravenous administration of diltiazem or verapamil leads to a rapid therapeutic response.

These agents all are bound extensively to plasma proteins (70-98%); their elimination half-lives vary widely and range from 1.3-64 hours. During repeated oral administration, bioavailability and t₁/₂ may increase because of saturation of hepatic metabolism. The bioavailability of some of these drugs may be increased by grapefruit juice, likely through inhibition of enzyme CYP3A4 expressed in the small bowel. A major metabolite of diltiazem is desacetyldiltiazem, which has about one-half of diltiazem’s potency as a vasodilator. N-Demethylation of verapamil results in production of norverapamil, which is biologically active but much less potent than the parent compound. The t₁/₂ of norverapamil is ~10 hours. The metabolites of the dihydropyridines are inactive or weakly active. In patients with hepatic cirrhosis, the bioavailabilities and half-lives of the Ca²⁺ channel blockers may be increased, and dosage should be decreased accordingly. The half-lives of these agents also may be longer in older patients. Except for diltiazem and nifedipine, all the Ca²⁺ channel blockers are administered as racemic mixtures (Abernethy and Schwartz, 1999).

Toxicity and Untoward Responses. The profile of adverse reactions to the Ca²⁺ channel blockers varies among the drugs in this class. Patients receiving immediate-release capsules of nifedipine develop headache, flushing, dizziness, and peripheral edema. However, short-acting formulations of nifedipine are not appropriate in the long-term treatment of angina or hypertension. Dizziness and flushing are much less of a problem with the sustained-release formulations and with the dihydropyridines having a long t₁/₂ and relatively constant concentrations of drug in plasma. Peripheral edema may occur in some patients with Ca²⁺ channel blockers but is not the result of generalized fluid retention; it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction (Epstein and Roberts, 2009). Some other adverse effects of these drugs are due to actions in nonvascular smooth muscle. Contraction of the lower esophageal sphincter is inhibited by the Ca²⁺ channel blockers. For example, Ca²⁺ channel blockers can cause or aggravate gastroesophageal reflux. Constipation is a common side effect of verapamil, but it occurs less frequently with other Ca²⁺ channel blockers. Urinary retention is a rare adverse effect. Uncommon adverse effects include rash and elevations of liver enzymes. Worsened myocardial ischemia has been observed with nifedipine (Egstrup and Andersen, 1993). Worsening of angina was observed in patients with an angiographically demonstrable coronary collateral circulation. The worsening of angina may have resulted from excessive hypotension and decreased coronary perfusion, selective coronary vasodilation in nonischemic regions of the myocardium in a setting where vessels perfusing ischemic regions were already maximally dilated (i.e., coronary steal), or an increase in O₂ demand owing to increased sympathetic tone and excessive tachycardia. In a study of monotherapy with an immediate-release formulation of isradipine, the dihydropyridine was not superior to placebo and was associated with a trend toward an increased incidence of serious adverse events, a process termed proischemia (Waters, 1991).

Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with verapamil, these responses usually have occurred after intravenous administration of verapamil in patients with disease of the SA node or AV nodal conduction disturbances or in the presence of β blockade. The use of intravenous verapamil with an intravenous β adrenergic receptor antagonist is contraindicated because of the increased propensity for AV block and/or severe depression of ventricular function. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, and systolic blood pressures below 90 mm Hg should not be treated with verapamil or diltiazem, particularly intravenously. Some Ca²⁺ channel antagonists can cause an increase in the concentration of digoxin in plasma, although toxicity from the cardiac glycoside rarely develops. The use of verapamil to treat digitalis toxicity thus is contraindicated; AV nodal conduction disturbances may be exacerbated.

Several studies have raised concerns about the long-term safety of short-acting nifedipine (Opie et al., 2000). The proposed mechanism for this adverse effect lies in abrupt vasodilation with reflex sympathetic activation. There does not appear to be either significant reflex tachycardia or long-term adverse outcomes from treatment with sustained-release forms of nifedipine or with the dihydropyridine Ca²⁺ blockers such as amiodipine or felodipine, which have more favorable (slower) pharmacokinetics.

Important drug–drug interactions may be encountered with Ca²⁺ channel blockers. Verapamil blocks the P-glycoprotein drug transporter. Both the renal and hepatic disposition of digoxin occurs via this transporter. Accordingly, verapamil inhibits the elimination of digoxin and other drugs that are cleared from the body by the P-glycoprotein (see Chapter 5). When used with quinidine, Ca²⁺ channel blockers may cause excessive hypotension, particularly in patients with idiopathic hypertrophic subaortic stenosis.

Therapeutic Uses

Variant Angina. Variant angina results from reduced blood flow (a consequence of transient localized vasoconstriction) rather than increased oxygen demand. Controlled clinical trials have demonstrated efficacy of the Ca²⁺ channel blocking agents for the treatment of variant angina (Gibbons et al., 2003). These drugs can attenuate ergonovine-induced vasospasm in patients with variant angina, which suggests that protection in variant angina is due to coronary dilation rather than to alterations in peripheral hemodynamics.
**Exertional Angina.** Ca\(^{2+}\) channel antagonists also are effective in the treatment of exertional, or exercise-induced, angina. Their utility may result from an increase in blood flow owing to coronary arterial dilation, from a decrease in myocardial oxygen demand (secondary to a decrease in arterial blood pressure, heart rate, or contractility), or both. Numerous double-blind, placebo-controlled studies have shown that these drugs decrease the number of anginal attacks and attenuate exercise-induced ST-segment depression.

The double product, calculated as heart rate × systolic blood pressure, is an approximate if easily measured index of myocardial O\(_2\) demand. Because these agents reduce the level of the double product at a given external workload, and because the value of the double product at peak exercise is not altered, the beneficial effect of Ca\(^{2+}\) channel blockers likely is due primarily to a decrease in O\(_2\) demand rather than to an increase in coronary flow.

As described earlier, Ca\(^{2+}\) channel antagonists, particularly the dihydropyridines, may aggravate anginal symptoms in some patients when used without a β adrenergic receptor antagonist. This adverse effect is not prominent with verapamil or diltiazem because of their limited ability to induce marked peripheral vasodilation and reflex tachycardia. Concurrent therapy with nifedipine and the β receptor antagonist propranolol or with amlodipine and any of several β receptor antagonists has proven more effective than either agent given alone in exertional angina, presumably because the β antagonist suppresses reflex tachycardia (Gibbons et al., 2003). This concurrent drug therapy is particularly attractive because the dihydropyridines, unlike verapamil and diltiazem, do not delay AV conduction and will not enhance the negative dromotropic effects associated with β receptor blockade. Although concurrent administration of verapamil or diltiazem with a β receptor antagonist also may reduce angina, the potential for AV block, severe bradycardia, and decreased left ventricular function requires that these combinations be used judiciously, especially if left ventricular function is compromised prior to therapy. Amlodipine produces less reflex tachycardia than does nifedipine probably because of a flatter plasma concentration profile. Isradipine, approximately equivalent to nifedipine in enhancing exercise tolerance, also produces less rise in heart rate, possibly because of its slower onset of action.

**Unstable Angina.** Medical therapy for unstable angina involves the administration of aspirin, which reduces mortality, nitrates, β adrenergic receptor blocking agents, and heparin, which are effective in controlling ischemic episodes and angina. Because vasospasm occurs in some patients with unstable angina (Yeghihazarians et al., 2000), Ca\(^{2+}\) channel blockers may offer an additional approach to the treatment of unstable angina. However, there is insufficient evidence to assess whether such treatment decreases mortality except when the underlying mechanism is vasospasm. In a randomized, double-blind clinical trial, the short-acting dihydropyridine nifedipine was found to be less effective than metoprolol, and there are no studies supporting the administration of a dihydropyridine to patients with unstable angina. In contrast, therapy directed toward reduction of platelet function and thrombotic episodes clearly decreases morbidity and mortality in patients with unstable angina (see Chapters 34 and 30), and administration of statins also can reduce adverse cardiac events.

**Myocardial Infarction.** There is no evidence that Ca\(^{2+}\) channel antagonists are of benefit in the early treatment or secondary prevention of acute MI. In several trials, higher doses of the short-acting formulation of the dihydropyridine nifedipine had a detrimental effect on mortality (Opie et al., 2000; Furberg et al., 1995). Diltiazem and verapamil may reduce the incidence of reinfarction in patients with myocardial infarction who are not candidates for a β adrenergic receptor antagonist (Gibbons et al., 2003), but β adrenergic receptor antagonists remain the drugs of first choice. Again, administration of statins can lead to improvements in the rate of adverse cardiac events, apparently independent of changes in serum lipid levels.

**Other Uses.** The use of Ca\(^{2+}\) channel antagonists as antiarrhythmic agents is discussed in Chapter 29; their use for the treatment of hypertension is discussed later; and use of amlodipine in the treatment of heart failure is reviewed in Chapter 28. Clinical trials are under way to evaluate the capacity of Ca\(^{2+}\) channel blockers to slow the progression of renal failure and to protect the transplanted kidney. Verapamil has been demonstrated to improve left ventricular outflow obstruction and symptoms in patients with hypertrophic cardiomyopathy. Verapamil also has been used in the prophylaxis of migraine headaches. While several studies suggest that dihydropyridines may suppress the progression of mild atherosclerosis, there is no evidence that this alters mortality or reduces the incidence of ischemic events. Nimodipine has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm. Nifedipine, diltiazem, amlodipine, and felodipine appear to provide symptomatic relief in Raynaud’s disease. The Ca\(^{2+}\) channel antagonists cause relaxation of the myometrium in vitro and may be effective in stopping preterm uterine contractions in preterm labor (see Chapter 66).

**β ADRENERGIC RECEPTOR ANTAGONISTS**

β Adrenergic receptor antagonists are effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients who have had an MI. In contrast, these agents are not useful for vasospastic angina and, if used in isolation, may worsen the condition. Most β adrenergic receptor antagonists apparently are equally effective in the treatment of
exertional angina (Gibbons et al., 2003). Timolol, metoprolol, atenolol, and propranolol have been shown to exert cardioprotective effects. The effectiveness of β adrenergic receptor antagonists in the treatment of exertional angina is attributable primarily to a fall in myocardial O₂ consumption at rest and during exertion, although there also is some tendency for increased flow toward ischemic regions. The decrease in myocardial O₂ consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise. Not all actions of β adrenergic receptor antagonists are beneficial in all patients. The decreases in heart rate and contractility cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O₂ consumption. However, the net effect of β receptor blockade usually is to decrease myocardial O₂ consumption, particularly during exercise. Nevertheless, in patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β receptor blockade can result in profound decreases in left ventricular function. Despite this, several β adrenergic receptor antagonists have been shown to reduce mortality in patients with congestive heart failure, and treatment of patients with heart failure with β adrenergic antagonist drugs has become standard therapy for many such patients (see Chapters 12 and 28). Numerous β receptor antagonists are approved for clinical use in the U.S. Their pharmacology and the criteria for choosing between selective agents, agent with intrinsic sympathomimetic activity, or a nonspecific agent are considered in detail in Chapter 12.

Therapeutic Uses

Unstable Angina. β Adrenergic receptor antagonists are effective in reducing recurrent episodes of ischemia and the risk of progression to acute MI (Braunwald et al., 2002). Clinical trials have lacked sufficient statistical power to demonstrate beneficial effects of β receptor antagonists on mortality. On the other hand, if the underlying pathophysiology is coronary vasospasm, nitrates and Ca²⁺ channel blockers may be effective, and β receptor antagonists should be used with caution. In some patients, there is a combination of severe fixed disease and superimposed vasospasm; if adequate anti-platelet therapy and vasodilation have been provided by other agents and angina continues, the addition of a β receptor antagonist may be helpful.

Myocardial Infarction. β Adrenergic receptor antagonists that do not have intrinsic sympathomimetic activity improve mortality in MI. They should be given early and continued indefinitely in patients who can tolerate them (Gibbons et al., 2003).

COMPARISON OF ANTI-ANGINAL THERAPEUTIC STRATEGIES

In evaluating trials in which different forms of anti-anginal therapy are compared, careful attention must be paid to the patient population studied and to the pathophysiology and stage of the disease. An important placebo effect may be seen in these trials. The efficacy of anti-anginal treatment will depend on the severity of angina, the presence of coronary vasospasm, and myocardial O₂ demand. Optimally, the dose of each agent should be titrated to maximum benefit.

Task forces from the ACC and the AHA (Gibbons et al., 2003; updated in 2007) have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris. Patients with coronary artery disease should be treated with aspirin and a β receptor blocking drug (particularly if there is a history of prior MI). The ACC/AHA guidelines also note that solid data support the use of ACE inhibitors in patients with coronary artery disease who also have left ventricular dysfunction and/or diabetes. Therapy of hypercholesterolemia also is indicated. Nitrates, for treatment of angina symptoms, and Ca²⁺ antagonists also may be used (Gibbons et al., 2003). Table 27–3 summarizes the issues that the ACC/AHA task force considered to be relevant in choosing between β receptor antagonists and Ca²⁺ channel blockers in patients with angina and other medical conditions. A meta-analysis of publications that compared two or more anti-anginal therapies has been conducted (Heidenreich et al., 1999). Comparison of β adrenergic receptor antagonists with Ca²⁺ channel blockers showed that β receptor antagonists are associated with fewer episodes of angina per week and a lower rate of withdrawal because of adverse events. However, there were no differences in time to ischemia during exercise or in the frequency of adverse events when Ca²⁺ channel blockers other than nifedipine were compared with β adrenergic receptor antagonists. There were no significant differences in outcome between the studies comparing long-acting nitrates and Ca²⁺ channel blockers and the studies comparing long-acting nitrates with β receptor antagonists.

Combination Therapy and New Anti-Anginal Drugs. Because the different categories of anti-anginal agents have different mechanisms of action, it has been suggested that combinations of these agents would allow the use of lower doses, increasing effectiveness and reducing the incidence of side effects. However, despite the predicted advantages, combination therapy rarely achieves this potential and may be accompanied by serious side effects. The new anti-anginal agent ranolazine elicits its therapeutic effects by different and incompletely understood mechanisms that distinguish this new drug from the “classical” classes of anti-anginal drugs (organic nitrates, β adrenergic blockers and Ca\(^{2+}\) channel blockers). Some studies have suggested that ranolazine may have additional efficacy in combination with other anti-anginal agents (Chaitman et al., 2004), and the effects of ranolazine on cardiac arrhythmias and glucose metabolism may identify indications for this drug independent of its role as an anti-anginal agent (Morrow et al., 2009). Indeed, most of the anti-anginal drugs have broader indications in cardiovascular therapeutics, including (among others): β blockers for treatment of hypertension, arrhythmias, and heart failure; dihydropyridine calcium channel blockers in treatment of hypertension and heart failure; and diltiazem and verapamil to treat cardiac arrhythmias and hypertension. Table 27–3 shows some of the important indications and contraindications for use of anti-anginal agents in the context of other disease states.

Nitrates and β Adrenergic Receptor Antagonists. The concurrent use of organic nitrates and β adrenergic receptor antagonists can be very effective in the treatment of typical exertional angina. The additive efficacy primarily is a result of the blockade by one drug of a reflex effect elicited by the other. β Adrenergic receptor antagonists can block the baroreceptor-mediated reflex tachycardia and positive inotropic effects that are sometimes associated with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β receptor blockade. Concurrent administration of nitrates also can alleviate the increase in coronary vascular resistance associated with blockade of β adrenergic receptors.

Ca\(^{2+}\) Channel Blockers and β Receptor Antagonists. Because there is a proven mortality benefit from the use of β adrenergic receptor antagonists in patients with heart disease, this class of drugs represents the first line of therapy. However, when angina is not controlled adequately by a β receptor antagonist plus nitrates, additional improvement sometimes can be achieved by the addition of a Ca\(^{2+}\) channel blocker, especially if there is a component of coronary vasospasm. The differences among the chemical classes of Ca\(^{2+}\) channel blockers can lead to important adverse or salutary drug interactions with β receptor antagonists. If the patient already is being treated with maximal doses of verapamil or diltiazem, it is difficult to demonstrate any additional benefit of β receptor blockade, and excessive bradycardia, heart block, or heart failure may ensue. However, in patients treated with a dihydropyridine such as nifedipine or with nitrates, substantial reflex tachycardia often limits the effectiveness of these agents. A β receptor antagonist may be a helpful addition in this situation, resulting in a lower heart rate and blood pressure with exercise. The efficacy of amlodipine is improved by combination with a β adrenergic receptor antagonist. However, in the Total Ischaemic Burden European Trial (TIBET), which compared the effects of atenolol, a sustained-release form of nifedipine, and their combination on exercise parameters and ambulatory ischemia in patients with mild angina, there were no differences between the agents, either singly or in combination, on any of the measured ischemic parameters (Fox et al., 1996). On the other hand, in studies of patients with more severe but still stable angina, atenolol and propranolol were shown to be superior to nifedipine, and the combination of propranolol and nifedipine was more effective than a β receptor antagonist alone.

Relative contraindications to the use of β receptor antagonists for treatment of angina—bronchospasm, Raynaud’s syndrome, or Prinzmetal angina—may lead to a choice to initiate therapy with a Ca\(^{2+}\) channel blocker. Fluctuations in coronary tone are important determinants of variant angina. It is likely that episodes of increased tone, such as those precipitated by cold and by emotion, superimposed on fixed disease have a role in the variable anginal threshold seen in some patients with otherwise chronic stable angina. Increased coronary tone also may be important in the anginal episodes occurring early after MI and after coronary angioplasty, and it probably accounts for those patients with unstable angina who respond to dihydropyridines. Atherosclerotic arteries have abnormal vasomotor responses to a number of stimuli (Dudzinski et al., 2006), including exercise, other forms of sympathetic activation, and cholinergic agonists; in such vessels, stenotic segments actually may become more severely stenosed during exertion. This implies that the normal exercise-induced increase in coronary flow is lost in atherosclerosis. Similar exaggerated vascular contractile responses are seen in hyperlipidemia, even before anatomical evidence of atherosclerosis develops. Because of this, coronary vasodilators (nitrates and/or Ca\(^{2+}\) channel blockers) are an important part of the therapeutic program in the majority of patients with ischemic heart disease.

Ca\(^{2+}\) Channel Blockers and Nitrates. In severe exertional or vasospastic angina, the combination of a nitrate and...
a Ca\(^{2+}\) channel blocker may provide additional relief over that obtained with either type of agent alone. Because nitrates primarily reduce preload, whereas Ca\(^{2+}\) channel blockers reduce afterload, the net effect on reduction of O\(_2\) demand should be additive. However, excessive vasodilation and hypotension can occur. The concurrent administration of a nitrate and nifedipine has been advocated in particular for patients with exertional angina with heart failure, the sick-sinus syndrome, or AV nodal conduction disturbances, but excessive tachycardia may be seen.

**Ca\(^{2+}\) Channel Blockers, \(\beta\) Receptor Antagonists, and Nitrates.** In patients with exertional angina that is not controlled by the administration of two types of antianginal agents, the use of all three may provide improvement, although the incidence of side effects increases significantly. The dihydpyridines and nitrates dilate epicardial coronary arteries, the dihydpyridines decrease afterload, the nitrates decrease preload, and the \(\beta\) receptor antagonists decrease heart rate and myocardial contractility. Therefore, there is theoretical, and sometimes real, benefit with their combination, although adverse drug interactions may lead to clinically important events. For example, combining verapamil or diltiazem with a \(\beta\) receptor antagonist greatly increases the risk of conduction system and left ventricular dysfunction–related side effects and should be undertaken only with extreme caution and only if no other alternatives exist.

### ANTI-PLATELET, ANTI-INTEGRIN, AND ANTI-TROMBOTHIC AGENTS

Aspirin reduces the incidence of MI and death in patients with unstable angina. In addition, low doses of aspirin appear to reduce the incidence of MI in patients with chronic stable angina. Aspirin, given in doses of 160-325 mg at the onset of treatment of MI, reduces mortality in patients presenting with unstable angina. The addition of the thienopyridine clopidogrel to aspirin therapy reduces mortality in patients with acute coronary syndromes (Hillis and Lange, 2009); a related thienopyridine, prasugrel, has been approved for treatment of acute coronary syndromes (Wiviott et al., 2007). Heparin, in its unfractionated form and as low-molecular-weight heparin, also reduces symptoms and prevents infarction in unstable angina (Yeghiazarians et al., 2000). Thrombin inhibitors, such as hirudin or bivalirudin, directly inhibit even clot-bound thrombin, are not affected by circulating inhibitors, and function independently of antithrombin III. Thrombolytic agents, on the other hand, are of no benefit in unstable angina (Yeghiazarians et al., 2000). Intravenous inhibitors of the platelet GPIIb/IIIa receptor (abciximab, tirofiban, and epifibatide) are effective in preventing the complications of PCIs and in the treatment of some patients presenting with acute coronary syndromes (Hillis and Lange, 2009).

### TREATMENT OF CLAUDICATION AND PERIPHERAL VASCULAR DISEASE

Most patients with peripheral vascular disease also have coronary artery disease, and the therapeutic approaches for peripheral and coronary arterial diseases overlap. Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease (Regensteiner and Hiatt, 2002), and treatment of coronary disease remains the central focus of therapy. Many patients with advanced peripheral arterial disease are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms of peripheral arterial disease in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle O\(_2\) demand exceeding blood flow impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies shown to be efficacious for treatment of coronary artery disease also have a salutary effect on progression of peripheral artery disease (Hirsch et al., 2005). Reductions in cardiovascular morbidity and mortality in patients with peripheral arterial disease have been documented with anti-platelet therapy using aspirin, clopidogrel, or ticlopidine, administration of ACE inhibitors, and treatment of hyperlipidemia (Regensteiner and Hiatt, 2002). Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication. Other risk factor and lifestyle modifications remain cornerstones of therapy for patients with claudication: Physical exercise, rehabilitation, and smoking cessation have proven efficacy. Drugs used specifically in the treatment of lower-extremity claudication include pentoxifylline and cilostozol (Hiatt, 2001). Pentoxifylline is a methylxanthine derivative that is called a *rheologic modifier* for its effects on increasing the deformability of red blood cells. However, the
effects of pentoxifylline on lower-extremity claudication appear to be modest. Cilostazol is an inhibitor of PDE3 and promotes accumulation of intracellular cyclic AMP in many cells, including blood platelets. Cilostazol-mediated increases in cyclic AMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important drug interactions with other drugs metabolized via this pathway (see Chapter 6). Cilostazol treatment improves symptoms of claudication but has no effect on cardiovascular mortality.

As a PDE3 inhibitor, cilostazol is in the same drug class as milrinone, which had been used orally as an inotropic agent for patients with heart failure. Milrinone therapy was associated with an increase in sudden cardiac death, and the oral form of the drug was withdrawn from the market. Concerns about several other inhibitors of PDE3 (inamrinone, flosequinan) followed. Cilostazol, therefore, is labeled as being contraindicated in patients with heart failure, although it is not clear that cilostazol itself leads to increased mortality in such patients. Cilostazol has been reported to increase non-sustained ventricular tachycardia; headache is the most common side effect. Other treatments for claudication, including naftidrofuryl, propionyl levocarnitine, and prostaglandins, have been explored in clinical trials, and there is some evidence that some of these therapies may be efficacious.

**MECHANO-PHARMACOLOGICAL THERAPY: DRUG-ELUTING ENDOVASCULAR STENTS**

Intracoronary stents can ameliorate angina and reduce adverse events in patients with acute coronary syndromes. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which occurs in a substantial minority of patients. The pathways that lead to “in-stent restenosis” are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding. Local antiproliferative therapies at the time of stenting have been explored over many years, and the development of drug-eluting stents has had an important impact on clinical practice (Moses et al., 2003; Stone et al., 2004). Two drugs are currently being used in intravascular stents: paclitaxel and sirolimus. Paclitaxel is a tricyclic diterpene that inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. Sirolimus is a hydrophobic macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12–sirolimus complex inhibits the mammalian kinase target of rapamycin (mTOR), thereby inhibiting cell cycle progression (see Chapter 60). Paclitaxel and sirolimus differ markedly in their mechanisms of action but share common chemical properties as hydrophobic small molecules. Differences in the intracellular targets of these two drugs are associated with marked differences in their distribution in the vascular wall (Levin et al., 2004). Stent-induced damage to the vascular endothelial cell layer can lead to thrombosis; patients typically are treated with antiplatelet agents, including clopidogrel (for up to 6 months) and aspirin (indeinitely), sometimes in conjunction with intravenous heparin and/or GPIIb/IIIa inhibitors administered at the time of the revascularization procedure. The inhibition of cellular proliferation by paclitaxel and sirolimus not only affects vascular smooth muscle cell proliferation but also attenuates the formation of an intact endothelial layer within the stented artery. Therefore, antiplatelet therapy (typically with clopidogrel) is continued for several months after intracoronary stenting with drug-eluting stents. The rate of restenosis with drug-eluting stents is reduced markedly compared with “bare metal” stents, and the ongoing development of mechanopharmacological approaches likely will lead to novel approaches in intravascular therapeutics.

An important caveat in the use of drug-eluting stents is that stent thrombosis can occur even many months after placement of the stent, sometimes temporally associated with discontinuation of antiplatelet therapy with clopidogrel (Hillis and Lange, 2009). Long-term therapy with clopidogrel added to lifelong therapy with aspirin may be considered for many patients with drug-eluting stents; such long-term therapy carries an increased risk of bleeding. In some patients, the risk-benefit ratio between bare metal and drug-eluting stents may lead to the choice of a bare metal stent. The relative efficacy, morbidity, and morbidity of percutaneous coronary revascularization versus surgical coronary artery bypass grafting are topics of active investigation and debate, well beyond the scope of this chapter. Mechano-pharmacological therapies influence this important ongoing discussion.

**THERAPY OF HYPERTENSION**

Hypertension is the most common cardiovascular disease. The prevalence of hypertension increases with advancing age; for example, about 50% of people between the ages of 60 and 69 years old have hypertension, and the prevalence is further increased beyond age 70 (Chobanian et al., 2003).

Elevated arterial pressure causes pathological changes in the vasculature and hypertrophy of the left ventricle. As a consequence, hypertension is the principal cause of stroke; a major risk factor for coronary artery disease and its attendant complications, MI and sudden cardiac death; and a major contributor to cardiac failure, renal insufficiency, and dissecting aneurysm of the aorta.
Hypertension is defined conventionally as a sustained increase in blood pressure ≥140/90 mm Hg, a criterion that characterizes a group of patients whose risk of hypertension-related cardiovascular disease is high enough to merit medical attention. Actually, the risk of both fatal and nonfatal cardiovascular disease in adults is lowest with systolic blood pressures of <120 mm Hg and diastolic BP <80 mm Hg; these risks increase progressively with higher systolic and diastolic blood pressures. Recognition of this continuously increasing risk provides a simple definition of hypertension (Chobanian et al., 2003) (Table 27–4). Although many of the clinical trials classify the severity of hypertension by diastolic pressure, progressive elevations of systolic pressure are similarly predictive of adverse cardiovascular events; at every level of diastolic pressure, risks are greater with higher levels of systolic blood pressure. Indeed, beyond age 50 years, systolic blood pressure predicts outcome better than diastolic blood pressure. Systolic blood pressure tends to rise disproportionately greater in the elderly due to decreased compliance in blood vessels associated with aging and atherosclerosis. Isolated systolic hypertension (sometimes defined as systolic BP >140-160 mm Hg with diastolic BP <90 mm Hg) is largely confined to people older than 60 years of age.

At very high blood pressures (systolic ≥210 mm Hg and/or diastolic ≥120 mm Hg), a subset of patients develops fulminant arteriopathy characterized by endothelial injury and a marked proliferation of cells in the intima, leading to intimal thickening and ultimately to arteriolar occlusion. This is the pathological basis of the syndrome of immediately life-threatening hypertension, which is associated with rapidly progressive microvascular occlusive disease in the kidney (with renal failure), brain (hypertensive encephalopathy), congestive heart failure, and pulmonary edema. These patients typically require in-hospital management on an emergency basis for prompt lowering of blood pressure. Interestingly, isolated retinal changes with papilledema in an otherwise asymptomatic patient with very high blood pressure (formerly called “malignant hypertension”) may benefit from a more gradual lowering of blood pressure over days rather than hours.

The presence of pathological changes in certain target organs heralds a worse prognosis than the same level of blood pressure in a patient lacking these findings. Consequently, retinal hemorrhages, exudates, and papilledema in the eyes indicate a far worse short-term prognosis for a given level of blood pressure. Left ventricular hypertrophy defined by electrocardiogram, or more sensitively by echocardiography, is associated with a substantially worse long-term outcome that includes a higher risk of sudden cardiac death. The risk of cardiovascular disease, disability, and death in hypertensive patients also is increased markedly by concomitant cigarette smoking, diabetes, or elevated low-density lipoprotein; the coexistence of hypertension with these risk factors increases cardiovascular morbidity and mortality to a degree that is compounded by each additional risk factor. Because the purpose of treating hypertension is to decrease cardiovascular risk, other dietary and pharmacological interventions may be required to treat these conditions.

Pharmacological treatment of patients with hypertension decreases morbidity and mortality from cardiovascular disease. Effective antihypertensive therapy markedly reduces the risk of strokes, cardiac failure, and renal insufficiency due to hypertension. However, reduction in risk of MI may be less impressive.

**Principles of Antihypertensive Therapy.** Nonpharmacological therapy is an important component of treatment of all patients with hypertension. In some stage 1 hypertensives (see Table 27–4), blood pressure may be adequately controlled by a combination of weight loss (in overweight individuals), restricting sodium intake, increasing aerobic exercise, and moderating consumption of alcohol. These lifestyle changes, though difficult for many to implement, may facilitate pharmacological control of blood pressure in patients whose responses to lifestyle changes alone are insufficient.

Arterial pressure is the product of cardiac output and peripheral vascular resistance. Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both. Drugs may decrease the cardiac output by inhibiting myocardial contractility or by decreasing ventricular filling pressure. Reduction in ventricular filling pressure may be achieved by actions on the venous tone or on blood volume via renal effects. Drugs can decrease peripheral resistance by acting on smooth muscle to cause relaxation of resistance vessels or by interfering with the activity of systems that produce constriction of resistance vessels (e.g., the sympathetic nervous system, the renin–angiotensin system [RAS]). In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated by changes in peripheral resistance but also via effects on large artery stiffness (Franklin, 2000). Antihypertensive drugs can

be classified according to their sites or mechanisms of action (Table 27–5).

The hemodynamic consequences of long-term treatment with antihypertensive agents (Table 27–6) provide a rationale for potential complementary effects of concurrent therapy with two or more drugs. The simultaneous use of drugs with similar mechanisms of action and hemodynamic effects often produces little additional benefit. However, concurrent use of drugs from different classes is a strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects.

It generally is not possible to predict the responses of individuals with hypertension to any specific drug. For example, for some antihypertensive drugs, on average about two-thirds of patients will have a meaningful clinical response, whereas about one-third of patients will not respond to the same drug. Racial origin and age may have modest influence on the likelihood of a favorable response to a particular class of drugs. There is considerable interest in identifying genetic variation to improve selection of antihypertensive drugs in individual patients. Polymorphisms in a number of genes involved in the metabolism of antihypertensive drugs have been identified, for example in the CYP family (phase I metabolism) and in phase II metabolism, such as catechol- O-methyltransferase (see Chapters 6 and 7). While these polymorphisms change the pharmacokinetics of specific drugs, it is not clear that there will be substantial differences in efficacy given the dose range available clinically for these drugs. Consequently, identification of polymorphisms that influence pharmacodynamic responses to antihypertensive drugs are of considerable interest. Polymorphisms influencing the actions of a number of classes of antihypertensive drugs, including ACE inhibitors and diuretics, have been identified; so far, individual genes have not been found to have a major impact on pharmacodynamic responses. Genome-wide scanning may lead to identification of novel genes that are more clinically significant. Likewise, treatment may benefit from an increased understanding of the molecular and genetic bases of hypertension (Charchar et al., 2008; Shih and O’Connor, 2008).

### DIURETICS

An early strategy for the management of hypertension was to alter Na⁺ balance by restriction of salt in the diet. Pharmacological alteration of Na⁺ balance became practical with the development of the orally active thiazide diuretics (see Chapter 25). These and related diuretic agents have antihypertensive effects when used...
alone, and they enhance the efficacy of virtually all other antihypertensive drugs. On account of these considerations, coupled with the very large favorable experience with diuretics in randomized trials in patients with hypertension, this class of drugs remains very important in the treatment of hypertension.

The exact mechanism for reduction of arterial blood pressure by diuretics is not certain. The initial action of these drugs decreases extracellular volume by interacting with a thiazide-sensitive NaCl co-transporter (NCC; gene symbol SLC12A3) expressed in the distal convoluted tubule in the kidney, enhancing Na+ excretion in the urine, and leading to a fall in cardiac output. However, the hypotensive effect is maintained during long-term therapy due to decreased vascular resistance; cardiac output returns to pretreatment values and extracellular volume returns almost to normal due to compensatory responses such as activation of the RAS. The explanation for the long-term vasodilation induced by these drugs is unknown. Thiazides directly promote vasodilation in isolated arteries in vitro. On the other hand, there is suggestive evidence that vasodilation may occur as an indirect consequence of action of the drugs on the kidneys (Ellison and Loffing, 2009).

*Hydrochlorothiazide* may open Ca^{2+}-activated K⁺ channels, leading to hyperpolarization of vascular smooth muscle cells, which leads in turn to closing of L-type Ca^{2+} channels and lower probability of opening, resulting in decreased Ca^{2+} entry and reduced vasoconstriction. Hydrochlorothiazide also inhibits vascular carbonic anhydrase, which hypothetically may alter smooth-cell systolic pH and thereby cause opening of Ca^{2+}-activated K⁺ channels with the consequences noted above (Pickkers et al., 1999). The relevance of these findings—largely assessed in vitro—to the observed antihypertensive effects of thiazides is speculative. The major action of these drugs on SLC12A3—expressed predominantly in the distal convoluted tubules and not in vascular smooth muscle or the heart—has contributed to repeated suggestions that these drugs decrease peripheral resistance as an indirect effect of negative sodium balance. That thiazides lose efficacy in treating hypertension in patients with co-existing renal insufficiency is compatible with this hypothesis. Moreover, carriers of rare functional mutations in SLC12A3 that decrease renal Na⁺ reabsorption have lower blood pressure than appropriate controls (Ji et al., 2008); in a sense, this is an experiment of nature that may mimic the therapeutic effect of thiazides. Nonetheless, sorting out direct versus indirect actions of thiazides in promoting decreased peripheral resistance requires further experimental testing (Ellison and Loffing, 2009).

### Benzothiadiazines and Related Compounds

Benzothiadiazines ("thiazides") and related diuretics are the most frequently used class of antihypertensive agents in the U.S. Following the discovery of *chlorothiazide*, a number of oral diuretics were developed that

have an arylsulfonamide structure and block the NaCl co-transporter. Some of these are not benzothiadiazines but have structural features and molecular functions that are similar to the original benzothiadiazine compounds; consequently, they are designated as members of the thiazide class of diuretics. For example, chlorthalidone, one of the non-benzothiadiazines, is widely used in the treatment of hypertension, as is indapamide.

**Regimen for Administration of the Thiazide-Class Diuretics in Hypertension.** Because members of the thiazide class have similar pharmacological effects, they generally have been viewed as interchangeable with appropriate adjustment of dosage (see Chapter 25). However, the pharmacokinetics and pharmacodynamics of these drugs may differ, so they may not necessarily have the same clinical efficacy in treating hypertension (Carter et al., 2004). Indeed, there has been renewed debate about whether or not this group of diuretics should be considered as a class in terms of capacity to lower blood pressure and also decrease adverse clinical events due to hypertension (Sicca, 2006).

A direct comparison using 24-hour ambulatory blood pressure monitoring suggested that the antihypertensive efficacy of chlorthalidone is more favorable than that of hydrochlorothiazide (Ernst et al., 2006). Interestingly, the differences were primarily due to greater antihypertensive efficacy during the night and not with routine daytime office measurements of blood pressure. It is possible that the greater effect at night arises on account of the much longer $t_{1/2}$ of chlorthalidone (>24 hours) compared to hydrochlorothiazide (several hours). In light of the considerable clinical trial data supporting the capacity of chlorthalidone to diminish adverse cardiovascular events—in comparison to that available for currently used low doses of hydrochlorothiazide—there is a growing concern that chlorthalidone may be an underutilized drug in hypertensives requiring a diuretic.

When a thiazide-class diuretic is utilized as the sole antihypertensive drug (monotherapy), its dose-response curve for lowering blood pressure in patients with hypertension should be kept in mind. Antihypertensive effects can be achieved in many patients with as little as 12.5 mg daily of chlorthalidone or hydrochlorothiazide. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of hydrochlorothiazide or chlorthalidone (or equivalent). Even though more diuresis can be achieved with higher doses of these diuretics, some evidence suggests that doses higher than this are not generally more efficacious in lowering blood pressure in patients with normal renal function. For example, a large study comparing 25 and 50 mg of hydrochlorothiazide daily in an elderly population did not show a greater decrease in blood pressure with the larger dose (Medical Research Council Working Party, 1987). However, these conclusions are based on conventional rather than ambulatory blood pressure measurements. Other studies suggest that low doses of hydrochlorothiazide have inadequate effects on blood pressure when monitored in this more detailed manner (Lacourcière et al., 1995). In summary, recent critical attention has been focused on whether low doses of hydrochlorothiazide are as efficacious as low doses of chlorthalidone and whether low doses of hydrochlorothiazide are efficacious as monotherapy in protecting against the cardiovascular complications of hypertension. Relatively low doses of either thiazide are not at the top of the dose-response curve for adverse effects such as K$^+$ wasting and inhibition of uric acid excretion, emphasizing the importance of knowledge about the dose-response relationships for both beneficial and adverse effects.

In the clinical trials of antihypertensive therapy in the elderly that demonstrated the best outcomes in cardiovascular morbidity and mortality, 25 mg of hydrochlorothiazide or chlorthalidone was the maximum dose given; if this dose did not achieve the target blood pressure reduction, treatment with a second drug was initiated (SHEP Cooperative Research Group, 1991; Dahlöf et al., 1991; Medical Research Council Working Party, 1992). With respect to safety, a case-control study (Siscovick et al., 1994) found a dose-dependent increase in the occurrence of sudden death at doses of hydrochlorothiazide >25 mg daily. This finding supports the hypothesis proposed by the Multiple Risk Factor Intervention Trial Research Group (1982), suggesting that increased cardiovascular mortality is associated with higher diuretic doses. Taken together, clinical studies indicate that if adequate blood pressure reduction is not achieved with the 25-mg daily dose of hydrochlorothiazide or chlorthalidone, a second drug should be added rather than increasing the dose of diuretic. There is some concern that thiazide diuretics, especially at higher doses and in the absence of K$^+$-sparing diuretics or K$^+$ supplements, may increase the risk of sudden death. However, their overall therapeutic benefits are well established.

Urinary K$^+$ loss can be a problem with thiazides. ACE inhibitors and angiotensin receptor antagonists will attenuate diuretic-induced loss of K$^+$ to some degree, and this is a consideration if a second drug is required to achieve further blood pressure reduction beyond that attained with the diuretic alone. Because the diuretic and hypotensive effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each of these drugs. Administration of ACE inhibitors or angiotensin receptor antagonists together with other K$^+$-sparing agents or with K$^+$ supplements requires great caution; combining K$^+$-sparing agents with each other or with K$^+$ supplementation can cause potentially dangerous hyperkalemia in some patients.

In contrast to the limitation on the dose of thiazide-class diuretics used as monotherapy, the treatment of severe hypertension that is unresponsive to three or more drugs may require larger doses of the thiazide-class diuretics. Indeed, hypertensive patients may become
refractory to drugs that block the sympathetic nervous system or to vasodilator drugs, because these drugs engender a state in which the blood pressure is very volume dependent. Therefore, it is appropriate to consider the use of thiazide-class diuretics in doses of 50 mg of daily hydrochlorothiazide equivalent when treatment with appropriate combinations and doses of three or more drugs fails to yield adequate control of the blood pressure. Alternatively, there may be a need to use higher-capacity diuretics such as furosemide, especially if renal function is not normal, in some of these patients. Dietary Na+ restriction is a valuable adjunct to the management of such refractory patients and will minimize the dose of diuretic that is required. This can be achieved by a modest restriction of Na+ intake to 2 g daily. More stringent Na+ restriction is not feasible for most patients. Because the degree of K+ loss relates to the amount of Na+ delivered to the distal tubule, such restriction of Na+ can minimize the development of hypokalemia and alkalois. The effectiveness of thiazides as diuretics or antihypertensive agents is progressively diminished when the glomerular filtration rate falls below 30 mL/min. One exception is metolazone, which retains efficacy in patients with this degree of renal insufficiency.

Most patients will respond to thiazide diuretics with a reduction in blood pressure within about 4-6 weeks. Therefore, doses should not be increased more often than every 4-6 weeks. There is no way to predict the antihypertensive response from the duration or severity of the hypertension in a given patient, although diuretics are unlikely to be effective as sole therapy in patients with stage 2 hypertension (Table 27-4). Because the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. A wide range of fixed-dose combination products containing a thiazide are marketed for this purpose. Diuretics also have the advantage of minimizing the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of “resistant hypertension.”

**Adverse Effects and Precautions.** The adverse effects of diuretics are discussed in Chapter 25. Some of these determine whether patients can tolerate and adhere to diuretic treatment.

Erectile dysfunction is a troublesome adverse effect of the thiazide-class diuretics, and physicians should inquire specifically regarding its occurrence in conjunction with treatment with these drugs. Gout may be a consequence of the hyperuricemia induced by these diuretics. The occurrence of either of these adverse effects is a reason for considering alternative approaches to therapy. However, precipitation of acute gout is relatively uncommon with low doses of diuretics. Hydrochlorothiazide may cause rapidly developing, severe hyponatremia in some patients. Thiazides inhibit renal Ca2+ excretion, occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients subject to hypercalcemia, such as those with primary hyperparathyroidism. The thiazide-induced decreased Ca2+ excretion may be used therapeutically in patients with osteoporosis or hypercalciumia.

Some other effects of thiazide diuretics are laboratory observations that are of concern primarily because they are putative surrogate markers for adverse drug effects on morbidity and mortality. The effects of diuretic drugs on several surrogate markers for adverse outcomes merit consideration. The K+ depletion produced by thiazide-class diuretics is dose dependent and is variable among individuals, such that a subset of patients may become substantially K+ depleted on diuretic drugs. Given chronically, even small doses lead to some K+ depletion.

There are two types of ventricular arrhythmias that are thought to be enhanced by K+ depletion. One of these is polymorphic ventricular tachycardia (torsades de pointes), which is induced by a number of drugs, including quinidine. Drug-induced polymorphic ventricular tachycardia is initiated by abnormal ventricular repolarization; because K+ currents normally mediate repolarization, drugs that produce K+ depletion potentiate polymorphic ventricular tachycardia. Accordingly, thiazide diuretics should not be given together with drugs that can cause polymorphic ventricular tachycardia (see Chapter 29).

The most important concern regarding K+ depletion is its influence on ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. Studies in experimental animals have demonstrated that K+ depletion lowers the threshold for electrically induced ventricular fibrillation in the ischemic myocardium and also increases spontaneous ischemic ventricular fibrillation (Curtis and Hearse, 1989). There is a positive correlation between diuretic dose and sudden cardiac death, and an inverse correlation between the use of adjunctive K+-sparing agents and sudden cardiac death (Siscovick et al., 1994). One controlled clinical trial demonstrated a significantly greater occurrence of sudden cardiac death in patients treated with 50 mg of hydrochlorothiazide daily in comparison with the β receptor antagonist metoprolol (Medical Research Council Working Party, 1992).

Thiazide diuretics have been associated with changes in plasma lipids and glucose tolerance that have led to some concern. The clinical significance of the changes has been disputed. Nonetheless, clinical studies demonstrate the efficacy of the thiazide diuretics in reducing cardiovascular risk (ALLHAT Officers, 2002).

All of the thiazide-like drugs cross the placenta, but they have not been shown to have direct adverse effects on the fetus. However, if administration of a thiazide is begun during pregnancy, there is a risk of transient volume depletion that may result in placental hypoperfusion. Because the thiazides appear in breast milk, they should be avoided by nursing mothers.

**Other Diuretic Antihypertensive Agents**

The thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, such as
furosemide and bumetanide, in patients who have normal renal function. This differential effect is most likely related to the short duration of action of loop diuretics, such that a single daily dose does not cause a significant net loss of Na⁺ for an entire 24-hour period. Indeed, loop diuretics are frequently and inappropriately prescribed as a once-a-day medication in the treatment not only of hypertension, but also of congestive heart failure and ascites. The spectacular efficacy of the loop diuretics in producing a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, the acute diuresis can be excessive and lead to more side effects than occur with a slower-acting, milder thiazide diuretic. Loop diuretics may be particularly useful in patients with azotemia or with severe edema associated with a vasodilator such as minoxidil.

Amiloride is a K⁺-sparing diuretic that has some efficacy in lowering blood pressure in patients with hypertension. Another K⁺-sparing diuretic, spironolactone, also lowers blood pressure but has some significant adverse effects, especially in men (e.g., erectile dysfunction, gynecomastia, benign prostatic hyperplasia). Eplerenone is a newer aldosterone receptor antagonist that does not have the sexually related adverse effects induced by spironolactone. As a result of their capacity to inhibit loss of K⁺ in the urine, these drugs are used in the medical treatment of patients with hyperaldosteronism, a syndrome that can lead to hypokalemia. Triamterene is a K⁺-sparing diuretic that decreases the risk of hypokalemia in patients treated with a thiazide diuretic but does not have efficacy in lowering blood pressure by itself. These agents should be used cautiously with frequent measurements of K⁺ concentrations in plasma in patients predisposed to hyperkalemia. Patients taking spironolactone, amiloride, or triamterene should be cautioned regarding the possibility that concurrent use of K⁺-containing salt substitutes could produce hyperkalemia. Renal insufficiency is a relative contraindication to the use of K⁺-sparing diuretics. Concomitant use of an ACE inhibitor or an angiotensin receptor antagonist magnifies the risk of hyperkalemia with these agents.

Diuretic-Associated Drug Interactions
Because the antihypertensive effects of diuretics are frequently additive with those of other antihypertensive agents, a diuretic commonly is used in combination with other drugs. The K⁺- and Mg²⁺-depleting effects of the thiazides and loop diuretics also can potentiate arrhythmias that arise from digitalis toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. All diuretics can decrease the clearance of Li⁺, resulting in increased plasma concentrations of Li⁺ and potential toxicity. Nonsteroidal anti-inflammatory drugs (NSAIDs; see Chapter 34) that inhibit the synthesis of prostaglandins reduce the antihypertensive effects of diuretics. The effects of selective cyclooxygenase-2 (COX-2) inhibitors on renal prostaglandin synthesis and function are similar to those of the traditional NSAIDs. NSAIDs, β receptor antagonists, and ACE inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K⁺-sparing diuretic.

**SYMPATHOLYTIC AGENTS**
With the demonstration in 1940 that bilateral excision of the thoracic sympathetic chain could lower blood pressure, there was a search for effective chemical sympatholytic agents. Many of the early sympathetics drugs were poorly tolerated and had adverse side effects. A number of sympathetics agents are currently in use (Table 27–5). Antagonists of α and β adrenergic receptors have been mainstays of antihypertensive therapy.

**β Adrenergic Receptor Antagonists**
β Adrenergic receptor antagonists were not expected to have antihypertensive effects when they were first investigated in patients with angina, their primary indication. However, pronethalol, a drug that was never marketed, was found to reduce arterial blood pressure in hypertensive patients with angina pectoris. This antihypertensive effect was subsequently demonstrated for propranolol and all other β adrenergic receptor antagonists. The pharmacology of these drugs is discussed in Chapter 12; characteristics relevant to their use in hypertension are described here.

*Locus and Mechanism of Action.* Antagonism of β adrenergic receptors affects the regulation of the circulation through a number of mechanisms, including a reduction in myocardial contractility, heart rate, and cardiac output (see Chapter 26). An important consequence is blockade of the β receptors of the juxtaglomerular complex, reducing renin secretion and thereby diminishing production of circulating AngII. This action likely contributes to the antihypertensive action of this class of drugs, in concert with the cardiac effects. β receptor antagonists may lower blood pressure by other mechanisms. Some members of this large, heterogeneous class of drugs have additional effects unrelated to their capacity to bind to β adrenergic receptors. For example, labetalol is an α receptor antagonist, and nebivolol...
promotes endothelial cell dependent vasodilation via activation of the NO pathway (Pedersen and Cockcroft, 2006).

**Pharmacological Effects.** The β adrenergic blockers vary in their selectivity for the β<sub>1</sub> receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and vasodilating capacity. Despite these differences, all of the β receptor antagonists are effective as antihypertensive agents. However, these differences do influence the clinical pharmacokinetics and spectrum of adverse effects of the various drugs. Drugs without intrinsic sympathomimetic activity produce an initial reduction in cardiac output and a reflex-induced rise in peripheral resistance, generally with no net change in arterial pressure. In patients who respond with a reduction in blood pressure, peripheral resistance gradually returns to pretreatment values or less. Generally, persistently reduced cardiac output and possibly decreased peripheral resistance accounts for the reduction in arterial pressure. Drugs with intrinsic sympathomimetic activity produce lesser decreases in resting heart rate and cardiac output; the fall in arterial pressure correlates with a fall in vascular resistance below pretreatment levels, possibly because of stimulation of vascular β<sub>2</sub> receptors that mediate vasodilation.

The clinical significance, if any, of these differences is uncertain. However, there is increasing concern that some β receptor blockers, particularly atenolol, may have less efficacy as monotherapy for hypertension than some other drug classes in terms of decreasing risk of adverse cardiovascular consequences of hypertension, particularly due to stroke and coronary artery disease (Carlberg et al., 2004; Kaplan, 2008; Pedersen and Cockcroft, 2009). Particular interest has focused on evidence suggesting that atenolol-based therapy may not lower central (aortic) blood pressure as effectively as it appears when conventionally measured in the brachial artery using a standard arm cuff (CAFE Investigators, 2006). However, teasing out the comparative efficacy of the various classes of antihypertensive drugs represents a complex undertaking. Results of a detailed meta-analysis of 147 randomized trials of blood pressure reduction showed that, regardless of blood pressure before treatment, lowering systolic blood pressure by 10 mm Hg or diastolic blood pressure by 5 mm Hg using any of the main classes of antihypertensive drugs significantly reduces coronary events and stroke without an increase in nonvascular mortality (Law et al., 2009).

**Adverse Effects and Precautions.** The adverse effects of β adrenergic blocking agents are discussed in Chapter 12. These drugs should be avoided in patients with reactive airway disease (asthma) or with SA or AV nodal dysfunction or in combination with other drugs that inhibit AV conduction, such as verapamil. The risk of hypoglycemic reactions may be increased in diabetics taking insulin. β Receptor antagonists without intrinsic sympathomimetic activity increase concentrations of triglycerides in plasma and lower those of HDL cholesterol without changing total cholesterol concentrations. β receptor blocking agents with intrinsic sympathomimetic activity have little or no effect on blood lipids or increase HDL cholesterol. The long-term consequences of these effects are unknown.

Sudden discontinuation of β adrenergic blockers can produce a withdrawal syndrome that is likely due to upregulation of β receptors during blockade, causing enhanced tissue sensitivity to endogenous catecholamines; this can exacerbate the symptoms of coronary artery disease. The result, especially in active patients, can be rebound hypertension. Thus, β adrenergic blockers should not be discontinued abruptly except under close observation; dosage should be tapered gradually over 10-14 days prior to discontinuation.

NSAIDs such as indomethacin can blunt the antihypertensive effect of propranolol and probably other β receptor antagonists. This effect may be related to inhibition of vascular synthesis of prostacyclin, as well as to retention of Na+ (Beckmann et al., 1988).

**Epinephrine.** can produce severe hypertension and bradycardia when a nonselective β antagonist is present. The hypertension is due to the unopposed stimulation of α<sub>2</sub> adrenergic receptors when vascular β<sub>2</sub> receptors are blocked; the bradycardia is the result of reflex vagal stimulation. Such paradoxical hypertensive responses to β receptor antagonists have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from clonidine, following administration of epinephrine as a therapeutic agent, or in association with the illicit use of cocaine.

**Therapeutic Uses.** The β receptor antagonists provide effective therapy for all grades of hypertension. Despite marked differences in their pharmacokinetic properties, the antihypertensive effect of all the β blockers is of sufficient duration to permit once- or twice-daily administration. Populations that tend to have a lesser antihypertensive response to β blocking agents include the elderly and African-Americans. However, intrapatient differences in antihypertensive efficacy are generally much larger than statistical evidence of differences between racial or age-related groups. Consequently, these observations should not discourage the use of these drugs in individual patients in groups reported to be less responsive.

The β receptor antagonists usually do not cause retention of salt and water, and administration of a diuretic is not necessary to avoid edema or the development of tolerance. However, diuretics do have additive antihypertensive effects when combined with β blockers. The combination of a β receptor antagonist, a diuretic, and a vasodilator is effective for patients who require a third drug. β Receptor antagonists are highly preferred drugs for hypertensive patients with conditions such as MI, ischemic heart disease, or congestive heart failure. However, for other hypertensive patients, enthusiasm for their early use in treatment has diminished, as noted earlier.

**α<sub>1</sub> Adrenergic Receptor Antagonists**

The availability of drugs that selectively block α<sub>1</sub> adrenergic receptors without affecting α<sub>2</sub> adrenergic receptors adds another group of antihypertensive
agents. The pharmacology of these drugs is discussed in detail in Chapter 12. Prazosin, terazosin, and doxazosin are the agents that are available for the treatment of hypertension.

Pharmacological Effects. Initially, \( \alpha_1 \) adrenergic receptor antagonists reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During long-term therapy, vasodilation persists, but cardiac output, heart rate, and plasma renin activity return to normal. Renal blood flow is unchanged during therapy with an \( \alpha_1 \) receptor antagonist. The \( \alpha_1 \) adrenergic blockers cause a variable amount of postural hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients during continued administration, and this attenuates the postural hypotension. \( \alpha_1 \) Receptor antagonists reduce plasma concentrations of triglycerides and total LDL cholesterol and increase HDL cholesterol. These potentially favorable effects on lipids persist when a thiazide-type diuretic is given concurrently. The long-term consequences of these small, drug-induced changes in lipids are unknown.

Adverse Effects. The use of doxazosin as monotherapy for hypertension increased the risk for developing congestive heart failure (ALLHAT Officers, 2002). This may be a class effect that represents an adverse effect of all of the \( \alpha_1 \) receptor antagonists. However, this interpretation of the outcome of the ALLHAT study is controversial.

A major precaution regarding the use of the \( \alpha_1 \) receptor antagonists for hypertension is the so-called first-dose phenomenon, in which symptomatic orthostatic hypotension occurs within 30-90 minutes (or longer) of the initial dose of the drug or after a dosage increase. This effect may occur in up to 50% of patients, especially in patients who are already receiving a diuretic or an \( \alpha_1 \) receptor antagonist. After the first few doses, patients develop a tolerance to this marked hypotensive response.

Therapeutic Uses. \( \alpha_1 \) Receptor antagonists are not recommended as monotherapy for hypertensive patients primarily as a consequence of the ALLHAT study. Consequently, they are used primarily in conjunction with diuretics, \( \beta \) blockers, and other antihypertensive agents. \( \beta \) Receptor antagonists enhance the efficacy of the \( \alpha_1 \) blockers. \( \alpha_1 \) Receptor antagonists are not the drugs of choice in patients with pheochromocytoma, because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular \( \alpha_1 \) adrenergic receptors. \( \alpha_1 \) Receptor antagonists are attractive drugs for hypertensive patients with benign prostatic hyperplasia, because they also improve urinary symptoms.

**COMBINED \( \alpha_1 \) AND \( \beta \) ADRENERGIC RECEPTOR ANTAGONISTS**

Labetalol (see Chapter 12) is an equimolar mixture of four stereoisomers. One isomer is an \( \alpha_1 \) antagonist (like prazosin), another is a nonselective \( \beta \) antagonist with partial agonist activity (like pindolol), and the other two isomers are inactive. Because of its capacity to block \( \alpha_1 \) adrenergic receptors, labetalol given intravenously can reduce blood pressure sufficiently rapidly to be useful for the treatment of hypertensive emergencies. Labetalol has efficacy and adverse effects that would be expected with any combination of \( \beta \) and \( \alpha_1 \) receptor antagonists; it also has the disadvantages that are inherent in fixed-dose combination products: the extent of \( \alpha \)-receptor antagonism compared to \( \beta \) receptor antagonism is somewhat unpredictable and varies from patient to patient.

Carvedilol (see Chapters 12) is a \( \beta \) receptor antagonist with \( \alpha_1 \) receptor antagonist activity. The drug has been approved for the treatment of hypertension and symptomatic heart failure. The ratio of \( \alpha_1 \) to \( \beta \) receptor antagonist potency for carvedilol is approximately 1:10. Carvedilol undergoes oxidative metabolism and glucuronidation in the liver; the oxidative metabolism occurs via CYP2D6. Carvedilol reduces mortality in patients with congestive heart failure associated with systolic dysfunction when used as an adjunct to therapy with diuretics and ACE inhibitors. It should not be given to those patients with decompensated heart failure who are dependent on sympathetic stimulation. As with labetalol, the long-term efficacy and side effects of carvedilol in hypertension are predictable based on its properties as a \( \beta \) and \( \alpha_1 \) adrenergic receptor antagonist.

Nebivolol is a \( \beta_1 \) selective adrenergic antagonist that also promotes vasodilatation; rather than blocking \( \alpha_1 \) receptors, nebivolol augments arterial smooth muscle relaxation via NO (Veverka et al., 2006). In addition, nebivolol has agonist activity at \( \beta_2 \) receptors, although the clinical significance of this effect is not known.

**Methyldopa**

Methyldopa is a centrally acting antihypertensive agent. It is a prodrug that exerts its antihypertensive action via an active metabolite. Although used frequently as an antihypertensive agent in the past, methyldopa’s significant adverse effects limit its current use largely to treatment of hypertension in pregnancy, where it has a record for safety.
Methyldopa (α-methyl-3,4-dihydroxy-L-phenylalanine), an analog of 3,4-dihydroxyphenylalanine (DOPA), is metabolized by the L-aromatic amino acid decarboxylase in adrenergic neurons to α-methyldopamine, which then is converted to α-methylnorepinephrine. α-Methylnorepinephrine is stored in the secretory vesicles of adrenergic neurons, substituting for norepinephrine (NE) itself. Consequently, when the adrenergic neuron discharges its neurotransmitter, α-methylnorepinephrine is released instead of norepinephrine. α-Methylnorepinephrine acts in the central nervous system (CNS) to inhibit adrenergic neuronal outflow from the brainstem and probably acts as an agonist at presynaptic α2 adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

Absorption, Metabolism, and Excretion. Because methyldopa is a pro-drug that is metabolized in the brain to the active form, its concentration in plasma has less relevance for its effects than that for many other drugs. Peak concentrations in plasma occur after 2-3 hours. The drug is eliminated with a t1/2 of ~2 hours. Methyldopa is excreted in the urine primarily as the sulfate conjugate (50-70%) and as the parent drug (25%). The remaining fraction is excreted as other metabolites, including methyldopamine, methylnorepinephrine, and O-methylated products of these catecholamines. The t1/2 of methyldopa is prolonged to 4-6 hours in patients with renal failure.

In spite of its rapid absorption and short t1/2, the peak effect of methyldopa is delayed for 6-8 hours, even after intravenous administration, and the duration of action of a single dose is usually about 24 hours; this permits once- or twice-daily dosing. The discrepancy between the effects of methyldopa and the measured concentrations in the drug in plasma is most likely related to the time required for transport into the CNS, conversion to the active metabolite storage of α-methylnorepinephrine and its subsequent release in the vicinity of relevant α2 receptors in the CNS. This is a good example of the potential for a complex relationship between a drug’s pharmacokinetics and its pharmacodynamics. Patients with renal failure are more sensitive to the antihypertensive effect of methyldopa, but it is not known if this is due to alteration in excretion of the drug or to an increase in transport into the CNS.

Adverse Effects and Precautions. Methyldopa produces sedation that is largely transient. A diminution in psychic energy may persist in some patients, and depression occurs occasionally. Methyldopa may produce dryness of the mouth. Other adverse effects include diminished libido, parkinsonian signs, and hyperprolactinemia that may become sufficiently pronounced to cause gynecomastia and galactorrhea. Methyldopa may precipitate severe bradycardia and sinus arrest.

Methyldopa also produces some adverse effects that are not related to its pharmacological action. Hepatotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect of methyldopa. At least 20% of patients who receive methyldopa for a year develop a positive Coombs test (antiglobulin test) that is due to autoantibodies directed against the Rh antigen on erythrocytes. The development of a positive Coombs test is not necessarily an indication to stop treatment with methyldopa; 1-5% of these patients will develop a hemolytic anemia that requires prompt discontinuation of the drug. The Coombs test may remain positive for as long as a year after discontinuation of methyldopa, but the hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Adverse effects that are even more rare include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus–like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperitoneal fibrosis, pancreatitis, diarrhea, and malabsorption.

Therapeutic Uses. Methyldopa is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus. The usual initial dose of methyldopa is 250 mg twice daily, and there is little additional effect with doses >2 g/day. Administration of a single daily dose of methyldopa at bed-time minimizes sedative effects, but administration twice daily is required for some patients.

Clonidine, Guanabenz, and Guanfacine

The detailed pharmacology of the α2 adrenergic agonists clonidine, guanabenz, and guanfacine is discussed in Chapter 12. These drugs stimulate the α2A subtype of α2 adrenergic receptors in the brainstem, resulting in a reduction in sympathetic outflow from the CNS (Macmillan et al., 1996). The decrease in plasma concentrations of NE is correlated directly with the hypotensive effect (Goldstein et al., 1985). Patients who have had a spinal cord transection above the level of the sympathetic outflow tracts do not display a hypotensive response to clonidine. At doses higher than those required to stimulate central α2A receptors, these drugs can activate α2 receptors of the α2B subtype on vascular smooth muscle cells (MacMillan et al., 1996). This effect accounts for the initial vasoconstriction that is seen when overdoses of these drugs are taken, and may be responsible for the loss of therapeutic effect that is observed with high doses. A major limitation in the use of these drugs is the paucity of information about their efficacy in reducing the risk of cardiovascular consequences of hypertension.

Pharmacological Effects. The α2 adrenergic agonists lower arterial pressure by an effect on both cardiac output and peripheral resistance. In the supine position, when the sympathetic tone to the vasculature is low, the major effect is to reduce both heart rate and stroke volume; however, in the upright position, when sympathetic outflow to the vasculature is normally increased, these drugs reduce vascular resistance. This action may lead to postural hypotension. The decrease in cardiac sympathetic tone leads to a reduction in myocardial contractility and heart rate that could promote congestive heart failure in susceptible patients.

Adverse Effects and Precautions. Many patients experience annoying and sometimes intolerable adverse effects with these drugs. Sedation and xerostomia are prominent adverse effects. The xerostomia may be accompanied by dry nasal mucosa, dry eyes, and
parotid gland swelling and pain. Postural hypotension and erectile dysfunction may be prominent in some patients. Clonidine may produce a lower incidence of dry mouth and sedation when given transdermally, perhaps because high peak concentrations are avoided. Less common CNS side effects include sleep disturbances with vivid dreams or nightmares, restlessness, and depression. Cardiac effects related to the sympatholytic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the SA node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15-20% of patients who receive transdermal clonidine may develop contact dermatitis.

Sudden discontinuation of clonidine and related $\alpha_2$ adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. The arterial blood pressure may rise to levels above those that were present prior to treatment, but the syndrome may occur in the absence of an overshoot in pressure. Symptoms typically occur 18-36 hours after the drug is stopped and are associated with increased sympathetic discharge, as evidenced by elevated plasma and urine concentrations of catecholamines. The exact incidence of the withdrawal syndrome is not known, but it is likely dose related and more dangerous in patients with poorly controlled hypertension. Rebound hypertension also has been seen after discontinuation of transdermal administration of clonidine (Metz et al., 1987).

Treatment of the withdrawal syndrome depends on the urgency of reducing the arterial blood pressure. In the absence of life-threatening target organ damage, patients can be treated by restoring the use of clonidine. If a more rapid effect is required, sodium nitroprusside or a combination of an $\alpha$ and $\beta$ adrenergic blocker is appropriate. $\beta$ Adrenergic blocking agents should not be used alone in this setting, because they may accentuate the hypertension by allowing unopposed $\alpha$ adrenergic vasoconstriction caused by activation of the sympathetic nervous system and elevated circulating catecholamines.

Because perioperative hypertension has been described in patients in whom clonidine was withdrawn the night before surgery, surgical patients who are being treated with an $\alpha_2$ adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose and/or transdermal clonidine prior to the procedure. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly, and patients suspected of being noncompliant with medications should not be given $\alpha_2$ adrenergic agonists for hypertension.

Adverse drug interactions with $\alpha_2$ adrenergic agonists are rare. Diuretics predictably potentiate the hypertensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of clonidine, but the mechanism of this interaction is not known.

**Therapeutic Uses.** The CNS effects are such that this class of drugs is not a leading option for monotherapy of hypertension. Indeed, there is no fixed place for these drugs in the treatment of hypertension. They effectively lower blood pressure in some patients who have not responded adequately to combinations of other agents. Enthusiasm for these drugs is diminished by the relative absence of evidence demonstrating reduction in risk of adverse cardiovascular events.

Clonidine has been used in hypertensive patients for the diagnosis of pheochromocytoma. The lack of suppression of the plasma concentration of NE to $>$500 pg/mL 3 hours after an oral dose of 0.3 mg of clonidine suggests the presence of such a tumor. A modification of this test, wherein overnight urinary excretion of NE and epinephrine is measured after administration of a 0.3-mg dose of clonidine at bedtime, may be useful when results based on plasma NE concentrations are equivocal. Other uses for $\alpha_2$ adrenergic agonists are discussed in Chapters 12, 13, and 23.

**Guanadrel**

Guanadrel specifically inhibits the function of peripheral postganglionic adrenergic neurons. The structure of guanadrel, which contains the strongly basic guanidine group, is:

![Guanadrel Structure](Image)

**Locus and Mechanism of Action.** Guanadrel is an exogenous false neurotransmitter that is accumulated, stored, and released like NE but is inactive at adrenergic receptors. The drug reaches its site of action by active transport into the neuron by the same transporter that is responsible for the reuptake of NE (see Chapter 8). In the neuron, guanadrel is concentrated within the adrenergic storage vesicle, where it replaces NE. During chronic administration, guanadrel acts as a “false neurotransmitter”: It is present in storage vesicles, depletes the normal transmitter, and can be released by stimuli that normally release NE, but is inactive at adrenergic receptors. This replacement of NE with an inactive transmitter is probably the principal mechanism of action of guanadrel. Because guanadrel can promote NE release from pheochromocytomas, it is contraindicated in those patients.

**Pharmacological Effects.** Essentially all of the therapeutic and adverse effects of guanadrel result from functional sympathetic blockade. The antihypertensive effect is achieved by a reduction in peripheral vascular resistance that results from inhibition of $\alpha$ receptor-mediated vasoconstriction. Consequently, arterial pressure is reduced modestly in the supine position when sympathetic activity is usually low, but the pressure can fall to a greater extent during situations in which reflex sympathetic activation is an important mechanism for maintaining arterial pressure, particularly when standing.

**Absorption, Distribution, Metabolism, and Excretion.** Because guanadrel must be transported into and accumulate in adrenergic neurons, the maximum effect on blood pressure is not seen until 4-5 hours. The $t_{1/2}$ of the pharmacological effect of guanadrel is determined by the drug’s persistence in this neuronal pool and is probably at least 10 hours.

**Adverse Effects.** Guanadrel produces undesirable effects that are related to sympathetic blockade. Symptomatic hypotension during standing, exercise, ingestion of alcohol, or in hot weather is the
result of the lack of sympathetic compensation for these stresses. A
general feeling of fatigue and lassitude is partially, but not entirely,
related to postural hypotension. Sexual dysfunction usually presents
as delayed or retrograde ejaculation. Diarrhea also may occur.

Because guanadrel is actively transported to its site of action,
drugs that block or compete for the catecholamine transporter on the
presynaptic membrane will inhibit the effect of guanadrel. Such
drugs include the tricyclic antidepressants cocaine, chlorpromazine,
ephedrine, phenylpropanolamine, and amphetamine (see Chapter 8).

Therapeutic Uses. Because of the availability of a number of drugs
that lower blood pressure without producing similar adverse effects,
guanadrel is used very rarely; the drug is no longer marketed in the
U.S. The usual starting dose is 10 mg daily, and side effects can be
minimized by not exceeding 20 mg daily.

Reserpine

Reserpine was the first drug that was found to interfere
with the function of the sympathetic nervous system in
humans, and its use began the modern era of effective
pharmacotherapy of hypertension.

Reserpine is an alkaloid extracted from the root of Rauwolfia
serpentina, a climbing shrub indigenous to India. Ancient Hindu
Ayurvedic writings describe medicinal uses of the plant; Sen and
Bose described its use in the Indian biomedical literature. However,
rauwolfia alkaloids were not used in western medicine until the
mid-1950s.

Locus and Mechanism of Action. Reserpine binds tightly to adrener-
gic storage vesicles in central and peripheral adrenergic neurons and
remains bound for prolonged periods of time. The interaction
inhibits the vesicular catecholamine transporter, VMAT2, so that
nerve endings lose their capacity to concentrate and store NE and
dopamine. Catecholamines leak into the cytoplasm, where they are
metabolized. Consequently, little or no active transmitter is released
from nerve endings, resulting in a pharmacological sympathectomy.
Recovery of sympathetic function requires synthesis of new storage
vesicles, which takes days to weeks after discontinuation of the drug.
Because reserpine depletes amines in the CNS as well as in the
peripheral adrenergic neuron, it is probable that its antihypertensive
effects are related to both central and peripheral actions.

Pharmacological Effects. Both cardiac output and peripheral vascu-
lar resistance are reduced during long-term therapy with reserpine.

Absorption, Metabolism, and Excretion. Few data are available on
the pharmacokinetic properties of reserpine because of the lack of an
assay capable of detecting low concentrations of the drug or its
metabolites. Reserpine that is bound to isolated storage vesicles can-
not be removed by dialysis, indicating that the binding is not in equi-
librium with the surrounding medium. Because of the irreversible
nature of reserpine binding, the amount of drug in plasma is unlikely
to bear any consistent relationship to drug concentration at the site
of action. Free reserpine is entirely metabolized; none of the parent
drug is excreted unchanged.

Toxicity and Precautions. Most adverse effects of reserpine are due
to its effect on the CNS. Sedation and inability to concentrate or per-
form complex tasks are the most common adverse effects. More seri-
ous is the occasional psychotic depression that can lead to suicide.
Depression usually appears insidiously over many weeks or months
and may not be attributed to the drug because of the delayed and
gradual onset of symptoms. Reserpine must be discontinued at the
first sign of depression; reserpine-induced depression may last sev-
eral months after the drug is discontinued. The risk of depression is
likely dose related. Depression appears to be uncommon, but not
unknown, with doses of 0.25 mg/day or less. The drug should never
be given to patients with a history of depression. Other adverse
effects include nasal stuffiness and exacerbation of peptic ulcer dis-
ease, which is uncommon with small oral doses.

Therapeutic Uses. With the availability of newer drugs that are both
effective and well tolerated, the use of reserpine has diminished
because of its CNS side effects. Nonetheless, there has been some
recent interest in using reserpine at low doses, in combination with
diuretics, in the treatment of hypertension, especially in the elderly.
Reserpine is used once daily with a diuretic, and several weeks are
necessary to achieve a maximum effect. The daily dose should be
limited to 0.25 mg or less, and as little as 0.05 mg/day may be effi-
cacious when a diuretic is also used. One advantage of reserpine is
that it is considerably less expensive than other antihypertensive
drugs; thus, it is still used in developing nations.

Metyrosine

Metyrosine (DEMSER) is (−)-α-methyl-L-tyrosine. Metyrosine inhibits
tyrosine hydroxylase, the enzyme that catalyzes the conversion of
tyrosine to DOPA and the rate-limiting step in catecholamine biosyn-
thesis (see Chapter 8). At a dose of 1-4 g/day, metyrosine
decreases catecholamine biosynthesis by 35-80% in patients with
pheochromocytoma. The maximal decrease in synthesis occurs only
after several days and may be assessed by measurements of urinary
catecholamines and their metabolites.

Metyrosine is used as an adjuvant to phenoxybenzamine and other α-adrenergic blocking agents for the management of pheochro-
mocytoma and in the preoperative preparation of patients for resec-
tion of pheochromocytoma. Metyrosine carries a risk of crystalluria, which
can be minimized by maintaining a daily urine volume of >2 L. Other
adverse effects include orthostatic hypotension, sedation, extrapyrami-
dal signs, diarrhea, anxiety, and psychic disturbances. Doses must be
titrated carefully to achieve significant inhibition of catecholamine
biosynthesis and yet minimize these substantial side effects.

Ca²⁺ CHANNEL ANTAGONISTS

Ca²⁺ channel blocking agents are an important group of
drugs for the treatment of hypertension. The general
The pharmacology of these drugs is presented earlier in this chapter. The basis for their use in hypertension comes from the understanding that hypertension generally is the result of increased peripheral vascular resistance. Because contraction of vascular smooth muscle is dependent on the free intracellular concentration of Ca$^{2+}$, inhibition of transmembrane movement of Ca$^{2+}$ through voltage-sensitive Ca$^{2+}$ channels can decrease the total amount of Ca$^{2+}$ that reaches intracellular sites. Indeed, all of the Ca$^{2+}$ channel blockers lower blood pressure by relaxing arteriolar smooth muscle and decreasing peripheral vascular resistance (Weber, 2002). As a consequence of a decrease in peripheral vascular resistance, the Ca$^{2+}$ channel blockers evoke a baroreceptor-mediated sympathetic discharge. In the case of the dihydropyridines, tachycardia may occur from the adrenergic stimulation of the SA node; this response is generally quite modest except when the drug is administered rapidly. Tachycardia is typically minimal to absent with verapamil and diltiazem because of the direct negative chronotropic effect of these two drugs. Indeed, the concurrent use of a β receptor antagonist drug may magnify negative chronotropic effects of these drugs or cause heart block in susceptible patients. Consequently, the concurrent use of β receptor antagonists with either verapamil or diltiazem may be problematic.

Ca$^{2+}$ channel blockers are effective when used alone or in combination with other drugs for the treatment of hypertension; this view has been strengthened by a number of recent large clinical trials (Dahlöf et al., 2005; Jamerson et al., 2008).

Oral administration of nifedipine as an approach to urgent reduction of blood pressure has been abandoned. Sublingual administration does not achieve the maximum plasma concentration any more quickly than does oral administration. Moreover, in the absence of deleterious consequences of high arterial pressure, data do not support the rapid lowering of blood pressure. There is no place in the treatment of hypertension for the use of nifedipine or other dihydropyridine Ca$^{2+}$ channel blockers with short half-lives when administered in a standard (immediate-release) formulation, because of the oscillation in blood pressure and concurrent surges in sympathetic reflex activity within each dosage interval. As noted earlier, parenteral administration of the novel dihydropyridine clevidipine may be useful in treating severe or perioperative hypertension.

Compared with other classes of antihypertensive agents, there may be a greater frequency of achieving blood pressure control with Ca$^{2+}$ channel blockers as monotherapy in elderly subjects and in African-Americans, population groups in which the low renin status is more prevalent. However, intrasubject variability is more important than relatively small differences between population groups. Ca$^{2+}$ channel blockers are effective in lowering blood pressure and decreasing cardiovascular events in the elderly with isolated systolic hypertension (Staessen et al., 1997). Indeed, these drugs may be a preferred treatment in patients with isolated systolic hypertension.

**ANGIOTENSIN-CONVERTING ENZYME INHIBITORS**

Angiotensin II is an important regulator of cardiovascular function (see Chapter 26). The ability to reduce levels of AngII with orally effective inhibitors of ACE represents an important advance in the treatment of hypertension. Captopril was the first such agent to be developed for the treatment of hypertension. Since then, enalapril, lisinopril, quinapril, ramipril, benazepril, moexipril, fosinopril, trandolapril, and perindopril also have become available. These drugs have proven to be very useful for the treatment of hypertension because of their efficacy and their very favorable profile of adverse effects, which enhances patient adherence. Chapter 26 presents the pharmacology of ACE inhibitors in detail.

The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes, slowing the development and progression of diabetic glomerulopathy. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis, and many of these patients also have hypertension. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are candidates for treatment with ACE inhibitors; administration of ACE inhibitors in the immediate post-MI period has been shown to improve ventricular function and reduce morbidity and mortality (see Chapter 28).

The endocrine consequences of inhibiting the biosynthesis of AngII are of importance in a number of facets of hypertension treatment. Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na$^+$ loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretic drugs. This means that even very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors; conversely, the use of high doses of diuretics together with ACE inhibitors may lead to excessive reduction in blood pressure and to Na$^+$ loss in some patients.

The attenuation of aldosterone production by ACE inhibitors also influences K$^+$ homeostasis. There is only a very small and clinically unimportant rise in serum K$^+$ when these agents are used alone in patients with
normal renal function. However, substantial retention of $K^+$ can occur in some patients with renal insufficiency. Furthermore, the potential for developing hyperkalemia should be considered when ACE inhibitors are used with other drugs that can cause $K^+$ retention, including the $K^+$-sparking diuretics (amiloride, triamterene, and spironolactone), NSAIDs, $K^+$ supplements, and $\beta$ receptor antagonists. Some patients with diabetic nephropathy may be at greater risk of hyperkalemia.

There are several cautions in the use of ACE inhibitors in patients with hypertension. Angioedema is a rare but serious and potentially fatal adverse effect of the ACE inhibitors. Patients starting treatment with these drugs should be explicitly warned to discontinue their use with the advent of any signs of angioedema. Due to the risk of severe fetal adverse effects, ACE inhibitors are contraindicated during pregnancy, a fact that should be communicated to women of childbearing age.

In most patients, there is no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. However, in renovascular hypertension, the glomerular filtration rate is generally maintained as the result of increased resistance in the postglomerular arteriole caused by AngII. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will reduce the filtration fraction and cause a substantial reduction in glomerular filtration rate. In some patients with preexisting renal disease, the glomerular filtration may decrease with an ACE inhibitor. More information is needed on how to balance the potential risk of reversible drug-induced impairment of glomerular filtration rate versus inhibition of the progression of kidney disease.

ACE inhibitors lower the blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, there may be a considerable fall in blood pressure in some patients; this response to the initial dose is a function of plasma renin activity prior to treatment. The potential for a large initial fall in blood pressure is the reason for using a low dose to initiate therapy, especially in patients who may have a very active RAS supporting blood pressure, such as patients with diuretic-induced volume contraction or congestive heart failure. With continuing treatment, there usually is a progressive fall in blood pressure that in most patients does not reach a maximum for several weeks. The blood pressure seen during chronic treatment is not strongly correlated with the pretreatment plasma renin activity. Young and middle-aged Caucasian patients have a higher probability of responding to ACE inhibitors; elderly African-American patients as a group are more resistant to the hypertensive effect of these drugs. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients has a response that lasts <24 hours and may require twice-daily dosing for adequate control of blood pressure.

AT$_1$ RECEPTOR ANTAGONISTS

The importance of AngII in regulating cardiovascular function has led to the development of nonpeptide antagonists of the AT$_1$ AngII receptor for clinical use. Losartan, candesartan, irbesartan, valsartan, telmisartan, olmesartan, and eprosartan have been approved for the treatment of hypertension. The pharmacology of AT$_1$ receptor antagonists is presented in detail in Chapter 26. By antagonizing the effects of AngII, these agents relax smooth muscle and thereby promote vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy. AngII-receptor antagonists also theoretically overcome some of the disadvantages of ACE inhibitors, which not only prevent conversion of angiotensin I (AngI) to AngII but also prevent ACE-mediated degradation of bradykinin and substance P.

There are two distinct subtypes of AngII receptors, AT$_1$ and AT$_2$. The AT$_1$ receptor subtype is located predominantly in vascular and myocardial tissue and also in brain, kidney, and adrenal glomerulosa cells, which secrete aldosterone (see Chapter 26). The AT$_2$ subtype is found in the adrenal medulla, kidney, and CNS and may play a role in vascular development (Horiuchi et al., 1999). Because the AT$_1$ receptor mediates feedback inhibition of renin release, renin and AngII concentrations are increased during AT$_1$ receptor antagonism. The clinical consequences of increased AngII effects on an uninhibited AT$_2$ receptor are unknown; however, emerging data suggest that the AT$_2$ receptor may elicit anti-growth and anti-proliferative responses.

Adverse Effects and Precautions. The adverse effects of AT$_1$ receptor antagonists may be considered in the context of those known to be associated with the ACE inhibitors. ACE inhibitors cause problems of two major types, those related to diminished concentrations of AngII and those due to molecular actions independent of abrogating the function of AngII.

Adverse effects of ACE inhibitors that result from inhibiting AngII-related functions (see above and Chapter 26) also occur with AT$_1$ receptor antagonists. These include hypotension, hyperkalemia, and reduced renal function, including that associated with bilateral renal artery stenosis and stenosis in the artery of a solitary kidney. Hypotension is most likely to occur in patients in whom the blood pressure is highly dependent on AngII, including those with volume depletion (e.g., with diuretics), renovascular hypertension, cardiac failure, and cirrhosis; in such patients, initiation of treatment with low doses and attention to blood volume are essential. Hyperkalemia may occur in conjunction with other factors that alter $K^+$ homeostasis, such as renal insufficiency, ingestion of excess $K^+$, and the use of drugs that promote $K^+$ retention. Cough, an adverse effect of ACE inhibitors, is less frequent with AT$_1$ receptor antagonists. Angioedema occurs very rarely.

ACE inhibitors and AT$_1$ receptor antagonists should not be administered during pregnancy and should be discontinued as soon as pregnancy is detected.

Therapeutic Uses. When given in adequate doses, the AT$_1$ receptor antagonists appear to be as effective as
ACE inhibitors in the treatment of hypertension. The full effect of AT1 receptor antagonists on blood pressure typically is not observed until about 4 weeks after the initiation of therapy. If blood pressure is not controlled by an AT1 receptor antagonist alone, a second drug acting by a different mechanism (e.g., a diuretic or Ca²⁺ channel blocker) may be added. The combination of an ACE inhibitor and an AT1 receptor antagonist is not recommended for the treatment of hypertension.

**DIRECT RENIN INHIBITORS**

Drugs that inhibit the renin–angiotensin pathway at various steps have efficacy in the treatment of cardiovascular disease. This concept has been most extensively developed for the many drugs that inhibit the conversion of AngI to AngII (ACE inhibitors), block the actions of AngII (AT1 receptor antagonists) or antagonize the actions of aldosterone (aldosterone-receptor antagonists). On the other hand, drugs that interrupt this pathway by inhibiting the capacity of renin to produce AngI from angiotensinogen have developed more slowly. Aliskiren, the first orally-effective direct renin inhibitor available in the U.S., was approved by the FDA in 2007.

Aliskiren has been shown to lower blood pressure in patients with hypertension. However, its efficacy in preventing adverse cardiovascular outcomes, especially in comparison with other more established drugs, awaits the results of large-scale clinical trials or other types of epidemiological inquiry. Until that information becomes available, aliskiren has a place as an add-on drug in patients with hypertension, rather than as a replacement for other successful therapies. The detailed pharmacology of aliskiren is covered in Chapter 26.

**Locus and Mechanism of Action.** The initial renin inhibitors were peptide analogs of sequences either in renin itself or included the renin cleavage site in angiotensinogen (Staessen et al., 2006). While effective in inhibiting renin and lowering blood pressure, these peptide analogs were effective only parenterally. However, aliskiren is effective following oral administration; it directly and competitively inhibits the catalytic activity of renin.

**Pharmacological Effects.** Aliskiren’s inhibition of renin leads to diminished production of Ang—ultimately AngII and aldosterone—with a resulting fall in blood pressure. Aliskiren along with ACE inhibitors and AT1 receptor antagonists lead to an adaptive increase in the plasma concentrations of renin; however, because aliskiren inhibits renin activity, plasma renin activity does not increase as occurs with these other classes of drugs (Table 26–1).

**Absorption, Metabolism, and Excretion.** Aliskiren is poorly absorbed, with a bioavailability of <3% (Frampton and Curran, 2007). Taking the drug with a high-fat meal may substantially decrease plasma concentrations. Aliskiren has an elimination t½ of at least 24 hours. Elimination of the drug may be primarily through hepatobiliary excretion with limited metabolism via CYP3A4.

**TOXICITY AND PRECAUTIONS.** Aliskiren is generally well tolerated. Diarrhea may occur, especially at higher than recommended doses. The incidence of cough may be higher than for placebo but substantially less than found with ACE inhibitors. Aliskiren has been associated with several cases of angioedema in clinical trials (Frampton and Curran, 2007). Drugs acting on the RAS may damage the fetus and should not be used in pregnant women.

**Therapeutic Uses.** Aliskiren is effective as monotherapy in treating patients with hypertension with dose-dependent increasing efficacy at 150-300 mg/day (top recommended dose). The drug’s action appears to persist for 24 hours as assessed with ambulatory blood pressure monitoring. The combination of aliskiren with hydrochlorothiazide has a greater lowering effect on blood pressure than either drug alone (Baldwin and Plosker, 2009). Aliskiren formulated in combination with hydrochlorothiazide (TEKTURNA HCT) or with valsartan (VALTURNA) is available in the U.S. Aliskiren appears to have greater efficacy when added to other agents in the treatment of hypertension, including ACE inhibitors, AT1 receptor antagonists, and Ca²⁺ channel blockers. Overall, aliskiren appears to be an effective antihypertensive drug that is well tolerated. Long-term outcome studies—including assessments of target organ damage in the heart, brain, and kidneys—will be important in establishing the role of this relatively new drug in the therapy of hypertension.

**VASODILATORS**

**Hydralazine**

Hydralazine (1-hydrazinophthalazine) was one of the first orally active antihypertensive drugs to be marketed in the U.S.; however, the drug initially was used infrequently because of tachycardia and tachyphylaxis. With a better understanding of the compensatory cardiovascular responses that accompany use of arteriolar vasodilators, hydralazine was combined with sympatholytic agents and diuretics with greater therapeutic success. Nonetheless, its role in the treatment of hypertension has markedly diminished with the introduction of new classes of antihypertensive drugs.

**Locus and Mechanism of Action.** Hydralazine directly relaxes arteriolar smooth muscle. The molecular mechanisms mediating this action are not clear but may ultimately involve a fall in intracellular calcium concentrations. While a variety of changes in cellular signaling pathways are influenced by hydralazine, precise molecular targets that explain its capacity to dilate arteries remain uncertain. There is evidence suggesting that hydralazine inhibits IP3-induced release of Ca²⁺ from intracellular storage sites in arteries, leading to diminished contraction (Ellershaw and Gurney, 2001). There is also evidence that hydralazine promotes arterial dilation by opening high conductance Ca²⁺-activated K⁺ channels (Bang et al., 1998). Hydralazine induces transient
expression of hypoxia-inducible factor (HIF-1) and downstream targets of HIF in vascular smooth muscle cells (Knowles et al., 2004). However, the relationship between these pharmacological effects and the clinical consequence of use of hydralazine are unclear. In addition, hydralazine has been found to induce DNA demethylation (Arce et al., 2006).

The drug does not relax venous smooth muscle. Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, which results in increased heart rate and contractility, increased plasma renin activity, and fluid retention; all of these effects tend to counteract the antihypertensive effect of hydralazine.

**Pharmacological Effects.** Most of the effects of hydralazine are confined to the cardiovascular system. The decrease in blood pressure after administration of hydralazine is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilatation of arterioles over veins, postural hypotension is not a common problem; hydralazine lowers blood pressure similarly in the supine and upright positions.

**Absorption, Metabolism, and Excretion.** Hydralazine is well absorbed through the gastrointestinal tract, but the systemic bioavailability is low (16% in fast acetylators and 35% in slow acetylators). Hydralazine is N-acetylated in the bowel and/or the liver. The \( t_{1/2} \) of hydralazine is 1 hour, and systemic clearance of the drug is \( \sim 50 \) mL/kg/min.

The rate of acetylation is genetically determined; about half of the U.S. population acetylates rapidly, and half do so slowly. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators. Because the systemic clearance exceeds hepatic blood flow, extrahepatic metabolism must occur. Indeed, hydralazine rapidly combines with circulating \( \alpha \)-keto acids to form hydrazones, and the major metabolite recovered from the plasma is hydralazine pyruvic acid hydrazone. This metabolite has a longer \( t_{1/2} \) than hydralazine, but it does not appear to be very active. Although the rate of acetylation is an important determinant of the bioavailability of hydralazine, it does not play a role in the systemic elimination of the drug, probably because the hepatic clearance is so high that systemic elimination is principally a function of hepatic blood flow.

The peak concentration of hydralazine in plasma and the peak hypotensive effect of the drug occur within 30-120 minutes of ingestion. Although its \( t_{1/2} \) in plasma is about an hour, the duration of the hypotensive effect of hydralazine can last as long as 12 hours. There is no clear explanation for this discrepancy.

**Toxicity and Precautions.** Two types of adverse effects occur after the use of hydralazine. The first, which are extensions of the pharmacological effects of the drug, include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia can occur on account of increased \( O_2 \) demand induced by the baroreceptor reflex-induced stimulation of the sympathetic nervous system. Following parenteral administration to patients with coronary artery disease, the myocardial ischemia may be sufficiently severe and protracted to cause frank MI. For this reason, parenteral administration of hydralazine is not advisable in hypertensive patients with coronary artery disease, hypertensive patients with multiple cardiovascular risk factors, or older patients. In addition, if the drug is used alone, there may be salt retention with development of high-output congestive heart failure. When combined with a \( \beta \) adrenergic receptor blocker and a diuretic, hydralazine is better tolerated, although adverse effects such as headache are still commonly described and may necessitate discontinuation of the drug.

The second type of adverse effect is caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Administration of hydralazine also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis. The mechanism of these autoimmune reactions is unknown, although it has been suggested that the drug’s capacity to promote DNA demethylation may be involved (Arce et al., 2006).

The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with hydralazine, and its incidence is related to dose, sex, acetylator phenotype, and race. In one study, after 3 years of treatment with hydralazine, drug-induced lupus occurred in 10% of patients who received 200 mg daily, 5% who received 100 mg daily, and none who received 50 mg daily (Cameron and Ramsay, 1984). The incidence is four times higher in women than in men, and the syndrome is seen more commonly in Caucasians than in African-Americans. The rate of conversion to a positive antinuclear antibody test is faster in slow acetylators than in rapid acetylators, suggesting that the native drug or a nonacetylated metabolite is responsible. However, because the majority of patients with positive antinuclear antibody tests do not develop the drug-induced lupus syndrome, hydralazine need not be discontinued unless clinical features of the syndrome appear. These features are similar to those of other drug-induced lupus syndromes and consist mainly of arthralgia, arthritis, and fever. Pleuritis and pericarditis may be present, and pericardial effusion can occasionally cause cardiac tamponade. Discontinuation of the drug is all that is necessary for most patients with the hydralazine-induced lupus syndrome, but symptoms may persist in a few patients, and administration of corticosteroids may be necessary.

Hydralazine also can produce a pyridoxine-responsive polyneuropathy. The mechanism appears to be related to the ability of hydralazine to combine with pyridoxine to form a hydrazone. This side effect is very unusual with doses \( \leq 200 \) mg/day.

**Therapeutic Uses.** Hydralazine is no longer a first-line drug in the treatment of hypertension on account of its relatively unfavorable adverse-effect profile. The drug is marketed as a combination pill containing isosorbide dinitrate (BiDil) that is used for the treatment of heart failure (see Chapter 28). Hydralazine may have utility in the treatment of some patients with severe hypertension, can be part of evidence-based therapy in patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or \( \beta_1 \) receptor antagonists), and may be useful in the treatment of hypertensive emergencies in pregnant women (especially preeclampsia). Hydralazine should be used with the great caution in elderly patients and in hypertensive patients with coronary artery disease because of the possibility of precipitation of myocardial ischemia due to reflex tachycardia. The usual oral dosage of hydralazine is 25-100 mg twice daily. Off-label twice-daily administration is as effective as administration four times a day for control of blood pressure, regardless of acetylator phenotype. The
maximum recommended dose of hydralazine is 200 mg/day to minimize the risk of drug-induced lupus syndrome.

**K<sub>ATP</sub> Channel Openers: Minoxidil**

The discovery in 1965 of the hypotensive action of minoxidil was a significant advance in the treatment of hypertension, because the drug has proven to be efficacious in patients with the most severe and drug-resistant forms of hypertension.

**Locus and Mechanism of Action.** Minoxidil is not active in vitro but must be metabolized by hepatic sulfotransferase to the active molecule, minoxidil N-O sulfate; the formation of this active metabolite is a minor pathway in the metabolic disposition of minoxidil. Minoxidil sulfate relaxes vascular smooth muscle in isolated systems where the parent drug is inactive. Minoxidil sulfate activates the ATP-modulated K<sup>+</sup> channel. By opening K<sup>+</sup> channels in smooth muscle and thereby permitting K<sup>+</sup> efflux, it causes hyperpolarization and relaxation of smooth muscle (Leblanc et al., 1989).

**Pharmacological Effects.** Minoxidil produces arteriolar vasodilation with essentially no effect on the capacitance vessels; the drug resembles hydralazine and diazoxide in this regard. Minoxidil increases blood flow to skin, skeletal muscle, the gastrointestinal tract, and the heart more than to the CNS. The disproportionate increase in blood flow to the heart may have a metabolic basis, in that administration of minoxidil is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase markedly, as much as 3- to 4-fold. The principal determinant of the elevation in cardiac output is the action of minoxidil on peripheral vascular resistance to enhance venous return to the heart; by inference from studies with other drugs, the increased venous return probably results from enhancement of flow in the regional vascular beds, with a fast time constant for venous return to the heart (Ogilvie, 1985). The adrenergically mediated increase in myocardial contractility contributes to the increased cardiac output but is not the predominant causal factor.

The effects of minoxidil on the kidney are complex. Minoxidil is a renal artery vasodilator, but systemic hypotension produced by the drug occasionally can decrease renal blood flow. Renal function usually improves in patients who take minoxidil for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension (Mitchell et al., 1980). Minoxidil is a very potent stimulator of renin secretion; this effect is mediated by a combination of renal sympathetic stimulation and activation of the intrinsic renal mechanisms for regulation of renin release.

Discovery of K<sub>ATP</sub> channels in a variety of cell types and in mitochondria is prompting consideration of K<sub>ATP</sub> channel modulators as therapeutic agents in myriad cardiovascular diseases (Pollesello and Mebazaa, 2004) and may provide explanations for some of the effects of minoxidil noted in the previous section. Various K<sub>ATP</sub> channels possess different regulatory sulfonamide receptor subunits and thus exhibit tissue-specific responses. Recent studies suggest that certain actions of K<sub>ATP</sub> channel openers can be influenced by hypercholesterolemia and by concurrent administration of sulfonamide hypoglycemic agents (Miura and Miki, 2003).

**Absorption, Metabolism, and Excretion.** Minoxidil is well absorbed from the GI tract. Although peak concentrations of minoxidil in blood occur 1 hour after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed.

The bulk of the absorbed drug is eliminated by hepatic metabolism; ~20% is excreted unchanged in the urine. The major metabolite of minoxidil is the glucuronide conjugate at the N-oxide position in the pyrimidine ring. This metabolite is less active than minoxidil, but it persists longer in the body. The extent of biotransformation of minoxidil to its active metabolite, minoxidil N-O sulfate, has not been evaluated in humans. Minoxidil has a plasma t<sub>1/2</sub> of 3-4 hours, but its duration of action is 24 hours or occasionally even longer. It has been proposed that persistence of minoxidil in vascular smooth muscle is responsible for this discrepancy. However, without knowledge of the pharmacokinetic properties of the active metabolite, an explanation for the prolonged duration of action cannot be given.

**Adverse Effects and Precautions.** The adverse effects of minoxidil can be severe and are divided into three major categories: fluid and salt retention, cardiovascular effects, and hypertrichosis.

Retention of salt and water results from increased proximal renal tubular reabsorption, which is in turn secondary to reduced renal perfusion pressure and to reflex stimulation of renal tubular α-adrenergic receptors. Similar antinatriuretic effects can be observed with the other arteriolar dilators (e.g., diazoxide and hydralazine). Although administration of minoxidil causes increased secretion of renin and aldosterone, this is not an important mechanism for retention of salt and water in this case. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any degree of renal dysfunction. Retention of salt and water in patients taking minoxidil may be profound, requiring large doses of loop diuretics to prevent edema formation.

The cardiac consequences of the baroreceptor-mediated activation of the sympathetic nervous system during minoxidil therapy are similar to those seen with hydralazine; there is an increase in heart rate, myocardial contractility, and myocardial O<sub>2</sub> consumption. Thus, myocardial ischemia can be induced by minoxidil in patients with coronary artery disease. The cardiac sympathetic responses are attenuated by concurrent administration of a β-adrenergic blocker. The adrenergically induced increase in renin secretion also can be
ameliorated by a β receptor antagonist or an ACE inhibitor, with enhancement of blood pressure control.

The increased cardiac output evoked by minoxidil has particularly adverse consequences in those hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This probably is a major contributor to the increased pulmonary artery pressure seen with minoxidil (and hydralazine) therapy in hypertensive patients and is compounded by the retention of salt and water caused by minoxidil. Cardiac failure can result from minoxidil therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy. Pericardial effusion is an uncommon but serious complication of minoxidil. Although more commonly described in patients with cardiac and renal failure, pericardial effusion can occur in patients with normal cardiovascular and renal function. Mild and asymptomatic pericardial effusion is not an indication for discontinuing minoxidil, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with minoxidil is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of minoxidil treatment. These are not ischemic in origin and are seen with other drugs that activate K+ channels. These drugs accelerate myocardial repolarization, shorten the refractory period, and one of them, pinacidil, lowers the ventricular fibrillation threshold and increases spontaneous ventricular fibrillation in the setting of myocardial ischemia (Chi et al., 1990). The effect of minoxidil on the refractory period and ischemic ventricular fibrillation has not been investigated; whether or not such findings enhance the risk of ventricular fibrillation in human myocardial ischemia is unknown.

Hypertrichosis occurs in patients who receive minoxidil for an extended period and is probably a consequence of K+ channel activation. Growth of hair occurs on the face, back, arms, and legs and is particularly offensive to women. Frequent shaving or depilatory agents can be used to manage this problem. Topical minoxidil (ROGAINE) is marketed over-the-counter for the treatment of male pattern baldness and hair thinning and loss on the top of the head in women. The topical use of minoxidil also can cause measurable cardiovascular effects in some individuals.

Other side effects of the drug are rare and include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia.

**Therapeutic Uses.** Systemic minoxidil is best reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency (Campese, 1981). It has been used successfully in the treatment of hypertension in both adults and children. Minoxidil should never be used alone; it must be given concurrently with a diuretic to avoid fluid retention and with a sympatholytic drug (usually a β receptor antagonist) to control reflex cardiovascular effects. The drug usually is administered either once or twice a day, but some patients may require more frequent dosing for adequate control of blood pressure. The initial daily dose of minoxidil may be as little as 1.25 mg, which can be increased gradually to 40 mg in one or two daily doses.

**Sodium Nitroprusside**

Although sodium nitroprusside has been known since 1850 and its hypotensive effect in humans was described in 1929, its safety and usefulness for the short-term control of severe hypertension were not demonstrated until the mid-1950s. Several investigators subsequently demonstrated that sodium nitroprusside also was effective in improving cardiac function in patients with left ventricular failure (see Chapter 28).

![Sodium Nitroprusside](image)

**Locus and Mechanism of Action.** Nitroprusside is a nitrovasodilator that acts by releasing NO. NO activates the guanylyl cyclase–cyclic GMP–PKG pathway, leading to vasodilation (Linder et al., 2005), mimicking the production of NO by vascular endothelial cells, which is impaired in many hypertensive patients (Ramchandra et al., 2005). The mechanism of release of NO is not clear and likely involves both enzymatic and nonenzymatic pathways (Feelisch, 1998). Tolerance develops to nitroglycerin but not to nitroprusside (Fung, 2004). The pharmacology of the organic nitrates, including nitroglycerin, was presented earlier.

**Pharmacological Effects.** Nitroprusside dilates both arterioles and venules, and the hemodynamic response to its administration results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output tends to fall. In contrast, in patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance is the predominant effect, leading to a rise in cardiac output (see Chapter 28).

Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In general, renal blood flow and
glomerular filtration are maintained, and plasma renin activity increases. Unlike minoxidil, hydralazine, diazoxide, and other arteriolar vasodilators, sodium nitroprusside usually causes only a modest increase in heart rate and an overall reduction in myocardial O₂ demand.

**Absorption, Metabolism, and Excretion.** Sodium nitroprusside is an unstable molecule that decomposes under strongly alkaline conditions or when exposed to light. The drug must be protected from light and given by continuous intravenous infusion to be effective. Its onset of action is within 30 seconds; the peak hypotensive effect occurs within 2 minutes, and when the infusion of the drug is stopped, the effect disappears within 3 minutes.

The metabolism of nitroprusside by smooth muscle is initiated by its reduction, which is followed by the release of cyanide and then NO (Bates et al., 1991). Cyanide is further metabolized by liver rhodanase to form thiocyanate, which is eliminated almost entirely in the urine. The mean elimination t½ for thiocyanate is 3 days in patients with normal renal function, and it can be much longer in patients with renal insufficiency.

**Therapeutic Uses.** Sodium nitroprusside is used primarily to treat hypertensive emergencies but also can be used in many situations when short-term reduction of cardiac preload and/or afterload is desired. Nitroprusside has been used to lower blood pressure during acute aortic dissection; improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (see Chapter 28); and decrease myocardial oxygen demand after acute MI. In addition, nitroprusside is used to induce controlled hypotension during anesthesia in order to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is important to administer a β-adrenergic receptor antagonist with nitroprusside, because reduction of blood pressure with nitroprusside alone can increase the rate of rise in pressure in the aorta as a result of increased myocardial contractility, thereby enhancing propagation of the dissection.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2-3 mL of 5% dextrose in water. Addition of this solution to 250-1000 mL of 5% dextrose in water produces a concentration of 50-200 μg/mL. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the patient must be closely observed. The majority of hypertensive patients respond to an infusion of 0.25-1.5 μg/kg/min. Higher rates of infusion are necessary to produce controlled hypotension in normotensive patients under surgical anesthesia. Patients who are receiving other antihypertensive medications usually require less nitroprusside to lower blood pressure. If infusion rates of 10 μg/kg/min do not produce adequate reduction of blood pressure within 10 minutes, the rate of administration of nitroprusside should be reduced to minimize potential toxicity.

**Toxicity and Precautions.** The short-term adverse effects of nitroprusside are due to excessive vasodilation, with hypotension and the consequences thereof. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will prevent an excessive hemodynamic response to the drug in the majority of cases.

Less commonly, toxicity may result from conversion of nitroprusside to cyanide and thiocyanate. Toxic accumulation of cyanide leading to severe lactic acidosis usually occurs when sodium nitroprusside is infused at a rate >5 μg/kg/min but also can occur in some patients receiving doses ~2 μg/kg/min for a prolonged period. The limiting factor in the metabolism of cyanide appears to be the availability of sulfur-containing substrates in the body (mainly thiosulfate). The concomitant administration of sodium thiosulfate can prevent accumulation of cyanide in patients who are receiving higher-than-usual doses of sodium nitroprusside; the efficacy of the drug is unchanged (Schulz, 1984). The risk of thiocyanate toxicity increases when sodium nitroprusside is infused for more than 24-48 hours, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged infusions of nitroprusside and should not be allowed to exceed 0.1 mg/mL. Rarely, excessive concentrations of thiocyanate may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed readily by hemodialysis.

Nitroprusside can worsen arterial hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic pulmonary vasoconstriction and therefore promotes mismatching of ventilation with perfusion.

**Diazoxide.** Diazoxide was used in the treatment of hypertensive emergencies but fell out of favor at least in part due to the risk of marked falls in blood pressure when large bolus doses of the drug were used. Other drugs are now preferred for parenteral administration in the control of hypertension. Diazoxide also is administered orally (proglycem) to treat patients with various forms of hypoglycemia (see Chapter 43).

**Nonpharmacological Therapy of Hypertension**

Nonpharmacological approaches to the treatment of hypertension may be sufficient in patients with modestly elevated blood pressure. Such approaches also can augment the effects of antihypertensive drugs in patients with more marked initial elevations in blood pressure. The indications and efficacy of various lifestyle modifications in hypertension are reviewed in a summary statement from the Joint National Committee (Chobanian et al., 2003).

- Reduction in body weight for people who are modestly overweight or frankly obese may be useful (Horvath et al., 2008).
- Restricting sodium consumption lowers blood pressure in some patients. The Dietary Approaches to
Stop Hypertension (DASH) diet may be particularly useful (Champagne, 2006).

- For some patients, restriction of ethanol intake to modest levels may lower blood pressure.
- Increased physical activity may improve control of hypertension.

### SELECTION OF ANTIHYPERTENSIVE DRUGS IN INDIVIDUAL PATIENTS

Choice of antihypertensive drugs for individual patients may be complex; there are many sources of influence that modify therapeutic decisions. While results derived from randomized controlled clinical trials are the optimal foundation for rational therapeutics, it may be difficult to sort through the multiplicity of results and address how they apply to an individual patient. While therapeutic guidelines can be useful in reaching appropriate therapeutic decisions, it often is difficult for clinicians to apply guidelines at the point of care, and guidelines often do not provide enough information about recommended drugs. In addition, intense marketing of specific drugs to both clinicians and patients may confound optimal decision making. Moreover, persuading patients to continue taking sometimes expensive drugs for an asymptomatic disease is a challenge. Clinicians may be reluctant to prescribe and patients reluctant to consume the number of drugs that may be necessary to adequately control blood pressure. For these and other reasons, perhaps one-half of patients being treated for hypertension have not achieved therapeutic goals in blood pressure lowering.

Choice of an antihypertensive drug should be driven by the likely benefit in an individual patient, taking into account concomitant diseases such as diabetes mellitus, problematic adverse effects of specific drugs, and cost.

National guidelines (Chobanian et al., 2003) recommend diuretics as preferred initial therapy for most patients with uncomplicated stage 1 hypertension (Table 27–4) who are unresponsive to nonpharmacological measures. Patients also are commonly treated with other drugs: β-receptor antagonists, ACE inhibitors/AT1-receptor antagonists, and Ca2+ channel blockers. Patients with uncomplicated stage 2 hypertension will likely require the early introduction of a diuretic and another drug from a different class. Subsequently, doses can be titrated upward and additional drugs added to achieve goal blood pressures (blood pressure <140/90 mm Hg in uncomplicated patients). Some of these patients may require four different drugs to reach the goal.

An important and high-risk group of patients with hypertension are those with compelling indications for specific drugs on account of other underlying serious cardiovascular disease (heart failure, post-MI, or with high risk for coronary artery disease), chronic kidney disease, or diabetes (Chobanian et al., 2003). For example, a hypertensive patient with congestive heart failure ideally should be treated with a diuretic, β-receptor antagonist, ACE inhibitor/AT1-receptor antagonist, and (in selected patients) spironolactone because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension (see Chapter 28). Similarly, ACE inhibitors/AT1-receptor antagonists should be first-line drugs in the treatment of diabetics with hypertension in view of these drugs' well-established benefits in diabetic nephropathy.

Other patients may have less serious underlying diseases that could influence choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α1 receptor antagonist as part of his or her therapeutic program, because α1 antagonists are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β-receptor antagonist because a number of drugs in this class are efficacious in preventing migraine attacks. On the other hand, in pregnant hypertensives, some drugs that are otherwise little used (methyldopa) may be preferred and popular drugs (ACE inhibitors) avoided on account of concerns about safety.

Patients with isolated systolic hypertension (systolic blood pressure >160 mm Hg and diastolic blood pressure <90 mm Hg) benefit particularly from diuretics and also from Ca2+ channel blockers and ACE inhibitors. These should be first-line drugs in these patients in terms of efficacy, but compelling indications as noted earlier need to be taken into account.

These considerations apply to patients with hypertension that need treatment to reduce long-term risk, not patients in immediately life-threatening settings due to hypertension. While there are very limited clinical trial data, clinical judgment favors rapidly lowering blood pressure in patients with life-threatening complications of hypertension, such as patients with hypertensive encephalopathy or pulmonary edema due to severe hypertension. However, rapid reduction in blood pressure has considerable risks for the patients; if blood pressure is decreased too quickly or extensively, cerebral blood flow may diminish due to adaptations in the cerebral circulation that protect the brain from the sequelae of very high blood pressures. The temptation
to rapidly treat patients merely on the basis of increased blood pressure should be resisted. Appropriate therapeutic decisions need to encompass how well the patients’ major organs are reacting to the very high blood pressures. While many drugs have been used parenterally to rapidly decrease blood pressure in emergencies (including nitroprusside, enalaprilat, esmolol, fenoldapam, labetalol, clevidipine and nicardipine, hydralazine, and phentolamine), the clinical significance of differing actions of many of these drugs in this setting is largely unknown (Perez et al., 2008).

RESISTANT HYPERTENSION

Some patients with hypertension do not appear to respond to recommended treatments. There are many potential explanations. To achieve stringent control of hypertension, many patients require two, three, or four appropriately selected drugs used at optimal doses. Clinicians may be reluctant to prescribe sufficient numbers of medications that exploit the full dose–response curve (therapeutic inertia), or patients may not adhere to the recommended pharmacological regimen. Sometimes multiple drugs in the same therapeutic class are chosen. Excess salt intake and the tendency of some antihypertensive drugs (especially vasodilators) to promote salt retention may mitigate falls in blood pressure; consequently, inadequate diuretic treatment commonly is found in patients with resistant hypertension. Patients may take prescription drugs, over-the-counter drugs, or herbal preparations that oppose the actions of antihypertensive drugs: for example, NSAIDs, sympathomimetic decongestants, cyclosporine, erythropoietin, ephedra (ma huang) or licorice. Illicit drugs such as cocaine and amphetamines may raise blood pressure.

Congestive heart failure (CHF) is responsible for more than half a million deaths annually in the U.S., carries a 1-year mortality rate of more than 50% in patients with advanced forms of the condition, and is responsible for nearly $27 billion annually in healthcare costs (Binanay et al., 2005). Fortunately, substantive advances in CHF pharmacotherapy have altered clinical practice by shifting the paradigm of its management from exclusively symptom palliation to modification of disease progression and, in some cases, an expectation of prolonged survival.

In the past, drug therapies targeted the endpoints of this syndrome: volume overload (congestion) and myocardial dysfunction (pump failure). As a consequence, diuretics and cardiac glycosides dominated the medical management of CHF for more than 40 years. These drugs remain effective for symptom relief and in stabilizing patients with hemodynamic decompensation but do not improve long-term survival. The contemporary focus of CHF as a disorder of circulatory hemodynamics, pathologic cardiac remodeling, and increased arrhythmogenic instability has translated into the development of novel pharmacotherapies that reduce CHF-associated morbidity and mortality rates. Before discussing the clinical pharmacology of CHF in specific, it is useful to establish a pathophysiologic framework through which its treatment is approached.

**Defining Congestive Heart Failure.** The onset and progression of clinically evident CHF from left ventricular (LV) systolic dysfunction follows a pathophysiologic sequence in response to an initial insult to myocardial dysfunction. A reduction in forward cardiac output leads to expanded activation of the sympathetic nervous system and the renin–angiotensin–aldosterone axis that, together, maintain perfusion of vital organs by increasing LV preload, stimulating myocardial contractility, and increasing arterial tone. Acutely, these mechanisms sustain cardiac output by allowing the heart to operate at elevated end-diastolic volumes, while peripheral vasoconstriction promotes regional redistribution of the cardiac output to the central nervous system, coronary, and renal vascular beds.

Unfortunately, however, these compensatory mechanisms over time propagate disease progression. Intravascular volume expansion increases diastolic and systolic wall stress that disrupts myocardial energetics and causes pathologic LV hypertrophy. By increasing LV afterload, peripheral arterial vasoconstriction also adversely affects diastolic ventricular wall stress, thereby increasing myocardial O$_2$ demand. Finally, neurohumoral effectors such as norepinephrine (NE) and angiotensin II (AngII) are associated with myocyte apoptosis, abnormal myocyte gene expression, and pathologic changes in the extracellular matrix that increase LV stiffness (Villarreal, 2005).

In clinical practice, the term CHF describes a final common pathway for the expression of myocardial dysfunction. While some emphasize the clinical distinction between systolic versus diastolic heart failure, many patients demonstrate dysfunction in both contractile performance and ventricular relaxation/filling. Indeed, these physiologic processes are interrelated; for example, the rate and duration of LV diastolic filling are directly influenced by impairment in systolic contractile performance. Despite inherent difficulties in creating a singular description to encompass the diverse pathophysiologic mechanisms that result in CHF (e.g., myocardial infarction (MI), viral myocarditis), the following definitions are useful for establishing a conceptual framework to describe this clinical syndrome:
Congestive heart failure is the pathophysiologic state in which the heart is unable to pump blood at a rate commensurate with the requirements of metabolizing tissues, or can do so only from an elevated filling pressure (Braunwald and Bristow, 2000).

Heart failure is a complex of symptoms—fatigue, shortness of breath, and congestion—that are related to the inadequate perfusion of tissue during exertion and often to the retention of fluid. Its primary cause is an impairment of the heart’s ability to fill or empty the left ventricle properly (Cohn, 1996).

From these definitions, one may consider CHF as a condition in which failure of the heart to provide adequate forward output at normal end-diastolic filling pressures results in a clinical syndrome of decreased exercise tolerance with pulmonary and systemic venous congestion. Numerous cardiovascular comorbidities are associated with CHF, including coronary artery disease, MI, and sudden cardiac death.

PHARMACOLOGIC TREATMENT OF HEART FAILURE

The abnormalities of myocardial structure and function that characterize CHF are often irreversible. These changes narrow the end-diastolic volume range that is compatible with normal cardiac function. Although CHF is predominately a chronic disease, subtle changes to an individual’s hemodynamic status (e.g., increased circulating volume from high dietary sodium intake, increased systemic blood pressure from medication nonadherence) often provoke an acute clinical decompensation.

Not surprisingly, therefore, CHF therapy has for many years utilized diuretics to control volume overload and subsequent worsening in LV function. Other proven pharmacotherapies target ventricular wall stress, the renin–angiotensin–aldosterone axis, and the sympathetic nervous system to decrease pathologic ventricular remodeling, attenuate disease progression, and improve survival in selected patients with severe CHF and low LV ejection fraction. Figure 28–1 provides an overview of the sites of action for major drug classes commonly used in clinical practice. Note that these therapies largely improve cardiac hemodynamics and function through preload reduction, afterload reduction, and enhancement of inotropy (i.e., myocardial contractility). In addition, pharmacotherapeutics that target peripheral and coronary vascular function are receiving increased attention as potential participants in the comprehensive management of CHF patients.

Diuretics

Diuretics remain central in the pharmacologic management of congestive symptoms in patients with CHF. The pharmacologic properties of these agents are presented in detail in Chapter 25. Their importance (and frequency of use) in CHF management reflects the deleterious downstream effects of volume expansion on increased LV end-diastolic volume, an intermediate step in the development of elevated right-heart pressure, pulmonary venous congestion, and peripheral edema (Hillege et al., 2000).

Diuretics reduce extracellular fluid volume and ventricular filling pressure (or “preload”). Because CHF patients often operate on a “plateau” phase of the Frank-Starling curve (Figure 28–2), incremental preload reduction occurs under these conditions without a reduction in cardiac output. Sustained natriuresis and/or a rapid decline in intravascular volume, however, may “push” one’s profile leftward on the Frank-Starling curve, resulting in an unwanted decrease in cardiac output. In this way, excessive diuresis is counterproductive secondary to reciprocal neurohormonal overactivation from volume depletion (McCurley et al., 2004). For this reason, it is preferable to avoid diuretics in patients with asymptomatic LV dysfunction and to only administer the minimal dose required to maintain euvolemia in those patients symptomatic from hypervolemia. Despite the efficacy of loop or thiazide diuretics in controlling congestive symptoms and improving exercise capacity, their use is not associated with a reduction in CHF mortality.

Dietary Sodium Restriction. All patients with clinically significant LV dysfunction, regardless of symptom status, should be advised to limit dietary sodium intake to 2-3 g/day. More stringent salt restriction is seldom necessary and may be counterproductive, as it can lead to hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis when combined with loop diuretic administration.

Loop Diuretics. Of the loop diuretics currently available, furosemide (Lasix, others), bumetanide (Bumex, others), and torsemide (Demadex, others) are widely used in the treatment of CHF. Due to the increased risk of ototoxicity, ethacrynic acid (Edecrin) is recommended only for patients with sulfonamides allergies or who are intolerant to alternative options.

Loop diuretics inhibit a specific ion transport protein, the Na⁺-K⁺-2Cl⁻ symporter on the apical membrane of renal epithelial cells in the ascending limb of the loop of Henle to increase Na⁺ and fluid delivery to
distal nephron segments (see Chapter 25). These drugs also enhance K⁺ secretion, particularly in the presence of elevated aldosterone levels, as is typical in CHF.

The bioavailability of orally administered furosemide ranges from 40-70%. High drug concentrations often are required to initiate diuresis in patients with worsening symptoms or in those with impaired gastrointestinal absorption, as may occur in severely hypervolemic patients with CHF-induced gut edema (Gottlieb, 2004). In contrast, the oral bioavailabilities of bumetanide and torsemide are >80%, and as a result, these agents are more consistently absorbed but are financially more costly.

Furosemide and bumetanide are short-acting drugs, and rebound Na⁺ retention that occurs with sub-steady state drug levels make ≥2/day dosing an acceptable treatment strategy when using these agents, provided adequate monitoring of daily body weight and blood electrolyte level monitoring is possible.

**Thiazide Diuretics.** Monotherapy with thiazide diuretics (DIURIL, HYDRODIURIL, others) has a limited role in CHF. However, combination therapy with loop diuretics is often effective in those refractory to loop diuretics alone. Thiazide diuretics act on the Na⁺Cl⁻ cotransporter in the distal convoluted tubule (see Chapter 25) and are associated with a greater degree K⁺ wasting per fluid volume reduction when compared to loop diuretics (Gottlieb, 2004).

**K⁺-Sparing Diuretics.** K⁺-sparring diuretics (see Chapter 25) inhibit apical membrane Na⁺-conductance channels in renal epithelial cells (e.g., amiloride, triamterene) or are mineralocorticoid (e.g., aldosterone) receptor antagonists (e.g., canrenone [not commercially available in the U.S.], spironolactone, and eplerenone). Collectively, these agents are weak diuretics, but have historically been used to achieve volume reduction with limited K⁺ and Mg²⁺ wasting. The beneficial role of aldosterone receptor blockers on survival in CHF is discussed later.

**Diuretics in Clinical Practice.** The majority of CHF patients will require chronic administration of a loop diuretic to maintain euvolemia. In patients with clinically
Diuretics in the Decompensated Patient. In patients with uncompensated CHF warranting hospital admission, repetitive intravenously administered boluses or a constant infusion titrated to achieve a desired response may be needed to provide expeditious (and reliable) diuresis (Dormans et al., 1996). One advantage to intravenous infusion is that sustained natriuresis is achieved as a consequence of consistently elevated drug levels within the lumen of the renal tubules. In addition, the risk of ototoxicity is reduced by continuous infusion when compared to repetitive, intermittent intravenous dosing (Lahav et al., 1992).

A typical continuous furosemide infusion is initiated with a 40-mg bolus injection followed by a constant rate of 10 mg/h, with uptitration as necessary. If renal perfusion is reduced, drug efficacy may be enhanced by co-administration of drugs that increase cardiac output (e.g., dobutamine).

Diuretic Resistance. As mentioned earlier, a compensatory increase in renal tubular Na+ reabsorption may prevent effective diuresis when dosed daily; as a result, reduction of diuretic dosing intervals may be warranted. In advanced CHF, invasive assessment of intracardiac filling pressures and cardiac output may be required to distinguish between low intravascular volume from aggressive diuresis versus low cardiac output states, although both states are aligned with lower diuretic delivery and drug efficacy. Furthermore, edema, decreased bowel-wall motility, and reduced splanchnic blood flow impair absorption and may delay or attenuate peak diuretic effect.

Atherosclerotic renal artery disease is associated with reduced renal perfusion pressures to levels below that necessary for adequate drug delivery. In patients with reduced renal arterial perfusion pressure (e.g., renal artery stenosis or low cardiac output), AngII-mediated efferent glomerular arteriole tone is important for preservation of normal glomerular filtration pressure. Angiotensin-converting enzyme (ACE) inhibitors or AT1 receptor antagonists in combination with loop diuretics may, therefore, be met with a decline in creatinine clearance that is associated with low diuretic delivery and decreased drug efficacy (Ellison, 1999). Other common causes of diuretic resistance are listed in Table 28–1.

Metabolic Consequences of Diuretic Therapy. The side effects of diuretics are discussed in Chapter 25. With regard to diuretic use in CHF, the most important adverse sequelae of diuretics are electrolyte abnormalities, including hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis. The clinical importance (or even existence) of significant Mg2+ deficiency with chronic diuretic use is controversial (Bigger, 1994).

Adenosine A1 Receptor Antagonists. Adenosine A1 receptor antagonists may provide a renal protective therapeutic strategy for enhanced volume loss in decompensated CHF. Adenosine is secreted from the macula densa in the renal arteriole in response to diuretic-induced increases in Na+ and Cl− tubular flow concentrations. This results in increased Na+ resorption, a volume-loss counterregulatory mechanism (see Chapter 26). Na+ reabsorption, in addition to adenosine-induced renal
Aldosterone Antagonists and Clinical Outcome

LV systolic dysfunction decreases renal blood flow and results in overactivation of the renin–angiotensin–aldosterone axis and may increase circulating plasma aldosterone levels in CHF to 20-fold above normal (Figure 28–3). The pathophysiologic effects of hyperaldosteronemia are diverse (Table 28–2) and extend beyond Na⁺ and fluid retention; importantly, however, the precise mechanism by which aldosterone receptor blockade improves outcome in CHF remains unresolved (Weber, 2004).

In the Randomized Aldactone Evaluation Study, CHF patients with low LV ejection fraction receiving spironolactone (25 mg/day) had a significant (~30%) reduction in mortality (from progressive heart failure or sudden cardiac death) and fewer CHF-related hospitalizations compared with the placebo group (Pitt et al., 1999). Treatment was well tolerated overall; most notably, however, 10% of men reported gynecomastia and 2% of all patients developed severe hyperkalemia (>6.0 mEq/L) on spironolactone (Pitt et al., 1999). Data from this and other clinical studies (Pitt et al., 2003) suggest that despite maximum ACE inhibition, clinically important aldosterone levels are still achieved in CHF. This may account for the beneficial effects observed in these trials where aldosterone-receptor antagonists were used in combination with ACE inhibitor therapy. Combination therapy in those with renal impairment, however, increases the probability of drug-induced hyperkalemia.

The role of aldosterone antagonists in patients with asymptomatic LV dysfunction or in those with minimal CHF-associated symptoms has not been established.

### Vasodilators

The rationale for oral vasodilator drugs in the pharmacotherapy of CHF derives from experience with parenterally administered phentolamine and nitroprusside in patients with advanced disease and elevated systemic vascular resistance (Cohn and Franciosa, 1977). Although numerous vasodilators have since been developed that improve CHF symptoms, only the hydralazine–isosorbide dinitrate combination, ACE inhibitors, and AT₁ receptor blockers (ARBs) demonstrably improve survival. The therapeutic use of vasodilators in the treatment of hypertension and myocardial ischemia is considered in detail in Chapter 27. This chapter will focus on the uses for some of these same vasodilator drugs in the treatment of CHF. Table 28–3 summarizes properties of vasodilators commonly used to treat CHF.

**Nitrovasodilators.** Nitrovasodilators are nitric oxide (NO) donors that activate soluble guanylate cyclase in vascular smooth muscle cells, leading to vasodilation. The mechanism underlying the variable response profiles to nitrovasodilators in different vascular beds remains controversial; e.g., nitroglycerin preferentially induces epicardial coronary artery vasodilation. Furthermore, the mechanisms by which nitrovasodilators are converted to their active forms in vivo depend on the particular agent. Unlike nitroprusside, which is converted to NO⁺ by cellular reducing agents such as glutathione, nitroglycerin and other organic nitrates undergo a more complex enzymatic biotransformation.

arteriole vasoconstriction, appears responsible (in part) for the development of complications common to the use of diuretics in decompensated CHF patients, particularly prerenal azotemia. The role of adenosine in the macula densa and juxtaglomerular (granular) cells (see Figure 26–2) suggests other effects of A₁ antagonists on the renin-angiotensin system.

As an example of the use of A₁ antagonists, the administration of KW-3902 (ROLOFYLLINE) (30 mg) to patients with decompensated CHF already treated with loop diuretics is associated with increased volume reduction, improved renal function, and lower diuretic dosing, as compared to placebo (Givertz et al., 2007). Favorable effects on urine output and renal function were also observed in similar patients with the A₁ receptor antagonist BG9179 (NAXIFYLLINE) (Gottlieb et al., 2002). A large clinical trial failed to show significant benefits of rolofylline in patients with CHF, and clinical development of the drug was stopped in 2009. No A₁ antagonists are currently marketed in the U.S.
to NO• or bioactive S-nitrosothiols. The activities of specific enzyme(s) and cofactor(s) required for this biotransformation appear to differ by target organ and even by different vasculature beds within a particular organ (Münzel et al., 2005).

**Organic Nitrates.** As discussed in Chapter 27, organic nitrates are available in a number of formulations that include rapid-acting nitroglycerin tablets or spray for sublingual administration, short-acting oral agents such as isosorbide dinitrate (ISORDIL, others), long-acting oral agents such as isosorbide mononitrate (ISMO, others), topical preparations such as nitroglycerin ointment and transdermal patches, and intravenous nitroglycerin. These preparations are relatively safe and effective; specifically, their principal action in CHF is reducing LV filling pressure. This occurs, in part, by augmentation of peripheral venous capacitance that results in preload reduction. Additional effects of organic nitrates include pulmonary and systemic vascular resistance

![Figure 28–3. The renin–angiotensin–aldosterone axis.](image-url)
reduction, particularly at higher doses, and epicardial coronary artery vasodilation for which systolic and diastolic ventricular function is enhanced by increased coronary blood flow. Collectively, these beneficial physiologic effects translate into improved exercise capacity and CHF-symptom reduction. However, these drugs do not substantially influence systemic vascular resistance, and pharmacologic tolerance greatly limits their utility over time. For these reasons and others, organic nitrates are not commonly used alone; rather, a number of trials have shown that when used together, selected organic nitrates increase the clinical effectiveness of other vasodilators, such as hydralazine, resulting in a sustained improvement in hemodynamics.

Nitrate tolerance. Nitrate tolerance may limit the long-term effectiveness of these drugs in the treatment of CHF. Blood nitrate levels may be permitted to fall to negligible levels for at least 6-8 hours each day (see Chapter 27). The timing of nitrate withdrawal symptoms, if present, may be useful, however, for developing an appropriate drug-dosing schedule. Patients with recurrent orthopnea or paroxysmal nocturnal dyspnea, e.g., might benefit from nighttime nitrate use. Likewise, co-treatment with hydralazine (e.g., isosorbide dinitrate and hydralazine [BIDIL]) may decrease nitrate tolerance by an antioxidant effect that attenuates superoxide formation, thereby increasing the bioavailable NO levels (Münzel et al., 1996).

## Parenteral Vasodilators

**Sodium Nitroprusside.** Sodium nitroprusside (NITROPRESS, others) is a direct NO donor and potent vasodilator that is effective in reducing both ventricular filling pressure and systemic vascular resistance. The downstream beneficial physiologic effects of afterload reduction in CHF are outlined in Figure 28–4. Onset to

Ang II, angiotensin II; AT_1_, type 1 angiotensin II receptor; NO, nitric oxide; ACE, angiotensin converting enzyme; PDE, cyclic nucleotide phosphodiesterase; BK, bradykinin.
activation of sodium nitroprusside is rapid (2-5 minutes), and the drug is quickly metabolized to NO, properties that afford easy titration to achieve the desired hemodynamic effect.

Nitroprusside is particularly effective in treating critically ill patients with CHF who have elevated systemic vascular resistance or mechanical complications that follow acute MI (e.g., mitral regurgitation or ventricular septal defect-induced left-to-right shunts). As with other vasodilators, the most common adverse side effect of nitroprusside is hypotension. In general, nitroprusside initiation in patients with severe CHF results in increased cardiac output and a parallel increase in renal blood flow, improving both glomerular filtration and diuretic effectiveness. However, excessive reduction of systemic arterial pressure may limit or prevent an increase in renal blood flow in patients with more severe LV contractile dysfunction.

Cyanide produced during the biotransformation of nitroprusside is rapidly metabolized by the liver to thiocyanate, which is then renally excreted. Thiocyanate and/or cyanide toxicity is uncommon but may occur in the setting of hepatic or renal failure, or following prolonged periods of high-dose drug infusion (see Chapter 27 for details). Typical symptoms include unexplained abdominal pain, mental status changes, convulsions, and lactic acidosis. Methemoglobinemia is another unusual complication and is due to the oxidation of hemoglobin by NO⁺.

**Intravenous Nitroglycerin.** Intravenous nitroglycerin, like nitroprusside, is a vasoactive NO donor that is commonly used in the intensive care unit setting. Unlike nitroprusside, nitroglycerin is relatively selective for venous capacitance vessels, particularly at low infusion rates. In CHF, intravenous nitroglycerin is most commonly used in the treatment of LV dysfunction due to an acute myocardial ischemia. Parenteral nitroglycerin also is used in the treatment of nonischemic cardiomyopathy when expeditious LV filling pressure reduction is desired. At higher infusion rates, this drug also may decrease systemic arterial resistance, although this effect is less predictable. Nitroglycerin therapy may be limited by headache and nitrate tolerance; tolerance may be partially offset by increasing the dosage. Administration requires the use of an infusion pump capable of controlling the rate of administration.

**Hydralazine.** Hydralazine is a direct vasodilator that has long been in clinical use, yet its precise mechanism of action is poorly understood. The effects of this agent are not mediated through recognized neurohumoral systems, and its mechanism of action at the cellular level in vascular smooth muscle is uncertain. Lack of mechanistic understanding not with standing, hydralazine is an effective antihypertensive drug (see Chapter 27), particularly when combined with agents that blunt compensatory increases in sympathetic tone and salt and water retention. In CHF, hydralazine reduces right and left ventricular afterload by reducing pulmonary and systemic vascular resistance. This results in an augmentation of forward stroke volume and a reduction in ventricular wall stress in systole. Hydralazine also appears to have moderate “direct” positive inotropic activity in cardiac muscle independent of its afterload-reducing effects. Hydralazine is effective in reducing renal vascular resistance and in increasing renal blood flow to a greater degree than are most other vasodilators, with the exception of ACE inhibitors. For this reason, hydralazine often is used in CHF patients with renal dysfunction intolerant of ACE-inhibitor therapy.

The landmark Veterans Administration Cooperative Vasodilator-Heart Failure Trial I (V-HeFT I) demonstrated that combination therapy with isosorbide dinitrate and hydralazine (a pill
containing these two compounds in combination is marketed as BiDil) reduces CHF mortality in patients with systolic dysfunction (Cohn et al., 1986). In V-HeFT I, the mortality benefit was agent specific: the α1 receptor antagonist prazosin offered no advantage over placebo when compared with isosorbide plus hydralazine.

Hydralazine provides additional hemodynamic improvement for patients with advanced CHF (with or without nitrates) already treated with conventional doses of an ACE inhibitor, digoxin, and diuretics (Cohn, 1994). The hypothesis that hydralazine-mediated antioxidant effects benefit CHF patients at elevated risk for vascular endothelial dysfunction is supported by the African-American Heart Failure Trial, in which isosorbide dinitrate-hydralazine substantially decreased all-cause mortality in self-described black patients, a group associated with impaired vascular endothelial function and diminished bioavailable levels of NO when compared to white counterparts (Taylor et al., 2007).

There are several important considerations for hydralazine use. First, ACE inhibitors appear to be superior to hydralazine for mortality reduction in severe CHF. Second, side effects requiring dose adjustment of hydralazine withdrawal are common. In V-HeFT I, e.g., only 55% of patients were taking full doses of both hydralazine and isosorbide dinitrate after 6 months. The lupus-like side effects associated with hydralazine are relatively uncommon and may be more likely to occur in selected patients with the “slow-acetylator” phenotype (see Chapter 27). Finally, hydralazine is a medication taken three or four times daily, and adherence may be difficult for CHF patients, who are often prescribed multiple medications concurrently.

The oral bioavailability and pharmacokinetics of hydralazine are not altered significantly in CHF, unless severe hepatic congestion or hypoperfusion is present. Intravenous hydralazine is available but provides little practical advantage over oral formulations except for urgent use in pregnant patients. In these individuals, hydralazine is often used owing to contraindications that exist for use of most other vasodilators in pregnancy. Hydralazine is typically started at a dose of 10-25 mg three or four times per day and uptitrated to a maximum of 100 mg three or four times daily, as tolerated. At total daily doses >200 mg, hydralazine is associated with an increased risk of lupus-like effects.

Targeting Neurohormonal Regulation: The Renin–Angiotensin–Aldosterone Axis and Vasopressin Antagonists

**Renin–Angiotensin–Aldosterone Axis Antagonists.**

The renin–angiotensin–aldosterone axis plays a central role in the pathophysiology of CHF (Figure 28–3). AngII is a potent arterial vasoconstrictor and an important mediator of Na+ and water retention through its effects on glomerular filtration pressure and aldosterone secretion. AngII also modulates neural and adrenal medulla catecholamine release, is arrhythmogenic, promotes vascular hyperplasia and myocardial hypertrophy, and induces myocyte death. Consequently, reduction of the effects of AngII constitutes a cornerstone of CHF management (Weber, 2004).

ACE inhibitors suppress AngII (and aldosterone) production, decrease sympathetic nervous system activity, and potentiate the effects of diuretics in CHF. However, AngII levels frequently return to baseline values following chronic treatment with ACE inhibitors (see Chapter 26), due in part to AngII production via ACE-independent enzymes. The sustained clinical effectiveness of ACE inhibitors despite this AngII “escape” suggests that alternate mechanisms contribute to the clinical benefits of ACE inhibitors in CHF. ACE is identical to kininase II, which degrades bradykinin and other kinins that stimulate production of NO, cyclic GMP, and vasoactive eicosanoids. These oppose AngII-induced vascular smooth muscle cell and cardiac fibroblasts proliferation and inhibit unfavorable extracellular matrix deposition.

ACE inhibitors are preferential arterial vasodilators. ACE-inhibitor–mediated decreases in LV afterload result in increased stroke volume and cardiac output; ultimately, the magnitude of these effects is associated with the observed change in mean arterial pressure. Heart rate typically is unchanged with treatment, often despite decreases in systemic arterial pressure, a response that probably is a consequence of decreased sympathetic nervous system activity from ACE inhibition.

Most clinical actions of AngII, including its deleterious effects in CHF, are mediated through the AT1 angiotensin receptor, whereas AT2 receptor activation appears to counterbalance the downstream biologic effects of AT1 receptor stimulation. Owing to enhanced target specificity, AT1 receptor antagonists more efficiently block the effects of AngII than do ACE inhibitors. In addition, the elevated level of circulating AngII that occurs secondary to AT1 receptor blockade results in a relative increase in AT2 receptor activation. Unlike ACE inhibitors, AT1 blockers do not influence bradykinin metabolism (see the next section).

**Angiotensin-Converting Enzyme Inhibitors.** The first orally administered ACE inhibitor, captopril (CAPOTEN, others), was introduced in 1977. Since then, six additional ACE inhibitors—enalapril (VASOTEC, others), ramipril (ALTACE, others), lisinopril (PRINIVIL, ZESTRIL, others), quinapril (ACCUPRIL, others), trandolapril (MAVIK, others) and fosinopril (MONOPRIL, others) have been FDA-approved for the treatment of CHF. Data from numerous clinical trials involving well over 100,000 patients support ACE inhibition in the management of CHF of any severity, including those with asymptomatic LV dysfunction.

ACE-inhibitor therapy typically is initiated at a low dose (e.g., 6.25 mg of captopril, 5 mg of lisinopril) to avoid iatrogenic hypotension, particularly in the setting of volume contraction. Hypotension following drug administration usually can be reversed by intravascular volume expansion, but, of course, this may be
counterproductive in symptomatic CHF patients. Therefore, it is reasonable to consider initiation of these drugs while congestive symptoms are present. ACE-inhibitor doses customarily are increased over several days in hospitalized patients or over weeks in ambulatory patients, with careful observation of blood pressure, serum electrolytes, and serum creatinine levels.

If possible, drug doses are targeted in practice to match those affording maximum clinical benefit in controlled trials: captopril, 50 mg three times daily (Pfeffer et al., 1992); enalapril, 10 mg twice daily (SOLVD Investigators, 1992; Cohn et al., 1991); lisinopril, 10 mg once daily (GISSI-3, 1994); and ramipril, 5 mg twice daily (AIRE Study Investigators, 1993). If an adequate clinical response is not achieved at these doses, further increases, as tolerated, may be effective (Packer et al., 1999).

In CHF patients with decreased renal blood flow, ACE inhibitors, unlike nitrososavasodilators, impair autoregulation of glomerular perfusion pressure, reflecting their selective effect on efferent (over afferent) arteriolar tone (Kittleson et al., 2003). In the event of acute renal failure or a decrease in the glomerular filtration rate by >20%, ACE-inhibitor dosing should be reduced or the drug discontinued. Rarely, renal function impairment following drug initiation is indicative of bilateral renal artery stenosis.

**ACE-Inhibitor Side Effects.** Elevated bradykinin levels from ACE inhibition are associated with angioedema, a potentially life-threatening drug side effect. If this occurs, immediate and permanent cessation of all ACE inhibitors is indicated. Angioedema may occur at any time over the course of ACE inhibitor therapy. A characteristic, dry cough from the same mechanism is common; in this case, substitution of an AT₁ receptor antagonist for the ACE inhibitor often is curative. A small rise in serum K⁺ levels is common with ACE-inhibitor use. This increase may be substantial, however, in patients with renal impairment or in diabetic patients with type IV renal tubular acidosis. Mild hyperkalemia is best managed by institution of a low-potassium diet but may require drug dose adjustment. The inability to implement ACE inhibitors as a consequence of cardiorenal side effects (e.g., excessive hypotension, progressive renal insufficiency, hyperkalemia) is itself a poor prognostic indicator in the CHF patient (Kittleson et al., 2003).

**ACE Inhibitors and Survival in CHF.** A number of randomized, placebo-controlled clinical trials have demonstrated that ACE inhibitors improve survival in patients with CHF due to systolic dysfunction, independent of etiology. For example, ACE inhibitors prevent mortality and the development of clinically significant LV dysfunction after acute MI (Pfeffer et al., 1992; Konstam et al., 1992; St. John Sutton et al., 1994). This occurs through attenuation or prevention of increased LV end-diastolic and end-systolic volumes, and the decline in LV ejection fraction that is central to the natural history of AMI. ACE inhibitors appear to confer these benefits by preventing postinfarction-associated adverse ventricular remodeling.

The Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS Trial Study Group 1987) demonstrated a 40% mortality reduction after 6 months of enalapril therapy in severe CHF, while others have shown that enalapril also improves survival in patients with mild-to-moderate CHF (SOLVD Investigators, 1992). Furthermore, across the spectrum of CHF severity, when compared with other vasodilators, ACE inhibitors appear superior in reducing mortality (Fonarow et al., 1992). In asymptomatic patients with LV dysfunction, ACE inhibitors slow the development of symptomatic CHF.

**AT₁Receptor Antagonists.** Activation of the AT₁ receptor mediates most of the deleterious effects of AngII that are described earlier. AT₁-receptor antagonism, in turn, largely obviates AngII “escape” and substantially decreases the probability of developing bradykinin-mediated side effects associated with ACE inhibition. Importantly, however, although rare, angioedema has been reported with AT₁-receptor antagonist use. Therefore, caution is still warranted when prescribing these agents to patients with a history of ACE-inhibitor–associated angioedema.

**AT₁ receptor blockers (ARBs)** are effective antihypertensives, and their influence on mortality in acute or chronic CHF from systolic dysfunction after acute MI is akin to that of ACE-inhibitor therapy (Konstam et al., 2005; Dickstein et al., 2002; White et al., 2005). Owing to their favorable side-effect profile, ARBs are an excellent alternative in CHF patients intolerant of ACE inhibitors (Pitt et al., 1997; Doggrell, 2005). Interestingly, age >75 years may increase the probability of developing clinically significant hypotension, renal dysfunction, and hyperkalemia (White et al., 2005).

The role of combination ACE-inhibitor and ARB therapy in the treatment of CHF remains unresolved. Although preliminary studies suggested that combined therapy with candesartan and enalapril, e.g., favorably affected cardiovascular hemodynamics, LV remodeling, and neurohormonal profile compared to therapy with either agent alone (McKelvie et al., 1999), subsequent trials have been unable to demonstrate an incremental mortality benefit from combination therapy despite a significant reduction in CHF-associated hospitalizations (McMurray et al., 2003).

Based on the hypothesis that ARB efficacy is at least in part a consequence of reduced circulating aldosterone levels, combined treatment with aldosterone receptor inhibition has been explored. Combination therapy is associated with a significant increase in LV ejection fraction and quality of life scores in patients with CHF from systolic dysfunction treated for 1 year with candesartan (8 mg daily) and spironolactone (25 mg daily) compared to those treated with candesartan alone (Chan et al., 2007). Others have corroborated the beneficial effects of combined therapy on LV remodeling, 6-minute walk distance, and functional capacity (Kum et al., 2008). The beneficial effects of dual therapy are provocative but must be
weighed against the increased likelihood for inducing hyperkalemia, hypotension, and elevated elective treatment withdrawal rates reported in some trials. Data regarding mortality benefit attendant to combination therapy are not available at present.

In CHF from impaired diastolic relaxation (i.e., preserved LV ejection fraction), the role of AT₁ receptor antagonists is unresolved. These drugs do not appear to improve mortality or echocardiographic indices of diastolic relaxation but are associated with fewer CHF hospitalizations (Yusuf et al., 2003; Solomon et al., 2007; Massie et al., 2008). Some have suggested that ARB-induced improvement in arteriolar flow reserve may be protective in patients with diastolic CHF, although this hypothesis remains speculative at present (Kamezaki et al., 2007).

**Direct Renin Inhibitors.** There is accumulating scientific and clinical evidence to suggest that maximal pharmacologic ACE inhibition alone is insufficient for optimal attenuation of AngII-induced cardiovascular dysfunction in patients with CHF. Several molecular mechanisms have been ascribed to explain this hypothesis (Abassi et al., 2009), including:

- the presence of ACE-independent pathways that facilitate AngI conversion to AngII
- the activation of ACE homologues (e.g., ACE2) that are insensitive to conventional ACE-I therapy
- the suppression of the negative feedback effect exerted by AngI on renin secretion in the kidney

For these reasons, inhibition of renin has pharmacotherapeutic objectives for enhanced suppression of AngII synthesis in CHF.

Renin-mediated conversion of angiotensinogen to AngI is the first and rate-limiting step in the biochemical cascade that generates AngII and aldosterone (see Figures 26–1 and 28–3). The first generation of orally administered direct renin inhibitors was studied in the 1980s and was designed for the treatment of hypertension, but the broader use of these agents was hampered by the drugs’ suboptimal efficacy, reflecting, at least in part, their limited bioavailability (Staessen et al., 2006). Aliskiren (TEKTURNA, RASILEZ) is the first orally administered direct renin inhibitor to obtain FDA approval for use in clinical practice. The pharmacokinetic advantages of aliskiren over earlier direct renin inhibitor prototypes include an increased bioavailability (2.7%) and a long plasma t₁/₂ (~23 hour). Pilot clinical trials in humans established that aliskiren induces a concentration-dependent decrease in plasma renin activity and AngI and AngII levels that was associated with a decrease in systemic blood pressure without significant reflex tachycardia. The pharmacology of aliskiren is presented in more detail in Chapter 26.

The effect of aliskiren on blood pressure is the most thoroughly evaluated cardiovascular treatment endpoint. Several small studies have concluded that aliskiren is superior to placebo or to an ARB for monotherapy of mild-to-moderate hypertension (Sanoski, 2009). Aliskiren also appears to exert beneficial effects on myocardial remodeling by decreasing LV mass in hypertensive patients, suggesting that, similar to observations in ACE inhibitor or ARB therapy, direct renin inhibition may attenuate hypertension-induced end-organ damage (Solomon et al., 2009). Collectively, these observations provide evidence that aliskiren-mediated reductions in plasma renin activity and circulating levels of AngII may have salutary effects on the cardiovascular system in hypertension, thus opening the door for investigation of this therapy in patients with CHF.

The safety profile of aliskiren in CHF was established recently by the Aliskiren Observation of Heart Failure Treatment (ALOFT) trial (McMurray et al., 2008). Aliskiren (150 mg/day) add-on therapy to a β receptor antagonist and an ACE inhibitor or ARB was not associated with a significant increase in hypotension or hyperkalemia in a study cohort that mainly included symptomatic CHF patients with a low LV ejection fraction (<30%). Results from this trial also demonstrated that compared with placebo, aliskiren significantly decreased plasma N-terminal-proBNP levels, a clinically useful neurohumoral biomarker of active CHF. These findings affirm that inhibition of renin activity is an important potential target for improving symptoms and functional capacity in CHF. However, aliskiren has not yet been studied in sufficiently powered randomized-controlled clinical trials designed to analyze the efficacy of this drug in treatment of CHF.

**Vasopressin Receptor Antagonists.** Neurohumoral dysregulation in CHF extends beyond the renin–angiotensin–aldosterone axis to include abnormal arginine vasopressin (AVP) secretion, resulting in the perturbation of fluid balance, among various additional pathophysiologic effects. In response to 1) serum hypertonicity-induced activation of anterior pituitary osmoreceptors and 2) a perceived drop in blood pressure detected by baroreceptors in the carotid artery, aortic arch, and left atrium, AVP is secreted into the systemic circulation (Arai et al., 2007). The physiology and pharmacology of vasopressin are presented in Chapter 25.

The active form of AVP is a 9–amino acid peptide that interacts with three receptor subtypes: V₁a, V₁b, and V₂ (see Chapter 25). The AVP-V₂ receptor interaction on the basolateral membrane of the renal collecting ducts stimulates de novo synthesis of aquaporin-2 water channels that mediate free water reabsorption, thereby impairing diuresis and, ultimately, correcting plasma hypertonicity. Additional cell signaling pathways important in the pathophysiology of CHF include vasocostriction, cell hypertrophy, and increased platelet aggregation mediated by activation of V₁a receptors in vascular smooth muscle cells and cardiac myocytes. In addition, AngII-mediated activation of centrally located AT₁ receptors is associated with increased AVP levels in

...
CHF and may represent one mechanism by which the use of AT₁-receptor antagonists are effective in the clinical management of these patients.

LV systolic dysfunction can be associated with hyponatremia. Numerous observational and case-controlled studies have reported AVP levels nearly 2-fold above normal in CHF patients (Finley et al., 2008). The mechanisms to account for dysregulated AVP synthesis in CHF may involve impaired atrial stretch receptor sensitivity, normally a counterregulatory mechanism for AVP secretion, and increased adrenergic tone (Bristow et al., 2005). These probably do not fully explain the relationship between CHF and AVP levels; e.g., elevated levels of AVP have been observed in asymptomatic patients with significantly decreased LV function, calling into question the attributable role of sympathetically mediated adrenergic tone as a cause of hyponatremia (Francis et al., 1990).

In addition, there is evidence to suggest that CHF is a disease of abnormal responsiveness to vasopressin rather than one of excessive vasopressin production alone. For example, vasopressin infusion in CHF patients decreases cardiac output and stroke volume and causes an exaggerated increase in systemic vascular resistance and pulmonary capillary wedge pressure (Finley et al., 2008). In turn, V₂ antagonists attenuate the adverse pathophysiologic effects of hyponatremia by decreasing capillary wedge pressure, right atrial pressure, and pulmonary artery systolic blood pressure (Udelson et al., 2008). These agents also restore and maintain normal serum sodium levels in decompensated CHF patients, but their long-term use has not yet been convincingly linked to a decrease in CHF-associated symptoms or mortality (Gheorghiade et al., 2004).

Generally, trials designed to measure the effect of vasopressin-receptor antagonists have used agents selective for the V₂ receptor, although some drugs with both V₂ and V₁₄ receptor affinity also have been studied. Tolvaptan (Samsca), which preferentially binds the V₂ receptor over the V₁₄ receptor (receptor affinity ~29:1), is perhaps the most widely tested vasopressin receptor antagonist in patients with CHF and also is approved for hyponatremia (Gheorghiade et al., 2004).

Generally, trials designed to measure the effect of vasopressin-receptor antagonists have used agents selective for the V₂ receptor, although some drugs with both V₂ and V₁₄ receptor affinity also have been studied. Tolvaptan (Samsca), which preferentially binds the V₂ receptor over the V₁₄ receptor (receptor affinity ~29:1), is perhaps the most widely tested vasopressin receptor antagonist in patients with CHF and also is approved for hyponatremia (Gheorghiade et al., 2004).

Due to the risk of overly rapid correction of hyponatremia causing osmotic demyelination, tolvaptan should be started only in a hospital setting where Na⁺ levels can be monitored closely and possible drug interactions mediated by CYP and P-gp can be considered (black box warning). Conivaptan, used mainly for the treatment of hyponatremia rather than for CHF per se, differs from tolvaptan in that it may be intravenously administered, demonstrates high affinity for both V₂- and V₁₄-vasopressin receptors, and has a t₁/₂ that is nearly twice as long.

In the randomized, placebo-controlled EVEREST trial, the effect of tolvaptan (30 mg/day) in addition to standard therapy on immediate symptom improvement was assessed in patients administered the drug <48 hours into hospitalization for CHF (Gheorghiade et al., 2007). Data from this study substantiated that from the others, indicating that AVP antagonists decrease body weight, self-reported dyspnea, and physician-assessed peripheral edema, rules, and fatigue after a short course of therapy (<7 days). Long-term outcomes (survival, hospitalizations) were not significantly different from placebo. The identification of a CHF subgroup that stands to benefit most from AVP antagonists, in addition to the preferred agent and therapy duration, are questions of ongoing clinical investigation.

**β Adrenergic Receptor Antagonists**

Sympathetic nervous system activation in CHF supports circulatory function by enhancing contractility (inotropy), augmenting venricular relaxation and filling (lusitropy), and increasing heart rate (chronotropy). For many years, pharmacologic approaches to CHF treatment targeted drugs with sympathomimetic properties. This reflected the viewpoint that CHF is fundamentally a disorder of impaired stroke volume and cardiac output. For example, CHF symptom relief from short-term dobutamine and dopamine use in patients with ventricular dysfunction led to the belief that long-term sympathomimetic use would further improve clinical outcome. Under this model, the use of β receptor antagonists was believed to be counterproductive; however, the reverse appears to be the case. Long-term sympathomimetic use is associated with increased CHF mortality rates, whereas a survival benefit is associated with chronic administration of β receptor antagonists. Initially, clinical investigation of β receptor antagonists in the treatment of CHF encountered skepticism, but reports beginning in the early 1990s demonstrated that β antagonists (e.g., metoprolol) improve symptoms, exercise tolerance, and are measures of LV function over several months in idiopathic dilated cardiomyopathy patients with CHF (Waagstein et al., 1993; Gottlieb et al., 1998; Swedberg, 1993; Bristow, 2000). Serial echocardiographic measurements in CHF patients indicate that a decrease in systolic function occurs immediately after initiation of a β antagonist treatment, but this recovers and improves beyond baseline over the ensuing 2-4 months (Hall et al., 1995). This trend may be due to attenuation or prevention of the β receptor–mediated adverse effects of catecholamines on the myocardium (Eichhorn and Bristow, 1996).

**Mechanism of Action.** The mechanisms by which β receptor antagonists influence outcome in CHF patients are not fully delineated. By preventing myocardial ischemia without significantly influencing serum electrolytes, β receptor antagonists probably influence mortality, in part, by decreasing the frequency of unstable tachyarrhythmias to which CHF patients are particularly prone. In addition, these agents may influence survival by favorably affecting LV geometry, specifically by decreasing LV chamber size and increasing LV ejection fraction. Through inhibition of sustained sympathetic nervous system activation, these agents prevent or delay progression of myocardial contractile dysfunction by inhibiting maladaptive proliferative cell
signaling in the myocardium, reducing catecholamine-induced cardiomyocyte toxicity, and decreasing myocyte apoptosis (Communal et al., 1998; Bisognano et al., 2000). β Receptor antagonists may also induce positive LV remodeling by decreasing oxidative stress in the myocardium (Sawyer and Colucci, 2000).

**Metoprolol.** Metoprolol (Lopressor, Toprol XL, others) is a β₁-selective receptor antagonist. The short-acting form of this drug has a drug elimination t₁/₂ of ~6 hours, and therefore appropriate dosing is three to four times daily. Conversely, the extended-release formulation is sufficiently dosed once daily. A number of clinical trials have demonstrated the beneficial effects of β-antagonist therapy in CHF. In the Metoprolol Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF Study Group 1999), patients with low LV ejection fraction and severe CHF receiving metoprolol succinate (target dose, 200 mg/day) received a 34% all-cause mortality benefit, an effect attributable to reductions in sudden death and death from worsening CHF. Despite the high target drug dose, the majority of patients achieved this therapeutic goal.

**Carvedilol.** Carvedilol (COREG, others) is a nonselective β receptor antagonist and α₁-selective antagonist that is FDA approved for the management of mild-to-severe CHF. The U.S. Carvedilol Trial randomized patients with symptomatic but compensated CHF (New York Heart Association [NYHA] classes II to IV) and low LV ejection fraction to receive carvedilol or placebo (Packer et al., 1996). Carvedilol (25 mg twice daily) was associated with a 65% reduction in all-cause mortality that was independent of age, sex, CHF etiology, or LV ejection fraction. The mortality benefit and improvement in LV ejection fraction was carvedilol concentration dependent (Bristow et al., 1996). Exercise capacity (e.g., 6-minute walk test) did not improve with carvedilol, however, but therapy did appear to slow the progression of CHF in a subgroup of patients with good exercise capacity and mild symptoms at baseline (Colucci et al., 1996).

In the Carvedilol Post Infarct Survival Control in LV Dysfunction Trial (Dargie, 2001), patients with recent MI (3-21 days prior to enrollment) and impaired LV systolic function were randomized to carvedilol (25 mg twice daily) or placebo. Patients with symptomatic CHF and those with asymptomatic LV dysfunction were included. Although there was no difference in the primary endpoint of all-cause mortality, carvedilol therapy was associated with a significant reduction in the combined endpoint of all-cause mortality and nonfatal MI. At the opposite end of the spectrum, patients with symptomatic CHF at rest or with minimal exertion and impaired LV systolic function were randomized to carvedilol versus placebo in the Carvedilol Prospective Randomized Cumulative Survival Study (Packer et al., 2002b). Consistent with previous trials, there was a 35% decrease in all-cause mortality. Although the patients included in the trial had established CHF, it merits emphasis that the placebo group mortality at 1 year was ~18%, a finding suggestive that the patient cohort was not representative of patients with advanced CHF.

**Clinical Use of β Adrenergic Receptor Antagonists in Heart Failure**

Data from more than 15,000 patients with mild-to-moderate chronic CHF enrolled in various clinical trials have established that β receptor antagonists improve disease-associated symptoms, hospitalization, and mortality. Accordingly, β antagonists are recommended for use in patients with an LV ejection fraction <35% and NYHA class II or III symptoms in conjunction with an ACE inhibitor or AT₁ receptor antagonist, and diuretics as required to palliate symptoms. Interpretation of these and other clinical guidelines should, however, consider the following areas of uncertainty.

The role of β receptor antagonists in severe CHF or under circumstances of an acute clinical decompensation is not yet clear. Likewise, the utility of β blockade in patients with asymptomatic LV dysfunction has not been systematically evaluated. The marked heterogeneous pharmacologic characteristics (e.g., receptor selectivity, pharmacokinetics) of specific agents within this general drug class, as discussed in Chapter 12, play a key role in predicting the overall efficacy of a particular β receptor antagonist.

β receptor antagonist therapy is customarily initiated at very low doses, generally less than one-tenth of the final target dose, and titrated cautiously upward. Even when initiated properly, a tendency to retain fluid exists that may require diuretic dose adjustment. Insufficient evidence exists to support the unrestricted administration of β receptor antagonists in patients with severe (NYHA class IIIIB and IV), new-onset, or acutely decompensated CHF.

**Cardiac Glycosides**

The English botanist, chemist, and physician Sir William Withering is credited with the first published observation in 1785 that digitalis purpurea, a derivative of the purple foxglove flower, could be used for the treatment of “cardiac dropsy,” or congestive heart failure. The benefits of cardiac glycosides in CHF have been extensively studied (Eichhorn and Gheorghiade, 2002) and are generally attributed to:

- Inhibition of the plasma membrane Na⁺, K⁺-ATPase in myocytes
- A positive inotropic effect on the failing myocardium
- Suppression of rapid ventricular rate response in CHF-associated atrial fibrillation
- Regulation of downstream deleterious effects of sympathetic nervous system overactivation
**Mechanism of the Positive Inotropic Effect.** With each cardiac myocyte depolarization, $\text{Na}^+$ and $\text{Ca}^{2+}$ ions shift into the intracellular space (Figure 28–5). $\text{Ca}^{2+}$ that enters the cell via the L-type $\text{Ca}^{2+}$ channel during depolarization triggers the release of stored intracellular $\text{Ca}^{2+}$ from the sarcoplasmic reticulum via the ryanodine receptor (RyR). This $\text{Ca}^{2+}$-induced $\text{Ca}^{2+}$ release increases the level of cytosolic $\text{Ca}^{2+}$ available for interaction with myocyte contractile proteins, ultimately increasing myocardial contraction force. During myocyte repolarization and relaxation, cellular $\text{Ca}^{2+}$ is re-sequestered by the sarcoplasmic reticular $\text{Ca}^{2+}$-ATPase and is removed from the cell by the sarcolemmal $\text{Na}^+\text{Ca}^{2+}$ exchanger and, to a much lesser extent, by the sarcolemmal $\text{Ca}^{2+}$-ATPase.

Cardiac glycosides bind and inhibit the phosphorylated (α subunit of the sarcolemmal $\text{Na}^+,\text{K}^+$-ATPase and thereby decreasing $\text{Na}^+$ extrusion and increasing cytosolic $[\text{Na}^+]$. This decreases the transmembrane $\text{Na}^+$ gradient that drives $\text{Na}^+-\text{Ca}^{2+}$ exchange during myocyte repolarization. As a consequence, less $\text{Ca}^{2+}$ is removed from the cell and more $\text{Ca}^{2+}$ is accumulated in the sarcoplasmic reticulum (SR) by SERCA2. This increase in releasable $\text{Ca}^{2+}$ (from the SR) is the mechanism by which cardiac glycosides

---

**Figure 28–5. Sarcolemmal exchange of $\text{Na}^+$ and $\text{Ca}^{2+}$ during cell depolarization and repolarization.** $\text{Na}^+$ and $\text{Ca}^{2+}$ enter the cardiac myocyte via the $\text{Na}^+$ channel and the L-type $\text{Ca}^{2+}$ channel during each cycle of membrane depolarization, triggering the release, through the ryanodine receptor (RyR), of larger amounts of $\text{Ca}^{2+}$ from internal stores in the sarcoplasmic reticulum (SR). The resulting increase in intracellular $\text{Ca}^{2+}$ interacts with troponin C and activates interactions between actin and myosin that result in sarcomere shortening. The electrochemical gradient for $\text{Na}^+$ across the sarcolemma is maintained by active transport of $\text{Na}^+$ out of the cell by the sarcolemmal $\text{Na}^+,\text{K}^+$-ATPase. The bulk of cytosolic $\text{Ca}^{2+}$ is pumped back into the SR by a $\text{Ca}^{2+}$-ATPase, SERCA2. The remainder is removed from the cell by either a sarcolemmal $\text{Ca}^{2+}$-ATPase or a high-capacity $\text{Na}^+\text{-Ca}^{2+}$ exchanger, NCX. NCX exchanges 3 $\text{Na}^+$ for every $\text{Ca}^{2+}$, using the electrochemical potential of $\text{Na}^+$ to drive $\text{Ca}^{2+}$ extrusion. The direction of $\text{Na}^+-\text{Ca}^{2+}$ exchange may reverse briefly during depolarization, when the electrical gradient across the sarcolemma is transiently reversed. β adrenergic agonists and PDE inhibitors, by increasing intracellular cyclic AMP levels, activate PKA, which phosphorylates phospholamban (PL), the α subunit of the L-type $\text{Ca}^{2+}$ channel, and regulatory components of the RyR, as well as TnI, the inhibitory subunit of troponin (not shown). As a result, the probabilities of opening of the L-type $\text{Ca}^{2+}$ channel and the RyR2 $\text{Ca}^{2+}$ channel are doubled; SERCA2 is uninhibited and accumulates $\text{Ca}^{2+}$ into the SR faster, more avidly, and to a higher concentration; and relaxation occurs at slightly higher $[\text{Ca}^{2+}]$, due to slightly reduced sensitivity of the troponin complex to $\text{Ca}^{2+}$. The net effect of these phosphorylations is a positive inotropic effect: a faster rate of tension development to a higher level of tension, followed by a faster rate of relaxation. ▲ indicates site of cardiac glycoside binding. See the text for the mechanism of positive inotropic effect of cardiac glycosides.
enhance myocardial contractility. Elevated extracellular K⁺ levels (i.e., hyperkalemia) cause dephosphorylation of the ATPase α subunit, altering the site of action of the most commonly used cardiac glycoside, digoxin, and thereby reducing the drug’s binding and effect.

**Electrophysiologic Actions.** At therapeutic serum or plasma concentrations (i.e., 1-2 ng/mL), digoxin decreases automaticity and increases the maximal diastolic resting membrane potential in atrial and atrioventricular (AV) nodal tissues. This occurs via increases in vagal tone and sympathetic nervous system activity inhibition. In addition, digoxin prolongs the effective refractory period and decreases conduction velocity in AV nodal tissue. Collectively, these may contribute to sinus bradycardia, sinus arrest, prolongation of AV conduction, or high-grade AV block. At higher concentrations, cardiac glycosides may increase sympathetic nervous system activity that influences cardiac tissue automaticity, change associated with the genesis of atrial and ventricular arrhythmias. Increased intracellular Ca²⁺ loading and sympathetic tone increases the spontaneous (phase 4) rate of diastolic depolarization as well as promoting delayed afterdepolarization; together, these decrease the threshold for generation of a propagated action potential and predisposes to malignant ventricular arrhythmias (see Chapter 29).

**Regulation of Sympathetic Nervous System Activity.** Sympathetic nervous system overactivation in CHF occurs, in part, from aberrant arterial baroreflex responses to low cardiac output. Specifically, a decline in baroreflex response to blood pressure results in a decline in baroreflex-mediated tonic suppression of CNS-directed sympathetic activity. This cascade contributes to the sustained elevation in plasma NE, renin, and vasopressin (Ferguson et al., 1989). Cardiac glycosides favorably influence carotid baroreflex responsiveness to changes in carotid sinus pressure (Wang et al., 1990). In patients with moderate-to-advanced CHF, cardiac glycoside infusion increases forearm blood flow and cardiac index and decreased heart rate. There is clinical evidence to suggest that digoxin decreases centrally mediated sympathetic nervous system tone, although the mechanism to explain this is unresolved (Ferguson et al., 1989).

**Pharmacokinetics.** The elimination t½ for digoxin is 36-48 hours in patients with normal or near-normal renal function, permitting once-daily dosing. Near steady-state blood levels are achieved ~7 days after initiation of maintenance therapy. Digoxin is excreted by the kidney, and increases in cardiac output or renal blood flow from vasodilator therapy or sympathomimetic agents may increase renal digoxin clearance, necessitating adjustment of daily maintenance doses. The volume of distribution and drug clearance rate are both decreased in elderly patients.

Despite renal clearance, digoxin is not removed effectively by hemodialysis due to the drug’s large (4-7 L/kg) volume of distribution. The principal tissue reservoir is skeletal muscle and not adipose tissue, and thus dosing should be based on estimated lean body mass. Most digoxin tablets average 70-80% oral bioavailability; however, ~10% of the general population harbors the enteric bacterium *Eubacterium lentum*, which inactivates digoxin and thus may account for drug tolerance that is observed in some patients. Liquid-filled capsules of digoxin (LANOXICAPS) have a higher bioavailability than do tablets (LANOXIN); thus, the drug requires dosage adjustment if a patient is switched from one delivery form to the other. Digoxin is available for intravenous administration, and maintenance doses can be given intravenously when oral dosing is inappropriate. Digoxin administered intramuscularly is erratically absorbed, causes local discomfort, and usually is unnecessary. A number of clinical conditions may alter the pharmacokinetics of digoxin or patient susceptibility to the toxic manifestations of this drug. For example, chronic renal failure decreases the volume of distribution of digoxin and therefore requires a decrease in maintenance dosage of the drug. In addition, drug interactions that may influence circulating serum digoxin levels include several commonly used cardiovascular medications such as verapamil, amiodarone, propafenone, and spironolactone. The rapid administration of Ca²⁺ increases the risk of inducing malignant arrhythmias in patients already treated with digoxin. Electrolyte disturbances, especially hypokalemia, acid–base imbalances, and one’s form of underlying heart disease also may alter a patient’s susceptibility to digoxin side effects.

Maximal increase in LV contractility becomes apparent at serum digoxin levels ~1.4 ng/mL (1.8 nmol) (Kelly and Smith, 1992). The neurohormonal benefits of digoxin, however, may occur between 0.5-1 ng/mL. In turn, higher serum concentrations are not associated with incrementally increased clinical benefit. Moreover, there are data to suggest that the risk of death is greater with increasing serum concentrations, even at values within the traditional therapeutic range, and therefore many advocate maintaining digoxin levels <1 ng/mL.

**Clinical Use of Digoxin in Heart Failure.** Data from contemporary clinical trials have re-characterized the utility of cardiac glycosides, once first-line agents, in CHF, especially in patients with normal sinus rhythm (as opposed to atrial fibrillation).

Digoxin discontinuation in clinically stable patients with mild-to-moderate CHF from LV systolic dysfunction worsened symptoms and decreased maximal treadmill exercise (Uretsky et al., 1993; Packer et al., 1993). However, even though digoxin may decrease CHF-associated hospitalizations in patients with severe forms of the disease, drug use does not reduce all-cause mortality. Overall, digoxin use usually is limited to CHF patients with LV systolic dysfunction in atrial fibrillation or to patients in sinus rhythm who remain symptomatic despite maximal therapy with ACE inhibitors and β adrenergic receptor antagonists. The latter agents are viewed as first-line therapies because of their proven mortality benefit.

**Digoxin Toxicity.** The incidence and severity of digoxin toxicity have declined substantially in the past 2 decades as a consequence of alternative drugs available for the treatment of supraventricular arrhythmias in CHF, increased understanding of digoxin pharmacokinetics, improved serum digoxin level monitoring, and identification of important interactions between digoxin and other commonly co-administered drugs. Nevertheless, the
recognition of digoxin toxicity remains an important consideration in the differential diagnosis of arrhythmias, and neurologic or gastrointestinal symptoms in patients receiving cardiac glycosides. An antidote, digoxin immune Fab (DIGIBIND, DIGIFAB), is available to treat toxicity.

Among the more common electrophysiologic manifestations of digoxin toxicity are ectopic beats originating from the AV junction or ventricle, first-degree AV block, abnormally slow ventricular rate response to atrial fibrillation, or an accelerated AV junctional pacemaker. When present, only dosage adjustment and appropriate monitoring are usually necessary. Sinus bradycardia, sinoatrial arrest or exit block, and second- or third-degree AV conduction delay requiring atropine or temporary ventricular pacing are uncommon. Unless in the setting of high-degree AV block, potassium administration should be considered for patients with evidence of increased AV junctional or ventricular automaticity even if serum K+ levels are in the normal range. Lidocaine or phenytoin, which have minimal effects on AV conduction, may be used for the treatment of digoxin-induced ventricular arrhythmias that threaten hemodynamic compromise (see Chapter 29). Electrical cardioversion carries an increased risk of inducing severe rhythm disturbances in patients with overt digitalis toxicity and should be used with particular caution. Note, too, that inhibition of the Na⁺,K⁺-ATPase activity of skeletal muscle can cause hyperkalemia. An effective antidote for life-threatening digoxin (or digitoxin) toxicity is available in the form of anti-digoxin immunotherapy. Purified Fab fragments from ovine anti-digoxin antisera (DIGIBIND) are usually dosed by the estimated total dose of digoxin ingested in order to achieve a fully neutralizing effect. For a more comprehensive review of the treatment of digitalis toxicity, see Kelly and Smith (1992).

**β** Adrenergic and Dopaminergic Agonists

In the setting of severely decompensated CHF from reduced cardiac output, the principal focus of initial therapy is to increase myocardial contractility. Dopamine and dobutamine are positive inotropic agents most often used to accomplish this. These drugs provide short-term circulatory support in advanced CHF via stimulation of cardiac myocyte dopamine (D₁) and β adrenergic receptors that stimulate the G protein–guanyl cyclase-cyclic AMP–PKA pathway. The catalytic subunit of PKA phosphorylates a number of substrates that enhance Ca²⁺-dependent myocardial contraction and accelerate relaxation (Figure 28–5). Isoproterenol, epinephrine, and norepinephrine are useful in certain circumstances but have little role in routine CHF management. Indeed, inotropic agents that elevate cardiac cell cyclic AMP are consistently associated with increased risks of hospitalization and death, particularly in patients with NYHA class IV. At the cellular level, enhanced cyclic AMP levels have been associated with apoptosis (Brunton, 2005; Yan et al., 2007). The basic pharmacology of adrenergic agonists is discussed in Chapter 12.

**Dopamine.** Dopamine is an endogenous catecholamine with only limited utility in the treatment of most patients with cardiogenic circulatory failure. The pharmacologic and hemodynamic effects of dopamine are concentration dependent. Low doses (≤2 µg/kg lean body mass/min) induce cyclic AMP–dependent vascular smooth muscle vasodilation. In addition, activation of D₂ receptors on sympathetic nerves in the peripheral circulation at these concentrations also inhibits NE release and reduces α adrenergic stimulation of vascular smooth muscle, particularly in splanchnic and renal arterial beds. Therefore, low-dose dopamine infusion often is used to increase renal blood flow and thereby maintain an adequate glomerular filtration rate in hospitalized CHF patients with impaired renal function refractory to diuretics. Dopamine also exhibits a pro-diuretic effect directly on renal tubular epithelial cells that contributes to volume reduction.

At intermediate infusion rates (2–5 µg/kg/min), dopamine directly stimulates cardiac α receptors and vascular sympathetic neurons that enhance myocardial contractility and neural NE release. At higher infusion rates (5–15 µg/kg/min), α adrenergic receptor stimulation–mediated peripheral arterial and venous constriction occurs. This may be desirable in patients with critically reduced arterial pressure or in those with circulatory failure from severe vasodilation (e.g., sepsis, anaphylaxis). However, high-dose dopamine infusion has little role in the treatment of patients with primary cardiac contractile dysfunction; in this setting, increased vasoconstriction will lead to increased afterload and worsening of LV performance. Tachycardia, which is more pronounced with dopamine than with dobutamine, may actually provoke ischemia (and ischemia–induced malignant arrhythmias) in patients with coronary artery disease.

**Dobutamine.** Dobutamine is the β agonist of choice for the management of CHF patients with systolic dysfunction. In the formulation available for clinical use, dobutamine is a racemic mixture that stimulates both β₁ and β₂ receptor subtypes. In addition, the (−) enantiomer is an agonist for α adrenergic receptors, whereas the (+) enantiomer is a weak, partial agonist. At infusion rates that result in a positive inotropic effect in humans, the β₁ adrenergic effect in the myocardium predominates. In the vasculature, the α adrenergic agonist effect of the (−) enantiomer appears to be offset by the (+) enantiomer and vasodilating effects of β₂ receptor stimulation. Thus, the principal hemodynamic effect of dobutamine is an increase in stroke volume from
positive inotropy, although $\beta_3$ receptor activation may cause a decrease in systemic vascular resistance and, therefore, mean arterial pressure. Despite increases in cardiac output, there is relatively little chronotropic effect.

Continuous dobutamine infusions are typically initiated at 2-3 $\mu$g/kg/min without a loading dose and uptitrated until the desired hemodynamic response is achieved. Pharmacologic tolerance may limit infusion efficacy beyond 4 days, and, therefore, addition or substitution with a class III PDE inhibitor may be necessary to maintain adequate circulatory support. The major side effects of dobutamine are tachycardia and sphylinen-dependent ventricular or ventricular arrhythmias, which may require a reduction in dosage. Recent $\beta$ receptor antagonist use is a common cause of blunted clinical responsiveness to dobutamine.

**Phosphodiesterase Inhibitors.** The cyclic AMP–PDE inhibitors decrease cellular cyclic AMP degradation, resulting in elevated levels of cyclic AMP in cardiac and smooth muscle myocytes. The physiologic effects of this are positive myocardial inotropism and dilation of resistance and capacitance vessels. Collectively, therefore, PDE inhibition improves cardiac output through ionotropy and by decreasing preload and afterload (thus giving rise to the term *inodilator*). The clinical application of early-generation PDE inhibitors (e.g., theophylline, caffeine) is limited by low cardiovascular specificity and an unfavorable side-effect profile, whereas inamrinone, milrinone, and other more recently developed PDE inhibitors are preferred.

**Inamrinone and Milrinone.** Parenteral formulations of inamrinone (previously named amrinone) and milrinone are approved for short-term circulation support in advanced CHF. Both drugs are bipyridine derivatives and are selective PDE3 inhibitors, the cyclic GMP–inhibited cyclic AMP–PDE. These drugs directly stimulate myocardial contractility and accelerate myocardial relaxation. In addition, they cause balanced arterial and venous dilation with a consequent fall in systemic and pulmonary vascular resistances and left and right-heart filling pressure. As a result of its effect on LV contractility, the increase in cardiac output from milrinone is superior to that from nitrogen oxide, despite comparable reductions in systemic vascular resistance. Conversely, the arterial and venodilatory effects of milrinone are greater than those of dobutamine at concentrations that produce similar increases in cardiac output.

Parenteral administration of inamrinone and milrinone in patients with CHF from systolic dysfunction should be initiated with a loading dose followed by continuous infusion. For inamrinone, a 0.75-mg/kg bolus injection administered over 2-3 minutes is typically followed by a 2-20-$\mu$g/kg/min infusion. The loading dose of milrinone is ordinarily 50 $\mu$g/kg, and the continuous infusion rate ranges from 0.25-1 $\mu$g/kg/min. The elimination half-lives of inamrinone and milrinone in normal individuals are 2-3 hours and 0.5-1 hour, respectively, but are nearly doubled in patients with severe CHF. Clinically significant thrombocytopenia occurs in ~10% of those receiving inamrinone but is rare with milrinone. Because of enhanced selectivity for PDE3, short $t_{1/2}$, and favorable side-effect profile, milrinone is the agent of choice among currently available PDE inhibitors for short-term, parenteral inotropic support. However, vasodilation-mediated reductions in mean arterial pressure are one practical barrier to milrinone administration in patients with marginal systemic arterial blood pressure from low cardiac output.

**Sildenafil.** In contrast to inamrinone and milrinone, sildenafil (Revatio) inhibits PDE5, which is the most common PDE isoform in lung tissue. This characteristic of PDE5 likely accounts for the enhanced pulmonary artery specificity observed with sildenafil use. In fact, until recently, the primary clinical application of sildenafil in CHF has mainly been limited to those with isolated right ventricular systolic failure from pulmonary artery hypertension. However, recently published reports suggest that sildenafil favorably influences exercise capacity and right-heart hemodynamics in patients with pulmonary hypertension from LV systolic dysfunction as well (Lewis et al., 2007). Preclinical experimental models also have raised the possibility that PDE5 inhibition is directly cardioprotective via attenuation of adrenergic stimulation-induced myocardial contraction and by suppressing pressure-overload mediated myocardial hypertrophy and attendant ventricular dysfunction (Kass et al., 2007). The pharmacology of PDE5 inhibitors is presented in Chapter 27.

**Chronic Positive Inotropic Therapy**

Several orally administered agents with combined inotropic and vasodilator properties are available for clinical use. Although improvements in CHF symptoms, functional status, and hemodynamic profile have been reported, the effect of long-term therapy on mortality is disappointing. In fact, the dopaminergic agonist ibopamine; PDE inhibitors milrinone, inamrinone, and vesnarinone; and pimobendan are associated with increased mortality (Hampton et al., 1997; Packer et al., 1991; Cohn et al., 1998). At present, digoxin remains the only oral inotropic agent available for CHF patient use.

Continuous or intermittent outpatient therapy with intravenous dobutamine or milrinone, administered by a portable or home-based infusion pump through a central venous catheter, is available for end-stage CHF patients with symptoms refractory to optimized medical therapy.

**Diastolic Heart Failure**

Data from population studies suggest that up to 40% of CHF patients have preserved LV systolic function. The pathogenesis of diastolic CHF includes structural and functional abnormalities of the ventricle(s) that are associated with impaired ventricular relaxation and LV distensibility. These abnormalities are reflected in the
LV pressure–volume relationship during diastole, which is shifted upward and to the left relative to normal subjects (Figure 28–6). Consonant with the definition of CHF outlined earlier in this chapter, the diagnosis of diastolic CHF is made when the LV is unable to maintain adequate cardiac output without filling at an abnormally elevated end-diastolic filling pressure.

In patients with primary diastolic dysfunction, the myocardial abnormality that accounts for abnormal filling is intrinsic to the myocardium; e.g., by infiltrative disorders including cardiac amyloidosis, hemochromatosis, sarcoidosis, and rarer conditions such as endomyocardial fibrosis and Fabry’s disease. Although not a disease of myocardium infiltration, clinically evident CHF may occur despite intact LV systolic function in familial hypertrophic cardiomyopathy.

Secondary diastolic dysfunction occurs as a consequence of excessive preload (e.g., renal failure), excessive afterload (e.g., systemic hypertension), or changes in LV geometry that occur in response to chronically abnormal loading conditions. Diastolic CHF also is observed in patients with long-standing epicardial coronary artery or pericardial disease. The prevalence of secondary diastolic dysfunction is higher in women and with advanced age. Reported annual mortality rates for diastolic CHF are 5–8%, although this range likely represents an underestimation (Jones et al., 2004).

Patients with diastolic CHF are typically dependent on preload to maintain adequate cardiac output. Although hypervolemic patients generally benefit from careful intravascular volume reduction, this should be accomplished gradually and treatment goals reassessed frequently. Maintaining synchronous atrial contraction (or at least ventricular rate response control) helps to maintain adequate LV filling during the latter phase of diastole and is therefore a paramount goal in the management of CHF from diastolic dysfunction. Evaluation and treatment of predisposing conditions to impaired diastolic function, such as myocardial ischemia and poorly controlled systemic hypertension, are fundamental to the overall pharmacotherapeutic strategy of this complex form of CHF.

Future Therapies: Targeting Vascular Dysfunction in Congestive Heart Failure from Systolic Dysfunction

Vascular dysfunction is an established component of the CHF syndrome and has evolved into a novel pharmacotherapeutic target for the clinical management of patients with this disease (Varin et al., 2000) (Figure 28–7). Contemporary scientific observations suggest that the blood vessel is a dynamic structure integral to normal myocardial function. This represents a paradigm shift away from the traditional perspective that blood vessels are conduit “tubes” necessary only for blood transport. Elevated levels of oxidant, nitrosative, and other forms of inflammatory stress observed in patients with CHF may impair vascular reactivity by disruption of normal vasodilatory cell signaling pathways (Erwin et al., 2005; Doehner et al., 2001). The precise mechanism by which impaired vascular reactivity is aligned with the progressive natural history of CHF is unresolved; when present, however, vascular dysfunction is associated with decreased exercise tolerance and a poorer clinical outcome. For example, hyperaldosteronism due to overactivation of the renin–angiotensin–aldosterone axis in the setting of LV dysfunction adversely affects both endothelium-dependent and endothelium-independent vascular reactivity (Leopold et al., 2007, Maron et al., 2009) endothei locomune oxidase inhibn vascular reactivity. This process is in part mediated by increased levels of reactive oxygen species, decreased endogenous levels of antioxidant enzymes, and decreased levels of bioavailable NO (Leopold et al., 2007; Farquharson and Struthers, 2000). As discussed previously, the undesirable effects of hyperaldosteronism on vascular dysfunction are attenuated clinically by aldosterone receptor blockade, resulting in significantly decreased CHF-associated morbidity and mortality (Pitt et al., 1999).
Xanthine Oxidase and Vascular Dysfunction. Xanthine oxidase (XO) is necessary for normal purine metabolism and catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid in a reaction that generates superoxide. Elevated levels of uric acid are associated with clinically evident CHF (Hare et al., 2008). For example, epidemiologic data support a positive, graded association between impaired exercise capacity and circulating uric acid levels (Doehner et al., 2001). Although the myocardium is rich in XO, vascular endothelial cells also contain high concentrations of XO, an observation that ultimately lead to the hypothesis that increased XO-generated superoxide impairs vascular reactivity in CHF patients (Hare et al., 2008).

Early studies suggested allopurinol (300 mg/day), an XO inhibitor, effectively decreases generation of free oxygen radicals and improves peripheral arterial vasodilation and blood flow in hyperuricemic patients with mild-to-moderate CHF from systolic dysfunction (Doehner et al., 2002). Interestingly, probenecid, which decreases circulating urate levels by enhancing its elimination rather than by inhibiting XO activity, has not been shown to influence vascular reactivity. In patients with advanced CHF, allopurinol-induced serum uric
acid level reduction (over 24 weeks) is associated with functional
class improvement, but only in those with baseline serum uric acid
levels >9.5 mg/dL. Overall, randomized, placebo-controlled clinical
trials examining the long-term efficacy of allopurinol therapy in CHF
are sparse, and active investigation in this area continues.

Statins and Vascular Dysfunction. HMG-CoA (3-hydroxy-
3-methyl-glutaryl–coenzyme A) reductase catalyzes the
formation of L-mevalonic acid, a key biochemical pre-
cursor in the cholesterol synthesis pathway (Goldstein
and Brown, 1990). Current evidence suggests a role of
crosstalk between mevalonate metabolism and cell sig-
naling pathways involved in inflammation and oxidant
stress. In this way, HMG-CoA reductase inhibitors, or
“statins”, may exert beneficial cardiovascular effects
beyond their original intent of low-density lipoprotein
reduction; specifically, statins are associated with posi-
tive LV remodeling, increased arteriolar blood flow, and
decreased circulating platelet aggregation (Liao et al.,
2005).

Intermediate byproducts of mevalonate metabolism
(i.e., isopenylated proteins that upregulate activation of
Rho, RAS, and other G proteins) are linked to impaired
vascular function by increasing levels of oxidant stress
decreasing bioavailable NO levels (Hernandez-Perera
et al., 1998). Statins inhibit these intermediary pathways
and appear to restore endothelium-dependent (Feron et
al., 1998) and endothelium-independent vascular func-
tion (Drexler et al., 1993). The pharmacology of the
statins and other cholesterol-lowering agents is presented
in Chapter 31.

A large number of population studies have demonstrated a
favorable effect of statin therapy on outcome in CHF. For example,
one retrospective analysis of ischemic- and non-ischemic cardiomy-
opathy patients with CHF reported a significant reduction in mortal-
ity in those treated with a statin for 1 year compared to case-matched
patients treated only with standard medical therapy (Horwich et al.,
2004). Others have suggested that statins delay CHF in at-risk
patients with ischemic heart disease (Kjekshus et al., 1997).
Unfortunately, there is a paucity of sufficiently powered prospec-
tive, randomized, placebo-controlled clinical trials demonstrating a
favorable effect of statin therapy on outcome in patients with CHF.
Overall, the evidence in support of statin use in CHF (of either
ischemic or non-ischemic etiologies) is primarily based on observa-
tional clinical data. The clinical indications for statin therapy in CHF,
preferred drug isoform, and optimal drug concentration, for exam-
ple, remain undefined.

Direct Activators of Soluble Guanylyl Cyclase. Soluble
guanylyl cyclase (sGC) is an enzyme that catalyzes the
conversion of guanosine triphosphate to cyclic GMP, a
second messenger necessary for normal vascular
smooth muscle cell relaxation (Koesling, 1999). Under
physiologic conditions, NO is the primary biologically
active stimulator of sGC. Elevated levels of oxidant
stress deactivate sGC through various molecular mech-
anisms. For example, aldosterone levels comparable to
those observed in patients with decompensated CHF
are associated with increased oxidant stress that con-
verts sGC to an NO-insensitive state (Maron et al.,
2009), thereby disrupting vasodilatory signaling neces-
sary for normal vascular function.

Organic nitrates, which promote sGC activation by
increasing bioavailable NO levels, are subject to pharma-
cologic tolerance that complicates long-term drug use,
dosing, and administration frequency (see the organic
nitrates section in Chapter 27). Although the precise
mechanism to explain this phenomenon is unknown, it is
likely mediated in part by elevated levels of oxidant stress
that convert sGC to an NO-insensitive state. BAY com-
pounds (e.g., BAY 58-2667 [cinaciguat]) activate sGC by
an NO-independent mechanism, thereby promoting nor-
mal sGC function despite conditions of oxidant stress
(Stasch et al., 2006). Data from preclinical CHF studies
in animals have validated these beneficial molecular
effects. In healthy humans, BAY compound administra-
tion has not been associated with severe side effects, but
hypotension and headache have been reported. Likewise
in humans, circulating plasma drug concentrations are
decreased to clinically insignificant levels ≤30 minutes
after infusion termination (Frey et al., 2008).

The utility of BAY 58-2667 in the clinical management of
patients with CHF is a topic of ongoing investigation, although early
published reports suggest potential for the use of this novel drug
class. In a group of patients with acutely decompensated CHF, BAY
58-2667 responders demonstrated a significant decrease in pul-
monary capillary wedge pressure, mean right atrial pressure, mean
pulmonary artery pressure, pulmonary vascular resistance, and sys-
temic vascular resistance. Cardiac output was significantly increased
as well (Lapp et al., 2009). The potential mainstream application of
BAY 58-2667 (and other similar compounds) is currently under eval-
uation in larger clinical trials. Nevertheless, these preliminary obser-
vations are encouraging and may expose sustained sGC activity
despite enzyme insensitivity to NO as a promising therapeutic tar-
get for CHF patients.

**CLINICAL SUMMARY**

Congestive heart failure is a chronic and usually pro-
gressive illness instigated by a primary myocardial
insult that impairs myocardial structure and function.
Treatment (Figure 28–8) ideally begins with *prevention*
of cardiac dysfunction via the identification and reme-
diation of risk factors that predispose individuals to the
development of structural heart disease. For example,
because coronary artery disease is the most common
etiology of LV systolic dysfunction, public health tactics to address strategies for prevention of MI through lipid lowering, blood pressure control, and smoking cessation are critical for effective CHF primary prevention.

In asymptomatic patients with LV dysfunction or impaired diastolic dysfunction, neurohormonal compensatory mechanisms that support cardiovascular function are activated, but, paradoxically, further disease progression. Indeed, treatment in this clinical stage is directed at attenuation of sustained neurohormonal activation, with individualized regimens of \( \beta \) adrenergic receptor blockers and ACE inhibitors or AT\(_1\) receptor antagonists.

In most cases, there is unwanted progression to clinically evident CHF, indicating the development of significantly abnormal cardiovascular hemodynamics. Treatment goals in these patients include symptom relief and prevention of disease progression. This may be achieved with diuretics, load-reducing agents, and renin–angiotensin–aldosterone axis antagonists.

Symptomatic patients with hemodynamic decompensation require hospitalization, because oral diuretic and vasodilator therapy alone often are inadequate to reestablish euvolemia and adequate peripheral perfusion. Parenteral vasodilator and inotropic agents are administered parenterally to restore forward cardiac output and to reverse Na\(^+\) and water retention. Effective treatment of these patients often is complicated by concurrent renal insufficiency and hypotension, despite evidence of persistently elevated intracardiac filling pressures. In this setting, selection of parenteral agents guided by data obtained from an indwelling pulmonary artery catheter may prove useful.

Consider as an example the clinical scenario in which a decompensated CHF patient presents with normal systemic vascular resistance. In this case, afterload reduction may be contraindicated in the short term and treatment with a parenteral agent such as dobutamine may be preferable. The risk attendant to treatment with sympathomimetic drugs is related to the increase in myocardial O\(_2\) consumption that may occur; this is of particular concern in patients with left-heart failure that occurs as a direct consequence of myocardial ischemia. This clinical quandary has become less common in the era of aggressive myocardial revascularization; when it is encountered, coadministration of dobutamine with parenteral nitroglycerin may be necessary.

In CHF patients who are persistently symptomatic or hemodynamically unstable, referral to a specialized tertiary center with expertise in the evaluation
and management of end-stage CHF should be considered. Under these circumstances, resource-intensive treatment, including cardiac resynchronization therapy, mechanical assist devices, high-risk surgical interventions, and cardiac transplantation, may be considered.

Despite the numerous pharmacotherapeutic advances outlined in this chapter, a poor prognosis still remains for patients suffering from severe or end-stage CHF. For these patients, the empathetic initiation of end-of-life discussions may be useful in order to establish appropriate treatment expectations compatible with effective and patient-centered medical care.

Cardiac cells undergo depolarization and repolarization to form cardiac action potentials ~60 times/minute. The shape and duration of each action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and the genes encoding most of these proteins now have been identified. Thus, each heartbeat results from the highly integrated electrophysiologic behavior of multiple proteins on multiple cardiac cells. Ion channel function can be perturbed by inherited mutation/polymorphism, acute ischemia, sympathetic stimulation, or myocardial scarring to create abnormalities of cardiac rhythm, or arrhythmias. Available anti-arrhythmic drugs suppress arrhythmias by blocking flow through specific ion channels or by altering autonomic function. An increasingly sophisticated understanding of the molecular basis of normal and abnormal cardiac rhythm may lead to identification of new targets for anti-arrhythmic drugs and perhaps improved therapies.

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. Mechanisms underlying cardiac arrhythmias have been identified in cellular and animal experiments. In some human arrhythmias, precise mechanisms are known, and treatment can be targeted specifically against those mechanisms. In other cases, mechanisms can be only inferred, and the choice of drugs is based largely on the results of prior experience. Anti-arrhythmic drug therapy can have two goals: termination of an ongoing arrhythmia or prevention of an arrhythmia. Unfortunately, anti-arrhythmic drugs not only help to control arrhythmias but also can cause them, especially during long-term therapy. Thus, prescribing anti-arrhythmic drugs requires that precipitating factors be excluded or minimized, that a precise diagnosis of the type of arrhythmia (and its possible mechanisms) be made, that the prescriber has reason to believe that drug therapy will be beneficial, and that the risks of drug therapy can be minimized.

**PRINCIPLES OF CARDIAC ELECTROPHYSIOLOGY**

The flow of ions across cell membranes generates the currents that make up cardiac action potentials. The factors that determine the magnitude of individual currents and their modulation by drugs can be explained at the cellular and molecular levels (Priori et al., 1999; Nerbonne and Kass, 2005). However, the action potential is a highly integrated entity wherein changes in one current almost inevitably produce secondary changes in other currents. Most anti-arrhythmic drugs affect more than one ion current, and many exert ancillary effects such as modification of cardiac contractility or autonomic nervous system function. Thus, anti-arrhythmic drugs usually exert multiple actions and can be beneficial or harmful in individual patients (Roden, 1994; Priori et al., 1999).

**The Cardiac Cell at Rest: a K⁺-permeable membrane**

Ions move across cell membranes in response to electrical and concentration gradients, not through the lipid bilayer but through specific ion channels or transporters. The normal cardiac cell at rest maintains a transmembrane potential ~80-90 mV negative to the exterior; this gradient is established by pumps, especially the Na⁺, K⁺-ATPase, and fixed anionic charges within cells. There are both an electrical and a concentration gradient that would move Na⁺ ions into resting cells (Figure 29–1). However, Na⁺ channels, which allow Na⁺ to move along this gradient, are closed at negative transmembrane potentials, so Na⁺ does not enter normal resting cardiac cells. In contrast, a specific type of K⁺ channel protein (the inward rectifier channel) is in an open conformation at negative potentials. Hence, K⁺ can move through these channels across the cell membrane at negative potentials in response to either electrical or concentration gradients (Figure 29–1). For each individual ion, there is an equilibrium potential $E_x$ at which there is no net driving force for...
Inward rectifier K⁺ channels are open at a resting cardiac cell and thus not enter the cell despite a large net driving force because Na⁺ does not enter the cell. In contrast, Na⁺ does not enter the cell despite a large net driving force because Na⁺ channel proteins are in the closed conformation.

The changes in transmembrane potential generated by the inward Na⁺ current produce, in turn, a series of openings (and in some cases subsequent inactivation) of other channels (Figure 29–3). For example, when a cell is depolarized by the Na⁺ current, "transient outward" K⁺ channels quickly change conformation to enter a voltage-sensing domain, a selectivity filter, a conducting pore, and often an inactivating particle. In response to changes in local transmembrane potential, ion channels undergo conformational changes allowing for, or preventing, the flow of ions through the conducting pore along their electrochemical gradient (Figure 29–2).

To initiate an action potential, a cardiac myocyte at rest is depolarized above a threshold potential, usually via gap junctions by a neighboring myocyte. Upon membrane depolarization, Na⁺ channel proteins change conformation from the "closed" (resting) state to the "open" (conducting) state (Figure 29–2, allowing up to $10^7$ Na⁺ ions/sec to enter each cell and moving the transmembrane potential toward $E_{Na}$ (+65 mV)). This surge of Na⁺ ions lasts only about a millisecond, after which the Na⁺ channel protein rapidly changes conformation from the "open" state to an "inactivated," non-conducting state (Figure 29–2). The maximum upstroke slope of phase 0 (dV/dt$_{max}$ or $V_{max}$) of the action potential (Figure 29–3) is largely governed by Na⁺ current and plays a role in the conduction velocity of a propagating action potential. Under normal conditions, Na⁺ channels, once inactivated, cannot reopen until they reassume the closed conformation. However, a small population of Na⁺ channels may continue to open during the action potential plateau in some cells (Figure 29–3), providing further inward current. Certain mutations in the cardiac isoform of the Na⁺ channel can further increase the number of channels that do not properly inactivate, thereby prolonging the action potential, and cause one form of the congenital long QT syndrome (Keating and Sanguinetti, 2001). In general, however, as the cell membrane repolarizes, the negative membrane potential moves Na⁺ channel proteins from inactivated to "closed" conformations. The relationship between Na⁺ channel availability and transmembrane potential is an important determinant of conduction and refractoriness in many cells, as discussed in the following discussion.

The changes in transmembrane potential generated by the inward Na⁺ current produce, in turn, a series of openings (and in some cases subsequent inactivation) of other channels (Figure 29–3). For example, when a cell is depolarized by the Na⁺ current, "transient outward" K⁺ channels quickly change conformation to enter an open, or conducting, state; because the transmembrane potential at the end of phase 0 is positive to $E_K$, the opening of transient outward channels results in an outward, or repolarizing, K⁺ current.

**The Cardiac Action Potential**

Transmembrane current through voltage-gated ion channels is the primary determinant of cardiac action potential morphology and duration. Channels are macromolecular complexes consisting of a pore-forming α subunit, as well as β subunits and further accessory proteins. These channels are transmembrane proteins consisting of
Multiple types of Ca\(^{2+}\) current, transient outward current (termed \(I_{TO}\)), which contributes to the phase 1 “notch” seen in action potentials from these tissues. Transient outward K\(^{+}\) channels, like Na\(^{+}\) channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through Ca\(^{2+}\) channels, are balanced by outward, repolarizing currents primarily through K\(^{+}\) (“delayed-rectifier”) channels. Delayed-rectifier currents (collectively termed \(I_{K}\)) increase with time, whereas Ca\(^{2+}\) currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na\(^{+}\) channel opening. Mutations in the genes encoding repolarizing K\(^{+}\) channels are responsible for the most common forms of the congenital long QT syndrome (Nerbonne and Kass, 2005). Identification of these specific channels has allowed more precise characterization of the pharmacologic effects of anti-arrhythmic drugs. A common mechanism whereby drugs prolong cardiac action potentials and provoke arrhythmias is inhibition of a specific delayed-rectifier current, \(I_{Kr}\), generated by expression of the human ether-a-go-go-related gene (HERG). The ion channel protein generated by HERG expression differs from other ion channels in important structural features that make it much more susceptible to drug block; understanding these structural constraints is an important first step to designing drugs lacking \(I_{Kr}\)-blocking properties (Mitcheson et al., 2000). Avoiding \(I_{Kr}/HERG\) channel block has become a major issue in the development of new anti-arrhythmic drugs (Roden, 2004).

**Action Potential Heterogeneity in the Heart**

The diversity of action potentials seen throughout different regions of the heart plays a role in understanding the pharmacologic profiles of anti-arrhythmic drugs. This general description of the action potential and the currents that underlie it must be modified for certain cell types (Figure 29–4), primarily due to variability in the expression of ion channels and electrogenic ion transport pumps. In the ventricle, action potential duration (APD) and shape vary across the wall of each chamber, as well as apico-basally (Figure 29–4). In the neighboring His–Purkinje system, action potentials are characterized by a more hyperpolarized plateau potential and prolongation of the action potential due to divergent ion channel expression and differences in intercellular Ca\(^{2+}\) handling (Dun and Boyden, 2008). Atrial cells have short action potentials, probably because \(I_{TO}\) is larger, and an additional repolarizing K\(^{+}\) current, activated by the neurotransmitter acetylcholine, is present. As a result, vagal stimulation further shortens atrial action potentials. Cells of the sinus and atrioventricular (AV) nodes lack substantial Na\(^{+}\) currents, and depolarization is achieved by the movement of Ca\(^{2+}\) across the membrane. In addition, these cells, as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4 depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart. Several ionic channels and transport pumps underlie pacemaker currents in the heart.

One of the pacemaking currents responsible for this automaticity is generated via specialized K\(^{+}\) channels, the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels that are permeable to both potassium and sodium (Cohen and Robinson, 2006). Another major mechanism responsible for automaticity is the repetitive spontaneous Ca\(^{2+}\) release from the sarcoplasmic reticulum (SR), a specialized endoplasmic reticulum found in striated muscle cells (Vinogradova and Lakatta, 2009). The rise in cytosolic Ca\(^{2+}\) causes membrane depolarizations when Ca\(^{2+}\) is extruded from the cell via the electrogenic Na-Ca exchanger (NCX). In addition, sinus node cells lack inward rectifier K\(^{+}\) currents that are primarily responsible for protecting working myocardium against spontaneous membrane depolarizations.

Molecular biologic and electrophysiologic techniques have refined the description of ion channels important for the normal functioning of cardiac cells and have identified channels that may be particularly important under pathologic conditions. For example, the transient outward and delayed-rectifier currents actually result from multiple ion channel subtypes (Tseng and Hoffman, 1989; Sanguinetti and Jurkiewicz, 1990) (Figure 29–3).
The acetylcholine-evoked hyperpolarization results from activation of a K⁺ channel formed by hetero-oligomerization of multiple, distinct channel proteins (Krapivinsky et al., 1995). The understanding that molecularly diverse entities subserve regulation of the cardiac action potential is important because drugs may target one channel subtype selectively. Furthermore, ancillary function-modifying proteins (the products of diverse genes) have been identified for most ion channels.

**Maintenance of Intracellular Ion Homeostasis**

With each action potential, the cell interior gains Na⁺ ions and loses K⁺ ions. An ATP-requiring Na⁺–K⁺ exchange mechanism, or pump, is activated in most cells to maintain intracellular homeostasis. This Na⁺,K⁺-ATPase extrudes three Na⁺ ions for every two K⁺ ions shuttled from the exterior of the cell to the interior; as a result, the act of pumping itself generates a net outward (repolarizing) current.

Normally, basal intracellular Ca²⁺ is maintained at very low levels (<100 nM). In cardiac myocytes, the entry of Ca²⁺ during each action potential through L-type Ca²⁺ channels is a signal to the sarcoplasmic reticulum to release its Ca²⁺ stores. The efflux of Ca²⁺ from the sarcoplasmic reticulum occurs through ryanodine-receptor (RyR2) Ca²⁺ release channels, and the resulting increase in intracellular Ca²⁺ subsequently triggers Ca²⁺-dependent contractile processes (= excitation-contraction coupling). Removal of intracellular Ca²⁺ occurs by both Ca²⁺-ATPase (which moves Ca²⁺ ions back into the sarcoplasmic reticulum) and NCX, which exchanges three Na⁺ ions from the exterior for each Ca²⁺ ion extruded. Abnormal regulation of intracellular Ca²⁺ is increasingly well described in heart failure and contributes to arrhythmias in this setting. Furthermore, mutations that disrupt the normal activity of the RyR2 channels and the cardiac isoform of calsequestrin have been linked to catecholaminergic polymorphic ventricular tachycardia (CPVT), thereby demonstrating a direct link between spontaneous sarcoplasmic reticulum Ca²⁺ release and cardiac arrhythmias (Mohamed et al., 2007). Inhibiting RyR2 channels with flecainide appears to prevent CPVT in mouse models and in humans (Watanabe et al., 2009). Thus, in both CPVT and heart disease, the cardiac ryanodine receptor has become an intriguing target for future anti-arrhythmic drug therapies.

**Impulse Propagation and the Electrocardiogram**

Normal cardiac impulses originate in the sinus node. Impulse propagation in the heart depends on two factors: the magnitude of the depolarizing current (usually Na⁺ current) and the geometry of cell–cell electrical connections. Cardiac cells are relatively long and thin and well coupled through specialized gap junction proteins at their ends, whereas lateral (“transverse”) gap junctions are sparser.
As a result, impulses spread along cells two to three times faster than across cells. This “anisotropic” (direction-dependent) conduction may be a factor in the genesis of certain arrhythmias described later (Priori et al., 1999). Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the surface electrocardiogram (ECG; Figure 29–4). Propagation slows markedly through the A V node, where the inward current (through Ca2+ channels) is much smaller than the Na+ current in atria, ventricles, or the subendocardial conducting system. This conduction delay allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output. Once impulses exit the AV node, they enter the conducting system, where Na+ currents are larger than elsewhere and propagation is correspondingly faster, up to 0.75 m/s longitudinally. Activation spreads from the His–Purkinje system on the endocardium of the ventricles throughout the rest of the ventricles, stimulating coordinated ventricular contraction. This electrical activation manifests itself as the QRS complex on the ECG. Due to the aforementioned heterogeneity in ventricular APDs, the T wave of the ECG, which represents ventricular repolarization, is broader than the QRS complex and of opposite polarity to what one would expect if repolarization directly followed activation.

The ECG can be used as a rough guide to some cellular properties of cardiac tissue (Figure 29–4):

- Heart rate reflects sinus node automaticity.
- PR-interval duration reflects A V nodal conduction time.
- QRS duration reflects conduction time in the ventricle.
- The QT interval is a measure of ventricular APD.

Refractoriness and Conduction Failure

In atrial, ventricular, and His–Purkinje cells, if a single action potential is restimulated very early during the plateau, no Na+ channels are available to open, so no inward current results, and no action potential is generated: At this point, the cell is termed refractory (Figure 29–5). On the other hand, if a stimulus occurs after the cell has repolarized completely, Na+ channels have recovered from inactivation, and a normal Na+ channel–dependent upstroke results with the same amplitude as the previous upstroke (Figure 29–5A). When a stimulus occurs during phase 3 of the action potential, the upstroke of the premature action potential is slower and of smaller magnitude. The magnitude depends on the number of Na+ channels that have recovered from inactivation (Figure 29–5B). The recovery from inactivation is faster at more hyperpolarized membrane potentials. Thus, refractoriness is determined by the voltage-dependent recovery of Na+ channels from inactivation. Refractoriness is frequently measured by assessing whether premature stimuli applied to tissue preparations (or the whole heart) result in propagated impulses. Although the magnitude of the Na+ current is one major determinant of propagation of premature beats, cellular geometry also is important in multicellular preparations. Propagation from cell to cell requires current flow from the first site of activation and consequently can fail if inward current is insufficient to drive activation in many neighboring cells. The effective refractory period (ERP) is the longest interval at which a premature stimulus fails to generate a propagated response and often is used to describe drug effects in intact tissue.

The situation is different in tissue whose depolarization is largely controlled by Ca2+ channel current such as the AV node. As Ca2+ channels have a slower recovery from inactivation, these tissues often are referred to as slow response, in contrast to fast response in the remaining cardiac tissues (Figure 29–5C). Even after a Ca2+ channel–dependent action potential has repolarized to its initial resting potential, not all Ca2+ channels are available for re-excitation. Therefore, an extra stimulus applied shortly after repolarization is complete and generates a reduced Ca2+ current, which may propagate slowly to adjacent cells prior to extinction. An extra stimulus applied later will result in a larger Ca2+ current and faster propagation. Thus, in Ca2+ channel–dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is prolonged and propagation occurs slowly. Conduction that exhibits such dependence on the timing of premature stimuli is termed decremental. Slow conduction in the heart, a critical factor in the genesis of re-entrant arrhythmias (see next section), also can occur when Na+ currents are depressed by disease or membrane depolarization (e.g., elevated [K+]o), resulting in decreased steady-state Na+ channel availability (Figure 29–5B).

Figure 29–5. Qualitative differences in responses of nodal and conducting tissues to premature stimuli. A. With a very early premature stimulus (black arrow) in ventricular myocardium, all Na+ channels still are in the inactivated state, and no upstroke results. As the action potential repolarizes, Na+ channels recover from the inactivated to the resting state, from which opening can occur. The phase 0 upstroke slope of the premature action potentials (purple) are greater with later stimuli because recovery from inactivation is voltage dependent. B. The relationship between transmembrane potential and degree of recovery of Na+ channels from inactivation. The dotted line indicates 25% recovery. Most Na+ channel–blocking drugs shift this relationship to the left. C. In nodal tissues, premature stimuli delivered even after full repolarization of the action potential are depressed; recovery from inactivation is time dependent.
MECHANISMS OF CARDIAC ARRHYTHMIAS

When the normal sequence of impulse initiation and propagation is perturbed, an arrhythmia occurs. Failure of impulse initiation, in the sinus node, may result in slow heart rates (bradyarrhythmias), whereas failure in the normal propagation of action potentials from atrium to ventricle results in dropped beats (commonly referred to as heart block) that usually reflect an abnormality in either the AV node or the His–Purkinje system. These abnormalities may be caused by drugs (Table 29–1) or by structural heart disease; in the latter case, permanent cardiac pacing may be required.

Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with anti-arrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and re-entry. These often are interrelated mechanisms, as the first two often serve to initiate re-entry.

Enhanced Automaticity

Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His–Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and so accelerate pacemaker rate, whereas acetylcholine reduces pacemaker rate both by decreasing phase 4 slope and through hyperpolarization (making the maximum diastolic potential more negative). In addition, automatic behavior may occur in sites that ordinarily lack spontaneous pacemaker activity; for example, depolarization of ventricular cells (e.g., by ischemia) may produce “abnormal” automaticity. When impulses propagate from a region of enhanced normal or abnormal automaticity to excite the rest of the heart, more complex arrhythmias may result from the induction of functional re-entry.

Afterdepolarizations and Triggered Automaticity

Under some pathophysiologic conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization (Figure 29–6). If this abnormal depolarization reaches threshold, it may, in turn, give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or “triggering,” upstroke and so are termed triggered rhythms.

Two major forms of triggered rhythms are recognized. In the first case, under conditions of intracellular or sarcoplasmic reticulum Ca²⁺ overload (e.g., myocardial ischemia, adrenergic stress, digitalis intoxication, heart failure), a normal action potential may be followed by a delayed afterdepolarization (DAD; Figure 29–6A). If this afterdepolarization reaches threshold, a secondary triggered beat or beats may occur. DAD amplitude is increased in vitro by rapid pacing, and clinical arrhythmias thought to correspond to DAD-mediated triggered beats are more frequent when the underlying cardiac rate is rapid (Priori et al., 1999). DADs are also responsible for exercise-induced ventricular tachycardia in congenital CPVT syndrome caused by mutations in RyR channels (Knollmann and Roden, 2008). In the second type of triggered activity, the key abnormality is marked prolongation of the cardiac action potential. When this occurs, phase 3 repolarization may be interrupted by an early afterdepolarization (EAD; Figure 29–6B). EAD-mediated triggering in vitro and clinical arrhythmias are most common when the underlying heart rate is slow, extracellular K⁺ is low, and certain drugs that prolong APD (anti-arrhythmics and others) are present. EAD-related triggered upstrokes probably reflect inward current through Na⁺ or Ca²⁺ channels. EADs are induced much more readily in Purkinje cells than in epicardial or endocardial cells. When cardiac repolarization is markedly prolonged, polymorphic ventricular tachycardia with a long QT interval, known as the torsades de pointes syndrome, may occur. This arrhythmia is thought to be caused by EADs, which trigger functional re-entry (discussed in the following discussion) owing to heterogeneity of APDs across the ventricular wall (Priori et al., 1999). Congenital long QT syndrome, a disease in which torsades de pointes is common, can most often be caused by mutations in the genes encoding the Na⁺ channels or the channels underlying the repolarizing currents Iₖr and Iₖs (Nerbonne and Kass, 2005).

Re-entry

Re-entry occurs when a cardiac impulse travels in a path such as to return to its original site and reactivate the original site and self-perpetuate rapid activation independent of the normal sinus node conduction. This abnormal activation path (or re-entrant circuit) requires anisotropic conduction slowing (or failure) due to either an anatomic or functional barrier.

Anatomically Defined Re-entry. Re-entry can occur when impulses propagate by more than one pathway

between two points in the heart, and those pathways have heterogeneous electrophysiologic properties. Patients with Wolff–Parkinson–White (WPW) syndrome have accessory connections between the atrium and ventricle (Figure 29–7). With each sinus node depolarization, impulses can excite the ventricle via the normal structures (A V node) or the accessory pathway. However, the electrophysiologic properties of the A V node and accessory pathways are different: Accessory pathways usually consist of non-nodal tissue and consequently vastly differ in refractoriness with the A V node. Thus, with a premature atrial beat, conduction may fail in the accessory pathway but continue, albeit slowly, in the A V node and then through the His–Purkinje system; there, the propagating impulse may encounter the ventricular end of the accessory pathway when it is no longer refractory. The likelihood that the accessory pathway is no longer refractory increases as A V nodal conduction slows. When the impulse re-enters the atrium, it then can re-enter the ventricle via the A V node, re-enter the atrium via the accessory pathway, and so on (Figure 29–7). Re-entry of this type, referred to as A V re-entrant tachycardia, is determined by:

- the presence of an anatomically defined circuit
- heterogeneity in refractoriness among regions in the circuit
- slow conduction in one part of the circuit

Similar “anatomically defined” re-entry commonly occurs in the region of the A V node (A V nodal re-entrant tachycardia) and in the atrium (atrial flutter). The term paroxysmal supraventricular tachycardia (PSVT) includes both A V re-entry and A V nodal re-entry, which share many clinical features.

The primary therapy for anatomically defined re-entry is radiofrequency ablation, as its consistent pathway (or automatic foci) often makes it possible to identify and ablate critical segments of this pathway, effectively curing the patient and obviating the need for long-term drug therapy. Radiofrequency ablation is carried out through a catheter advanced to the interior of the heart and requires minimal convalescence.

Functionally Defined Re-entry. Re-entry also may occur in the absence of a distinct, anatomically defined pathway (Figure 29–8). For example, a premature beat (from an EAD or DAD) from within the ventricular wall may experience refractory tissue in only one direction, allowing for conduction throughout the rest of the wall until the originally refractory area recovers, re-excites, and then propagates back through the original location of the premature beat. Another example is...
localized ischemia or other electrophysiologic perturbations that result in an area of sufficiently slow conduction in the ventricle that impulses exiting from that area, find the rest of the myocardium re-excitable in which case re-entry may ensue. Atrial or ventricular fibrillation (VF) is an extreme example of “functionally defined” (or “leading circle”) re-entry: Cells are re-excited as soon as they are repolarized sufficiently to allow enough Na+ channels to recover from inactivation. The abnormal activation pathway subsequently provides abnormal spatial heterogeneity of repolarization that can cause other re-entrant circuits to form; this perpetuates until neither organized activation patterns nor coordinated contractile activity is present.

Common Arrhythmias and Their Mechanisms

The primary tool for diagnosis of arrhythmias is the ECG. More sophisticated approaches sometimes are used, such as recording from specific regions of the heart during artificial induction of arrhythmias by specialized pacing techniques. Table 29–2 lists common arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence. Examples of some arrhythmias discussed here are shown in Figure 29–9. Some arrhythmias, notably VF, are best treated not with drugs but with direct current (DC) cardioversion—the application of a large electric current across the chest. This technique also can be used to immediately restore normal rhythm in less serious cases; if the patient is conscious, a brief period of general anesthesia is required. Implanted cardioverter–defibrillators (ICDs), devices that are capable of detecting VF and automatically delivering a defibrillating shock, are used increasingly in patients judged to be at high risk for VF. Often drugs are used with these devices if defibrillating shocks, which are painful, occur frequently.

MECHANISMS OF ANTI-ARRHYTHMIC DRUG ACTION

Anti-arrhythmic drugs almost invariably have multiple effects in patients, and their effects on arrhythmias can be complex. A drug can modulate additional targets in addition to its primary mode of action. At the same time, a single arrhythmia may result from multiple underlying mechanisms (e.g., torsades de pointes (Figure 29–9H) can result either from increased Na+ channel late currents or decreased inward rectifier currents). Thus, anti-arrhythmic therapy should be tailored to target the most relevant underlying arrhythmia mechanism. Drugs may be anti-arrhythmic by suppressing the initiating mechanism or by altering the re-entrant circuit. In some cases, drugs may suppress the initiator but nonetheless promote re-entry.

<sup>a</sup>Indicates treatment of choice. *Acute drug therapy is administered intravenously; chronic therapy implies long-term oral use. *AV nodal block can be achieved clinically by adenosine, Ca<sup>2+</sup> channel block, β-adrenergic receptor blockade, or increased vagal tone (a major anti-arrhythmic effect of digitalis glycosides). *Ablation is a procedure in which tissue responsible for the maintenance of a tachycardia is identified by specialized recording techniques and then selectively destroyed, usually by high-frequency radio waves delivered through a catheter placed in the heart. *ICD, implanted cardioverter–defibrillator: a device that can sense VT or VF and deliver pacing and/or cardioverting shocks to restore normal rhythm. *These may be harmful in reentrant VT and so should be used for acute therapy only if the diagnosis is secure. DAD, delayed afterdepolarization; EAD, early afterdepolarization; WPW, Wolff–Parkinson–White syndrome; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation.
Drugs may slow automatic rhythms by altering any of the four determinants of spontaneous pacemaker discharge (Figure 29–10):

- decrease phase 4 slope
- increase threshold potential
- increase maximum diastolic potential
- increase APD

Adenosine and acetylcholine may increase maximum diastolic potential, and β receptor antagonists (see Chapter 12) may decrease phase 4 slope. Blockade of Na⁺ or Ca²⁺ channels usually results in altered threshold, and blockade of cardiac K⁺ channels prolongs the action potential.

Anti-arrhythmic drugs may block arrhythmias owing to DADs or EADs by two major mechanisms:

- inhibition of the development of afterdepolarizations
- interference with the inward current (usually through Na⁺ or Ca²⁺ channels), which is responsible for the upstroke

Thus, arrhythmias owing to digitalis-induced DADs may be inhibited by verapamil (which blocks the development of DAD by reducing Ca²⁺ influx into the cell, thereby decreasing sarcoplasmic reticulum Ca²⁺ load and the likelihood of spontaneous Ca²⁺ release from the sarcoplasmic reticulum) or by quinidine (which blocks Na⁺ channels, thereby elevating the threshold required to produce the abnormal upstroke). Similarly, two approaches are used in arrhythmias related to EAD-triggered beats (Tables 29–1 and 29–2). EADs can be inhibited by shortening APD; in practice, heart rate is accelerated by isoproterenol infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg²⁺, without normalizing repolarization in vitro or QT interval, through mechanisms that are not well understood. In patients with a congenitally prolonged QT interval, torsades de pointes often occurs with adrenergic stress; therapy includes β adrenergic blockade (which does not shorten the QT interval) as well as pacing.
In anatomically determined re-entry, drugs may terminate the arrhythmia by blocking propagation of the action potential. Conduction usually fails in a “weak link” in the circuit. In the example of the WPW-related arrhythmia described earlier, the weak link is the AV node, and drugs that prolong AV nodal refractoriness and slow AV nodal conduction, such as Ca\(^{2+}\) channel blockers, β adrenergic receptor antagonists, or digitalis glycosides, are likely to be effective. On the other hand, slowing conduction in functionally determined re-entrant circuits may change the pathway without extinguishing the circuit. In fact, slow conduction generally promotes the development of re-entrant arrhythmias, whereas the most likely approach for terminating functionally determined re-entry is prolongation of refractoriness (Task Force, 1991). In atrial and ventricular myocytes, refractoriness can be prolonged by delaying the recovery of Na\(^{+}\) channels from inactivation. Drugs that act by blocking Na\(^{+}\) channels generally shift the voltage dependence of recovery from block (Figure 29–5B) and so prolong refractoriness (Figure 29–11).

Drugs that increase APD without direct action on Na\(^{+}\) channels (e.g., by blocking delayed-rectifier currents) also will prolong refractoriness (Figure 29–11). Particularly in sinoatrial or AV nodal tissues, Ca\(^{2+}\) channel blockade prolongs refractoriness. Drugs that interfere with cell–cell coupling also theoretically should increase refractoriness in multicellular preparations; amiodarone may exert this effect in diseased tissue (Levine et al., 1988). Acceleration of conduction in an area of slow conduction also could inhibit re-entry; lidocaine may exert such an effect, and peptides that suppress

![Figure 29–10. Four ways to reduce the rate of spontaneous discharge. The blue horizontal line represents threshold potential.](image)

**Figure 29–10. Four ways to reduce the rate of spontaneous discharge.** The blue horizontal line represents threshold potential.

![Figure 29–11. Two ways to increase refractoriness.](image)

**Figure 29–11. Two ways to increase refractoriness.** In this figure, the black dot indicates the point at which a sufficient number of Na\(^{+}\) channels (an arbitrary 25%; see Figure 29–5B) have recovered from inactivation to allow a premature stimulus to produce a propagated response in the absence of a drug. Block of Na\(^{+}\) channels (A) shifts voltage dependence of recovery (see Figure 29–5B) and so delays the point at which 25% of channels have recovered (red diamond), prolonging refractoriness. Note that if the drug also dissociates slowly from the channel (see Figure 29–12), refractoriness in fast-response tissues actually can extend beyond full repolarization (“postrepolarization refractoriness”). Drugs that prolong the action potential (B) also will extend the point at which an arbitrary percentage of Na\(^{+}\) channels have recovered from inactivation, even without directly interacting with Na\(^{+}\) channels. ERP, effective refractory period.
experimental arrhythmias by increasing gap junction conductance have been described.

**State-Dependent Ion Channel Block**

Recent advances have elucidated the structural and molecular determinants of ion channel permeation and drug block. This information has begun to play an increasing role in analyzing the actions of available and new anti-arrhythmic compounds (MacKinnon, 2003). A key concept is that ion channel-blocking drugs bind to specific sites on the ion channel proteins to modify function (e.g., decrease current) and that the affinity of the ion channel protein for the drug on its target site will vary as the ion channel protein shuttles among functional conformations (or ion channel “states”; see Figure 29–2). Physicochemical characteristics, such as molecular weight and lipid solubility, are important determinants of state-dependent binding. State-dependent binding has been studied most extensively in the case of Na⁺ channel-blocking drugs. Most useful agents of this type block open and/or inactivated Na⁺ channels and have very little affinity for channels in the resting state. Most Na⁺ channel blockers bind to a local anesthetic binding site in the pore of Nav1.5, and drug affinity is reduced with mutation to critical residues in the pore (Fozzard et al., 2005). Thus, with each action potential, drugs bind to Na⁺ channels and block them, and with each diastolic interval, drugs dissociate, and the block is released.

As illustrated in Figure 29–12, the dissociation rate is a key determinant of steady-state block of Na⁺ channels. When heart rate increases, the time available for dissociation decreases, and steady-state Na⁺ channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia. This explains the finding that Na⁺ channel blockers depress Na⁺ current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open versus inactivated-state block also may be important in determining the effects of some drugs. Increased APD, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine or amiodarone.

The rate of recovery from block often is expressed as a time constant ($\tau_{\text{recovery}}$, the time required for ~63% of an exponentially determined process to be complete; Courtney, 1987). In the case of drugs such as lidocaine, $\tau_{\text{recovery}}$ is so short (<1 s) that recovery from block is very rapid, and substantial Na⁺ channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as flecainide have such long $\tau_{\text{recovery}}$ values (>10 s) that roughly the same number of Na⁺ channels is blocked during systole and diastole. As a result, marked slowing of conduction occurs even in normal tissues at normal rates.

**Classifying Anti-Arrhythmic Drugs**

Classifying drugs by common electrophysiologic properties emphasizes the connection between basic electrophysiologic actions and anti-arrhythmic effects (Vaughan Williams, 1992). To the extent that the clinical actions of drugs can be predicted from their basic electrophysiologic properties, such classification schemes have merit. However, as each compound is

---

**Figure 29–12. Recovery from block of Na⁺ channels during diastole.** This recovery is the critical factor determining extent of steady-state Na⁺ channel block. Na⁺ channel blockers bind to (and block) Na⁺ channels in the open and/or inactivated states, resulting in phasic changes in the extent of block during the action potential. As shown in the middle panel, a decrease in the rate of recovery from block increases the extent of block. Different drugs have different rates of recovery, and depolarization reduces the rate of recovery. The right panel shows that increasing heart rate, which results in relatively less time spent in the rest state, also increases the extent of block. (Modified from Roden et al., 1993, with permission from Wiley-Blackwell Publishing.)
better characterized in a range of in vitro and in vivo test systems, it becomes apparent that differences in pharmacologic effects occur even among drugs that share the same classification, some of which may be responsible for the observed clinical differences in responses to drugs of the same broad “class” (Table 29–3). An alternative way of approaching anti-arrhythmic therapy is to classify arrhythmia mechanisms and then to target drug therapy to the electrophysiologic mechanism most likely to terminate or prevent the arrhythmia (Task Force, 1991) (Table 29–2). Most recently, a genetic framework of arrhythmia mechanisms has been suggested as a new approach for classifying anti-arrhythmic drug therapy (Knollmann and Roden, 2008).

**Na+ Channel Block.** The extent of Na+ channel block depends critically on heart rate and membrane potential, as well as on drug-specific physicochemical characteristics that determine τ_recovery (Figure 29–12). The following description applies when Na+ channels are blocked (i.e., at rapid heart rates in diseased tissue with a rapid-recovery drug such as lidocaine or even at normal rates in normal tissues with a slow-recovery drug such as flecainide). When Na+ channels are blocked, threshold for excitability is decreased (i.e., greater membrane depolarization is required to open enough Na+ channels to overcome K+ currents at the resting membrane potential and elicit an action potential). This change in threshold probably contributes to the clinical findings that Na+ channel blockers tend to increase both pacing threshold and the energy required to defibrillate the fibrillating heart (Echt et al., 1989). These deleterious effects may be important if anti-arrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na+ channel block decreases conduction velocity in non-nodal tissue and increases QRS duration. Usual doses of flecainide prolong QRS intervals by 25% or more during normal rhythm, whereas lidocaine increases QRS intervals only at very fast heart rates. Drugs with τ_recovery values greater than 10 s (e.g., flecainide) also tend to prolong the PR interval; it is not known whether this represents additional Ca2+ channel block (see “Ca2+ Channel Block”) or block of fast-response tissue in the region of the AV node. Drug effects on the PR interval also are highly modified by autonomic effects. For example, quinidine actually tends to shorten the PR interval largely as a result of its vagolytic properties. Action potential duration either is unaffected or shortened by Na+ channel block; some Na+ channel–blocking drugs do prolong cardiac action potentials but by other mechanisms, usually K+ channel block (Table 29–3).

By increasing threshold, Na+ channel block decreases automaticity (Figure 29–10B) and can inhibit triggered activity arising from DADs or EADs. Many Na+ channel blockers also decrease phase 4 slope (Figure 29–10A). In anatomically defined re-entry, Na+ channel blockers may decrease conduction sufficiently to extinguish the propagating re-entrant wavefront. However, as described earlier, conduction slowing owing to Na+ channel block may exacerbate re-entry.

Block of Na+ channels also shifts the voltage dependence of recovery from inactivation (Figure 29–5B) to more negative potentials, thereby tending to increase refactoriness. Thus, whether a given drug exacerbates or suppresses re-entrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular re-entrant circuit. Lidocaine and mexiletine have short τ_recovery values and are not useful in atrial fibrillation or flutter, whereas quinidine, flecainide, propafenone, and similar agents are effective in some patients. Many of these agents owe part of their antiarrhythmic activity to blockade of K+ channels.

**Late Na+ Channel Current Block.** The long QT syndrome variant 3 (LQT3) is characterized by late inward Na+ current caused by defects in the inactivation of the cardiac isoform of the Na+ channel. This late current prolongs the APD and predisposes to arrhythmia. Many drugs with local anesthetic effects, including mexiletine, preferentially block this late current and can be used to successfully treat LQT3 patients. The lessons learned from LQT3 have led to a better understanding of blocking late Na+ current, which may be a more common pathologic condition than previously thought. Recently, a number of animal models of heart failure have been shown to have a similar increase in late Na+ current, and consequently late Na+ blockade is an attractive candidate for anti-arrhythmic drugs in this setting. Interestingly, recent studies have shown the local anesthetic late current blockade is not unique to selective Na+ channel blockers and other drugs bind to the same binding site, including commonly used β adrenergic antagonists (including propranolol) and an anti-anginal therapeutic (ranolazine), preferentially inhibiting late current, which may in turn play a role in their antiarrhythmic utility in both LQT3 and heart failure patients (Fredj et al., 2006; Bankston and Kass, 2010).

**Na+ Channel–Blocker Toxicity.** Conduction slowing in potential re-entrant circuits can account for toxicity of drugs that block the Na+ channel (Table 29–1). For example, Na+ channel block decreases conduction velocity and hence slows atrial flutter rate. Normal AV

✓ Indicates an effect that is important in mediating the clinical action of a drug. (x) Indicates a demonstrable effect whose relationship to drug action in patients is less well established. * Indicates drugs prescribed as racemates, and the enantiomers are thought to exert similar electrophysiologic effects. † Indicates racemates for which clinically relevant differences in the electrophysiologic properties of individual enantiomers have been reported (see text). One approach to classifying drugs is:

<table>

<tr>
<td>IV</td>
<td>Ca(^{2+} ) channel block</td>
</tr>
</tbody>
</table>

Drugs are listed here according to this scheme. It is important to bear in mind, however, that many drugs exert multiple effects that contribute to their clinical actions. It is occasionally clinically useful to subclassify Na\(^{+} \) channel blockers by their rates of recovery from drug-induced block (\( \tau_{\text{RECOVERY}} \)) under physiologic conditions. Because this is a continuous variable and can be modulated by factors such as depolarization of the resting potential, these distinctions can become blurred: class Ib, \( \tau_{\text{RECOVERY}} < 1 \) s; class Ia, \( \tau_{\text{RECOVERY}} 1-10 \) s; class Ic, \( \tau_{\text{RECOVERY}} > 10 \) s. These class and subclass effects are associated with distinctive ECG changes, characteristic “class” toxicities, and efficacy in specific arrhythmia syndromes (see text). † These data are dependent on experimental conditions, including species and temperature. The \( \tau_{\text{RECOVERY}} \) values cited here are from Courtney (1987). O, open-state blocker; I, inactivated-state blocker; APD, action potential duration.
nodal function permits a greater number of impulses to penetrate the ventricle, and heart rate actually may increase (Figure 29–9). Thus, atrial flutter rate may drop from 300/minute, with 2:1 or 4:1 AV conduction (i.e., a heart rate of 150 or 75 beats/minute), to 220 per minute, but with 1:1 transmission to the ventricle (i.e., a heart rate of 220 beats/minute), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common during treatment with quinidine because the drug also increases AV nodal conduction through its vagolytic properties; flecainide and propafenone also have been implicated. Therapy with Na+ channel blockers in patients with re-entrant ventricular tachycardia after a myocardial infarction (MI) can increase the frequency and severity of arrhythmic episodes. Although the mechanism is unclear, slowed conduction allows the re-entrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be very difficult to manage, and deaths owing to intractable drug-induced tachycardia can be very difficult to manage. Such drug-exacerbated arrhythmia can be very difficult to manage, and deaths owing to intractable drug-induced tachycardia have been reported. In this setting, Na+ infusion may be beneficial. Several Na+ channel blockers (e.g., procainamide, quinidine) have been reported to exacerbate neuromuscular paralysis by d-tubocurarine (Chapter 11).

**Action Potential Prolongation.** Most drugs that prolong the action potential do so by blocking K+ channels, although enhanced inward Na+ current also can cause prolongation. Enhanced inward current may underlie QT prolongation (and arrhythmia suppression) by ibutilide. Block of cardiac K+ channels increases APD and reduces normal automaticity (Figure 29–10D). Increased APD, seen as an increase in QT interval, increases refractoriness (Figure 29–11) and therefore should be an effective way of treating re-entry (Task Force, 1991). Experimentally, K+ channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of VF owing to acute ischemia, and increased contractility (Roden, 1993). As shown in Table 29–3, most K+ channel-blocking drugs also interact with β adrenergic receptors (sotalol) or other channels (e.g., amiodarone, quinidine). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na+ channel-blocking properties in both atrial and ventricular arrhythmias. “Pure” action potential–prolonging drugs (e.g., dofetilide, ibutilide) also are available (Murray, 1998; Torp-Pedersen et al., 1999).

**Toxicity of Drugs That Prolong QT Interval.** Most of these agents disproportionately prolong cardiac action potentials when underlying heart rate is slow and can cause *torsades de pointes* (Table 29–1 and Figure 29–9). While this effect usually is seen with QT-prolonging anti-arrhythmic drugs, it can occur more rarely with drugs that are used for noncardiac indications. For such agents, the risk of torsades de pointes may become apparent only after widespread use postmarketing, and recognition of this risk has been a common cause for drug withdrawal (Roden, 2004). Recent research has shown that sex hormones modify cardiac ion channels and help account for the clinically observed increased incidence of drug-induced torsades de pointes in women (Kurokawa et al., 2009).

**Ca2+ Channel Block.** The major electrophysiologic effects resulting from block of cardiac Ca2+ channels are in nodal tissues. Dihydropyridines, such as nifedipine, which are used commonly in angina and hypertension (Chapter 28), preferentially block Ca2+ channels in vascular smooth muscle; their cardiac electrophysiologic effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only verapamil, diltiazem, and bepridil block Ca2+ channels in cardiac cells at clinically used doses. These drugs generally slow heart rate (Figure 29–10A), although hypotension, if marked, can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs as a result of decremental conduction, as well as increased AV nodal refractoriness. These latter effects form the basis of the anti-arrhythmic actions of Ca2+ channel blockers in re-entrant arrhythmias whose circuit involves the AV node, such as AV re-entrant tachycardia (Figure 29–7).

Another important indication for anti-arrhythmic therapy is to reduce ventricular rate in atrial flutter or fibrillation. Rare forms of ventricular tachycardia appear to be DAD-mediated and respond to verapamil (Sung et al., 1983). Parenteral verapamil and diltiazem are approved for rapid conversion of PSVTs to sinus rhythm and for temporary control of rapid ventricular rate in atrial flutter or fibrillation. Oral verapamil may be used in conjunction with digoxin to control ventricular rate in chronic atrial flutter or fibrillation and for prophylaxis of repetitive PSVT. Unlike β adrenergic receptor antagonists, Ca2+ channel blockers have not been shown to reduce mortality after MI (Singh, 1990). In contrast to other Ca2+ channel blockers, bepridil increases APD in many tissues and can exert an anti-arrhythmic effect in atria and ventricles. However, because bepridil can cause torsades de pointes, it is not prescribed widely and has been discontinued in the U.S.
Verapamil and Diltiazem. The major adverse effect of intravenous verapamil or diltiazem is hypotension, particularly with bolus administration. This is a particular problem if the drugs are used mistakenly in patients with ventricular tachycardia (in whom Ca^{2+} channel blockers usually are not effective) misdiagnosed as AV nodal re-entrant tachycardia (Stewart et al., 1986). Hypotension also is frequent in patients receiving other vasodilators, including quinidine, and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block also occurs, especially in susceptible patients, such as those also receiving β blockers. With oral therapy, these adverse effects tend to be less severe. Constipation can occur with oral verapamil.

Verapamil (CALAN, ISOPTIN, VERELAN, COVERA-HS, and others) is prescribed as a racemate. L-Verapamil is a more potent calcium channel blocker than is D-verapamil. However, with oral therapy, the L-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of verapamil prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the L- and D-enantiomers are equivalent) than when administered orally (Echizen et al., 1985). Diltiazem (CARDIZEM, TIAZAC, DILACOR XR, and others) also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca^{2+} channel–blocking actions. In clinical practice, adverse effects during therapy with verapamil or diltiazem are determined largely by underlying heart disease and concomitant therapy; plasma concentrations of these agents are not measured routinely. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with atrial fibrillation.

Blockade of β Adrenergic Receptors. β Adrenergic stimulation increases the magnitude of the Ca^{2+} current and slows its inactivation, increases the magnitude of repolarizing K^+ and Cl^- currents (Sanguinetti et al., 1991), increases pacemaker current (thereby increasing sinus rate; DiFrancesco, 1993), increases the Ca^{2+} stored in the sarcoplasmic reticulum (thereby increasing likelihood of spontaneous Ca^{2+} release and DADs), and under pathophysiologic conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma epinephrine associated with severe stress (e.g., acute MI, resuscitation after cardiac arrest) lower serum K^+, especially in patients receiving chronic diuretic therapy (Brown et al., 1983). β Adrenergic receptor antagonists inhibit these effects and can be anti-arrhythmic by reducing heart rate, decreasing intracellular Ca^{2+} overload, and inhibiting afterdepolarization-mediated automaticity. Epinephrine-induced hypokalemia appears to be mediated by β_2_ adrenergic receptors and is blocked by “noncardioselective” antagonists such as propranolol (Chapter 12). In acutely ischemic tissue, β blockers increase the energy required to fibrillate the heart, an anti-arrhythmic action (Anderson et al., 1983). These effects may contribute to the reduced mortality observed in trials of chronic therapy with β blockers—including propranolol, timolol, and metoprolol—after MI (Singh, 1990). Atenolol and metoprolol have been shown to decrease mortality in the first week following MI.

As with Ca^{2+} channel blockers and digitalis, β blockers increase AV nodal conduction time (increased PR interval) and prolong AV nodal refractoriness; hence, they are useful in terminating re-entrant arrhythmias that involve the AV node and in controlling ventricular response in atrial fibrillation or flutter. In many (but not all) patients with the congenital long QT syndrome, as well as in many other patients, arrhythmias are triggered by physical or emotional stress; β blockers may be useful in these cases (Schwartz et al., 2000). β Adrenergic receptor antagonists also reportedly are effective in controlling arrhythmias Na^+ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na^+ channel block (Myerburg et al., 1989).

Adverse effects of β blockade include fatigue, bronchospasm, hypotension, impotence, depression, aggravation of heart failure, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients (Chapter 12). In patients with arrhythmias owing to excess sympathetic stimulation (e.g., pheochromocytoma, clonidine withdrawal), β blockers can result in unopposed α adrenergic stimulation, with resulting severe hypertension and/or α adrenergic–mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β adrenergic antagonists or with a drug such as labetalol that combines α and β blocking properties. Abrupt discontinuation of chronic β blocker therapy can lead to “rebound” symptoms, including hypertension, increased angina, and arrhythmias; thus, β receptor antagonists are tapered over 2 weeks prior to discontinuation of chronic therapy (Chapters 12 and 25 through 28).

Selected β Adrenergic Receptor Blockers. It is likely that most β adrenergic antagonists share anti-arrhythmic properties. Some, such as propranolol, also exert Na^+ channel–blocking effects at high concentrations. Similarly, drugs with intrinsic sympathomimetic activity may be less useful as anti-arrhythmics, at least in theory (Singh, 1990). Acebutolol is as effective as quinidine in suppressing ventricular ectopic beats, an arrhythmia that many clinicians no longer treat. Sotalol (see later in this chapter) is more effective for...
PRINCIPLES IN THE CLINICAL USE OF ANTI-ARRHYTHMIC DRUGS

Drugs that modify cardiac electrophysiology often have a very narrow margin between the doses required to produce a desired effect and those associated with adverse effects. Moreover, anti-arrhythmic drugs can induce new arrhythmias with possibly fatal consequences. Nonpharmacologic treatments, such as cardiac pacing, electrical defibrillation, or ablation of targeted regions, are indicated for some arrhythmias; in other cases, no therapy is required, even though an arrhythmia is detected. Therefore, the fundamental principles of therapeutics described here must be applied to optimize anti-arrhythmic therapy.

1. Identify and Remove Precipitating Factors

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs. Anti-arrhythmics, including cardiac glycosides, are not the only drugs that can precipitate arrhythmias (Table 29–1). For example, theophylline can cause multifocal atrial tachycardia, which sometimes can be managed simply by reducing the dose of theophylline. Torsades de pointes can arise not only during therapy with action potential–prolonging anti-arrhythmics but also with other drugs not ordinarily classified as having effects on ion channels. These include the antibiotic erythromycin (Chapter 55); the antiprotozoal pentamidine (Chapter 50); some antipsychotics, notably thioridazine, ziprasidone, risperidone, and quetiapine (Chapter 16); some analgesics, notably methadone and celecoxib; some antiemetics (e.g., droperidol, dolasetron); antihistamines such as diphenhydramine; azole antifungals such as voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; and celecoxib; some antiemetics (e.g., droperidol, dolasetron); antihistamines such as diphenhydramine; azole antifungals such as voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; prednisone; cisapride; famotidine; voriconazole and fluconazole; bronchodilators such as albuterol, fomoterol, and salmeterol; Anti-Arrhythmic Drugs Can Cause Arrhythmias. One well-recognized risk of anti-arrhythmic therapy is the possibility of provoking new arrhythmias, with potentially life-threatening consequences. Anti-arrhythmic drugs can provoke arrhythmias by different mechanisms (Table 29–1). These drug-provoked arrhythmias must be recognized because further treatment with anti-arrhythmic drugs often exacerbates the problem, whereas withdrawal of the causative agent often is curative. Thus, establishing a precise diagnosis is critical, and targeting therapies at underlying mechanisms of the arrhythmias may be required. For example, treating a ventricular tachycardia with verapamil not only may be ineffective but also can cause catastrophic cardiovascular collapse (Stewart et al., 1986).

Monitoring of Plasma Concentration. Some adverse effects of anti-arrhythmic drugs result from excessive plasma drug concentrations. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving anti-arrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease (Ruskin, 1989; Roden, 1994). Factors such as generation of unmeasured active metabolites, variability in elimination of enantiomers (which may exert differing pharmacologic effects), and disease- or enantiomer-specific abnormalities in drug binding to plasma proteins can complicate the interpretation of plasma drug concentrations.

Patient-Specific Contraindications. Another way to minimize the adverse effects of anti-arrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. For example, patients with a history of congestive heart failure are particularly prone to develop heart failure during disopyramide therapy. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. Amiodarone may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect. Specific diseases that constitute relative or absolute contraindications to specific drugs are listed in Table 29–4.

3. Minimize Risks

4. Consider the Electrophysiology of the Heart as a “Moving Target”

Cardiac electrophysiology varies dynamically in response to external influences such as changing autonomic tone, myocardial ischemia, and myocardial stretch (Priori et al., 1999). For example, myocardial ischemia results in changes in extracellular K+ that make the resting potential less negative, inactivate Na+ channels, decrease Na+ current, and slow conduction (Weiss et al., 1991). In addition, myocardial ischemia can result in the formation and release of metabolites such as lysophosphatidylcholine, which can alter ion channel function; ischemia also may activate channels that otherwise are quiescent, such as the ATP-inhibited K+ channels. Thus, in response to myocardial ischemia, a normal heart may display changes in resting potential, conduction velocity, intracellular Ca2+ concentrations, and repolarization, any one of which then may create arrhythmias or alter response to anti-arrhythmic therapy.
Antiarhythmic Drugs

Summaries of important electrophysiologic and pharmacokinetic features of the drugs considered here are presented in Tables 29–3 and 29–5, respectively. Ca²⁺ channel blockers and β-adrenergic antagonists are discussed in Chapters 12 and 25 to 28. The drugs are presented in alphabetical order.

Adenosine. Adenosine (ADENOCARD, others) is a naturally occurring nucleoside that is administered as a rapid intravenous bolus for the acute termination of re-entrant supraventricular arrhythmias (Lerman and Belardinelli, 1991). Adenosine also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease. Intravenous ATP appears to produce effects similar to those of adenosine.

Pharmacologic Effects. The effects of adenosine are mediated by its interaction with specific G protein-coupled adenosine receptors. Adenosine activates acetylcholine-sensitive K⁺ current in the atrium and sinus and AV nodes, resulting in shortening of APD, hyperpolarization, and slowing of normal automaticity (Figure 29–10C). Adenosine also inhibits the electrophysiologic effects of increased intracellular cyclic AMP that occur with sympathetic stimulation. Because adenosine thereby reduces Ca²⁺ currents, it can be anti-arrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation.

Administration of an intravenous bolus of adenosine to humans transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of adenosine can produce transient sympathetic activation by interacting with carotid baroreceptors (Biaggioni et al., 1991); a continuous infusion can cause hypotension.

Adverse Effects. A major advantage of adenosine therapy is that adverse effects are short lived because the drug is transported into cells and deaminated so rapidly. Transient asystole (lack of any cardiac rhythm whatsoever) is common but usually lasts less than 5 seconds and is in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6-12 mg) of adenosine are administered. Rarely, an adenosine bolus can precipitate bronchospasm or atrial fibrillation presumably by heterogeneously shortening atrial action potentials.

Clinical Pharmacokinetics. Adenosine is eliminated with a t₁/₂ of seconds by carrier-mediated uptake, which occurs in most cell types, including the endothelium, and subsequent metabolism by adenosine deaminase. Adenosine probably is the only drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration results in elimination of the drug prior to its arrival at the heart.

The effects of adenosine are potentiated in patients receiving dipyridamole, an adenosine uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methylxanthines (Chapter 36) such as theophylline and caffeine block adenosine receptors; therefore, larger than usual doses are required to produce an anti-arrhythmic effect in patients who have consumed these agents in beverages or as therapy.

Amiodarone. Amiodarone (CORDARONE, PACERONE, others) exerts a multiplicity of pharmacologic effects, none of which is clearly linked to its arrhythmia-suppressing properties (Mason, 1987). Amiodarone is a structural analog of thyroid hormone, and some of its anti-arrhythmic actions and its toxicity may be attributable to interaction with nuclear thyroid hormone receptors. Amiodarone is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the U.S., the drug is indicated for oral therapy in patients with recurrent ventricular tachycardia or fibrillation resistant to other drugs. Oral amiodarone also is effective in maintaining sinus rhythm in patients with atrial fibrillation (Connolly, 1999). An intravenous form is indicated for acute termination of ventricular tachycardia or fibrillation (Kowey et al., 1995) and is supplanting lidocaine as first-line therapy for out-of-hospital cardiac arrest (Dorian et al., 2002). Trials of oral amiodarone have shown a modest beneficial effect on mortality after acute MI (Amiodarone Trials Meta-Analysis Investigators, 1997). Despite uncertainties about its mechanisms of action and the potential for serious toxicity, amiodarone now is used very widely in the treatment of common arrhythmias such as atrial fibrillation (Roy et al., 2000).

Pharmacologic Effects. Studies of the acute effects of amiodarone in in vitro systems are complicated by its insolubility in water, necessitating the use of solvents.

✓ Indicates an effect that affects the clinical action of the drug. (x): metabolite or route of elimination probably of minor clinical importance. *The elimination $t_{1/2}$ is one, but not the only, determinant of how frequently a drug must be administered to maintain a therapeutic effect and avoid toxicity (Chapter 2). For some drugs with short elimination half-lives, infrequent dosing is nevertheless possible, e.g., verapamil. Formulations that allow slow release into the GI tract of a rapidly eliminated compound (available for many drugs, including procainamide, disopyramide, verapamil, diltiazem, and propranolol) also allow infrequent dosing. *The therapeutic range is bounded by a plasma concentration below which no therapeutic effect is likely, and an upper concentration above which the risk of adverse effects increases. Many serious adverse reactions to anti-arrhythmic drugs can occur at “therapeutic” concentrations in susceptible individuals. When only an upper limit is cited, a lower limit has not been well defined. Variable generation of active metabolites may further complicate the interpretation of plasma concentration data (Chapter 2). *Oral doses are presented unless otherwise indicated. Doses are presented as suggested ranges in adults of average build; lower doses are less likely to produce toxicity. Lower maintenance dosages may be required in patients with renal or hepatic disease. Loading doses are only indicated when a therapeutic effect is desired before maintenance therapy would bring drug concentrations into a therapeutic range—that is, for acute therapy (e.g., lidocaine, verapamil, adenosine) or when the elimination $t_{1/2}$ is extremely long (amiodarone). *Bioavailability reduced by incomplete absorption. \( ^{\dagger} \) Indicates suggested dosage using slow-release formulation. \( ^{\ddagger} \) This drug is available only in a restricted distribution system (see text). IV, intravenous.
such as dimethyl sulfoxide. Amiodarone’s effects may be mediated by perturbation of the lipid environment of the ion channels (Herbette et al., 1988). Amiodarone blocks inactivated Na⁺ channels and has a relatively rapid rate of recovery (time constant ~1.6 s) from block. It also decreases Ca²⁺ current and transient outward delayed-rectifier and inward rectifier K⁺ currents and exerts a noncompetitive adrenergic blocking effect. Amiodarone potently inhibits abnormal automaticity and, in most tissues, prolongs APD. Amiodarone decreases conduction velocity by Na⁺ channel block and by a poorly understood effect on cell–cell coupling that may be especially important in diseased tissue (Levine et al., 1988). Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na⁺ channel block, delayed repolarization owing to K⁺ channel block, and inhibition of cell–cell coupling all may contribute to this effect.

**Adverse Effects.** Hypotension owing to vasodilation and depressed myocardial performance are due in part to the intravenous form of amiodarone and may be due to the size of the drug and by a poorly understood effect on cell–cell coupling that may be especially important in diseased tissue (Levine et al., 1988). Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na⁺ channel block, delayed repolarization owing to K⁺ channel block, and inhibition of cell–cell coupling all may contribute to this effect.

Adverse Effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose, suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic amiodarone therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/day or more, and recent pulmonary insults such as pneumonia appear to be risk factors (Dusman et al., 1990). Serial chest X-rays or pulmonary function studies may detect early amiodarone toxicity, but monitoring plasma concentrations has not been useful. With low doses, such as 200 mg/day or less used in atrial fibrillation, pulmonary toxicity is unusual. Other adverse effects during long-term therapy include corneal microdeposits (which are asymptomatic), hepatic dysfunction, neuromuscular symptoms (most commonly peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. The multiple effects of amiodarone on thyroid function are discussed further in Chapter 39. Treatment consists of withdrawal of the drug and supportive measures, including corticosteroids, for life-threatening pulmonary toxicity; reduction of dosage may be sufficient if the drug is deemed necessary and the adverse effect is not life-threatening. Despite the marked QT prolongation and bradycardia typical of chronic amiodarone therapy, torsades de pointes and other drug-induced tachyarrhythmias are unusual.

**Clinical Pharmacokinetics.** Amiodarone’s oral bioavailability is ~30%, presumably because of poor absorption. This incomplete bioavailability is important in calculating equivalent dosing regimens when converting from intravenous to oral therapy. The drug is distributed in lipid; e.g., heart-tissue-to-plasma concentration ratios of greater than 20:1 and lipid-to-plasma ratios of greater than 300:1 have been reported. After the initiation of amiodarone therapy, increases in refractoriness, a marker of pharmacologic effect, require several weeks to develop. Amiodarone undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacologic effects similar to those of the parent drug. When amiodarone therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a t₁/₂ of weeks to months. The mechanism whereby amiodarone and desethyl-amiodarone are eliminated is not well established.

A therapeutic plasma amiodarone concentration range of 0.5-2 μg/mL has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity (Dusman et al., 1990). Because of amiodarone’s slow accumulation in tissue, a high-dose oral loading regimen (e.g., 800-1600 mg/day) usually is administered for several weeks before maintenance therapy is started. Maintenance dose is adjusted based on adverse effects and the arrhythmias being treated. If the presenting arrhythmia is life-threatening, dosages of >300 mg/day normally are used unless unequivocal toxicity occurs. On the other hand, maintenance doses of ≤200 mg/day are used if recurrence of an arrhythmia would be tolerated, as in patients with atrial fibrillation. Because of its very slow elimination, amiodarone is administered once daily, and omission of one or two doses during chronic therapy rarely results in recurrence of arrhythmia.

Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. Amiodarone potently inhibits the hepatic metabolism or renal elimination of many compounds. Mechanisms identified to date include inhibition of CYP3A4, CYP2C9 and P-glycoprotein (Chapters 5 and 6). Dosages of warfarin, other anti-arrhythmics (e.g., flecainide, procainamide, quinidine), or digoxin usually require reduction during amiodarone therapy.

**Bretylium.** Bretylium is a quaternary ammonium compound that prolongs cardiac action potentials and interferes with reuptake of noradrenaline by sympathetic neurons. In the past, bretylium was used to treat VF and prevent its recurrence; the drug is currently not available in the U.S.

**Digoxin**

[Diagram of Digoxin]

Digitoxin has H at C12 in place of the OH.
Pharmacologic Effects. Digitalis glycosides exert positive inotropic effects and are used in heart failure (Chapter 28). Their inotropic action results from increased intracellular Ca\(^{2+}\) (Smith, 1988), which also forms the basis for arrhythmias related to cardiac glycoside intoxication. Cardiac glycosides increase phase 4 slope (i.e., increase the rate of automaticity), especially if \([K]\) is low. These drugs (e.g., digoxin) also exert prominent vagotonic actions, resulting in inhibition of Ca\(^{2+}\) currents in the AV node and activation of acetylcholine-mediated K\(^{+}\) currents in the atrium. Thus, the major “indirect” electrophysiologic effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The latter action accounts for the utility of digoxin in terminating re-entrant arrhythmias involving the AV node and in controlling ventricular response in patients with atrial fibrillation. Cardiac glycosides may be especially useful in the latter situation because many such patients have heart failure, which can be exacerbated by other AV nodal blocking drugs such as Ca\(^{2+}\) channel blockers or β adrenergic receptor antagonists. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so digitalis is not very effective in decreasing the rate; on the other hand, even a modest decrease in rate can ameliorate heart failure. Similarly, in other conditions in which high sympathetic tone drives rapid AV conduction (e.g., chronic lung disease, thyrotoxosis), digitalis therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate digitalis-induced changes in automaticity and DADs, thus increasing the risk of digitalis toxicity. A further complicating feature in thyrotoxicosis is increased digoxin clearance. The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization (manifested by depression of the ST segment), whose underlying mechanism is not well understood.

Adverse Effects. Because of the low therapeutic index of cardiac glycosides, their toxicity is a common clinical problem (Chapter 28). Arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision are the usual manifestations. Elevated serum concentrations of digitalis, hypoxia (e.g., owing to chronic lung disease), and electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, hypercalcemia) predispose patients to digitalis-induced arrhythmias. Although digitalis intoxication can cause virtually any arrhythmia, certain types of arrhythmias are characteristic. Arrhythmias that should raise a strong suspicion of digitalis intoxication are those in which DAD-related tachycardias occur along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), “bidirectional” ventricular tachycardia (a very rare entity), AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (e.g., with suicidal ingestion), severe hyperkalemia owing to poisoning of Na\(^{+}\),K\(^{-}\)-ATPase and profound bradycardias, which may be unresponsive to pacing therapy, are seen. In patients with elevated serum digitalis levels, the risk of precipitating VF by DC cardioversion probably is increased; in those with therapeutic blood levels, DC cardioversion can be used safely.

Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous atropine, but the effect is transient. Mg\(^{2+}\) has been used successfully in some cases of digitalis-induced tachycardia. Any serious arrhythmia should be treated with antidigoxin Fab fragments (DIGIBIND, DIGIFAB), which are highly effective in binding digoxin and digitoxin and greatly enhance their renal excretion (Chapter 28). Serum glycoside concentrations rise markedly with antidigalistics antibodies, but these represent bound (pharmacologically inactive) drug. Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. Digitalis exerts direct arterial vasoconstrictor effects, which can be especially deleterious in patients with advanced atherosclerosis who receive intravenous drug: mesenteric and coronary ischemia have been reported.

Clinical Pharmacokinetics. The only digitalis glycoside used in the U.S. is digoxin (LANOXIN). Digitoxin (various generic preparations) also is used for chronic oral therapy outside the U.S. Digoxin tablets are incompletely (75%) bioavailable. In some patients, intestinal microflora may metabolize digoxin, markedly reducing bioavailability. In these patients, higher than usual doses are required for clinical efficacy: toxicity is a serious risk if antibiotics that destroy intestinal microflora are administered. Inhibition of P-glycoprotein (see “Adverse effects and Drug Interactions” under “Dronaderone”) also may play a role in cases of toxicity. Digoxin is 20-30% protein bound. The anti-arrhythmic effects of digoxin can be achieved with intravenous or oral therapy. However, digoxin undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable anti-arrhythmic effects such as PR-interval prolongation or slowing of the ventricular rate in atrial fibrillation. To avoid intoxication, a loading dose of ~0.6-1 mg digoxin is administered over 24 hours. Measurement of postdistribution serum digoxin concentration and adjustment of the daily dose (0.0625-0.5 mg) to maintain concentrations of 0.5-2 ng/mL are useful during chronic digoxin therapy (Table 29–5). Some patients may require and tolerate higher concentrations but with an increased risk of adverse effects.

The elimination t\(_{1/2}\) of digoxin ordinarily is ~36 hours, so maintenance doses are administered once daily. Renal elimination of unchanged drug accounts for less than 80% of digoxin elimination. Digoxin doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who
are hypothyroid. Digitoxin undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction. Digitoxin metabolism is accelerated by drugs such as phenytoin and rifampin that induce hepatic metabolism (Chapter 6). Digitoxin’s elimination $t_{1/2}$ is even longer than that of digoxin (~7 days); it is highly protein bound, and its therapeutic range is 10-30 ng/mL.

Amiodarone, quinidine, verapamil, diltiazem, cyclosporine, itraconazole, propafenone, and flecainide decrease digoxin clearance, likely by inhibiting P-glycoprotein, the major route of digoxin elimination (Fromm et al., 1999). New steady-state digoxin concentrations are approached after 4-5 $t_{1/2}$ (i.e., in about a week). Digitalis toxicity results so often with quinidine or amiodarone that it is routine to decrease the dose of digoxin if these drugs are started. In all cases, digoxin concentrations should be measured regularly and the dose adjusted if necessary. Hypokalemia, which can be caused by many drugs (e.g., diuretics, amphotericin B, corticosteroids), will potentiate digitalis-induced arrhythmias.

**Disopyramide.** Disopyramide (NORPACE, others) exerts electrophysiologic effects very similar to those of quinidine, but the drugs have different adverse effect profiles (Morady et al., 1982). Disopyramide is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF. Disopyramide is prescribed as a racemate. Its structure is as follows.

\[
\text{DISOPYRAMIDE}
\]

\[
(\text{CH}_3)_2\text{CH}^{-}\text{NCH}_2\text{CH}_2\text{C}^{-}\text{CONH}_2
\]

**Pharmacologic Actions and Adverse Effects.** The *in vitro* electrophysiologic actions of S-(+)-disopyramide are similar to those of quinidine. The $R$-(−)-enantiomer produces similar Na$^+$ channel block but does not prolong cardiac action potentials. Unlike quinidine, racemic disopyramide is not an $\alpha$ adrenergic receptor antagonist, but it does exert prominent anticholinergic actions that account for many of its adverse effects. These include precipitation of glaucoma, constipation, dry mouth, and urinary retention; the latter is most common in males with prostatism but also can occur in females. Disopyramide commonly depresses contractility, which can precipitate heart failure (Podrid et al., 1980) and also can cause torsades de pointes.

**Clinical Pharmacokinetics.** Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in total concentration may represent a disproportionately larger increase in free drug concentration (Lima et al., 1981). Disopyramide is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher than usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as phenytoin.

**Dofetilide.** Dofetilide (TIKOSYN) is a potent and “pure” $I_{Kr}$ blocker. As a result of this specificity, it has virtually no extracardiac pharmacologic effects. Dofetilide is effective in maintaining sinus rhythm in patients with atrial fibrillation. In the DIAMOND studies (Torp-Pedersen et al., 1999), dofetilide did not affect mortality in patients with advanced heart failure or in those convalescing from acute MI. Dofetilide currently is available through a restricted distribution system that includes only physicians, hospitals, and other institutions that have received special educational programs covering proper dosing and in-hospital treatment initiation.

**Adverse Effects.** Torsades de pointes occurred in 1-3% of patients in clinical trials where strict exclusion criteria (e.g., hypokalemia) were applied and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. The incidence of this adverse effect during more widespread use of the drug, marketed since 2000, is unknown. Other adverse effects were no more common than with placebo during premarketing clinical trials.

**Clinical Pharmacokinetics.** Most of a dose of dofetilide is excreted unchanged by the kidneys. In patients with mild to moderate renal failure, decreases in dosage based on creatinine clearance are required to minimize the risk of torsades de pointes. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. Dofetilide also undergoes minor hepatic metabolism.

**Dronedarone.** Dronedarone (MULTAQ) is a noniodinated benzofuran derivative of amiodarone that was approved by the FDA in 2009 for the treatment of atrial fibrillation and atrial flutter. In randomized placebo-controlled trials, it was effective in maintaining sinus rhythm and reducing the rate of ventricular response during episodes of atrial fibrillation (drug reviewed by Patel et al., 2009). Compared to amiodarone, dronedarone treatment is associated with significantly fewer adverse events, but it also is significantly less effective in maintaining sinus rhythm. Dronedarone reduces morbidity and mortality in patients with high-risk
atrial fibrillation. However, dronedarone increases mortality in patients with severe heart failure and is contraindicated in patients with NYHA class 4 heart failure and in patients with a recent decompensation of heart failure requiring hospitalization.

Pharmacologic Effects. Similar to amiodarone, dronedarone is a potent blocker of multiple ion currents, including the rapidly activating delayed-rectifier K⁺ current (Iₖr), the slowly activating delayed-rectifier K⁺ current (Iₖs), the inward rectifier K⁺ current (Iₖ1), the acetylcholine activated K⁺ current, the peak Na⁺ current, and the L-type Ca²⁺ current. It has stronger anti-adrenergic effects than amiodarone.

Adverse Effects and Drug Interactions. The most common adverse reactions are diarrhea, nausea, abdominal pain, vomiting, and asthenia. Dronedarone causes dose-dependent prolongation of QTc interval, but torsades de pointes is rare. Dronedarone is metabolized by CYP3A and is a moderate inhibitor of CYP3A4, CYP2D6, and P-glycoprotein. A potent CYP3A4 inhibitor such as ketoconazole may increase dronedarone exposure by as much as 25-fold. Consequently, dronedarone should not be co-administered with potent CYP3A4 inhibitors (e.g., antifungals, macrolide antibiotics). Co-administration with other drugs metabolized by CYP2D6 (e.g., metoprolol) or P-glycoprotein (e.g., digoxin) may result in increased drug concentrations.

Esmolol. (BREVIBLOC, others) is a β₁-selective agent that is metabolized by erythrocyte esterases and so has a very short elimination t₁/₂ (9 minutes). Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired (e.g., for rate control of rapidly conducted atrial fibrillation). Because of esmolol’s very rapid elimination, adverse effects due to β adrenergic blockade—should they occur—dissipate rapidly when the drug is stopped. Although methanol is a metabolite of esmolol, methanol intoxication has not been a clinical problem. Its pharmacology is described in detail in Chapter 12.

Flecainide. The effects of flecainide (TAMBOCOR, others) therapy are thought to be attributable to the drug’s very long τ_recovery from Na⁺ channel block (Roden and Woosley, 1986). In the CAST study, flecainide increased mortality in patients convalescing from MI (CAST Investigators, 1989). However, it continues to be approved for the maintenance of sinus rhythm in patients with supraventricular arrhythmias, including atrial fibrillation, in whom structural heart disease is absent (Anderson et al., 1989; Henthorn et al., 1991) and for life-threatening ventricular arrhythmias, such as sustained ventricular tachycardia.

Pharmacologic Effects. Flecainide blocks Na⁺ current and delayed-rectifier K⁺ current (Iₖr) in vitro at similar concentrations, 1 to 2 μM (Ikeda et al., 1985; Follmer and Colatsky, 1990). It also blocks Ca²⁺ currents in vitro. APD is shortened in Purkinje cells, probably owing to block of late-opening Na⁺ channels, but prolonged in ventricular cells, probably owing to block of delayed-rectifier current (Ikeda et al., 1985). Flecainide does not cause EADs in vitro but has been associated with rare cases of torsades de pointes. In atrial tissue, flecainide disproportionately prolongs action potentials at fast rates, an especially desirable anti-arrhythmic drug effect; this effect contrasts with that of quinidine, which prolongs atrial action potentials to a greater extent at slower rates (Wang et al., 1990). Flecainide prolongs the duration of PR, QRS, and QT intervals even at normal heart rates. Flecainide also is an open channel blocker of RyR2 Ca²⁺ release channels and prevents arrhythmogenic Ca²⁺ release from the sarcoplasmic reticulum in isolated myocytes (Hilliard et al., 2010). The blockade of the RyR2 channel by flecainide targets directly the underlying molecular defect in patients with mutations in the ryanodine receptor and cardiac calsequestrin, which may explain why flecainide suppresses ventricular arrhythmias in CPVT patients refractory to standard drug therapy (Watanabe et al., 2009).

Adverse Effects. Flecainide produces few subjective complaints in most patients; dose-related blurred vision is the most common non-cardiac adverse effect. It can exacerbate congestive heart failure in patients with depressed left ventricular performance. The most serious adverse effects are provocations or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of re-entrant ventricular tachycardia, and increased mortality in patients convalescing from MI (Crijns et al., 1988; CAST Investigators, 1989). As discussed earlier, it is likely that all these effects can be attributed to Na⁺ channel block. Flecainide also can cause heart block in patients with conduction system disease.

Clinical Pharmacokinetics. Flecainide is well absorbed. The elimination t₁/₂ is shorter with urinary acidification (10 hours) than with urinary alkalinization (17 hours), but it is nevertheless sufficiently long to allow dosing twice daily (Table 29–5). Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism.
to inactive metabolites. The latter is mediated by the polymorphically distributed enzyme CYP2D6 (Gross et al., 1989) (Chapter 6). However, even in patients in whom this pathway is absent because of genetic polymorphism or inhibition by other drugs (i.e., quinidine, fluoxetine), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient with renal dysfunction and lack of active CYP2D6, flecainide may accumulate to toxic plasma concentrations. Flecainide is a racemate, but there are no differences in the electrophysiologic effects or disposition kinetics of its enantiomers (Kroemer et al., 1989). Some reports have suggested that plasma flecainide concentrations greater than 1 μg/mL should be avoided to minimize the risk of flecainide toxicity; however, in susceptible patients, the adverse electrophysiologic effects of flecainide therapy can occur at therapeutic plasma concentrations.

**Ibutilide.** Ibutilide (CORVERT) is an $I_{kr}$ blocker that in some systems also activates an inward Na$^+$ current (Murray, 1998). The action potential–prolonging effect of the drug may arise from either mechanism.

Ibutilide is administered as a rapid infusion (1 mg over 10 minutes) for the immediate conversion of atrial fibrillation or flutter to sinus rhythm. The drug’s efficacy rate is higher in patients with atrial flutter (50-70%) than in those with atrial fibrillation (30-50%). In atrial fibrillation, the conversion rate is lower in those in whom the arrhythmia has been present for weeks or months compared with those in whom it has been present for days. The major toxicity with ibutilide is torsades de pointes, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these. The drug undergoes extensive first-pass metabolism and so is not used orally. It is eliminated by hepatic metabolism and has a $t_{1/2}$ of 2-12 hours (average of 6 hours).

**Lidocaine.** Lidocaine (XYLOCAINE, others) is a local anesthetic that also is useful in the acute inavenous therapy of ventricular arrhythmias. When lidocaine was administered to all patients with suspected MI, the incidence of VF was reduced (Lie et al., 1974). However, survival to hospital discharge tended to be decreased (Hine et al., 1989), perhaps because of lidocaine–exacerbated heart block or congestive heart failure. Therefore, lidocaine no longer is administered routinely to all patients in coronary care units.

**Pharmacologic Effects.** Lidocaine blocks both open and inactivated cardiac Na$^+$ channels. *In vitro* studies suggest that lidocaine-induced block reflects an increased likelihood that the Na$^+$ channel protein assumes a nonconducting conformation in the presence of drug (Balser et al., 1996). Recovery from block is very rapid, so lidocaine exerts greater effects in depolarized (e.g., ischemic) and/or rapidly driven tissues. Lidocaine is not useful in atrial arrhythmias possibly because atrial action potentials are so short that the Na$^+$ channel is in the inactivated state only briefly compared with diastolic (recovery) times, which are relatively long. In some studies, lidocaine increased current through inward rectifier channels; however, the clinical significance of this effect is not known. Lidocaine can hyperpolarize Purkinje fibers depolarized by low [K$^+$] or stretch; the resulting increased conduction velocity may be anti-arrhythmic in re-entry.

Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. APD usually is unaffected or is shortened; such shortening may be due to block of the few Na$^+$ channels that inactivate late during the cardiac action potential. Lidocaine usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug exerts little effect on hemodynamic function, although rare cases of lidocaine-associated exacerbations of heart failure have been reported, especially in patients with very poor left ventricular function. For additional information on lidocaine, see Chapter 20.

**Adverse Effects.** When a large intravenous dose of lidocaine is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of consciousness are more common. Nystagmus is an early sign of lidocaine toxicity.

**Clinical Pharmacokinetics.** Lidocaine is well absorbed but undergoes extensive though variable first-pass hepatic metabolism; thus, oral use of the drug is inappropriate. In theory, therapeutic plasma concentrations of lidocaine may be maintained by intermittent intramuscular administration, but the intravenous route is preferred (Table 29–5). Lidocaine’s metabolites, glycine xylidide (GX) and monoethyl GX, are less potent as Na$^+$ channel blockers than the parent drug. GX and lidocaine appear to compete for access to the Na$^+$ channel, suggesting that with infusions during which GX accumulates, lidocaine’s efficacy may be diminished (Bennett et al., 1988). With infusions lasting longer than 24 hours, the clearance of lidocaine falls—an effect that has been attributed to competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes.

Plasma concentrations of lidocaine decline biexponentially after a single intravenous dose, indicating that a multicompartment model is necessary to analyze lidocaine disposition. The initial drop in plasma lidocaine following intravenous administration occurs rapidly, with a $t_{1/2}$ of ~8 minutes, and represents distribution from the central compartment to peripheral tissues. The terminal elimination $t_{1/2}$, usually ~110 minutes, represents drug elimination by hepatic metabolism. Lidocaine’s efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of lidocaine can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment...
fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3-4 mg/kg over 20-30 minutes is used—e.g., an initial 100 mg followed by 50 mg every 8 minutes for three doses. Subsequently, stable concentrations can be maintained in plasma with an infusion of 1-4 mg/min, which replaces drug removed by hepatic metabolism. The time to steady-state lidocaine concentrations is ~8-10 hours. If the maintenance infusion rate is too low, arrhythmias may recur hours after the institution of apparently successful therapy. On the other hand, if the rate is too high, toxicity may result. In either case, routine measurement of plasma lidocaine concentration at the time of expected steady state is useful in adjusting the maintenance infusion rate.

In heart failure, the central volume of distribution is decreased, so the total loading dose should be decreased. Because lidocaine clearance also is decreased, the rate of the maintenance infusion should be decreased. Lidocaine clearance also is reduced in hepatic disease, during treatment with cimetidine or β blockers and during prolonged infusions (Nies et al., 1976). Frequent measurement of plasma lidocaine concentration and dose adjustment to ensure that plasma concentrations remain within the therapeutic range (1.5-5 μg/mL) are necessary to minimize toxicity in these settings. Lidocaine is bound to the acute-phase reactant α1-acid glycoprotein. Diseases such as acute MI are associated with increases in β1-acid glycoprotein and protein binding and hence a decreased proportion of free drug. These findings may explain why some patients require and tolerate higher than usual total plasma lidocaine concentrations to maintain anti-arrhythmic efficacy (Kessler et al., 1984).

Magnesium. The intravenous administration of 1-2 g MgSO₄ reportedly is effective in preventing recurrent episodes of torsades de pointes, even if the serum Mg²⁺ concentration is normal (Tzivoni et al., 1988). However, controlled studies of this effect have not been performed. The mechanism of action is unknown because the QT interval is not shortened; an effect on the inward current, possibly a Ca²⁺ current, responsible for the triggered upstroke arising from EADs (black arrow, Figure 29–6B) is possible. Intravenous Mg²⁺ also has been used successfully in arrhythmias related to digitalis intoxication.

Large placebo-controlled trials of intravenous magnesium to improve outcome in acute MI have yielded conflicting results (Woods and Fletcher, 1994; ISIS-4 Collaborative Group, 1995). Although oral Mg²⁺ supplements may be useful in preventing hypomagnesemia, there is no evidence that chronic Mg²⁺ ingestion exerts a direct anti-arrhythmic action.

Mexiletine. Mexiletine (MEXITIL, others) is an analog of lidocaine that has been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy (Campbell, 1987). The electrophysiologic actions are similar to those of lidocaine. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drugs with food.

Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as phenytoin. Mexiletine is approved for treating ventricular arrhythmias; combinations of mexiletine with quinidine or sotalol may increase efficacy while reducing adverse effects. In vitro studies and clinical case reports have suggested a role for mexiletine (or flecainide) in correcting the aberrant late inward Na⁺ current in congenital LQT3 (Napolitano et al., 2006).

**Procainamide.** Procainamide (PROCAN SR, others) is an analog of the local anesthetic procaine (Chapter 20). It exerts electrophysiologic effects similar to those of quinidine but lacks quinidine’s vagolytic and α adrenergic blocking activity. Procainamide is better tolerated than quinidine when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias. However, long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

**Pharmacologic Effects.** Procainamide is a blocker of open Na⁺ channels with an intermediate \( \tau \) recovery from block. It also prolongs cardiac action potentials in most tissues, probably by blocking outward K⁺ current(s). Procainamide decreases automaticity, increases refractory periods, and slows conduction. Its major metabolite, N-acetyl procainamide, lacks the Na⁺ channel-blocking activity of the parent drug but is equipotent in prolonging action potentials. Because the plasma concentrations of N-acetyl procainamide often exceed those of procainamide, increased refractoriness and QT prolongation during chronic procainamide therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS-interval prolongation. Although hypotension may occur at high plasma concentrations, this effect usually is attributable to ganglionic blockade rather than to any negative inotropic effect, which is minimal.

**Adverse Effects.** Hypotension and marked slowing of conduction are major adverse effects of high concentrations (>10 μg/mL) of procainamide, especially during intravenous use. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of N-acetyl procainamide. Torsades de pointes can occur, particularly when plasma concentrations of
**Procainamide.** Procainamide produces potentially fatal bone marrow aplasia in 0.2% of patients; the mechanism is not known, but high plasma drug concentrations are not suspected.

During long-term therapy, most patients will develop biochemical evidence of the drug-induced lupus syndrome, such as circulating antinuclear antibodies (Woosley et al., 1978). Therapy need not be interrupted merely because of the presence of antinuclear antibodies. However, 25-50% of patients eventually develop symptoms of the lupus syndrome; common early symptoms are rash and small-joint arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although renal involvement is unusual. The lupuslike symptoms resolve on cessation of therapy or during treatment with N-acetyl procainamide (see next section).

**Clinical Pharmacokinetics.** Procainamide is eliminated rapidly ($t_{1/2} = 3-4$ hours) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by N-acetyl transferase, whose activity is determined genetically, to form N-acetyl procainamide. N-Acetyl procainamide is eliminated by renal excretion ($t_{1/2} = 6-10$ hours) and is not significantly converted back to procainamide. Because of the relatively rapid elimination rates of both the parent drug and its major metabolite, oral procainamide usually is administered as a slow-release formulation. In patients with renal failure, procainamide and/or N-acetyl procainamide can accumulate to potentially toxic plasma concentrations. Reduction of procainamide dose and dosing frequency and monitoring of plasma concentrations of both compounds are required in this situation. Because the parent drug and metabolite exert different pharmacologic effects, the past practice of using the sum of their concentrations to guide therapy is inappropriate.

In individuals who are “slow acetylators,” the procainamide-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators (Woosley et al., 1978). In addition, the symptoms of procainamide-induced lupus resolve during treatment with N-acetyl procainamide. Both these findings support results of *in vitro* studies, suggesting that it is chronic exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome; these findings also provided one rationale for the further development of N-acetyl procainamide and its analogs as anti-arrhythmic agents (Roden, 1993).

**Propafenone.** Propafenone (Rythmol, others) is a Na$^+$ channel blocker with a relatively slow time constant for recovery from block (Funck-Brentano et al., 1990). Some data suggest that, like flecainide, propafenone also blocks K$^+$ channels. Its major electrophysiologic effect is to slow conduction in fast-response tissues. The drug is prescribed as a racemate; although the enantiomers do not differ in their Na$^+$ channel-blocking properties, $S$-(+)-propafenone is a β receptor antagonist in *in vitro* and in some patients. Propafenone prolongs PR and QRS durations. Chronic therapy with oral propafenone is used to maintain sinus rhythm in patients with supraventricular tachycardias, including atrial fibrillation; like other Na$^+$ channel blockers, it also can be used in ventricular arrhythmias, but with only modest efficacy.

**Adverse Effects.** Adverse effects during propafenone therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of re-entrant ventricular tachycardia, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm (see earlier in this chapter and Chapter 12).

**Clinical Pharmacokinetics.** Propafenone is well absorbed and is eliminated by both hepatic and renal routes. The activity of CYP2D6, an enzyme that functionally is absent in ~7% of Caucasians and African Americans (Chapter 6), is a major determinant of plasma propafenone concentration and thus the clinical action of the drug. In most subjects (“extensive metabolizers”), propafenone undergoes extensive first-pass hepatic metabolism to 5-hydroxy propafenone, a metabolite equipotent to propafenone as a Na$^+$ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, N-desalkyl propafenone, is formed by non-CYP2D6-mediated metabolism and is a less potent blocker of Na$^+$ channels and β adrenergic receptors. CYP2D6-mediated metabolism of propafenone is saturable, so small increases in dose can increase plasma propafenone concentration disproportionately. In “poor metabolizer” subjects, in whom functional CYP2D6 is absent, first-pass hepatic metabolism is much less than in extensive metabolizers, and plasma propafenone concentrations will be much higher after an equal dose. The incidence of adverse effects during propafenone therapy is significantly higher in poor metabolizers.

CYP2D6 activity can be inhibited markedly by a number of drugs, including quinidine and fluoxetine. In extensive metabolizer subjects receiving such drugs or in poor metabolizer subjects, plasma propafenone concentrations of more than 1 μg/mL are associated with clinical effects of β receptor blockade, such as reduction of exercise heart rate (Lee et al., 1990). It is recommended that dosage in patients with moderate to severe liver disease should be reduced to ~20-30% of the usual dose, with careful monitoring. It is not known if propafenone doses must be decreased in patients with renal disease. A slow-release formulation allows twice-daily dosing.

**Quinidine.** As early as the 18th century, the bark of the cinchona plant was used to treat “rebellious palpitations” (Levy and Azoulay, 1994). Studies in the early 20th century identified quinidine, a diastereomer of the antimalarial quinine, as the most potent of the antiarrhythmic substances extracted from the cinchona plant, and by the 1920s, quinidine was used as an antiarrhythmic agent. Quinidine is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF (Grace and Camm, 1998).
**Pharmacologic Effects.** Quinidine blocks $\text{Na}^+$ current and multiple cardiac $\text{K}^+$ currents. It is an open-state blocker of $\text{Na}^+$ channels, with a $\tau_{\text{recovery}}$ in the intermediate ($\sim$3 s) range; as a consequence, QRS duration increases modestly, usually by 10-20%, at therapeutic dosages. At therapeutic concentrations, quinidine commonly prolongs the QT interval up to 25%, but the effect is highly variable. At concentrations as low as 1 $\mu$M, quinidine blocks $\text{Na}^+$ current and the rapid component of delayed rectifier ($I_{\text{Kr}}$); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type $\text{Ca}^{2+}$ current.

Quinidine’s $\text{Na}^+$ channel–blocking properties result in an increased threshold for excitability and decreased automaticity. As a consequence of its $\text{K}^+$ channel–blocking actions, quinidine prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, quinidine consistently elicits EADs at slow heart rates, particularly when $[\text{K}]_o$ is low (Priori et al., 1999). Quinidine prolongs refractoriness in most tissues, probably as a result of both prolongation of APD and $\text{Na}^+$ channel blockade.

In intact animals and humans, quinidine also produces $\beta$ receptor blockade and vagal inhibition. Thus, the intravenous use of quinidine is associated with marked hypotension and sinus tachycardia. Quinidine’s vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so the effect of drug on the PR interval is variable. Moreover, quinidine’s vagolytic effect can result in increased AV nodal transmission of atrial tachycardias such as atrial flutter (Table 29–1).

**Adverse Effects—Noncardiac.** Diarrhea is the most common adverse effect during quinidine therapy, occurring in 30-50% of patients; the mechanism is not known. Diarrhea usually occurs within the first several days of quinidine therapy but can occur later. Diarrhea-induced hypokalemia may potentiate torsades de pointes due to quinidine.

A number of immunologic reactions can occur during quinidine therapy. The most common is thrombocytopenia, which can be severe but resolves rapidly with discontinuation of the drug. Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects is related to elevated plasma quinidine concentrations.

Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to quinidine therapy, cinchonism usually is related to elevated plasma quinidine concentrations and can be managed by dose reduction.

**Adverse Effects—Cardiac.** Of patients receiving quinidine therapy, 2-8% will develop marked QT-interval prolongation and torsades de pointes. In contrast to effects of sotalol, $N$-acetyl procaipamide, and many other drugs, quinidine-associated torsades de pointes generally occurs at therapeutic or even subtherapeutic plasma concentrations. The reasons for individual susceptibility to this adverse effect are not known.

At high plasma concentrations of quinidine, marked $\text{Na}^+$ channel block can occur, with resulting ventricular tachycardia. This adverse effect occurs when very high doses of quinidine are used to try to convert atrial fibrillation to normal rhythm; this aggressive approach to quinidine dosing has been abandoned, and quinidine-induced ventricular tachycardia is unusual.

Quinidine can exacerbate heart failure or conduction system disease. However, in most patients with congestive heart failure, quinidine is well tolerated, perhaps because of its vasodilating actions.

**Clinical Pharmacokinetics.** Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and, like lidocaine, the acute-phase reactant $\beta$-acid glycoprotein. As with lidocaine, greater than usual doses (and total plasma quinidine concentrations) may be required to maintain therapeutic concentrations of free quinidine in high-stress states such as acute MI (Kessler et al., 1984). Quinidine undergoes extensive hepatic oxidative metabolism, and ~20% is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as quinidine in blocking cardiac $\text{Na}^+$ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of quinidine are tolerated by some patients. Other metabolites are less potent than quinidine, and their plasma concentrations are lower; thus, they are unlikely to contribute significantly to the clinical effects of quinidine.

There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2–5 $\mu$g/mL. Some of this variability may be assay dependent because not all assays exclude quinidine metabolites. In patients with advanced renal disease or congestive heart failure, quinidine clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

**Drug Interactions.** Quinidine is a potent inhibitor of CYP2D6. As a result, the administration of quinidine to patients receiving drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects owing to accumulation of parent drug and failure of metabolite formation. For example, inhibition of CYP2D6-mediated metabolism of codeine to its active metabolite morphine results in decreased analgesia. On the other hand, inhibition of CYP2D6-mediated metabolism of propafenone results in elevated plasma propafenone concentrations and increased $\beta$ adrenergic receptor blockade. Quinidine reduces the clearance of digoxin; inhibition of P-glycoprotein–mediated digoxin transport has been implicated (Fromm et al., 1999).
Quinidine metabolism is induced by drugs such as phenobarbital and phenytoin (Data et al., 1976). In patients receiving these agents, very high doses of quinidine may be required to achieve therapeutic concentrations. If therapy with the inducing agent is then stopped, quinidine concentrations may rise to very high levels, and its dosage must be adjusted downward. Cimetidine and verapamil also elevate plasma quinidine concentrations, but these effects usually are modest.

Sotalol. Sotalol (BETAPACE, BETAPACE AF) is a nonselective β-adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed-rectifier and possibly other K⁺ currents (Hohnloser and Woosley, 1994). Sotalol is prescribed as a racemate; the L-enantiomer is a much more potent β-adrenergic receptor antagonist than the D-enantiomer, but the two are equipotent as K⁺ channel blockers. Its structure is shown below:

In the U.S., sotalol is an orphan drug approved for use in patients with both ventricular tachyarrhythmias (BETAPACE) and atrial fibrillation or flutter (BETAPACE AF). Clinical trials suggest that it is at least as effective as most Na⁺ channel blockers in ventricular arrhythmias (Mason, 1993).

Sotalol prolongs APD throughout the heart and QT interval on the ECG. It decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K⁺ channels and β-adrenergic receptors, but it exerts no effect on conduction velocity in fast-response tissue. Sotalol causes EADs and triggered activity in vitro and can cause torsades de pointes, especially when the serum K⁺ concentration is low. Unlike the situation with quinidine, the incidence of torsades de pointes (1.5-2% incidence) seems to depend on the dose of sotalol; indeed, torsades de pointes is the major toxicity with sotalol overdose. Occasional cases occur at low dosages, often in patients with renal dysfunction, because sotalol is eliminated by renal excretion of unchanged drug. The other adverse effects of sotalol therapy are those associated with β-receptor blockade (see earlier in this chapter and Chapter 12).

Vernakalant. Vernakalant (RSD1235, proposed trade-name KYNAPID) is an investigational inhibitor of several ion channels that are preferentially expressed in the atria, in particular the ultra-rapidly activating delayed-rectifier K⁺ current (Iₖur encoded by Kv1.5).

To a lesser extent, it also blocks the rapidly activating delayed-rectifier K⁺ current (Iₖr), the transient outward K⁺ current (Iₒt), the Na⁺ current, and the L-type Ca²⁺ current. Vernakalant selectively prolongs the atrial refractory period without significantly affecting ventricular refractoriness.

Vernakalant is effective for converting atrial fibrillation of short duration to sinus rhythm (Roy et al., 2008). Vernakalant (3 mg/kg) is administered as a 10-minute infusion, followed by a second infusion of 2 mg/kg 15 minutes later if AF is not terminated. Vernakalant is not effective in converting long-duration AF (>7 days) or atrial flutter. The intravenous formulation of vernakalant was recommended for approval by an FDA advisory committee in 2008, but the drug has not received FDA approval at the time of this printing. An oral formulation is currently in clinical trials for the maintenance of sinus rhythm in patients with chronic atrial fibrillation. Vernakalant seems to have little or no proarrhythmic effects, with no reported cases of torsades de pointes in phase II and III studies.

Vernakalant is metabolized by rapidly by CYP2D6 to one major and inactive metabolite (RSD1385) via 4-O-demethylation (Mao et al., 2009). There appears to be little difference in C_max between extensive and poor 2D6 metabolizers after single-dose IV administration. However, average t₁/₂ of vernakalant was much longer in two poor metabolizers (8.5 hours) than in 10 extensive metabolizers (2.7 hours). This profound difference in t₁/₂ will be important if vernakalant is used chronically to prevent atrial fibrillation.

The physiological systems that control the fluidity of blood are both complex and elegant. Blood must remain fluid within the vasculature and yet clot quickly when exposed to subendothelial surfaces at sites of vascular injury. When intravascular thrombi form, rapid activation of the fibrinolytic system restores fluidity. Under normal circumstances, a delicate balance between coagulation and fibrinolysis prevents both thrombosis and hemorrhages. Alteration of this balance in favor of coagulation results in thrombosis.

Composed of platelet aggregates, fibrin, and trapped red blood cells, thrombi can form in arteries or veins. Because of the predominance of platelets and fibrin in thrombi, anti-thrombotic drugs used to treat thrombosis include antiplatelet drugs, which inhibit platelet activation or aggregation, anticoagulants, which attenuate fibrin formation, and fibrinolytic agents, which degrade fibrin. These agents have very different mechanisms of action, but because they target key steps in clot formation, all anti-thrombotic drugs increase the risk of bleeding. With these drugs, toxicity typically represents an extension of the therapeutic effects. The more potent the agent, the greater the risk of bleeding.

This chapter reviews the agents commonly used for controlling blood fluidity, including:

- The parenteral anticoagulant heparin and its derivatives, which activate a natural inhibitor of coagulant proteases
- The coumarin anticoagulants, which block multiple steps in the coagulation cascade
- Fibrinolytic agents, which degrade thrombi
- Antiplatelet agents, including aspirin, thienopyridines, and glycoprotein (GP) IIb/IIIa inhibitors

In addition, some of the newer anti-thrombotic drugs in advanced stages of development also are described.

**OVERVIEW OF HEMOSTASIS: PLATELET FUNCTION, BLOOD COAGULATION, AND FIBRINOLYSIS**

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel, where they become activated. Adherent platelets release substances that activate nearby platelets, thereby recruiting them to the site of injury. Activated platelets then aggregate to form the primary hemostatic plug.

In addition to triggering platelet adhesion and activation, vessel wall injury also exposes tissue factor (TF), which initiates the coagulation system. Platelets support and enhance activation of the coagulation system by providing a surface onto which clotting factors assemble and by releasing stored clotting factors. This results in a burst of thrombin (factor IIa) generation. Thrombin then converts fibrinogen to fibrin, which reinforces the platelet aggregate and anchors it to the vessel wall. In addition, because it serves as a potent platelet agonist, thrombin also amplifies platelet activation and aggregation.

Later, as wound healing occurs, the platelet aggregates and fibrin clots are degraded. The processes of platelet aggregation and blood coagulation are summarized in Figures 30–1 and 30–2 (see also the animation on this book’s website). The pathway of clot removal, fibrinolysis, is shown in Figure 30–3, along with sites of action of fibrinolytic agents.
Figure 30–1. Platelet adhesion and aggregation. GPIa/IIa and GPIb are platelet receptors that bind to collagen and von Willebrand factor (vWF), causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR1 and PAR4 are protease-activated receptors that respond to thrombin (IIa); P2Y₁ and P2Y₁₂ are receptors for ADP; when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and cyclooxygenase-1 (COX-1) to promote platelet aggregation and secretion. Thromboxane A₂ (TxA₂) is the major product of COX-1 involved in platelet activation. Prostaglandin I₂ (prostacyclin, PGI₂), synthesized by endothelial cells, inhibits platelet activation.

Figure 30–2. Major reactions of blood coagulation. Shown are interactions among proteins of the “extrinsic” (tissue factor and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important in vivo. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals); the rounded boxes represent the active proteases. TF, tissue factor. Activated coagulation factors are followed by the letter “a”: II, prothrombin; IIa, thrombin.
Coagulation involves a series of zymogen activation reactions, as shown in Figure 30–2 (Mann et al., 2003). At each stage, a precursor protein, or zymogen, is converted to an active protease by cleavage of one or more peptide bonds in the precursor molecule. The components at each stage include a protease from the preceding stage, a zymogen, a non-enzymatic protein cofactor, Ca\(^{2+}\), and an organizing surface that is provided by a phospholipid emulsion \textit{in vitro} or by activated platelets \textit{in vivo}. The final protease generated is thrombin.

**Conversion of Fibrinogen to Fibrin.** Fibrinogen, a 340,000-Da protein, is a dimer, each half of which consists of three pairs of polypeptide chains (designated A\(\alpha\), B\(\beta\), and \(\gamma\)). Disulfide bonds covalently link the chains and the two halves of the molecule together. Thrombin converts fibrinogen to fibrin monomers by releasing fibrinopeptide A (a 16–amino acid fragment) and fibrinopeptide B (a 14–amino acid fragment) from the amino termini of the A\(\alpha\) and B\(\beta\) chains, respectively. Removal of the fibrinopeptides creates new amino termini, which fit into pre-formed holes on other fibrin monomers to form a fibrin gel, which is the end point of \textit{in vitro} tests of coagulation (see “Coagulation \textit{in vitro}”). Initially, the fibrin monomers are bound to each other non-covalently. Subsequently, factor XIII, a transglutaminase that is activated by thrombin, catalyzes interchain covalent cross-links between adjacent fibrin monomers, which enhance the strength of the clot.

**Structure of Coagulation Factors.** In addition to factor XIII, the coagulation factors include factors II (prothrombin), VII, IX, X, XI, XII, and prekallikrein. A stretch of about 200 amino acid residues at the carboxyl-termini of each of these zymogens exhibits homology to trypsin and contains the active site of the proteases. In addition, 9–12 glutamate residues near the amino termini of factors II, VII, IX, and X are converted to \(\gamma\)-carboxyglutamate (Gla) residues during their biosynthesis in the liver. The Gla residues bind Ca\(^{2+}\) and are necessary for the coagulant activities of these proteins.

**Nonenzymatic Protein Cofactors.** Factors V and VIII, which are homologous 350,000-Da proteins, serve as cofactors. Factor VIII circulates in plasma bound to von Willebrand factor, while factor V not only circulates in plasma but also is stored in platelets in a partially activated form. Platelets release this stored factor V when they are activated. Thrombin cleaves factors V and VIII to yield activated cofactors (factors Va and VIIIa) that have at least 50 times greater procoagulant activity than their nonactivated counterparts.

Factors Va and VIIIa serve as cofactors by binding to the surface of activated platelets, where they act as receptors for factors Xa and IXa, respectively. The activated cofactors also help localize prothrombin and factor X, the respective substrates for these enzymes, on the activated platelet surface. Assembly of these coagulation factor complexes increases the catalytic efficiency of factors Xa and IXa by \(\sim 10^{8}\)-fold.

TF is a non-enzymatic lipoprotein cofactor; it initiates coagulation by enhancing the catalytic efficiency of VIIa. Not normally present on blood-contacting cells, TF is constitutively expressed on the surface of subendothelial smooth muscle cells and fibroblasts, which are exposed when the vessel wall is damaged. Lipid-rich cores of atherosclerotic plaques also are rich in TF, which explains why atherosclerotic plaque disruption often triggers the
formation of a superimposed thrombus that can occlude the lumen of the vessel.

When exposed to stimuli such as endotoxin, tumor necrosis factor, or interleukin-1, monocytes also express TF on their surface. Circulating TF-bearing monocytes and membrane fragments derived from them, known as microparticles, contribute to thrombosis. In response to inflammatory stimuli or products of coagulation, such as thrombin, endothelial cells express adhesion molecules, which tether these monocytes and microparticles onto their surface. This augments coagulation by delivering more TF to sites of injury. TF-bearing monocytes and microparticles also home to thrombi by binding to P-selectin expressed on the surface of activated platelets. Additional TF from these sources maintains coagulation and promotes thrombus expansion.

Another plasma protein, high-molecular-weight kininogen, also serves as a cofactor. Negatively charged surfaces, such as catheters, stents, and other blood-contacting medical devices, activate factor XII in a reaction enhanced by high-molecular-weight kininogen. Factor XIIa then propagates coagulation by activating factor XI, a reaction also enhanced by high-molecular-weight kininogen. In the presence of activated platelets, thrombin also activates factor XI, thereby bypassing factor XIIa.

**Activation of Prothrombin.** By cleaving two peptide bonds on prothrombin, factor Xa converts it to thrombin. In the presence of factor Va, a negatively charged phospholipid surface, and Ca\(^{2+}\), factor Xa activates prothrombin with 10\(^5\)-fold greater efficiency. The maximal rate of activation only occurs when prothrombin and factor Xa contain Gla residues, which endow them with the capacity to bind to phospholipids. Artificial mixtures of anionic phospholipids substitute for activated platelets in laboratory tests of coagulation. However, activated platelets not only provide a surface for coagulation factor assembly but also release factor Va, which may be more important than circulating factor Va for thrombin generation.

**Initiation of Coagulation.** Under most circumstances, TF exposed at sites of vessel wall injury initiates coagulation via the extrinsic pathway. The small amount of factor VIIa circulating in plasma binds subendothelial TF and the TF-factor VIIa complex, then activates factors X and IX (Figure 30–2). In the absence of TF, factor VIIa has minimal activity. When bound to TF in the presence of anionic phospholipids and Ca\(^{2+}\), the activity of factor VIIa increases about 30,000-fold.

The intrinsic pathway is initiated *in vitro* when factor XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another surface to generate small amounts of factor XIIa. Activation of factor XI to factor Xla and factor IX to factor IXa follows. Factor IXa then activates factor X in a reaction accelerated by factor VIIIa, anionic phospholipids, and Ca\(^{2+}\). Optimal thrombin generation depends on the formation of this factor IXa complex because it activates factor X more efficiently than the TF-factor VIIa complex. The bleeding that occurs in hemophiliacs who are deficient in factor IX or factor VIII highlights the importance of the factor IXa–factor VIIIa complex in thrombin generation.

Activation of factor XII is not essential for hemostasis, as evidenced by the fact that patients deficient in factor XII, prekallikrein, or high-molecular-weight kininogen do not have excessive bleeding. Factor XI deficiency is associated with a variable and usually mild bleeding disorder. The mechanism responsible for factor XI activation *in vivo* is unknown. Activation may occur through feedback activation of factor XI by thrombin. Alternatively, factor XIa may activate factor XI after injury to the vessel wall because there is evidence that RNA released from damaged cells activates factor XII and administration of RNA-degrading enzymes to mice attenuates thrombus formation after arterial injury.

**Fibrinolysis.** The fibrinolytic system dissolves intravascular fibrin through the action of plasmin. To initiate fibrinolysis, plasminogen activators first convert single-chain plasminogen, an inactive precursor, into two-chain plasmin by cleavage of a specific peptide bond. There are two distinct plasminogen activators; tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), or simply urokinase. Although both activators are synthesized by endothelial cells, t-PA predominates under most conditions and drives intravascular fibrinolysis. In contrast, synthesis of u-PA mainly occurs in response to inflammatory stimuli, and u-PA promotes extravascular fibrinolysis.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds is preserved to maintain hemostasis (Lijnen and Collen, 2001). t-PA is released from endothelial cells in response to various stimuli, including the stasis that occurs when thrombi occlude vessels. Released t-PA is rapidly cleared from blood or inhibited by plasminogen activator inhibitor-1 (PAI-1) and, to a lesser extent, plasminogen activator inhibitor-2 (PAI-2); t-PA thus exerts little effect on circulating plasminogen in the absence of fibrin. α\(_2\)-antiplasmin rapidly inhibits any plasmin that is generated. However, when fibrin is present, t-PA binds to it, as does plasminogen. The catalytic efficiency of t-PA activation of plasminogen increases over 300-fold in the presence of fibrin, which promotes plasmin generation on its surface. Plasmin then degrades the fibrin.

Plasminogen and plasmin bind to lysine residues on fibrin via five loop-like regions near their amino termini, which are known as kringle domains. To inactivate plasmin, α\(_2\)-antiplasmin binds to the first of these kringle domains and then blocks the active site of plasmin. Because the kringle domains are occupied when plasmin binds to fibrin, plasmin on the fibrin surface is protected from inhibition by α\(_2\)-antiplasmin and can digest the fibrin. Once the fibrin clot undergoes
degradation, $\alpha_2$-antiplasmin rapidly inhibits any plasmin that escapes from this local milieu. To prevent premature clot lysis, factor XIIIa mediates the covalent cross-linking of small amounts of $\alpha_2$-antiplasmin onto fibrin.

When thrombi occlude major arteries or veins, therapeutic doses of plasminogen activators sometimes are administered to degrade the fibrin and rapidly restore blood flow. In high doses, these plasminogen activators promote the generation of so much plasmin that the inhibitory controls are overwhelmed. Plasmin is a relatively nonspecific protease; it not only digests fibrin but also digests other plasma proteins, including several coagulation factors. Reduction in the levels of these coagulation proteins impairs the capacity for thrombin generation, which can contribute to bleeding. In addition, unopposed plasmin tends to dissolve fibrin in hemostatic plugs as well as that in pathological thrombi, a phenomenon that also increases the risk of bleeding. Therefore, fibrinolytic drugs can be toxic, producing hemorrhage as their major side effect. The pathway of fibrinolysis and sites of pharmacological perturbation are summarized in Figure 30–3.

Coagulation in vitro. Whole blood normally clots in 4-8 minutes when placed in a glass tube. Clotting is prevented if a chelating agent such as ethylenediaminetetraacetic acid (EDTA) or citrate is added to bind $\text{Ca}^{2+}$. Recalcified plasma normally clots in 2-4 minutes. The clotting time after calcification is shortened to 26-33 seconds by the addition of negatively-charged phospholipids and a particulate substance, such as kaolin (aluminum silicate) or celite (diatomaceous earth), which activates factor XII; the measurement of this is termed the activated partial thromboplastin time (aPTT). Alternatively, recalcified plasma clots in 12-14 seconds after addition of “thromboplastin” (a mixture of TF and phospholipids); the measurement of this is termed the prothrombin time (PT).

Two pathways of coagulation are recognized. An individual with a prolonged aPTT and a normal PT is considered to have a defect in the intrinsic coagulation pathway because all of the components of the aPTT test (except kaolin or celite) are intrinsic to the plasma. A patient with a prolonged PT and a normal aPTT has a defect in the extrinsic coagulation pathway because thromboplastin is extrinsic to the plasma. Prolongation of both the aPTT and the PT suggests a defect in a common pathway.

Natural Anticoagulant Mechanisms. Platelet activation and coagulation do not normally occur within an intact blood vessel (Edelberg et al., 2001). Thrombosis is prevented by several regulatory mechanisms that require a healthy vascular endothelium. Nitric oxide and prostacyclin (PGI2) are synthesized by endothelial cells and released into the blood (Chapter 33). These substances induce vasodilation and inhibit platelet activation and subsequent aggregation.

Antithrombin is a plasma protein that inhibits coagulation enzymes of the intrinsic and common pathways (see “Mechanism of Action”). Heparan sulfate proteoglycans synthesized by endothelial cells enhance the activity of antithrombin by ~1000-fold. Another regulatory system involves protein C, a plasma zymogen that is homologous to factors II, VII, IX, and X; its activity depends on the binding of $\text{Ca}^{2+}$ to Gla residues within its amino-terminal domain. Thrombin activates protein C, but the efficiency of this reaction increases by several orders of magnitude when thrombin binds to thrombomodulin, its receptor on the surface of endothelial cells (Esmon, 2003). Protein C binds to another endothelial cell receptor, endothelial protein C receptor (EPCR), which presents protein C to the thrombin–thrombomodulin complex for activation. Activated protein C then dissociates from EPCR and, in combination with protein S, its non-enzymatic Gla-containing cofactor, activated protein C degrades factors Va and VIIIa. Without these activated cofactors, the rates of activation of prothrombin and factor X are greatly diminished. Therefore, activated protein C downregulates thrombin generation (Esmon, 2006). Deficiency of protein C or protein S is associated with an increased risk of pathological thrombus formation and tissue necrosis associated with the use of warfarin (see the “Warfarin” section, later in the chapter).

With antithrombin requiring endogenous heparan sulfate for its full activity and protein C requiring activation by thrombomodulin-bound thrombin, the effects of both of these natural anticoagulants are localized to the vicinity of intact endothelial cells. Tissue factor pathway inhibitor (TFPI), a natural anticoagulant found in the lipoprotein fraction of plasma, also regulates thrombin generation by inhibiting TF-bound factor VIIa in a two-step fashion. TFPI first binds and inhibits factor Xa, and this binary complex then inhibits factor VIIa. Therefore, factor Xa regulates its own generation through this mechanism. TFPI also can localize on the endothelial cell surface by binding to heparan sulfate proteoglycans.

**PARENTERAL ANTICOAGULANTS**

**Heparin and Its Derivatives**

Biochemistry. Heparin, a glycosaminoglycan found in the secretory granules of mast cells, is synthesized from UDP-sugar precursors as a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues (Sugahara and Kitagawa, 2002).
About 10–15 glycosaminoglycan chains, each containing 200-300 saccharide units, are attached to a core protein and yield a proteoglycan with a molecular mass of 750-1,000 kDa. The glycosaminoglycan then undergoes a series of modifications, which include the following: N-deacetylation and N-sulfation of glucosamine residues, epimerization of d-glucuronic acid to l-iduronic acid, O-sulfation of iduronic and glucuronic acid residues at the C2 position, and O-sulfation of glucosamine residues at the C3 and C6 positions. Each of these modifications is incomplete, yielding a variety of oligosaccharide structures. After transport of the heparin proteoglycan to mast cell granules, an endo-β-D-glucuronidase slowly degrades the glycosaminoglycan chains to fragments of 5-30 kDa (mean, ~15 kDa, corresponding to ~40 saccharide units).

**Source.** Heparin is commonly extracted from porcine intestinal mucosa, which is rich in mast cells, and preparations may contain small amounts of other glycosaminoglycans. Despite the heterogeneity in composition among different commercial preparations of heparin, their biological activities are similar (~150 USP units/mg). A USP unit reflects the quantity of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 hour after the addition of 0.2 mL of 1% CaCl₂. Although North American heparin manufacturers have traditionally quantified heparin potency in USP units, European manufacturers measure potency with an anti-factor Xa assay. This assay involves monitoring the activity of factor Xa added to human citrated plasma with a synthetic factor Xa–directed substrate that changes color when cleaved by the enzyme. The higher the heparin concentration in the sample, the less the residual factor Xa activity detected. To determine heparin potency, residual factor Xa activity in the sample is compared with that detected in controls containing known concentrations of an international heparin standard. When assessed this way, heparin potency is expressed in international units per mg.

Effective October 1, 2009, the new USP unit dose has been harmonized to the international unit dose. Contamination of heparin with oversulfated chondroitin sulfate, a non-heparin glycosaminoglycan, prompted this shift because this contaminant eludes detection with the USP assay but not with the anti-factor Xa assay. As a result, the new USP unit dose is less potent than the old USP unit dose by ~10%, and heparin doses using the new USP units will have to increase slightly to achieve the same level of anticoagulation. This likely is of little or no clinical consequence for subcutaneous administration, due to the low and variable bioavailability of heparin when administered by this route. However, for intravenous administration, dosing adjustments and more frequent monitoring of aPTT may be necessary.

**Heparin Derivatives.** Derivatives of heparin in current use include low-molecular-weight heparins (LMWHs) and fondaparinux. The features that distinguish these derivatives from heparin are outlined in Table 30–1. Several LMWH preparations are marketed (e.g., dalteparin [FRAGMIN], enoxaparin [LOVENOX], tinzaparin [INNOHEP]), but all are fragments of heparin ranging in molecular weight from 1-10 kDa (mean ~5 kDa, ~17 saccharide units). LMWH preparations differ from heparin and, to a lesser extent, from each other in their pharmacokinetic properties. The potency of LMWH is assessed with anti-factor Xa assays, which use an international LMWH standard for reference purposes.

In contrast to heparin and LMWHs, which are biologicals derived from animal tissues, fondaparinux (ARIXTRA) is a synthetic five-saccharide analog of a natural pentasaccharide sequence that is found in heparin and LMWHs and mediates their interaction with antithrombin. Fondaparinux has unique pharmacokinetic properties that distinguish it from LMWH. The potency of fondaparinux also is assessed with an anti-Xa assay.

**Mechanism of Action.** Heparin, LMWHs, and fondaparinux have no intrinsic anticoagulant activity. Instead, these agents bind to antithrombin and accelerate the rate at which it inhibits various coagulation proteases. Antithrombin is a glycosylated, single-chain polypeptide composed of 432 amino acid residues (Olson and Chuang, 2002). Synthesized in the liver, antithrombin circulates in plasma at an approximate concentration of 2.6 μM. Antithrombin inhibits activated coagulation factors involved in the intrinsic and common pathways but has relatively little activity against factor VIIa. Antithrombin is a “suicide substrate” for these proteases; inhibition occurs when the protease attacks a specific Arg–Ser peptide bond in the reactive center loop of antithrombin and becomes trapped as a stable 1:1 complex.

| **Table 30–1** Comparison of the Features of Heparin, LMWH, and Fondaparinux |
|-----------------------------|-----------------|-----------------|-----------------|

Heparin binds to antithrombin via a specific pentasaccharide sequence that contains a 3-O-sulfated glucosamine residue (Figure 30–4). This structure occurs on ~30% of heparin molecules and is less abundant on endogenous heparan sulfate molecules. Other glycosaminoglycans (e.g., dermatan sulfate, chondroitin-4-sulfate, and chondroitin-6-sulfate) lack the antithrombin-binding structure and do not activate antithrombin.

Pentasaccharide binding to antithrombin induces a conformational change in antithrombin that renders its reactive site more accessible to the target protease (Figure 30–5).

This conformational change accelerates the rate of factor Xa inhibition by at least two orders of magnitude but has no effect on the rate of thrombin inhibition. To enhance the rate of thrombin inhibition by antithrombin, heparin serves as a catalytic template to which both the inhibitor and the protease bind. Only heparin molecules composed of 18 or more saccharide units (molecular weight >5400 Da) are of sufficient length to bridge antithrombin and thrombin together. With a mean molecular weight of 15,000 Da, most of the chains of heparin are long enough to serve this role. Consequently, by definition, heparin catalyzes the rates of factor Xa and thrombin to a similar extent, as expressed by an anti-factor Xa to anti-factor IIa (thrombin) ratio of 1:1. In contrast, at least half of LMWH molecules (mean molecular weight of 5000 Da, ~17 saccharide units) are too short to provide this bridging function and have no effect on the rate of thrombin inhibition by antithrombin. Because these shorter molecules still induce the conformational change in antithrombin that accelerates inhibition of factor Xa, LMWHs have greater anti-factor Xa activity than anti-IIa activity, and the ratio ranges from 3:1 to 2:1 depending on the preparation. Fondaparinux, an analog of the pentasaccharide sequence in heparin or LMWHs that mediates their interaction with antithrombin, has only anti-factor Xa activity because it is too short to bridge antithrombin to thrombin (Figure 30–5).

Heparin, LMWHs, and fondaparinux act in a catalytic fashion. After binding to antithrombin and promoting the formation of covalent complexes between antithrombin and target proteases, the heparin, LMWH, or fondaparinux dissociates from the complex and can then catalyze other antithrombin molecules.

When the concentration of heparin in plasma is 0.1-1 units/mL, thrombin, factor IXa, and factor Xa are inhibited rapidly (t1/2 <0.1 second) by antithrombin. This effect prolongs both the aPTT (discussed earlier) and the thrombin time (i.e., the time required for plasma to clot when exogenous thrombin is added); the PT is affected to a lesser degree. Factor Xa bound to platelets in the prothrombinase complex and thrombin bound to fibrin are both protected from inhibition by antithrombin in the presence of heparin or LMWH. Thus, heparin and LMWHs may promote the inhibition of factor Xa and thrombin only after they have diffused away from these binding sites.

Platelet factor 4, a cationic protein released from the α granules during platelet activation, binds heparin and prevents it from interacting with antithrombin. This phenomenon may limit the activity of heparin in the vicinity of platelet-rich thrombi. Because LMWH and fondaparinux have a lower affinity for platelet factor 4, these agents may retain their activity in the vicinity of such thrombi to a greater extent than heparin.

Miscellaneous Pharmacological Effects. High doses of heparin can interfere with platelet aggregation and thereby prolong the bleeding time. In contrast, LMWHs and fondaparinux have little effect on platelets. It is unclear to what extent the antiplatelet effect of heparin contributes to the hemorrhagic complications of treatment with the drug. Heparin “clears” lipemic plasma in vivo by causing the release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect. Rebound hyperlipemia may occur after heparin administration is stopped.

Clinical Use. Heparin, LMWH, and fondaparinux can be used to initiate treatment of venous thrombosis and pulmonary embolism because of their rapid onset of action (Hirsh et al., 2001). An oral vitamin K antagonist, such as warfarin, usually is started concurrently, and the heparin or heparin derivative is continued for at least 5 days to allow warfarin to achieve its full therapeutic
Figure 30–5. Mechanism of action of heparin, low-molecular-weight heparin (LMWH), and fondaparinux, a synthetic pentasaccharide.

A. Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units (molecular weight ~5,400 Da) are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000 Da, virtually all of the heparin chains are long enough to do this.

B. LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because at least half of the LMWH chains (mean molecular weight 4,500-5,000 Da) are too short to bridge antithrombin to thrombin.

C. The pentasaccharide accelerates only factor Xa inhibition by antithrombin; the pentasaccharide is too short to bridge antithrombin to thrombin.
Effect (see the warfarin “Clinical Use” and “Monitoring Anticoagulant Therapy” sections later in the chapter). Heparin, LMWH, or fondaparinux also can be used in the initial management of patients with unstable angina or acute myocardial infarction. For most of these indications, LMWHs and fondaparinux have replaced continuous heparin infusions because of their pharmacokinetic advantages, which permit subcutaneous administration once or twice daily in fixed or weight-adjusted doses without coagulation monitoring. By contrast, full-dose heparin usually requires continuous intravenous infusion and frequent aPTT monitoring to ensure that a therapeutic level of anticoagulation has been achieved.

Because they do not require routine laboratory monitoring, LMWHs or fondaparinux can be used for out-of-hospital management of patients with venous thrombosis or pulmonary embolism, an approach that reduces healthcare expenditures. Patients who develop these disorders due to cancer often are treated with long-term LMWH instead of warfarin because nausea and vomiting from chemotherapy, involvement of the liver with cancer, and poor venous access can render therapy with warfarin problematic.

Heparin and LMWH are used during coronary balloon angioplasty with or without stent placement to prevent thrombosis. Fondaparinux is not used in this setting because of the risk of catheter thrombosis, a complication caused by catheter-induced activation of factor XII; longer heparin molecules are better than shorter ones for blocking this process. Cardiopulmonary bypass circuits also activate factor XII, which can cause clotting of the oxygenator. Heparin remains the agent of choice for surgery requiring cardiopulmonary bypass because it blocks this process and because the heparin can rapidly be neutralized with protamine sulfate after the procedure. Heparin also is used to treat selected patients with disseminated intravascular coagulation. While low-dose heparin, LMWH, or fondaparinux regimens all are effective, subcutaneous administration of low-dose heparin remains the recommended regimen for the prevention of post-operative deep venous thrombosis (DVT) and pulmonary embolism in patients undergoing major abdominothoracic surgery or who are at risk of developing thromboembolic disease. Specific recommendations for heparin use have been reviewed (Geerts et al., 2008).

In contrast to warfarin, heparin, LMWH, and fondaparinux do not cross the placenta and have not been associated with fetal malformations; therefore, these are the drugs of choice for anticoagulation during pregnancy. LMWH or fondaparinux is used most often in this setting because these agents need only be given once daily by subcutaneous injection. In addition, the risk of heparin-induced thrombocytopenia or osteoporosis is lower with LMWHs or fondaparinux than with heparin. Heparin, LMWH, and fondaparinux do not appear to increase fetal mortality or prematurity. If possible, the drugs should be discontinued 24 hours before delivery to minimize the risk of postpartum bleeding.

Absorption and Pharmacokinetics. Heparin, LMWHs, and fondaparinux are not absorbed through the GI mucosa and therefore must be given parenterally. Heparin is given by continuous intravenous infusion, intermittent infusion every 4-6 hours, or subcutaneous injection every 8-12 hours. Heparin has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed 1-2 hours. LMWH and fondaparinux are absorbed more uniformly after subcutaneous injection.

The $t_{1/2}$ of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives of the anticoagulant activities are approximately 1, 2.5, and 5 hours, respectively (see Appendix II for pharmacokinetic data). Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of degraded heparin also appears in the urine. LMWHs and fondaparinux have longer biological half-lives than heparin, 4-6 hours and ~17 hours, respectively. Because these smaller heparin fragments are cleared almost exclusively by the kidneys, the drugs can accumulate in patients with renal impairment, which can lead to bleeding. Both LMWH and fondaparinux are contraindicated in patients with a creatinine clearance <30 mL/min. In addition, fondaparinux is contraindicated in patients with body weight <50 kg undergoing hip fracture, hip replacement, knee replacement surgery, or abdominal surgery.

Administration and Monitoring. Full-dose heparin therapy usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a fixed-dose bolus injection of 5000 units or with a weight-adjusted bolus, followed by 800-1600 units/hour delivered by an infusion pump. Therapy routinely is monitored by measuring the aPTT. The therapeutic range for heparin is considered to be that which is equivalent to a plasma heparin level of 0.3-0.7 units/mL, as determined with an anti-factor Xa assay (Hirsh et al., 2001). The aPTT value that corresponds to this range varies depending on the reagent and instrument used to perform the assay. An aPTT two to three times the normal mean aPTT value generally is assumed to be therapeutic; however, values in this range obtained with some aPTT assays may overestimate the amount of circulating heparin and therefore be subtherapeutic. The risk of recurrence of thromboembolism is greater in patients who do not achieve a therapeutic level of anticoagulation within the first 24 hours. Initially, the aPTT should be measured and the infusion rate adjusted every 6 hours; dose adjustments may be aided by use of nomograms; weight-based nomograms appear to outperform those that used fixed doses (Hirsh et al., 2001). Once a steady dosage schedule has been established in a stable patient, daily laboratory monitoring usually is sufficient.

Very high doses of heparin are required to prevent coagulation during cardiopulmonary bypass. The aPTT is infinitely prolonged over the dosage range used. A less sensitive coagulation test, such as the activated clotting time, is employed to monitor therapy in this situation. Because the activated clotting time can be performed in a point-of-care fashion, patients undergoing coronary angioplasty also typically have their heparin therapy monitored this way.
For therapeutic purposes, heparin also can be administered subcutaneously on a twice-daily basis. A total daily dose of ~35,000 units administered as divided doses every 8-12 hours usually is sufficient to achieve an aPTT of twice the control value (measured midway between doses). Monitoring generally is unnecessary once a steady dosage schedule is established. For low-dose heparin therapy (to prevent DVT and thromboembolism in hospitalized medical or surgical patients), a subcutaneous dose of 5000 units is given two to three times daily. Laboratory monitoring of heparin administered in this way usually is unnecessary because low-dose regimens have negligible effects on the aPTT.

LMWH preparations include Enoxaparin (LOVENOX), dalteparin (FRAGMIN), tinzaparin (INNHOEP, others), ardeparin (NORMIFLO), nadroparin (FRAXIPARINE, others), and reviparin (CLIVARINE) (the latter three are not available in the U.S. currently). These agents differ considerably in composition, and one cannot assume that two preparations that have similar anti-factor Xa activity will have equivalent antithrombotic effects. The more predictable pharmacokinetic properties of LMWH, however, permit administration in a fixed or weight-adjusted dosage regimen once or twice daily by subcutaneous injection.

Because LMWHs produce a relatively predictable anticoagulant response, monitoring is not done routinely. Patients with renal impairment may require monitoring with an anti-factor Xa assay because this condition may prolong the t½ and slow the elimination of LMWHs. Obese patients and children given LMWHs also may require monitoring. Specific dosage recommendations for various LMWH preparations may be obtained from the manufacturer’s literature.

Fondaparinux (ARIETRA) is administered by subcutaneous injection, reaches peak plasma levels in 2 hours, and is excreted in the urine (t½ ~17 h). It should not be used in patients with renal failure. Because it does not interact significantly with blood cells or plasma proteins other than antithrombin, fondaparinux can be given once a day at a fixed dose without coagulation monitoring. Fondaparinux appears to be much less likely than heparin or LMWH to trigger the syndrome of heparin-induced thrombocytopenia (see later in the chapter). Fondaparinux is approved for thromboprophylaxis in patients undergoing hip or knee surgery or surgery for hip fracture (Buller et al., 2003) and in general medical or surgical patients. It also can be used for initial therapy in patients with pulmonary embolism or DVT.

Idraparinux, a hypermethylated version of fondaparinux, underwent phase III clinical testing. This drug has a t½ of 80 hours and is given subcutaneously on a once-weekly basis. To overcome the lack of an antidote, a biotin moiety was added to idraparinux to generate idrabiotaparinux, which can be neutralized with intravenous avidin. Ongoing phase III clinical trials are comparing idrabiotaparinux with warfarin for treatment of pulmonary embolism or for stroke prevention in patients with atrial fibrillation. Idraparinux, idrabiotaparinux, and avidin are not available for routine clinical use.

Heparin Resistance. The dose of heparin required to produce a therapeutic aPTT varies due to differences in the concentrations of heparin-binding proteins in plasma, such as histidine-rich glycoprotein, vitronectin, and large multimers of von Willebrand factor and platelet factor 4; these proteins competitively inhibit binding of heparin to antithrombin. Some patients do not achieve a therapeutic aPTT unless very high doses of heparin (>50,000 units/day) are administered. Such patients may have “therapeutic” concentrations of heparin in plasma at the usual dose when measured using an anti-factor Xa assay. This “pseudo” heparin resistance occurs because these patients have short aPTT values prior to treatment, as a result of increased concentrations of factor VIII. Other patients may require large doses of heparin because of accelerated clearance of the drug, as may occur with massive pulmonary embolism. Patients with inherited antithrombin deficiency ordinarily have 40-60% of the usual plasma concentration of this inhibitor and respond normally to intravenous heparin. However, acquired antithrombin deficiency, where concentrations may be <25% of normal, may occur in patients with hepatic cirrhosis, nephrotic syndrome, or disseminated intravascular coagulation; large doses of heparin may not prolong the aPTT in these individuals.

Because LMWHs and fondaparinux exhibit reduced binding to plasma proteins other than antithrombin, heparin resistance rarely occurs with these agents. For this reason, routine coagulation monitoring is unnecessary. Occasional patients, particularly those with underlying cancer, develop recurrent thrombosis despite therapeutic doses of a LMWH. Anti-factor Xa assays often are subtherapeutic in these patients, and higher doses of LMWH are needed to achieve a therapeutic response.

Toxicity and Adverse Events

Bleeding. Bleeding is the primary untoward effect of heparin. Major bleeding occurs in 1-5% of patients treated with intravenous heparin for venous thromboembolism (Hirsh et al., 2001). The incidence of bleeding is somewhat less in patients treated with LMWH for this indication. Although the risk of bleeding appears to increase with higher total daily doses of heparin and with the degree of prolongation of the aPTT, these correlations are weak, and patients can bleed with aPTT values that are within the therapeutic range. Often an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction.

The anticoagulant effect of heparin disappears within hours of discontinuation of the drug. Mild bleeding due to heparin usually can be controlled without the administration of an antagonist. If life-threatening hemorrhage occurs, the effect of heparin can be reversed quickly by the intravenous infusion of protamine sulfate, a mixture of basic polypeptides isolated from salmon sperm. Protamine binds tightly to heparin and thereby neutralizes its anticoagulant effect. Protamine also interacts with platelets, fibrinogen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of protamine required to neutralize the heparin present in the plasma. This amount is approximately 1 mg of protamine for every 100 units of heparin remaining in the patient; protamine (up to a maximum of 50 mg) is given intravenously at a slow rate (over 10 minutes).

Protamine is used routinely to reverse the anticoagulant effect of heparin after cardiac surgery and other vascular procedures. Anaphylactic reactions occur in about 1% of patients with diabetes mellitus who have received protamine-containing insulin (NPH insulin.
or protamine zinc insulin), but untoward reactions are not limited to this group. A less common reaction consisting of pulmonary vasoconstriction, right ventricular dysfunction, systemic hypotension, and transient neutropenia also may occur after protamine administration.

Protamine only binds long heparin molecules. Therefore, protamine only partially reverses the anticoagulant activity of LMWHs and has no effect on that of fondaparinux. Because the long heparin molecules account for the anti-factor IIa activity of LMWH, protamine completely reverses this activity. In contrast, protamine only partially reverses the anti-factor Xa activity of LMWH, which is mediated by shorter heparin molecules. The very short molecules of fondaparinux do not bind protamine. Therefore, fondaparinux lacks a specific antidote.

**Heparin-Induced Thrombocytopenia.** Heparin-induced thrombocytopenia (platelet count <150,000/mL or a 50% decrease from the pretreatment value) occurs in ~0.5% of medical patients 5-10 days after initiation of therapy with heparin (Warkentin, 2007). Although the incidence may be lower, thrombocytopenia also occurs with LMWHs and fondaparinux, and platelet counts should be monitored. Thrombotic complications that can be life-threatening or lead to amputation occur in about one-half of the affected heparin-treated patients and may precede the onset of thrombocytopenia. The incidence of heparin-induced thrombocytopenia and thrombosis is higher in surgical patients than in medical patients. Women are twice as likely as men to develop this condition.

Venous thromboembolism occurs most commonly, but arterial thromboses causing limb ischemia, myocardial infarction, and stroke also occur. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous heparin injection, and a variety of systemic reactions may accompany heparin-induced thrombocytopenia. The development of IgG antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) appears to cause all of these reactions. These complexes activate platelets by binding to FcyRIIa receptors, which results in platelet aggregation, release of more platelet factor 4, and thrombin generation. The antibodies also may trigger vascular injury by binding to platelet factor 4 attached to endogenous heparan sulfate on the endothelium.

Heparin, LMWH, and fondaparinux should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned above occur 5 or more days after beginning therapy, regardless of the dose or route of administration. The onset of heparin-induced thrombocytopenia may occur earlier in patients who have received heparin within the previous 3-4 months and have residual circulating antibodies. The diagnosis of heparin-induced thrombocytopenia can be confirmed by a heparin-dependent platelet activation assay or an assay for antibodies that react with heparin/platelet factor 4 complexes. Because thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as lepirudin, argatroban (see the next section), or fondaparinux should be administered to patients with heparin-induced thrombocytopenia. LMWH preparations should be avoided, because these drugs often cross-react with heparin in heparin-dependent antibody assays. In contrast, fondaparinux does not cross-react with these heparin-dependent antibodies, and, although large clinical trials are lacking, fondaparinux has been used successfully in patients with heparin-induced thrombocytopenia. Warfarin may precipitate venous limb gangrene or multicentric skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the thrombocytopenia has resolved and the patient is adequately anticoagulated with another agent.

**Other Toxicities.** Abnormalities of hepatic function tests occur frequently in patients who are receiving heparin or LMWHs. Mild elevations of the activities of hepatic transaminases in plasma occur without an increase in bilirubin levels or alkaline phosphatase activity. Osteoporosis resulting in spontaneous vertebral fractures can occur, albeit infrequently, in patients who have received full therapeutic doses of heparin (>20,000 units/day) for extended periods (e.g., 3-6 months). The risk of osteoporosis is lower with LMWHs or fondaparinux than it is with heparin. Heparin can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia, even when low doses are given. Allergic reactions to heparin (other than thrombocytopenia) are rare.

**Other Parenteral Anticoagulants**

**Lepirudin.** Lepirudin (REFLUDAN) is a recombinant derivative (Leu¹-Thr²-63-desulfohirudin) of hirudin, a direct thrombin inhibitor present in the salivary glands of the medicinal leech. Lepirudin is a 65–amino acid polypeptide that binds tightly to both the catalytic site and the extended substrate recognition site (exosite I) of thrombin. It is approved in the U.S. for treatment of patients with heparin-induced thrombocytopenia.

Lepirudin is administered intravenously at a dose adjusted to maintain the aPTT at 1.5-2.5 times the median of the laboratory’s normal range for aPTT. The drug is excreted by the kidneys and has a t½ of ~1.3 hours. Lepirudin should be used cautiously in patients with renal failure because it can accumulate and cause bleeding in these patients. Patients may develop antibodies against hirudin that occasionally prolong the t½ and cause a paradoxical increase in the aPTT; therefore, daily monitoring of the aPTT is recommended. There is no antidote for lepirudin.

**Desirudin.** Desirudin (IPRIVASK) is a recombinant derivative of hirudin that differs only by the lack of a sulfate group on Tyr⁶₃.

Desirudin is indicated for the prophylaxis of DVT in patients undergoing elective hip replacement surgery. The recommended dose is 15 mg every 12 hours by subcutaneous injection. It is eliminated by the kidney; the t½ is ~2 hours following subcutaneous administration. Similar to lepirudin, the drug should be used cautiously in patients with decreased renal function, and serum creatinine and aPTT should be monitored daily.

**Bivalirudin.** Bivalirudin (ANGIOMAX) is a synthetic, 20–amino acid polypeptide that directly inhibits thrombin by a mechanism similar to that of lepirudin.
Bivalirudin contains the sequence Phe₁–Pro²–Arg³–Pro⁴, which occupies the catalytic site of thrombin, followed by a tetraglycine linker and a hirudin-like sequence that binds to exosite I. Thrombin slowly cleaves the Arg³–Pro⁴ peptide bond and thus regains activity.

Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty or cardiopulmonary bypass surgery. Patients with heparin-induced thrombocytopenia or a history of this disorder also can be given bivalirudin instead of heparin during coronary angioplasty. The t₁/₂ of bivalirudin in patients with normal renal function is 25 minutes; dosage reductions are recommended for patients with moderate or severe renal impairment.

**Argatroban.** Argatroban, a synthetic compound based on the structure of L-arginine, binds reversibly to the catalytic site of thrombin.

Argatroban is administered intravenously and has an immediate onset of action. Its t₁/₂ is 40-50 minutes. Argatroban is metabolized by hepatic CYPs and is excreted in the bile; therefore, dosage reduction is required for patients with hepatic insufficiency. The dosage is adjusted to maintain an aPTT of 1.5-3 times the baseline value. Argatroban can be used as an alternative to lepirudin for prophylaxis or treatment of patients with, or at risk of developing, heparin-induced thrombocytopenia. In addition to prolonging the aPTT, argatroban also prolongs the PT, which can complicate the transitioning of patients from argatroban to warfarin. A chromogenic factor X assay can be used instead of the PT to monitor warfarin in these patients.

**Drotrecogin Alfa.** Drotrecogin alfa (XIGRIS) is a recombinant form of human activated protein C that inhibits coagulation by proteolytic inactivation of factors Va and VIIIa. It also has anti-inflammatory effects (Esmon, 2003).

A 96-hour continuous infusion of drotrecogin alfa decreases mortality in adult patients who are at high risk for death from severe sepsis if given within 48 hours of the onset of organ dysfunction (e.g., shock, hypoxemia, oliguria). The major adverse effect is bleeding.

**Antithrombin.** Antithrombin (ATryn) is a recombinant form of human antithrombin produced from the milk of genetically modified goats. It is approved as an anticoagulant for patients with hereditary antithrombin deficiency undergoing surgical procedures.

**ORAL ANTICOAGULANTS**

**Warfarin**

**History.** Following the report of a hemorrhagic disorder in cattle that resulted from the ingestion of spoiled sweet clover silage, Campbell and Link, in 1939, identified the hemorrhagic agent asbishydroxycoumarin (dicoumarol). In 1948, a more potent synthetic congener was introduced as an extremely effective rodenticide; the compound was named warfarin as an acronym derived from the name of the patent holder, Wisconsin Alumni Research Foundation (WARF). Warfarin’s potential as a therapeutic anticoagulant was recognized but not widely accepted, partly due to fear of unacceptable toxicity. However, in 1951, an army inductee uneventfully survived an attempted suicide with massive doses of a preparation of warfarin intended for rodent control. Since then, these anticoagulants have become a mainstay for prevention of thromboembolic disease.

**Chemistry.** Numerous anticoagulants have been synthesized as derivatives of 4-hydroxycoumarin and of the related compound, indan-1,3-dione (Figure 30–6). Only the coumarin derivatives are widely used; the 4-hydroxycoumarin residue, with a nonpolar carbon substituent at the position 3, is the minimal structural requirement for activity. This carbon is asymmetrical in warfarin (and in phenprocoumon and acenocoumarol). The R- and S-enantiomers differ in anticoagulant potency, metabolism, elimination, and interactions with other drugs. Commercial preparations of these anticoagulants are racemic mixtures. No advantage of administering a single enantiomer has been established.

**Mechanism of Action.** The oral anticoagulants are antagonists of vitamin K (see the section on “Vitamin K,” later). Coagulation factors II, VII, IX, and X and the
anticoagulant proteins C and S are synthesized mainly in the liver and are biologically inactive unless 9-13 of the amino-terminal glutamate residues are carboxylated to form the Ca\(^{2+}\)-binding Gla residues. This reaction of the descarboxy precursor protein requires CO\(_2\), O\(_2\), and reduced vitamin K and is catalyzed by \(\gamma\)-glutamyl carboxylase (Figure 30–7). Carboxylation is directly coupled to the oxidation of vitamin K to its corresponding epoxide.

Reduced vitamin K must be regenerated from the epoxide for sustained carboxylation and synthesis of biologically competent proteins. The enzyme that catalyzes this, vitamin K epoxide reductase (VKOR), is inhibited by therapeutic doses of warfarin. Vitamin K (but not vitamin K epoxide) also can be converted to the corresponding hydroquinone by a second reductase, DT-diaphorase. This enzyme requires high concentrations of vitamin K and is less sensitive to coumarin drugs, which may explain why administration of sufficient vitamin K can counteract even large doses of oral anticoagulants.

Therapeutic doses of warfarin decrease by 30-50% the total amount of each vitamin K-dependent coagulation factor made by the liver; in addition, the secreted molecules are under-carboxylated, resulting in diminished biological activity (10-40% of normal). Congenital deficiencies of the procoagulant proteins to these levels cause mild bleeding disorders. Vitamin K antagonists have no effect on the activity of fully carboxylated molecules in the circulation. Thus, the time required for the activity of each factor in plasma to reach a new steady state after therapy is initiated or adjusted depends on its individual rate of clearance. The approximate t\(_{1/2}\) (in hours) are as follows: factor VII, 6; factor IX, 24; factor X, 36; factor II, 50; protein C, 8; and protein S, 30. Because of the long t\(_{1/2}\) of some of the coagulation factors, in particular factor II, the full anti-thrombotic effect of warfarin is not achieved for several days, even though the PT may be prolonged soon after administration due to the more rapid reduction of factors with a shorter t\(_{1/2}\), in particular factor VII. There is no obvious selectivity of the effect of warfarin on any particular vitamin K-dependent coagulation factor, although the anti-thrombotic benefit and the hemorrhagic risk of therapy may be correlated

![Figure 30–7. The vitamin K cycle and mechanism of action of warfarin.](image-url)

In the racemic mixture of S- and R-enantiomers, S-warfarin is more active. By blocking vitamin K epoxide reductase encoded by the VKORC1 gene, warfarin inhibits the conversion of oxidized vitamin K epoxide into its reduced form, vitamin K hydroquinone. This inhibits vitamin K-dependent \(\gamma\)-carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a \(\gamma\)-glutamyl carboxylase that catalyzes the \(\gamma\)-carboxylation process, thereby converting prozymogens to zymogens capable of binding Ca\(^{2+}\) and interacting with anionic phospholipid surfaces. S-warfarin is metabolized by CYP2C9. Common genetic polymorphisms in this enzyme can influence warfarin metabolism. Polymorphisms in the C1 subunit of vitamin K reductase (VKORC1) also can affect the susceptibility of the enzyme to warfarin-induced inhibition, thereby influencing warfarin dosage requirements.
with the functional level of prothrombin, and to a lesser extent, factor X (Zivelin et al., 1993).

**Dosage.** The usual adult dosage of warfarin is 2-5 mg/day for 2-4 days, followed by 1-10 mg/day as indicated by measurements of the international normalized ratio (INR), a value derived from the patient’s PT (see the functional definition of INR in the section on “Laboratory Monitoring”). As indicated later, common genetic polymorphisms render patients more or less sensitive to warfarin. A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly. Warfarin usually is administered orally; age correlates with increased sensitivity to the drug. Warfarin also can be given intravenously without modification of the dose. Intramuscular injection is not recommended because of the risk of hematoma formation.

**Absorption.** The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Bleeding has occurred from repeated skin contact with solutions of warfarin used as a rodenticide. However, different commercial preparations of warfarin tablets vary in their rate of dissolution, and this causes some variation in the rate and extent of absorption. Food in the GI tract also can decrease the rate of absorption. Warfarin usually is detectable in plasma within 1 hour of its oral administration, and concentrations peak in 2-8 hours.

**Distribution.** Warfarin is almost completely (99%) bound to plasma proteins, principally albumin, and the drug distributes rapidly into a volume equivalent to the albumin space (0.14 L/kg). Concentrations in fetal plasma approach the maternal values, but active warfarin is not found in milk (unlike other coumarins and indandiones). Therefore, warfarin can safely be administered to nursing mothers.

**Biotransformation and Elimination.** Warfarin is administered as a racemic mixture of S- and R-warfarin. S-warfarin is 3-5 fold more potent than R-warfarin and is metabolized principally by CYP2C9. Inactive metabolites of warfarin are excreted in urine and stool. The average rate of clearance from plasma is 0.045 mL/min·kg⁻¹. The t₁/₂ varies (25-60 hours), with a mean of ~40 hours; the duration of action of warfarin is 2-5 days.

Polymorphisms in two genes, CYP2C9 and VKORC1 (vitamin K epoxide reductase complex, subunit 1) account for most of the genetic contribution to the variability in warfarin response. CYP2C9 variants affect warfarin pharmacokinetics, whereas VKORC1 variants affect warfarin pharmacodynamics. Common variations in the CYP2C9 gene (designated CYP2C9*2 and *3), encode an enzyme with decreased activity, and thus are associated with higher drug concentrations and reduced warfarin dose requirements. At least one variant allele of CYP2C9*2 or CYP2C9*3 is present in ~25% of European-Americans, but these variants are relatively uncommon in African-American and Asian populations (Table 30-2). Heterozygosity for CYP2C9*2 or *3 decreases the dose of warfarin required for anticoagulation by approximately 20-30% compared with “wild type” individuals (CYP2C9*1/*1). Homozygosity for CYP2C9*2 or *3 can decrease the warfarin dose requirement by approximately 50-70%. Generally, the *3 allele has a greater effect than the *2 allele.

Consistent with decreased warfarin dose requirements, subjects who carry at least one copy of a CYP2C9 variant allele appear to have an increased risk of bleeding. Thus, compared with individuals with no variant alleles, carriers of CYP2C9*2 and CYP2C9*3 have relative risks of bleeding of 1.91 and 1.77, respectively.

VKORC1 reduces vitamin K epoxide to vitamin K hydroquinone (see Figure 30–7) and is the target of coumarin anticoagulants, such as warfarin. Several genetic variations in VKORC1 are in strong linkage disequilibrium and have been designated haplotypes A and B (or non-A). VKORC1 variants are more prevalent than those of CYP2C9. The prevalence of VKORC1 genetic variants is higher in Asians, followed by European-Americans and African-Americans. Polymorphism in VKORC1 explains ~30% of the variability in warfarin dose requirements. Compared with VKORC1 non-A/non-A homozygotes, the warfarin dose requirement is decreased by ~25% in heterozygotes and ~50% in A/A homozygotes.

The clinical relevance of these genetic polymorphisms remains uncertain. The goal of warfarin therapy is to maintain a patient within a target INR range, most often an INR value between 2 and 3. The risk of serious bleeding increases with INR values >4 and is highest during initiation of warfarin therapy. Variations in VKORC1 have a greater effect than CYP2C9 variants on warfarin responses early in therapy. Patients with VKORC1 haplotype A have significantly higher INR values in the first week of warfarin therapy than non-A homozygotes; those with one or two VKORC1 haplotype A alleles achieve a therapeutic INR more rapidly and are more likely to have an INR >4 than patients with two non-A alleles. Both the VKORC1 haplotype and CYP2C9 genotype have a significant effect on the warfarin dose after the first 2 weeks of therapy.

Based on evidence that genetic variations affect warfarin dose requirements and responses to therapy, the FDA amended the prescribing information for warfarin in 2007 to indicate that lower warfarin initiation doses be considered for patients with CYP2C9 and VKORC1 genetic variations. Efforts to facilitate the rational incorporation of genetic information into patient care have included the development of a warfarin dosing algorithm and point-of-care methods for CYP2C9 and VKORC1 genotyping. In a study of more than 4000 patients, the International Warfarin Pharmacogenetics Consortium (2009) compared the accuracy of a pharmacogenetic algorithm that included VKORC1 and CYP2C9 genotypes with two conventional clinical approaches: one based on clinical information to adjust the initial dose, and the other using a fixed-dose approach. The pharmacogenetic algorithm predicted the warfarin dose significantly better than the other two approaches. Moreover, the pharmacogenetic algorithm significantly improved the dose prediction for patients who required either high or low doses of warfarin (<21 mg/week or >49 mg/week).

Genetic variation clearly affects warfarin dose requirements and predisposition to toxicity. Table 30–2 summarizes the effect of
current known genetic factors on warfarin dose requirements. However, it is not clear whether genotyping patients and modifying warfarin therapy accordingly will improve the quality of anticoagulation as determined by such clinically important outcomes as time to therapeutic INR, time spent within the target INR range, and rates of serious bleeding. Large randomized controlled trials comparing genotype-based therapy with standard care are under way to define the clinical impact of incorporating genetic information into clinical practice.

**Drug and Other Interactions.** The list of drugs and other factors that may affect the action of oral anticoagulants is prodigious and expanding (Hirsh et al., 2003). Any substance or condition is potentially dangerous if it alters:

- The uptake or metabolism of the oral anticoagulant or vitamin K
- The synthesis, function, or clearance of any factor or cell involved in hemostasis or fibrinolysis
- The integrity of any epithelial surface

Patients must be educated to report the addition or deletion of any medication, including nonprescription drugs and food supplements.

Some of the more commonly described factors that cause a decreased effect of oral anticoagulants include:

- Reduced absorption of drug caused by binding to cholestyramine in the GI tract
- Increased volume of distribution and a short $t_{1/2}$ secondary to hypoproteinemia, as in nephrotic syndrome
- Increased metabolic clearance of drug secondary to induction of hepatic enzymes, especially CYP2C9, by barbiturates, carbamazepine, or rifampin
- Ingestion of large amounts of vitamin K-rich foods or supplements
- Increased levels of coagulation factors during pregnancy

The PT can be shortened in any of these cases.

Frequently cited interactions that enhance the risk of hemorrhage in patients taking oral anticoagulants include decreased metabolism due to CYP2C9 inhibition by amiodarone, azole antifungals, cinetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfipyrazone, tolcapone, or zafirlukast, and displacement from protein binding sites caused by loop diuretics or valproate. Relative deficiency of vitamin K may result from inadequate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and are an important source of this vitamin. Consequently, antibiotics can cause excessive PT prolongation in patients adequately controlled on warfarin. In addition to an effect on reducing intestinal flora, cephalosporins containing heterocyclic side chains also inhibit steps in the vitamin K cycle. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions increase the prolongation of the PT. Serious interactions that do not alter the PT include inhibition of platelet function by agents such as aspirin and gastritis or frank ulceration induced by anti-inflammatory drugs. Agents may have more than one effect; e.g., clofibrate increases the rate of turnover of coagulation factors and

Resistance to Warfarin. Some patients require >20 mg/day of warfarin to achieve a therapeutic INR. These patients often have excessive vitamin K intake from the diet or parenteral supplementation. Noncompliance and laboratory error are other causes of apparent warfarin resistance. There have been reported a few patients with hereditary warfarin resistance, in whom very high plasma concentrations of warfarin are associated with minimal depression of vitamin K-dependent coagulation factor biosynthesis; mutations in the VKORC1 gene have been identified in some of these patients (Rost et al., 2004).

Sensitivity to Warfarin. Approximately 10% of patients require <1.5 mg/day of warfarin to achieve an INR of 2-3. As indicated earlier, these patients often possess variant alleles of CYP2C9 or variant VKORC1 haplotypes, which affect the pharmacokinetics or pharmacodynamics of warfarin, respectively (Daly and King, 2003).

Toxicities

Bleeding. Bleeding is the major toxicity of warfarin (Hirsh et al., 2003). The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of a potential anatomical source of bleeding. Especially serious episodes involve sites where irreversible damage may result from compression of vital structures (e.g., intracranial, pericardial, nerve sheath, spinal cord) or from massive internal blood loss that may not be diagnosed rapidly (e.g., gastrointestinal, intraperitoneal, retroperitoneal).

Although the reported incidence of major bleeding episodes varies considerably, it is generally <3% per year in patients treated with a target INR of 2-3. The risk of intracranial hemorrhage increases dramatically with an INR >4, especially in older patients. In a large outpatient anticoagulation clinic, the most common factors associated with a transient elevation of the INR to a value >6 were use of a new medication known to potentiate warfarin (e.g., acetaminophen), advanced malignancy, recent diarrheal illness, decreased oral intake, and taking more warfarin than prescribed (Hylek et al., 1998). Patients must be informed of the signs and symptoms of bleeding, and laboratory monitoring should be done at frequent intervals during intercurrent illnesses or any changes of medication or diet.

If the INR is above the therapeutic range but <5 and the patient is not bleeding or in need of a surgical procedure, warfarin can be discontinued temporarily and restarted at a lower dose once the INR is within the therapeutic range (Hirsh et al., 2003). If the INR is ≥5, vitamin K₁ (phytonadione, MEPHYTON, AQUAMEPHYTON) can be given orally at a dose of 1-2.5 mg (for 5 ≤ INR ≤ 9) or 3-5 mg (for INR >9). These doses of oral vitamin K₁ generally cause the INR to fall substantially within 24-48 hours without rendering the patient resistant to further warfarin therapy. Higher doses or parenteral administration may be required if more rapid correction of the INR is necessary. The effect of vitamin K₁ is delayed for at least several hours because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is necessary because of serious bleeding or profound warfarin overdosage (INR >20), adequate concentrations of vitamin K-dependent coagulation factors can be restored by transfusion of fresh frozen plasma (10-20 mL/kg), supplemented with 10 mg of vitamin K₁, given by slow intravenous infusion. Transfusion of plasma may need to be repeated because the transfused factors (particularly factor VII) are cleared from the circulation more rapidly than the residual oral anticoagulant. Concentrates containing three or four of the vitamin K-dependent clotting factors are available in some countries; these rapidly restore the INR to normal. Vitamin K₁ administered intravenously carries the risk of anaphylactoid reactions and therefore should be used cautiously and administered slowly. Patients who receive high doses of vitamin K₁ may become unresponsive to warfarin for several days, but heparin can be used if continued anticoagulation is required.

Birth Defects. Administration of warfarin during pregnancy causes birth defects and abortion. A syndrome characterized by nasal hypoplasia and stippled epiphysyal calcifications that resemble chondrodysplasia punctata may result from maternal ingestion of warfarin during the first trimester. Central nervous system abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal PT values are in the therapeutic range. Vitamin K antagonists should not be used during pregnancy, but as indicated in the previous section, heparin, LMWH, or fondaparinux can be used safely in this circumstance.

Skin Necrosis. Warfarin-induced skin necrosis is a rare complication characterized by the appearance of skin lesions 3-10 days after treatment is initiated. The lesions typically are on the extremities, but adipose tissue, the penis, and the female breast also may be involved. Lesions are characterized by widespread thrombosis of the microvasculature and can spread rapidly, sometimes becoming necrotic and requiring disfiguring debridement or occasionally amputation. Because protein C has a shorter t₁/₂ than do the other vitamin K-dependent coagulation factors (factor VII), its functional activity falls more rapidly in response to the initial dose of vitamin K antagonist. It has been proposed that the dermal necrosis is a manifestation of a temporal imbalance between the anticoagulant protein C and one or more of the procoagulant factors and is exaggerated in patients who are partially deficient in protein C or protein S. However, not all patients with heterozygous deficiency of protein C or protein S develop skin necrosis when treated with warfarin, and patients with normal activities of these proteins also can be affected. Morphologically similar lesions can occur in patients with vitamin K deficiency.

Other Toxicities. A reversible, sometimes painful, blue-tinged discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3-8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

Warfarin can precipitate the syndromes of venous limb gangrene and multicentric skin necrosis when given to patients with heparin-induced thrombocytopenia who are not receiving a parenteral anticoagulant (Warkeint, 2003). Other anticoagulant agents, such as lepirudin, argatroban, or fondaparinux should be continued.
The INR value, supplied by the manufacturer of the test regent, indicates the relative sensitivity of the PT (determined from a given batch of thromboplastin) to decreases in the vitamin K-dependent coagulation factors in comparison with a World Health Organization human thromboplastin standard. Reagents with lower ISI values are more sensitive to the effects of vitamin K antagonists (i.e., the PT is prolonged to a greater extent in comparison with that obtained with a less-sensitive reagent having a higher ISI). Ideally, the ISI value of each batch of thromboplastin should be confirmed in each clinical laboratory using a set of reference plasmas to control for local variables of sample handling and instrumentation.

The INR does not provide a reliable indication of the degree of anticoagulation in patients with the lupus anticoagulant, in whom the PT and other phospholipid-dependent coagulation tests are prolonged at baseline. In these patients, a chromogenic factor X assay or the prothrombin-proconvertin time assay may be used to monitor therapy (Moll and Ortel, 1997).

### Other Vitamin K Antagonists

**Phenprocoumon and Acenocoumarol.** These agents generally are not available in the U.S. but are prescribed in the E.U. and elsewhere.

Phenprocoumon (Marcumar) has a longer plasma t\(_{1/2}\) (5 days) than warfarin, as well as a somewhat slower onset of action and a longer duration of action (7-14 days). It is administered in daily maintenance doses of 0.75-6 mg. By contrast, acenocoumarol (Sintrome) has a shorter t\(_{1/2}\) (10-24 hours), a more rapid effect on the PT, and a shorter duration of action (2 days). The maintenance dose is 1-8 mg daily.

**Indandione Derivatives.** Anisindione (Miradon) is available for clinical use in some countries. It is similar to warfarin in its kinetics of action but offers no clear advantages and may have a higher frequency of untoward effects. Phenindione (Dindevan) still is available in some countries. Serious hypersensitivity reactions, occasionally fatal, can occur within a few weeks of starting therapy with this drug, and its use can no longer be recommended.

**Rodenticides.** Bromadiolone, brodifacoum, diphenadione, chlorophacinone, and pindone are long-acting agents (prolongation of the PT may persist for weeks). They are of interest because they are agents of accidental or intentional poisoning. In this setting, reversal of the coagulopathy can require very large doses of vitamin K (i.e., >100 mg/day) for weeks or months.

### NEW ORAL ANTICOAGULANTS

**Dabigatran Etexilate (Pradaxa, Pradax).** A novel oral anticoagulant, dabigatran etexilate is a prodrug that is rapidly converted to dabigatran, which reversibly blocks the active site of thrombin.

The drug has oral bioavailability of ~6%, a peak onset of action in 2 hours, and a plasma t\(_{1/2}\) of 12-14 hours. When given in fixed doses, dabigatran etexilate produces such a predictable anticoagulant response that routine coagulation monitoring is unnecessary.
Dabigatran etexilate is approved in the E.U. and Canada for prevention of venous thromboembolism after elective hip or knee replacement surgery. It is not yet available in the U.S. In phase III trials, dabigatran etexilate was non-inferior to warfarin for treatment of patients with venous thromboembolism (Schulman et al., 2009) and superior to warfarin for stroke prevention in patients with atrial fibrillation (Connolly et al., 2009). Therefore, this drug represents a promising alternative to warfarin for patients who require long-term anticoagulation.

**Rivaroxaban (XARELTO).** An oral factor Xa inhibitor, rivaroxaban has 80% oral bioavailability, a peak onset of action in 3 hours, and a plasma t\(\text{_{1/2}}\) of 7-11 hours.

About one-third of the drug is excreted unchanged in the urine, the remainder is metabolized by the liver, and inactive metabolites are excreted in the urine or feces. This drug is given in fixed doses and does not require coagulation monitoring. Like dabigatran etexilate, rivaroxaban also is approved in the E.U. and Canada for thromboprophylaxis after hip or knee replacement surgery. Rivaroxaban is not available in the U.S. Ongoing trials are comparing rivaroxaban with warfarin for treatment of venous thromboembolism and stroke prevention in patients with atrial fibrillation.

**Other New Agents.** Other new oral anticoagulants include apixaban, edoxaban, betrixaban, YM150, and TAK-442, which are oral factor Xa inhibitors, and AZD0837, which is an oral thrombin inhibitor. Apixaban and edoxaban are currently undergoing phase III clinical evaluation.

**FIBRINOLYTIC DRUGS**

The fibrinolytic pathway is summarized by Figure 30–3. The action of fibrinolytic agents is best understood in conjunction with an understanding of the characteristics of the physiological components.

**Plasminogen.** Plasminogen is a single-chain glycoprotein of 791 amino acids; it is converted to an active protease by cleavage at Arg\(^{560}\).

Plasminogen’s five kringle domains mediate the binding of plasminogen (or plasmin) to carboxyl-terminal lysine residues in partially degraded fibrin; this enhances fibrinolysis. A plasma carboxypeptidase termed thrombin-activatable fibrinolysis inhibitor (TAFI) can remove these lysine residues and thereby attenuate fibrinolysis. The lysine binding kringle domains of plasminogen are located between amino acids 80 and 165, and they also promote formation of complexes of plasmin with \(\alpha_2\)-antiplasmin, the major physiological plasmin inhibitor. Plasminogen concentrations in human plasma average 2 \(\mu\)M. A plasmin-degraded form of plasmin termed \(\text{lys-plasminogen}\) binds to fibrin with higher affinity than intact plasminogen.

\(\alpha_2\)-Antiplasmin. \(\alpha_2\)-Antiplasmin, a glycoprotein of 452 amino acid residues, forms a stable complex with plasmin, thereby inactivating it.

Dissociation of the plasminogen complex is mediated by an inverse conformational change that exposes the active site on plasminogen that cleaves Arg\(^{560}\) on free plasminogen to form plasmin.

Plasma concentrations of \(\alpha_2\)-antiplasmin (1 \(\mu\)M) are sufficient to inhibit about 50% of potential plasmin. When massive activation of plasminogen occurs, the inhibitor is depleted, and free plasmin causes a “systemic lytic state” in which hemostasis is impaired. In this state, fibrinogen is degraded and fibrinogen degradation products impair fibrin polymerization and therefore increase bleeding from wounds. \(\alpha_2\)-Antiplasmin inactivates plasmin nearly instantaneously, as long as the first kringle domain on plasmin is unoccupied by fibrin or other antagonists, such as aminocaproic acid (see “Inhibitors of Fibrinolysis” section).

**Streptokinase.** Streptokinase (STREPTASE) is a 47,000-Da protein produced by \(\beta\)-hemolytic streptococci. It has no intrinsic enzymatic activity but forms a stable, noncovalent 1:1 complex with plasminogen. This produces a conformational change that exposes the active site on plasminogen that cleaves Arg\(^{560}\) on free plasminogen to form plasmin.

Since the advent of newer agents, streptokinase is rarely used clinically for fibrinolysis. It currently is not marketed in the U.S.

**Tissue Plasminogen Activator.** t-PA is a serine protease of 527 amino acid residues. It is a poor plasminogen activator in the absence of fibrin (Lijnen and Collen, 2001). t-PA binds to fibrin via its finger domain and second lysine-binding kringle domain and activates fibrin-bound plasminogen several hundredfold more rapidly than it activates plasminogen in the circulation. The finger domain is homologous to a similar site on fibronectin, whereas the lysine binding kringle domain is homologous to the kringle domains on plasminogen.

Because it has little activity except in the presence of fibrin, physiological t-PA concentrations of 5-10 ng/mL do not induce systemic plasmin generation. During therapeutic infusions of t-PA, however, when concentrations rise to 300-3000 ng/mL, a systemic lytic state can occur. Clearance of t-PA primarily occurs by hepatic metabolism, and its \(t_{1/2}\) is ~5 min. t-PA is effective in lysing thrombi during treatment of acute myocardial infarction or acute ischemic stroke.

t-PA (alteplase, ACTIVASE) is produced by recombinant DNA technology. The currently recommended (“accelerated”) regimen for coronary thrombolysis is a 15-mg intravenous bolus, followed by 0.75 mg/kg of body weight over 30 minutes (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant variants of t-PA now are available (reteplase, RETAVASE and tenecteplase, TNKASE). They differ from native t-PA by having longer plasma half-lives that allow convenient bolus dosing; reteplase is administered in two bolus doses given 30 minutes apart, while tenecteplase requires only a single bolus. In contrast to t-PA and reteplase, tenecteplase is relatively resistant to inhibition by PAI-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity (GUSTO III Investigators, 1997).

**Hemorrhagic Toxicity of Thrombolytic Therapy.** The major toxicity of all thrombolytic agents is hemorrhage,
which results from two factors: 1) the lysis of fibrin in hemostatic plugs at sites of vascular injury, and 2) the systemic lytic state that results from systemic plasmin generation, which produces fibrinogenolysis and degradation of other coagulation factors (especially factors V and VIII).

The contraindications to fibrinolytic therapy are listed in Table 30–3. Patients with these conditions should not receive such treatment.

If heparin is used concurrently with t-PA, serious hemorrhage will occur in 2-4% of patients. Intracranial hemorrhage is by far the most serious problem. Hemorrhagic stroke occurs with all regimens and is more common when heparin is used. In several large studies, t-PA was associated with an excess of hemorrhagic strokes of about 0.3% of treated patients. Based on the data of three large trials involving almost 100,000 patients, the efficacies of t-PA and streptokinase in treating myocardial infarction are essentially identical. Both agents reduce death and reinfarction by ~30% in regimens containing aspirin. With good evidence that primary coronary angioplasty with or without stent placement, when feasible, is superior to thrombolytic therapy, the use of fibrinolytic therapy has decreased. Fibrinolytic therapy remains the treatment of choice for patients with acute ischemic stroke who present within 3 hours of symptom onset.

Inhibitors of Fibrinolysis

**Aminocaproic Acid.** Aminocaproic acid (AMICAR, generic) is a lysine analog that competes for lysine binding sites on plasminogen and plasmin, blocking the interaction of plasmin with fibrin. Aminocaproic acid is thereby a potent inhibitor of fibrinolysis and can reverse states that are associated with excessive fibrinolysis. The main problem with its use is that thrombi that form during treatment with the drug are not lysed. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with aminocaproic acid. Aminocaproic acid has been used to reduce bleeding after prostatic surgery or after tooth extractions in hemophiliacs. Use of aminocaproic acid to treat a variety of other bleeding disorders has been unsuccessful, either because of limited benefit or because of thrombosis (e.g., after subarachnoid hemorrhage).

Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 hours. For intravenous use, a loading dose of 4-5 g is given over 1 hour, followed by an infusion of 1-1.25 g/hour until bleeding is controlled. No more than 30 g should be given in a 24-hour period. Rarely, the drug causes myopathy and muscle necrosis.

**Tranexamic Acid.** Tranexamic acid (CYKLOKAPRON, LYSTEDA) is a lysine analog that, like aminocaproic acid, competes for lysine binding sites on plasminogen and plasmin, thus blocking their interaction with fibrin. Tranexamic acid can be used for the same

| Table 30–3 |
| Absolute and Relative Contraindications to Fibrinolytic Therapy |

**Absolute Contraindications**
- Prior intracranial hemorrhage
- Known structural cerebral vascular lesion
- Known malignant intracranial neoplasm
- Ischemic stroke within 3 months
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head trauma or facial trauma within 3 months

**Relative Contraindications**
- Uncontrolled hypertension (systolic blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg)
- Traumatic or prolonged CPR or major surgery within 3 weeks
- Recent (within 2-4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction to streptokinase
- Pregnancy
- Active peptic ulcer
- Current use of warfarin and INR >1.7

CPR, cardiopulmonary resuscitation; INR, international normalized ratio.
indications as aminocaproic acid and can be given intravenously or orally. Like aminocaproic acid, tranexamic acid is excreted in the urine and dose reductions are necessary in patients with renal impairment. The FDA approved oral tranexamic acid tablets for treatment of heavy menstrual bleeding in 2009. When used for this indication, tranexamic acid usually is given at a dose of 1 g four times a day for 4 days.

**ANTIPLATELET DRUGS**

Platelets provide the initial hemostatic plug at sites of vascular injury. They also participate in pathological thromboses that lead to myocardial infarction, stroke, and peripheral vascular thromboses. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms; thus, in combination, their effects are additive or even synergistic. Their availability has led to a revolution in cardiovascular medicine, whereby angioplasty and vascular stenting of lesions now are feasible with low rates of restenosis and thrombosis when effective platelet inhibition is employed. The sites of pharmacological intervention by the various antiplatelet drugs are highlighted in Figure 30–8.

**Aspirin.** Processes including thrombosis, inflammation, wound healing, and allergy are modulated by oxygenated metabolites of arachidonate and related polyunsaturated fatty acids that are collectively termed eicosanoids. Interference with the synthesis of eicosanoids is the basis for the effects of many therapeutic agents, including analgesics, anti-inflammatory drugs, and anti-thrombotic agents (see Chapters 33 and 34).

In platelets, the major cyclooxygenase product is TxA\(_2\) (thromboxane \(A_2\)), a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of TxA\(_2\) by acetylating a serine residue near the active site of platelet cyclooxygenase-1 (COX-1), the enzyme that produces the cyclic endoperoxide precursor of TxA\(_2\). Because platelets do not synthesize new proteins, the action of aspirin on platelet COX-1 is permanent, lasting for the life of the platelet (7-10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function.

Complete inactivation of platelet COX-1 is achieved with a daily aspirin dose of 75 mg. Therefore, aspirin is maximally effective as an anti-thrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicate that aspirin, when used as an anti-thrombotic drug, is maximally effective at doses of 50-320 mg/day (Antithrombotic Trialists’ Collaboration, 2002; Patrono et al., 2004). Higher doses do not improve efficacy; moreover, they potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding.

Other NSAIDs that are reversible inhibitors of COX-1 have not been shown to have anti-thrombotic efficacy and in fact may even interfere with low-dose aspirin regimens (see Chapters 33 and 34 for details).

**Dipyridamole.** Dipyridamole (PERSANTINE, others) interferes with platelet function by increasing the cellular concentration of cyclic AMP. This effect is mediated by inhibition of cyclic nucleotide phosphodiesterases and/or by blockade of uptake of adenosine, which acts at adenosine \(A_2\) receptors to stimulate platelet adenylyl cyclase and hence cellular cyclic AMP. Dipyridamole...
is a vasodilator that, in combination with warfarin, inhibits embolization from prosthetic heart valves. The drug has little or no benefit as an anti-thrombotic agent.

In trials in which a regimen of dipyridamole plus aspirin was compared with aspirin alone, dipyridamole provided no additional beneficial effect (Antithrombotic Trialists’ Collaboration, 2002). Two studies suggest that dipyridamole plus aspirin reduces strokes in patients with prior strokes or transient ischemic attacks (Diener et al., 1996). A formulation containing 200 mg of dipyridamole, in an extended-release form, and 25 mg of aspirin (AGGRENOX) is available. A recent study comparing this combination with clopidogrel for secondary prevention in patients with stroke or transient ischemic attacks showed no advantage of dipyridamole plus aspirin.

**Ticlopidine (TICLID, others).** Platelets contain two purinergic receptors, P2Y<sub>1</sub> and P2Y<sub>12</sub>; both are GPCRs for ADP. The ADP-activated platelet P2Y<sub>1</sub> receptor couples to the G<sub>q</sub>–PLC–IP<sub>3</sub>–Ca<sup>2+</sup> pathway and induces a shape change and aggregation. The P2Y<sub>12</sub> receptor couples to G<sub>i</sub> and, when activated by ADP, inhibits adenyl cyclase, resulting in lower levels of cyclic AMP and thereby less cyclic AMP–dependent inhibition of platelet activation. Based on pharmacological studies, it appears that both receptors must be stimulated to result in platelet activation (Jin and Kunapuli, 1998), and inhibition of either receptor is sufficient to block platelet activation. Ticlopidine is a thienopyridine prodrug (Figure 30–9) that inhibits the P2Y<sub>12</sub> receptor.

Ticlopidine is converted to the active thiol metabolite by a hepatic CYP (Savi et al., 2000). It is rapidly absorbed and highly bioavailable. It permanently inhibits the P2Y<sub>12</sub> receptor by forming a disulfide bridge between the thiol on the drug and a free cysteine residue in the extracellular region of the receptor, and thus has a prolonged effect. Like aspirin, it has a short t<sub>1/2</sub> but a long duration of action, which has been termed “hit-and-run pharmacology” (Hollopeter et al., 2001). Maximal inhibition of platelet aggregation is not seen until 8-11 days after starting therapy. The usual dose is 250 mg twice daily. Loading doses of 500 mg sometimes are given to achieve a more rapid onset of action. Inhibition of platelet aggregation persists for a few days after the drug is stopped.

**Adverse Effects.** The most common side effects are nausea, vomiting, and diarrhea. The most serious is severe neutropenia (absolute neutrophil count <500/μL), which occurred in 2.4% of stroke patients given the drug during premarketing clinical trials. Fatal agranulocytosis with thrombocytopenia has occurred within the first 3 months of therapy; therefore, frequent blood counts should be obtained during the first few months of therapy, with immediate discontinuation of therapy should cell counts decline. Platelet counts also should be monitored, as thrombocytopenia has been reported. Rare cases of thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS) have been associated with ticlopidine, with a reported incidence of 1 in 1600-4800 patients when the drug is used after cardiac stenting; the mortality associated with these cases is reported to be as high as 18-57% (Bennett et al., 2000). Remission of TTP has been reported when the drug is stopped (Quinn and Fitzgerald, 1999).

**Therapeutic Uses.** Ticlopidine has been shown to prevent cerebrovascular events in secondary prevention of stroke and is at least as good as aspirin in this regard (Patrono et al., 1998). Because ticlopidine is associated with life-threatening blood dyscrasias and a relatively high rate of TTP, it has largely been replaced by clopidogrel.

**Clopidogrel (PLAVIX).** Clopidogrel is closely related to ticlopidine (Figure 30–9). Clopidogrel also is an irreversible inhibitor of platelet P2Y<sub>12</sub> receptors but is more potent and has a more favorable toxicity profile than ticlopidine, with thrombocytopenia and leukopenia occurring only rarely (Bennett et al., 2000). Clopidogrel is a prodrug with a slow onset of action.

The usual dose is 75 mg/day with or without an initial loading dose of 300 or 600 mg. The drug is somewhat better than aspirin in the secondary prevention of stroke, and the combination of clopidogrel plus aspirin is superior to aspirin alone for prevention of recurrent ischemia in patients with unstable angina. The superiority of the combination suggests that the actions of the two drugs are synergistic, as might be expected from their distinct mechanisms of action. Clopidogrel is used with aspirin after angioplasty and coronary stent implantation, and this combination should be continued for at least 4-6 weeks in patients with a bare metal stent and for at least 1 year in those with a drug-eluting stent. The FDA-approved indications...
for clopidogrel are to reduce the rate of stroke, myocardial infarction, and death in patients with recent myocardial infarction or stroke, established peripheral arterial disease, or acute coronary syndrome.

There is wide inter-individual variability in the capacity of clopidogrel to inhibit ADP-induced platelet aggregation, and some patients are designated resistant to the antiplatelet effects of the drug. This variability reflects, at least in part, genetic polymorphisms in the CYPs involved in the metabolic activation of clopidogrel, most importantly CYP2C19. Clopidogrel-treated patients with the loss-of-function CYP2C19*2 allele exhibit reduced platelet inhibition compared with those with the wild-type CYP2C19*1 allele and experience a higher rate of cardiovascular events (see Table 30–2). Even patients with the reduced-function CYP2C19*3, *4, or *5 alleles may derive less benefit from clopidogrel than those with the full-function CYP2C19*1 allele. Concomitant administration of proton pump inhibitors, which are inhibitors of CYP2C19, with clopidogrel, produces a small reduction in the inhibitory effects of clopidogrel on ADP-induced platelet aggregation. The extent to which this interaction increases the risk of cardiovascular events remains controversial. Although CYP3A4 also contributes to the metabolic activation of clopidogrel, polymorphisms in this enzyme do not appear to influence clopidogrel responsiveness. However, a small study in patients undergoing percutaneous coronary interventions revealed that atorvastatin, a competitive inhibitor of CYP3A4, reduced the inhibitory effect of clopidogrel on ADP-induced platelet aggregation. The impact of this interaction on clinical outcomes is unknown.

The observation that genetic polymorphisms that affect clopidogrel metabolism influence clinical outcomes raises the possibilities that pharmacogenetic profiling may be useful to identify clopidogrel-resistant patients and that point-of-care assessment of the extent of clopidogrel-induced platelet inhibition may help detect patients at higher risk for subsequent cardiovascular events. It is unknown whether administration of higher doses of clopidogrel to such patients will overcome this resistance.

**Prasugrel (EFFIENT or EFIENT).** The newest member of the thienopyridine class, prasugrel (Figure 30–9) also is a prodrug that requires metabolic activation. However, its onset of action is more rapid than that of ticlopidine or clopidogrel, and prasugrel produces greater and more predictable inhibition of ADP-induced platelet aggregation.

These characteristics reflect the rapid and complete absorption of prasugrel from the gut and its more efficient activation pathways. Virtually all of the absorbed prasugrel undergoes activation; by comparison, only 15% of absorbed clopidogrel undergoes metabolic activation, with the remainder inactivated by esterases.

Because the active metabolites of prasugrel and the other thienopyridines bind irreversibly to the P2Y12 receptor, these drugs have a prolonged effect after discontinuation. This can be problematic if patients require urgent surgery. Such patients are at increased risk for bleeding unless the thienopyridine is stopped at least 5 days prior to the procedure.

Prasugrel was compared with clopidogrel in patients with acute coronary syndromes scheduled to undergo a coronary intervention. The incidence of cardiovascular death, myocardial infarction, and stroke was significantly lower with prasugrel than with clopidogrel mainly reflecting a reduction in the incidence of nonfatal myocardial infarction. The incidence of stent thrombosis also was lower with prasugrel than with clopidogrel. However, these advantages were at the expense of significantly higher rates of fatal and life-threatening bleeding. Because patients with a history of a prior stroke or transient ischemic attack are at particularly high risk of bleeding, the drug is contraindicated in those with a history of cerebrovascular disease. Caution is required if prasugrel is used in patients weighing <60 kg or in those with renal impairment. After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg. Patients >75 years of age or weighing <60 kg may do better with a daily prasugrel dose of 5 mg.

In contrast to their effect on the bioactivation of clopidogrel, CYP2C19 polymorphisms appear to be less important determinants of the activation of prasugrel. There is no association between the loss-of-function allele and decreased platelet inhibition or increased rates of cardiovascular events with prasugrel. Therefore, prasugrel may be a reasonable alternative to clopidogrel in patients with the loss-of-function CYP2C19 allele.

**Glycoprotein IIb/IIIa Inhibitors.** Glycoprotein IIb/IIIa is a platelet-surface integrin, which is designated αIIbβ3 by the integrin nomenclature. There are about 80,000 copies of this dimeric glycoprotein on the platelet surface. Glycoprotein IIb/IIIa is inactive on resting platelets but undergoes a conformational transformation when platelets are activated by platelet agonists such as thrombin, collagen, or TxA2. This transformation endows glycoprotein IIb/IIIa with the capacity to serve as a receptor for fibrinogen and von Willebrand factor, which anchor platelets to foreign surfaces and to each other, thereby mediating aggregation. Inhibition of binding to this receptor blocks platelet aggregation induced by any agonist. Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or the thienopyridine platelet inhibitors. Three agents are approved for use at present, and their features are highlighted in Table 30–4.

**Abciximab.** Abciximab (REOPRO) is the Fab fragment of a humanized monoclonal antibody directed against the αIIbβ3 receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells.

The antibody is administered to patients undergoing percutaneous angioplasty for coronary thromboses, and when used in conjunction with aspirin and heparin, has been shown to prevent restenosis, recurrent myocardial infarction, and death. The unbound antibody is cleared from the circulation with a t1/2 of about 30 minutes, but antibody remains bound to the αIIbβ3 receptor and inhibits platelet aggregation as measured in vitro for 18-24 hours after infusion is stopped. It is given as a 0.25-mg/kg bolus followed by 0.125 μg/kg/min for 12 hours or longer.

**Adverse Effects.** The major side effect of abciximab is bleeding, and the contraindications to its use are similar to those for the fibrinolytic
agents listed in Table 30–3. The frequency of major hemorrhage in clinical trials varies from 1-10%, depending on the intensity of anti-coagulation with heparin. Thrombocytopenia with a platelet count <50,000 occurs in about 2% of patients and may be due to development of neo-epitopes induced by bound antibody. Since the duration of action is long, if major bleeding or emergent surgery occurs, platelet transfusions can reverse the aggregation defect because free antibody concentrations fall rapidly after cessation of infusion. Readministration of antibody has been performed in a small number of patients without evidence of decreased efficacy or allergic reactions. The expense of the antibody limits its use.

**Eptifibatide.** Eptifibatide (INTEGRILIN) is a cyclic peptide inhibitor of the fibrinogen binding site on \( \alpha_{\text{IIb}}\beta_3 \). It is administered intravenously and blocks platelet aggregation.

Eptifibatide is given as a bolus of 180 \( \mu \)g/kg followed by 2 \( \mu \)g/kg/min for up to 96 hours. It is used to treat acute coronary syndrome and for angioplasty coronary interventions. In the latter case, myocardial infarction and death have been reduced by ~20%. Although the drug has not been compared directly to abciximab, it appears that its benefit is somewhat less than that obtained with the antibody, perhaps because eptifibatide is specific for \( \alpha_{\text{IIb}}\beta_3 \) and does not react with the vitronectin receptor. The duration of action of the drug is relatively short, and platelet aggregation is restored within 6-12 hours after cessation of infusion. Eptifibatide generally is administered in conjunction with aspirin and heparin.

**Adverse Effects.** The major side effect is bleeding, as is the case with abciximab. The frequency of major bleeding in trials was about 10%, compared with ~9% in a placebo group, which included heparin. Thrombocytopenia has been seen in 0.5-1% of patients.

**Tirofiban.** Tirofiban (AGGRASTAT) is a nonpeptide, small-molecule inhibitor of \( \alpha_{\text{IIb}}\beta_3 \) that appears to have a mechanism of action similar to eptifibatide. Tirofiban has a short duration of action and has efficacy in non-Q-wave myocardial infarction and unstable angina. Reductions in death and myocardial infarction have been ~20% compared to placebo, results similar to those with eptifibatide.

Side effects also are similar to those of eptifibatide. The agent is specific to \( \alpha_{\text{IIb}}\beta_3 \) and does not react with the vitronectin receptor. Meta-analysis of trials using \( \alpha_{\text{IIb}}\beta_3 \) inhibitors suggests that their value in antiplatelet therapy after acute myocardial infarction is limited (Boersma et al., 2002). Tirofiban is administered intravenously at an initial rate of 0.4 \( \mu \)g/kg/min for 30 minutes, and then continued at 0.1 mg/kg/min for 12-24 hours after angioplasty or atherectomy. It is used in conjunction with heparin.

**Newer Antiplatelet Agents**

New agents in advanced stages of development include cangrelor and ticagrelor (BRILINTA), direct-acting reversible P2Y\(_{12}\) antagonists, and SCH530348 and E5555, orally active inhibitors of the protease-activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

**Cangrelor.** Cangrelor is an adenosine analog that binds reversibly to P2Y\(_{12}\) and inhibits its activity. The drug has a t\(_{1/2}\) of 3-6 minutes and is given intravenously as a bolus followed by an infusion. When stopped, platelet function recovers within 60 minutes. Recent trials comparing cangrelor with placebo during coronary interventions or comparing cangrelor with clopidogrel after such procedures revealed little or no advantages of cangrelor.

**Ticagrelor.** Ticagrelor is an orally active, reversible inhibitor of P2Y\(_{12}\). The drug is given twice daily and not only has a more rapid onset and offset of action than clopidogrel, but also produces greater and more predictable inhibition of ADP-induced platelet aggregation. When compared with clopidogrel in patients with acute coronary syndromes (Wallentin et al., 2009), ticagrelor produced a greater reduction in cardiovascular death, myocardial infarction, and stroke at 1 year than clopidogrel did. This difference reflected a significant reduction in both cardiovascular death and myocardial infarction with ticagrelor. Rates of stroke were similar with ticagrelor and clopidogrel, and there were no differences in rates of major bleeding. When minor bleeding was added to the major bleeding results, however, ticagrelor showed an increase relative to clopidogrel. Although not yet

approved, ticagrelor is the first new antiplatelet drug to demonstrate a reduction in cardiovascular death compared with clopidogrel in patients with acute coronary syndromes.

**SCH530348.** SCH530348 an orally active inhibitor of PAR-1, is under investigation as an adjunct to aspirin or aspirin plus clopidogrel. Two large phase III trials are under way. E5555, a second oral PAR-1 antagonist, is earlier in development.

## THE ROLE OF VITAMIN K

Vitamin K is essential in both mammals and photosynthetic organisms. In certain photosynthetic bacteria, vitamin K is a cofactor in the photosynthetic electron-transport system; in green plants, vitamin K₄ is a component of photosystem I, the membrane-bound, macromolecular light-sensitive complex. Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the γ-carboxylation of multiple glutamate residues of several clotting factors and anticoagulant proteins. The vitamin K-dependent formation of Gla residues permits the appropriate interactions of clotting factors, Ca²⁺, and membrane phospholipids and modulator proteins (Figures 30–1, 30–2, and 30–3). Vitamin K antagonists (coumarin derivatives; Figure 30–6) block Gla (γ-carboxyglutamate) formation and thereby inhibit clotting; excess vitamin K₁ can reverse the effects of these oral anticoagulants.

### History.

In 1929, Dam observed that chickens fed inadequate diets developed a deficiency disease characterized by spontaneous bleeding and reduced prothrombin in the blood. Subsequently, Dam and coworkers (1935, 1936) found that the condition could be alleviated rapidly by feeding an unidentified fat-soluble substance, named vitamin K (Koagulation vitamin) by Dam. Independently, Almquist and Stokstad (1935) performed similar work. Quick and coworkers (1935) observed a coagulation defect in jaundiced individuals that was due to a decrease in the plasma concentration of prothrombin. In the same year, Hawkins and Whipple reported that animals with biliary fistulas were likely to develop excessive bleeding. Subsequently, Hawkins and Brinkhous (1936) showed that this, too, was due to a deficiency in prothrombin and that the condition could be relieved by the feeding of bile salts. The culmination of these studies came with the demonstration by Butt and coworkers (1938) and Warner and associates (1938) that combination therapy with vitamin K and bile salts was effective in the treatment of the hemorrhagic diathesis of jaundice. Thus, the relationship between vitamin K, adequate hepatic function, and the physiological mechanisms operating in the normal clotting of blood was established.

### Chemistry and Occurrence.

Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K₁ and vitamin K₂. Vitamin K₁, or phytonadione (also referred to as phyloquinone), is 2-methyl-3-phytyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K₂ actually is a series of compounds (the menaquinones) in which the phytol side chain of phytonadione has been replaced by a side chain built up of 2-13 prenyl units. Considerable synthesis of menaquinones occurs in Gram-positive bacteria; indeed, intestinal flora synthesize the large amounts of vitamin K contained in human and animal feces (Bentley and Meganathan, 1982). Depending on the bioassay system used, menadione is at least as active on a molar basis as phytonadione.

![MENAQUINOINE (vitamin K₂) series](image)

**Physiological Functions and Pharmacological Actions.**

In animals and humans, phytonadione and menaquinones promote the biosynthesis of: the Gla forms of factors II (prothrombin), VII, IX, and X; anticoagulant proteins C and S; protein Z (a cofactor to the inhibitor of Xa); the bone Gla protein osteocalcin; the matrix Gla protein; the growth arrest–specific protein 6 (Gas6); and four transmembrane monospans of unknown function (Brown et al., 2000; Broze, 2001; Kulman et al., 2001).

Figure 30–7 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. Vitamin K₃, as KH₂, the reduced vitamin K hydroquinone, is an essential cofactor for γ-glutamyl carboxylase (Rishavy et al., 2004). Using KH₂, O₂, CO₂, and the glutamate-containing substrate, the enzyme forms a Gla protein and concomitantly, the 2,3-epoxide of vitamin K. A coumarin-sensitive 2,3-epoxide reductase regenerates KH₂. The γ-glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and seem to function as a multicomponent system that may include the chaperone protein, calumenin, which reportedly inhibits γ-carboxylation (Wajih et al., 2004). Two natural mutations in γ-glutamyl carboxylase lead to bleeding disorders (Mutucumara et al., 2003). With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ-carboxylation of glutamate also occurs in lung, bone, and other cell types. Vitamin K epoxide reductase recently has been cloned (Rost et al., 2004; Li et al., 2004).

The γ-carboxylation reaction is aided by the grouping of glutamate residues in a Gla domain (~45 residues in clotting factors) near the amino terminus of the nascent substrate protein; the reaction is guided by an adjacent propeptide (18-28 amino acids) that interacts with the carboxylase. In the case of the vitamin K-dependent clotting proteins, the Gla domain is ~45 residues long, and 9-13 glutamates...
Symptoms of Deficiency. The chief clinical manifestation of vitamin K deficiency is an increased tendency to bleed (see the discussion of hypoprothrombinemia in the section on “Oral anticoagulants,” earlier in the chapter). Ecchymoses, epistaxis, hematuria, GI bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptysis is uncommon. The discovery of a vitamin K-dependent protein in bone suggests that the fetal bone abnormalities associated with the administration of oral anticoagulants during the first trimester of pregnancy (“fetal warfarin syndrome”) may be related to a deficiency of the vitamin. Considerable evidence indicates a role for vitamin K in adult skeletal maintenance and the prevention of osteoporosis. Low concentrations of the vitamin are associated with deficits in bone mineral density and fractures; vitamin K supplementation increases the concentrations of the vitamin are associated with deficits in bone mineral density, but the relationship of these two effects is unclear (Feskanich et al., 1999). Bone mineral density in adults is not changed by therapeutic use of vitamin K antagonists (Rosen et al., 1993), but new bone formation may be affected.

Toxicity. Phytodetoxinone and the menaquinones are nontoxic to animals, even when given at 500 times the recommended daily allowance. However, menadione and its derivatives (synthetic forms of vitamin K) have been implicated in producing hemolytic anemia and kernicterus in neonates, especially in premature infants (Diploma and Ritchie, 1997). For this reason, menadione should not be used as a therapeutic form of vitamin K.

Absorption, Fate, and Excretion. The mechanism of intestinal absorption of compounds with vitamin K activity varies with their solubility. In the presence of bile salts, phytodetoxinone and the menaquinones are adequately absorbed from the intestine, almost entirely by way of the lymph. Phytodetoxinone is absorbed by an energy-dependent, saturable process in proximal portions of the small intestine; menaquinones are absorbed by diffusion in the distal portions of the small intestine and in the colon. Following absorption, phytodetoxinone is incorporated into chylomicrons in close association with triglycerides and lipoproteins. In a large survey, plasma phytodetoxinone and triglyceride concentration were well correlated (Sadowski et al., 1989). The extremely low phytodetoxinone levels in newborns may be partly related to very low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, phytodetoxinone and menaquinones are concentrated in the liver, but the concentration of phytodetoxinone declines rapidly. Menaquinones, produced in the lower bowel, are less biologically active than phytodetoxinone due to their long side chain. Very little vitamin K accumulates in other tissues.

Phytodetoxinone is metabolized rapidly to more polar metabolites, which are excreted in the bile and urine. The major urinary metabolites result from shortening of the side chain to five or seven carbon atoms, yielding carboxylic acids that are conjugated with glucuronate prior to excretion.

Apparentlly, there is only modest storage of vitamin K in the body. Under circumstances in which lack of bile interferes with absorption of vitamin K, hypoprothrombinemia develops slowly over several weeks.

Therapeutic Uses. Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin, or as a consequence of the action of a vitamin K antagonist.

Phytodetoxinone (AQUAMEPHYTON, KONAKION, MEPHYTON, generic) is available as tablets and in a dispersion with buffered polysorbate glycol (KONAKION) or polyoxyethylated fatty acid derivatives and dextrose (AQUAMEPHYTON). KONAKION is administered only intramuscularly. AQUAMEPHYTON may be given by any route; however, oral or subcutaneous injection is preferred because severe reactions resembling anaphylaxis have followed its intravenous administration.

Inadequate Intake. After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare: The vitamin is present in many foods and also is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce a hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation. It is recommended to give 1 mg of phytodetoxinone per week (the equivalent of about 150 μg/day) to patients on total parenteral nutrition.

Hypoprothrombinemia of the Newborn. Healthy newborn infants show decreased plasma concentrations of vitamin K-dependent clotting factors for a few days after birth, the time required to obtain an adequate dietary intake of the vitamin and to establish a normal intestinal flora. In premature infants and in infants with hemorrhagic disease of the newborn, the concentrations of clotting factors are particularly depressed. The degree to which these changes reflect true vitamin K deficiency is controversial. Measurements of non-γ-carboxylated prothrombin suggest that vitamin K deficiency occurs in about 3% of live births (Shapiro et al., 1986).

Hemorrhagic disease of the newborn has been associated with breast-feeding; human milk has low concentrations of vitamin K (Haroon et al., 1982). In addition, the intestinal flora of breast-fed infants may lack microorganisms that synthesize the vitamin (Keenan et al., 1971). Commercial infant formulas are supplemented with vitamin K.

In the neonate with hemorrhagic disease of the newborn, the administration of vitamin K raises the concentration of these clotting factors to the level normal for the newborn infant and controls the bleeding tendency within about 6 hours. The routine administration of 1 mg phytodetoxinone intramuscularly at birth is required by law in the U.S. This dose may have to be increased or repeated if the mother...
A variety of anticoagulant, fibrinolytic, and antiplatelet agents are available and are among the most widely used drugs. Heparin and LMWHs are commonly used to treat venous thromboembolism, unstable angina, and acute myocardial infarction; these agents also are used to prevent thrombosis during coronary angioplasty and for certain other high-risk indications. The major toxicities of heparin are bleeding and the syndrome of heparin-induced thrombocytopenia, which often precipitates venous or arterial thrombosis. Direct thrombin inhibitors, such as lepirudin, bivalirudin, and argatroban, are indicated for patients with heparin-induced thrombocytopenia.

Warfarin and other vitamin K antagonists are used to prevent the progression or recurrence of acute venous thromboembolism following an initial course of heparin. They also decrease the incidence of systemic embolization in patients with atrial fibrillation or prosthetic heart valves. Warfarin has a narrow therapeutic index drug and is associated with more than 200 drug-drug and drug-food interactions. Over- and under-dosing are associated with serious consequences, including thrombosis or major bleeding in a significant number of patients. Warfarin also produces fetal abnormalities when given during pregnancy. New oral anticoagulants that target thrombin or factor Xa hopefully will replace warfarin in the future. These drugs have the potential to streamline care because they can be given in fixed doses without coagulation monitoring.

Fibrinolytic agents, such as t-PA or its derivatives, reduce the mortality of acute myocardial infarction and are used in situations in which angioplasty is not readily available. Fibrinolytic therapy also is used for patients with acute ischemic stroke.

Antiplatelet agents, including aspirin, clopidogrel, prasugrel, and glycoprotein IIb/IIIa inhibitors, are used to prevent thrombosis after coronary angioplasty and in the secondary prevention of myocardial infarction and stroke. Bleeding is the major toxicity of the antiplatelet agents. Newer antiplatelet drugs that directly target the ADP or thrombin receptor on platelets are in advanced stages of development. These more potent antiplatelet drugs may produce more bleeding, highlighting the inevitable link between the efficacy and toxicity of anti-thrombotic drugs.

BIBLIOGRAPHY

Lijnen HR, Collen D. Fibrinolysis and the control of hemostasis. In: Stamatoyannopoulos G, Majerus PW, Perlmutter RM,
Hyperlipidemia is a major cause of atherosclerosis and atherosclerosis-induced conditions, such as coronary heart disease (CHD), ischemic cerebrovascular disease, and peripheral vascular disease. Although the incidence of these atherosclerosis-related cardiovascular disease (CVD) events has declined in the U.S., these conditions cause morbidity or mortality in a majority of middle-aged or older adults and account for about one-third of all deaths of persons in this age range. The incidence and absolute number of annual events will likely increase over the next decade because of the epidemic of obesity and the aging of the U.S. population. Dyslipidemias, including hyperlipidemia (hypercholesterolemia) and low levels of high-density-lipoprotein cholesterol (HDL-C), are major causes of increased atherogenic risk; both genetic disorders and lifestyle (sedentary behavior and diets high in calories, saturated fat, and cholesterol) contribute to the dyslipidemias seen in countries around the world. For many individuals, alterations in lifestyle have a far greater potential for reducing vascular disease risk and at a lower cost than drug therapy. When pharmacotherapy is indicated, providers can choose from multiple agents with proven efficacy.

Recognition that dyslipidemia is a risk factor has led to the development of drugs that modify cholesterol levels. This chapter focuses on the following classes of drugs:

- 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors—the statins
- Bile acid–binding resins
- Nicotinic acid (niacin)
- Fibric acid derivatives
- The cholesterol absorption inhibitor ezetimibe

These drugs provide benefit in patients across the entire spectrum of cholesterol levels, primarily by reducing levels of low-density-lipoprotein cholesterol (LDL-C).

In early well-controlled clinical trials employing drug regimens that reduce LDL-C levels moderately (30-40%), fatal and nonfatal CHD events and strokes were reduced by as much as 30-40% (Grundy et al., 2004b). Clinical trial data support extending lipid-modifying therapy to high-risk patients whose major lipid risk factor is a reduced plasma level of HDL-C, even if their LDL-C level does not meet the existing threshold values for initiating hypolipidemic drug therapy (Grundy et al., 2004b). In patients with low HDL-C and average LDL-C levels, appropriate drug therapy reduced CHD endpoint events by 20-35% (Heart Protection Study Collaborative Group, 2002). Because two-thirds of patients with CHD in the U.S. have low HDL-C levels (<40 mg/dL in men, <50 mg/dL in women), it is important to include low-HDL-C patients in management guidelines for dyslipidemia, even if their LDL-C levels are in the normal range (Bersot et al., 2003).

Severe hypertriglyceridemia (i.e., triglyceride levels of >1000 mg/dL) requires therapy to prevent pancreatitis. It is unclear whether hypertriglyceridemia is an independent risk factor for developing atherothrombotic CVD (Sarwar et al., 2007). Moderately elevated triglyceride levels (150-400 mg/dL) are of concern because they often occur as part of the metabolic syndrome, which includes insulin resistance, obesity, hypertension, low HDL-C levels, a procoagulant state, and substantially increased risk of CVD. The atherogenic dyslipidemia in patients with the metabolic syndrome also is characterized by lipid-depleted LDL (sometimes referred
to as “small, dense LDL”) (Grundy et al., 2004a). The metabolic syndrome affects ~25% of adults and is common in CVD patients; hence, identification of moderate hypertriglyceridemia in a patient, even if the total cholesterol level is normal, should trigger an evaluation to identify insulin-resistant patients with this disorder.

### PLASMA LIPOPROTEIN METABOLISM

Lipoproteins are macromolecular assemblies that contain lipids and proteins. The lipid constituents include free and esterified cholesterol, triglycerides, and phospholipids. The protein components, known as apolipoproteins or apoproteins, provide structural stability to the lipoproteins and also may function as ligands in lipoprotein–receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein metabolism. In all spherical lipoproteins, the most water-insoluble lipids (cholesteryl esters and triglycerides) are core components, and the more polar, water-soluble components (apolipoproteins, phospholipids, and unesterified cholesterol) are located on the surface. The major classes of lipoproteins and a number of their properties are summarized in Table 31–1.

Table 31–2 describes apolipoproteins that have well-defined roles in plasma lipoprotein metabolism. These apolipoproteins include apolipoprotein (apo) A-I, apoA-II, apoA-IV, apoA-V, apoB-100, apoC-I, apoC-II, apoC-III, apoE, and apo(a). Except for apo(a), the lipid-binding regions of all apoproteins contain amphipathic helices that interact with the polar, hydrophilic lipids (such as surface phospholipids) and with the aqueous plasma environment in which the lipoproteins circulate. Differences in the non–lipid-binding regions determine the functional specificities of the apolipoproteins.

**Chylomicrons.** Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed from the small intestine by epithelial cells. Fat-soluble vitamins also are incorporated into chylomicrons after absorption.

Chylomicrons, the largest plasma lipoproteins, are the only lipoproteins that float to the top of a tube of plasma that has been allowed to stand undisturbed for 12 hours. The buoyancy of chylomicrons reflects their high fat content (98-99%), of which 85% is from fatty acids of dietary triglycerides. In chylomicrons, the ratio of triglycerides to cholesterol is ~10 or greater. In normolipidemic individuals, chylomicrons are present in plasma for 3-6 hours after a fat-containing meal has been ingested. After a fast of 10-12 hours, no chylomicrons remain.

Intestinal cholesterol and plant sterol absorption is mediated by Niemann-Pick C1–Like 1 protein (NPC1L1), which appears to be the target of ezetimibe, a cholesterol absorption inhibitor (Davis and Altmann, 2009). Plant sterols, unlike cholesterol, are not normally esterified and incorporated into chylomicrons. Two ATP-binding cassette (ABC) half-transporters, ABCG5 and ABCG8, which reside on the apical plasma membrane of enterocytes, channel plant sterols back into the intestinal lumen, preventing their assimilation into the body. Patients with the autosomal recessive disorder sitosterolemia have mutations in either of the genes that encode ABCG5 and ABCG8. As a result, they absorb unusually large amounts of plant sterols, fail to excrete dietary sterols into the bile, and thus accumulate plant sterols in the blood and tissues; this accumulation is associated with tendon and subcutaneous xanthomas and a markedly increased risk of premature CHD.

Triglyceride synthesis is regulated by diacylglycerol transferase in many tissues. After their synthesis in the endoplasmic reticulum, triglycerides are transferred by *microsomal triglyceride transfer protein* (MTP) to the site where newly synthesized apoB-48 is available to form chylomicrons.

The apolipoproteins of chylomicrons include some that are synthesized by intestinal epithelial cells (apoB-48, apoA-I, and apoA-IV), and others acquired from HDL (apoE and apoC-I, C-II, and C-III) after chylomicrons have been secreted into the lymph and enter the plasma (Table 31–2). The apoB-48 of chylomicrons is one of two forms of apoB present in lipoproteins. ApoB-48, synthesized only by intestinal epithelial cells, is unique to chylomicrons. ApoB-100 is synthesized by the liver and incorporated into VLDL and intermediate-density lipoproteins (IDL) and LDL, which are products of VLDL catabolism. The apparent molecular weight of apoB-48 is ~48% that of apoB-100, which accounts for the name “apoB-48.” The amino acid sequence of apoB-48 is identical to the first 2152 of the 4536 residues of apoB-100. An RNA-editing mechanism unique to the intestine accounts for the premature termination of the translation of the apoB-100 mRNA. ApoB-48 lacks the portion of the sequence of apoB-100 that allows apoB-100 to bind to the LDL receptor, so apoB-48 functions primarily as a structural component of chylomicrons.

Dietary cholesterol is esterified by the type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase (ACAT-2). ACAT-2 is found in the intestine and in the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins [chylomicrons and very-low-density lipoproteins (VLDL)] are assembled. In the intestine, ACAT-2 regulates the absorption of dietary cholesterol and thus may be a potential pharmacological target for reducing blood cholesterol levels.

Another ACAT enzyme, ACAT-1, is expressed in macrophages, including foam cells, adrenocortical cells, and skin sebaceous glands. Although ACAT-1 esterifies cholesterol and promotes foam-cell development, ACAT-1 knockout mice do not have reduced susceptibility to atherosclerosis.

After gaining entry to the circulation via the thoracic duct, chylomicrons are metabolized initially at the capillary luminal surface of tissues that synthesize lipoprotein lipase (LPL), a triglyceride hydrolase (Figure 31–1). These tissues include adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. As the triglycerides are hydrolyzed by LPL, the resulting free fatty acids are taken up and utilized by the adjacent tissues. The interaction of chylomicrons and LPL requires apoC-II as an absolute cofactor. The absence of functional LPL or functional apoC-II prevents the hydrolysis of triglycerides in chylomicrons and results in severe hypertriglyceridemia and pancreatitis during childhood or even infancy (chylomicronemia syndrome). Potentially atherogenic roles for LPL have been identified that affect the metabolism and uptake of atherogenic lipoproteins by the liver and the arterial wall and that impact the dyslipidemia of insulin resistance (Brown and Rader, 2007).

The plasma concentration of chylomicrons is primarily controlled by reducing dietary fat consumption. Drugs that affect chylomycin metabolism include orlistat, which inhibits hydrolysis of dietary triglycerides, insulin replacement in patients with type I diabetes mellitus (insulin has a “permissive effect” on LPL-mediated triglyceride hydrolysis), and fibrates, which enhance LPL gene expression.

**Chylomicron Remnants.** After LPL-mediated removal of much of the dietary triglycerides, the chylomicron remnants, which still contain all of the dietary cholesterol, detach from the capillary surface and within minutes are removed from the circulation by the liver (Figure 31–1). First, the remnants are sequestered by the interaction of apoE with heparan sulfate proteoglycans on the surface of hepatocytes and are processed by hepatic lipase (HL), further reducing the remnant triglyceride content. Next, apoE mediates remnant uptake by interacting with the hepatic LDL receptor or the LDL receptor–related protein (LRP) (Lillis et al., 2008). The multifunctional LRP recognizes a variety of ligands, including apoE, and several ligands unrelated to lipid metabolism.

In plasma lipid metabolism, the LRP is important because it is the backup receptor responsible for the uptake of apoE-enriched remnants of chylomicrons and VLDL. Cell-surface heparan sulfate proteoglycans facilitate the interaction of apoE-containing remnant lipoproteins with the LRP, which mediates uptake by hepatocytes. Inherited absence of either functional HL (very rare) or functional apoE impedes remnant clearance by the LDL receptor and the LRP.
increasing triglyceride- and cholesterol-rich remnant lipoproteins in the plasma (type III hyperlipoproteinemia).

During the initial hydrolysis of chylomicron triglycerides by LPL, apoA-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent (preursor) HDL are generated. Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma LDL levels by reducing LDL receptor-mediated catabolism of LDL by the liver.

Very-Low-Density Lipoproteins. VLDL are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased de novo synthesis of fatty acids by the liver. VLDL particles are 40–100 nm in diameter and are large enough to cause plasma turbidity, but unlike chylomicrons, do not float spontaneously to the top of a tube of undisturbed plasma.

ApoB-100, apoE, and apoC-I, C-II, and C-III are synthesized constitutively by the liver and incorporated into VLDL (Table 31–2). If triglycerides are not available to form VLDL, the newly synthesized apoB-100 is degraded by hepatocytes. Triglycerides are synthesized in the endoplasmic reticulum, and along with other lipid constituents, are transferred by MTP to the site in the endoplasmic reticulum where newly synthesized apoB-100 is available to form nascent (precursor) VLDL. Small amounts of apoE and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of these apoproteins are acquired from plasma HDL after the VLDL are secreted by the liver.

ApoA-V modulates plasma triglyceride levels, possibly by several mechanisms: inhibition of hepatic VLDL triglyceride production and secretion, promoting LPL-mediated hydrolysis of chylomicrons and VLDL triglycerides, and facilitating hepatic uptake of triglyceride-rich lipoproteins and their remnants (Wong and Ryan, 2007). ApoA-V is produced solely by the liver, and despite its very low plasma concentration (~0.1% of the concentration of apoA-I), profoundly affects plasma triglyceride levels in mice and humans.

Without MTP, hepatic triglycerides cannot be transferred to apoB-100. As a consequence, patients with dysfunctional MTP fail to make any of the apoB-containing lipoproteins (VLDL, IDL, or LDL). MTP also plays a key role in the synthesis of chylomicrons in the intestine, and mutations of MTP that result in the inability of triglycerides to be transferred to either apoB-100 in the liver or apoB-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder abetalipoproteinemia. Experimental compounds that interfere with MTP function reduce triglyceride levels but cause hepatic steatosis that has precluded their use in humans. New approaches to MTP inhibition are under study (Hussain and Bakilah, 2008).

Plasma VLDL is then catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (Figure 31–1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed IDL, are released from the capillary endothelium and reenter the circulation. ApoB-100 containing small VLDL and IDL (VLDL remnants), which have a t1/2 <30 minutes, have two potential fates. About 40–60% are cleared from the plasma by the liver via interaction with LDL receptors and LRP, which recognize ligands (apoB-100 and apoE) on the remnants. LPL and HL convert the remainder of the IDL to LDL by removal of additional triglycerides. The C apoproteins, apoE, and apoA-V redistribute to HDL. Virtually all LDL particles in the plasma are derived from VLDL.

ApoE plays a major role in the metabolism of triglyceride-rich lipoproteins (chylomicrons, chylomicron remnants, VLDL, and LDL). About half of the apoE in the plasma of fasting subjects is associated with triglyceride-rich lipoproteins, and the other half is a constituent of HDL. About three-fourths of the apoE in plasma is synthesized by the liver; brain and macrophages synthesize the bulk of the remainder. In transgenic mice, overexpression of apoE by macrophages inhibits hypercholesterolemia-induced atherogenesis. Three alleles of the apoE gene (designated ε2, ε3, and ε4) occur with a frequency of ~8%, 77%, and 15%, respectively, and code for the three major forms of apoE: E2, E3, and E4.

Consequently, there are three homoyzgous apoE phenotypes (E2/2, E3/3, and E4/4) and three heterozygous phenotypes (E2/3, E2/4, and E3/4). Approximately 60% of the human population is homoyzgous for apoE3. Single amino acid substitutions result from genetic polymorphisms in the apoE gene. ApoE2, with a cysteine at residue 158, differs from apoE3, which has arginine at this site. ApoE3, with a cysteine at residue 112, differs from apoE4, which has arginine at this site. These single amino acid differences affect both receptor binding and lipid binding of the three apoE isoforms. Both apoE3 and apoE4 can bind to the LDL receptor, but apoE2 binds much less effectively, and as a consequence causes the remnant lipoprotein dyslipidemia of type III hyperlipoproteinemia.

Low-Density Lipoproteins. Virtually all of the LDL particles in the circulation are derived from VLDL. The LDL particles have a t1/2 of 1.5–2 days, which accounts for the higher plasma concentration of LDL than of VLDL and IDL. In subjects without hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL.

Plasma clearance of LDL particles is mediated primarily by LDL receptors; a small component is mediated by nonreceptor clearance mechanisms. The most common cause of autosomal dominant hypercholesterolemia involves mutations of the LDL receptor gene.
More than 900 mutations of the LDL receptor gene have been identified in association with defective or absent LDL receptors that cause high levels of plasma LDL and familial hypercholesterolemia.

ApoB-100, the primary apoprotein of LDL, is the ligand that binds LDL to its receptor. Residues 3000-3700 in the carboxy-terminal sequence are critical for binding. Mutations in this region disrupt binding and also are a cause of autosomal dominant hypercholesterolemia (familial defective apoB-100). A third disorder causing autosomal dominant hypercholesterolemia is caused by gain of function mutations in the gene encoding PCSK9, a serine protease that destroys LDL receptors in the liver (Horton et al., 2007). Autosomal recessive hypercholesterolemia closely resembles familial hypercholesterolemia but is not caused by LDL receptor mutations.

The liver expresses a large complement of LDL receptors and removes ~75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor gene expression is a most effective way to modulate plasma LDL-C levels. Thyroxine and estrogen enhance LDL receptor gene expression, which explains their LDL-C-lowering effects.

The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression. Regulation of LDL receptor expression is part of a complex process by which cells regulate their free cholesterol content. This regulatory process is mediated by transcription factors called sterol regulatory element binding proteins (SREBPs) and SREBP cleavage activating protein (Scap) (Radhakrishnan et al., 2008). Scap is both a sensor of cholesterol content in the endoplasmic reticulum (ER) and an escort of SREBPs from the ER to the Golgi apparatus. In the Golgi apparatus, SREBPs undergo proteolytic cleavage, and a dimer of the amino-terminal domain, transported by importin β, translocates to the nucleus, where it activates expression of the LDL receptor gene and of other genes encoding enzymes involved in cholesterol biosynthesis. Increased ER cholesterol content binds Scap, precluding Scap from escorting SREBP to the Golgi apparatus for processing and ultimately from reaching the nucleus.

LDL becomes atherogenic when modified by oxidation (Witztum and Steinberg, 2001), a required step for LDL uptake by the scavenger receptors of macrophages. This process leads to foam-cell formation in arterial lesions. At least two scavenger receptors (SRs) are involved (SR-AI/II and CD36). Knocking out either receptor in transgenic mice retards the uptake of oxidized LDL by macrophages. Expression of the two receptors is regulated differently: SR-AI/II appears to be expressed more in early atherogenesis, and CD36 expression is greater as foam cells form during lesion progression. Despite the large body of evidence implicating oxidation of LDL as a requisite step during atherogenesis, controlled clinical trials have not unequivocally demonstrated the efficacy of antioxidant vitamins in preventing vascular disease.

High-Density Lipoproteins. The metabolism of HDL is complex because of the multiple mechanisms by which HDL particles are modified in the plasma compartment. ApoA-I is the major HDL apoprotein, and its plasma concentration is a more powerful inverse predictor of CHD risk than is the HDL-C level (Mahley et al., 2008). ApoA-I synthesis is required for normal production of HDL. Mutations in the apoA-I gene that cause HDL deficiency are variable in their clinical expression and often are associated with accelerated atherogenesis. Conversely, overexpression of apoA-I in transgenic mice protects against experimentally induced atherogenesis.

Mature HDL can be separated by ultracentrifugation into HDL$_2$ (d = 1.063-1.125 g/mL), which are larger, more cholesterol-rich lipoproteins (70-100 Å in diameter), and HDL$_3$ (d = 1.125-1.21 g/mL), which are smaller particles (50-70 Å in diameter). In addition, two major subclasses of mature HDL particles in the plasma can be differentiated by their content of the major HDL apoproteins, apoA-I and apoA-II (Movva and Rader, 2008). Epidemiologic evidence in humans suggests that apoA-II may be atheroprotective (Birjmohun et al., 2007; Movva and Rader, 2008).

Lipoprotein particles may be distinguished by their electrophoretic mobilities: mature HDL particles have α mobility; LDL particles show β mobility. The precursor of most of the α-migrating plasma HDL is a discoidal particle containing apoA-I and phospholipid, called pre-β1 HDL because of its pre-β1 electrophoretic mobility. Pre-β1 HDL are synthesized by the liver and the intestine, and they also arise when surface phospholipids and apoA-I of chylomicrons and VLDL are lost as the triglycerides of these lipoproteins are hydrolyzed. Discoidal pre-β1 HDL can then acquire free unesterified cholesterol from the cell membranes of tissues, such as arterial wall macrophages. Two macrophage membrane transporters, ABCA1 and ABCG1, promote the efflux of cholesterol from macrophages of humans studied in vivo. Prior studies in vitro suggested that another transport protein, class B, type I scavenger receptor (SR-BI) facilitates cholesterol egress from macrophages to HDL, but in vivo studies in humans do not support an important role for SR-BI in this process (Wang et al., 2007). However, SR-BI in the liver facilitates the uptake of cholesteryl esters from HDL without internalizing and degrading the lipoproteins.

The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL (Attie, 2007). When ABCA1 is defective, the acquisition of cholesterol by HDL is greatly diminished, and HDL levels are markedly reduced because poorly lipiddated nascent HDL are metabolized rapidly. Loss-of-function mutations of ABCA1 cause the defect observed in...
Tangier disease, a genetic disorder characterized by extremely low levels of HDL and cholesterol accumulation in the liver, spleen, tonsils, and neurons of peripheral nerves. Transgenic animals overexpressing ABCA1 in the liver and macrophages have elevated plasma levels of HDL and apoA-I and reduced susceptibility to atherosclerosis (Van Eck et al., 2006).

After free cholesterol is acquired by the pre-β1 HDL, it is esterified by lecithin:cholesterol acyltransferase. The newly esterified and nonpolar cholesterol moves into the core of the discoidal HDL. As the cholesteryl ester content increases, the HDL particle becomes spherical and less dense. These newly formed spherical HDL particles (HDL₃) further enlarge by accepting more free cholesterol, which is in turn esterified by lecithin:cholesterol acyltransferase. In this way, HDL₃ are converted to HDL₂, which are larger and less dense than HDL₃.

As the cholesteryl ester content of the HDL₂ increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDL, remnant lipoproteins, and LDL). This exchange is mediated by the cholesteryl ester transfer protein (CETP), and in humans accounts for the removal of about two-thirds of the cholesterol associated with HDL. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred. Treatments that target CETP and the ABC transporters have yielded equivocal results in humans. While CETP inhibitors effectively reduce LDL, they also appear to paradoxically increase the frequency of adverse cardiovascular events (angina, revascularization, myocardial infarction, heart failure, and death) (Tall, 2007; Tall et al, 2008).

The triglyceride that is transferred into HDL₂ is hydrolyzed in the liver by HL, a process that regenerates smaller, spherical HDL₃ particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol. HL activity is regulated and modulates HDL-C levels. Both androgens and estrogens affect HL gene expression, but with opposite effects. Androgens increase HL activity, which accounts for the lower HDL-C values observed in men than in women. Estrogens reduce HL activity, but their impact on HDL-C levels in women is substantially less than that of androgens on HDL-C levels in men. HL appears to have a pivotal role in regulating HDL-C levels, as HL activity is increased in many patients with low HDL-C levels.

HDL are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDL are desirable. This protective effect may result from the participation of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion. HDL also may protect against atherogenesis by mechanisms not directly related to reverse cholesterol transport. These functions include putative anti-inflammatory, antioxidant, platelet anti-aggregatory, anticoagulant, and profibrinolytic activities (deGoma et al., 2008).

**Lipoprotein(a).** Lipoprotein(a) [Lp(a)] is composed of an LDL particle that has a second apoprotein in addition to apoB-100 (Mahley et al., 2008). The second apoprotein, apo(a), is attached to apoB-100 by at least one disulfide bond and does not function as a lipid-binding apoprotein. Apo(a) of Lp(a) is structurally related to plasminogen and appears to be atherogenic by interfering with fibrinolysis of thrombi on the surfaces of plaques.

**HYPERLIPIDEMIA AND ATHEROSCLEROSIS**

Despite a 59% decline in the death rate from CHD between 1950 and 1999, deaths from CVD accounted for 36.3% of the 2.4 million deaths in the U.S. during 2004. Most of these deaths were caused by atherosclerosis, which is responsible for more deaths than cancer, accidents, chronic lung disease, and diabetes combined. Two-thirds of atherosclerosis deaths were due to CHD. About 82% of CHD deaths occurred in individuals >65 years of age. Among the 18% dying prematurely (<65 years), 80% died during their first CHD event. Among those dying of sudden cardiac death, 50% of the men and 64% of the women had previously been asymptomatic (American Heart Association, 2003).

These statistics illustrate the importance of identifying and managing risk factors for CHD. The major conventional risk factors are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advancing age, and a family history of premature CHD events (men <55 years; women <65 years) in a first-degree relative. Control of the modifiable risk factors is especially important in preventing premature CHD. Observational studies suggest that modifiable risk factors account for 85% of excess risk (risk over and above that of individuals with optimal risk-factor profiles) for premature CHD. The presence of one or more conventional risk factors in 90% of patients with CHD belies claims that a large percentage of CHD is not attributable to conventional risk factors. When total cholesterol levels are below 160 mg/dL, CHD risk is markedly attenuated, even in the presence of additional
risk factors. This pivotal role of hypercholesterolemia in atherogenesis gave rise to the almost universally accepted cholesterol-diet-CHD hypothesis: elevated plasma cholesterol levels cause CHD; diets rich in saturated (animal) fat and cholesterol raise cholesterol levels; and lowering cholesterol levels reduces CHD risk. Although the relationship between cholesterol, diet, and CHD was recognized nearly 50 years ago, proof that cholesterol lowering was safe and prevented CHD death required extensive epidemiological studies and clinical trials.

**Epidemiological Studies.** Epidemiological studies have demonstrated the importance of the relationship between excess saturated fat consumption and elevated cholesterol levels. Reducing the consumption of dietary saturated fat and cholesterol is the cornerstone of population-based approaches to the management of hypercholesterolemia. In addition, it is clearly established that the higher the cholesterol level, the higher the CHD risk. However, very high cholesterol levels (values >300 mg/dL) account for only 5-10% of CHD events. In fact, one-third of CHD events occur in persons with total cholesterol levels between 150 and 200 mg/dL (Castelli, 2001). The challenge is how to identify and treat the 20% of individuals with cholesterol levels between 150 and 200 mg/dL who will develop CHD.

**Clinical Trials.** Studies of the efficacy of cholesterol lowering began in the 1960s, and the results of the earliest trials showed that modest reductions in total cholesterol and LDL-C were associated with reductions in fatal and nonfatal CHD events but not total mortality. It was not until the advent of a more efficacious class of cholesterol-lowering drugs, the statins, that cholesterol-reduction therapy was finally proven to prevent CHD events and reduce total mortality. Patients benefit regardless of gender, age (above or below 75 years of age), baseline lipid values, or whether they have a prior history of vascular disease or type 2 diabetes mellitus (Cholesterol Treatment Trialists’ Collaborators, 2008; Cholesterol Treatment Trialists’ Collaborators, 2005). Stroke risk is reduced by statin therapy, too, despite the rather weak relationship between total cholesterol and LDL-C levels. Statin therapy is effective in preventing first and subsequent atherothrombotic strokes. Evidence of a benefit or harm of statin therapy in patients with a prior hemorrhagic stroke is sparse and requires additional studies. Available studies suggest caution when considering statin therapy for a patient with hemorrhagic stroke (Amarenco and Labreuche, 2009).

Results of the clinical trials employing statins demonstrate benefit without offsetting adverse effects, and the benefit is proportionate to the extent of the reduction of LDL-C level. Moderate doses of statins that lower LDL-C levels by about 40% reduce cardiovascular events by about one-third (Cholesterol Treatment Trialists’ Collaborators, 2005). More intensive regimens that lower LDL-C by 45-50% reduce CVD events by as much as 50% (Cannon et al., 2006).

**National Cholesterol Education Program (NCEP) Guidelines for Assessing Risk**

The existing NCEP Adult Treatment Panel (ATP) III guidelines were formulated in 2001 and updated in 2004 (Grundy et al., 2004b). The key features of the update include abandoning the concept of a threshold LDL-C level that must be exceeded before initiating cholesterol-lowering drug therapy in CHD or CHD equivalent patients; adopting a new target LDL-C level (<70 mg/dL) for very high-risk patients; and employing a “standard statin dose” (a dosage sufficient to lower LDL-C by 30-40%) as a minimum therapy when initiating cholesterol-lowering therapy with statins (Grundy et al., 2004b) (Table 31–3). Subsequently, new information from clinical trials and new information about risk assessment has led to a need for a new revision, ATP IV, which is currently in progress. The new ATP IV guidelines are expected to be published in 2010. Revisions that are likely to be included in the ATP IV guidelines are described in the following discussion.

**Risk Assessment.** The intensity of treatment of dyslipidemia is based on the severity of a patient’s risk. The risk of sustaining a heart attack or stroke or of developing heart failure in the U.S. is striking. Before death, two-thirds of men and one-half of all women will be affected (Lloyd-Jones et al., 2009). Because of this very high prevalence, it is important that all adults ≥20 years and high-risk children undergo an assessment of their risk of developing CVD (Daniels et al., 2008; The Expert Panel, 2002).

Patients at greatest risk of developing an atherothrombotic CVD event are those who have had a prior event (myocardial infarction, acute coronary syndrome, transient ischemic attack, stroke, or claudication) or who are at high risk because of type 2 diabetes mellitus. These subjects are at very high risk and require intensive management of plasma lipids (Table 31–3). Other subjects who have not had a prior CVD event require assessment of plasma lipid levels and the other major CVD risk factors to determine if treatment to reduce lipid-related risk is necessary.

Lipid levels (total cholesterol, triglycerides, LDL-C, HDL-C, and non-HDL-C) and glucose concentration should be measured following a fasting period of 10-12 hours. The LDL-C should be calculated [total cholesterol – (HDL-C) – (triglycerides/5) = LDL-C] and not measured by any of the “direct” techniques (Mora et al., 2009). Non-HDL-C is derived as follows: total cholesterol – HDL-C = non-HDL-C. The classification of plasma lipid values is shown in Table 31–4.

Measurement of apoA-I and apoB afford better risk prediction of lipid-related risk than LDL-C and HDL-C. However, lack of an established national reference laboratory for quality control of these apolipoprotein assays has precluded formal adoption of apoA-I and apoB measurements by the NCEP thus far (Contois et al., 2009; Sniderman, 2009; Sniderman and Marcovina, 2006). Despite this, targets for apoB levels have been established by the American Diabetes Association for the management of patients with type 2 diabetes mellitus (Brunzell et al., 2008).

Measurements of lipoprotein fraction concentrations, their subfractions, and lipoprotein particle diameters also are widely available, but it is not clear that these tests add to the ability to predict risk.
based on measurements of levels of cholesterol or apoA-I and apoB (Mora, 2009).

In addition to plasma lipid levels and a fasting glucose level, each subject requires an evaluation to assess the presence or absence of the other major CVD risk factors: age, a family history of premature CVD event, smoking, hypertension, type 2 diabetes mellitus, and obesity (Table 31–5). There are a host of additional novel risk factors that are being evaluated to determine if they will improve current risk prediction assessment schemes based on lipid levels and the established major CVD risk factors (Table 31–5). Thus far, routine use of any of these novel risk factors has not been shown to improve risk prediction (Folsom et al., 2006; Lloyd-Jones and Tian, 2006). However, in certain primary prevention patients, two of the recently described risk factors, C-reactive protein (CRP) and assessment of the extent of coronary calcification, may improve risk assessment beyond that based on the traditional major risk factors (Tables 31–3 and 31–5).

Using the values for levels of total cholesterol and HDL-C and the results of the assessment for the other major CHD risk factors, the next step is to calculate a person’s risk of having a CHD event over the next 10 years. Risk prediction tables based on observational studies conducted by the Framingham Heart Study are used to calculate this 10-year risk. This approach to risk assessment was adopted by the NCEP, but in the 2001 ATP III guidelines, the risk prediction model predicted only the 10-year risk of having a fatal or nonfatal myocardial infarction. However, the same risk factors that are associated with development of myocardial infarction also promote other CVD events, including stroke, transient ischemic attack, peripheral vascular disease, and heart failure. Furthermore, many patients who develop acute coronary syndrome do not sustain a myocardial infarction because of thrombolytic therapy and revascularization procedures (angioplasty and bypass graft surgery). Because cholesterol-lowering therapy is beneficial to prevent CVD events in patients with any of these manifestations of CVD, it became apparent that it would be useful for primary care physicians to be able to predict a patient’s risk of developing any one of these manifestations of CVD, not just CHD. New general CVD 10-year risk prediction tables are now available from the Framingham Heart Study (D’Agostino et al., 2008; Wickramasinghe et al., 2009) (Table 31–6). Ten-year risk calculated with the general CVD tables will exceed 10-year risk calculated using the CHD tables from the ATP III guidelines.

$^a$If pretreatment LDL-C is near or below LDL-C goal value, then a statin dose sufficient to lower LDL-C by 30-40% should be prescribed.

$^b$Patients in this category include those with a 10-year risk of 10-20% and one of the following: age >60 years, three or more risk factors, a severe risk factor, triglycerides >200 mg/dL and HDL-C <40 mg/dL, metabolic syndrome, highly sensitive C-reactive protein (CRP) >3 mg/L, and coronary calcium score (age/gender adjusted) >75th percentile.

$^c$Patients include those with any severe single risk factor, multiple major risk factors, 10-year risk >8%.

After attaining the LDL-C goal, additional therapy may be necessary to reach the non-HDL-C goal. CHD, coronary heart disease; CHD equivalent, peripheral vascular disease, abdominal aortic aneurysm, symptomatic carotid artery disease, >20% 10-year CHD risk, or diabetes mellitus; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; NCEP, National Cholesterol Education Program.
Once the 10-year risk has been calculated, the patient’s category of risk can be assigned using Table 31–3. This establishes treatment goals for LDL-C and non-HDL-C as well as thresholds for initiating drug therapy. Because CVD, diabetes mellitus, and obesity are so prevalent, diet and exercise assessment and advice are appropriate for everyone and should not depend on an arbitrary threshold value for LDL-C for implementation. Ten-year risk assessment is recognized as the guideline-mandated method for managing dyslipidemia. Unfortunately, only about 50% of physicians correctly assess their patient’s risk, and 30% of adults nationwide are not being screened (Christian et al., 2006; Kuklina et al., 2009). Many high-risk patients are not being recognized and treated prior to developing clinical CHD. Among the nearly 75,000 patients admitted to 541 U.S. hospitals between 2000 and 2006 with first-ever episodes of acute coronary syndrome, only 14% were taking a cholesterol-lowering drug (Sachdeva et al., 2009).

NCEP Guidelines for Treatment: Managing Patients with Dyslipidemia

Current NCEP guidelines focus on identifying levels of risk factors associated with increased risk of a CHD event. Primary prevention involves management of risk factors to prevent a first-ever CHD event. Secondary prevention patients are those who have had a prior CHD event and whose risk factors are treated most aggressively. Recently, the concept of primordial prevention has been applied to CHD prevention (Lloyd-Jones et al., 2010). The strategy is to prevent the development of risk factors rather than treating already established risk factors. Primordial prevention is a population-based approach that targets smoking, weight management, physical activity, healthy eating habits, cholesterol and glucose levels, and blood pressure. Goals for each of these risk factors have been set for adults and children. Including children is important because adverse health behaviors are learned in childhood (Lloyd-Jones et al., 2010).

The primordial prevention guidelines include 150 minutes/week of moderate-intensity exercise (walking 20-30 minutes/day. Dietary recommendations

*Obesity was returned to the list of CHD risk factors in 1998, although it was not included as a risk factor in the 2001 NCEP guidelines (Pi-Sunyer et al., 1998). CHD, coronary heart disease; HDL-C, high-density-lipoprotein cholesterol. From The Expert Panel, 2002.*
include reducing total calories from fat to <30% and saturated fat to <7% to avoid trans fat; consuming <300 mg of cholesterol/day, a variety of oily fish twice a week or more often, and oils/foods rich in \( \alpha \)-linolenic acid (canola, flaxseed, and soybean oils; flaxseed; and walnuts); and restricting sugary beverages to <36 oz/week for a person consuming 2000 Kcal daily.

The patient-based approach to manage dyslipidemia is designed for primary and secondary prevention, requires a risk assessment as described earlier (Table 31–6), and focuses on lowering LDL-C and non-HDL-C (Grundy et al., 2004b). Non-lipid risk factors, if present, should be treated appropriately (Table 31–5). For patients with elevated levels of total cholesterol, non-HDL-C, LDL-C, or triglycerides, or reduced HDL-C values, further treatment is based on the patient’s risk-factor status (Table 31–5), LDL-C and non-HDL-C levels (Table 31–3), and calculation of the general CHD Framingham risk score (Table 31–6) of primary prevention patients with two or more risk factors.

All patients who meet the criteria for lipid-lowering therapy should receive instruction about therapeutic lifestyle change. Dietary
restrictions include <7% of calories from saturated and trans fatty acids, <200 mg of cholesterol daily, up to 20% of calories from monounsaturated fatty acids, up to 10% of calories from polyunsaturated fat, and total fat calories ranging between 25% and 35% of all calories. Two oily fish meals/week are especially important for post–myocardial infarction patients to provide a substantial reduction in the risk of sudden cardiac death. Patients with CHD or a CHD equivalent (symptomatic peripheral or carotid vascular disease, abdominal aortic aneurysm, >20% 10-year CHD risk, or diabetes mellitus) should immediately start appropriate lipid-lowering drug therapy irrespective of their baseline LDL-C level. Patients without CHD or CHD equivalent should be managed with lifestyle advice (diet, exercise, weight management) for 3-6 months before drug therapy is implemented.

Before drug therapy is initiated, secondary causes of hyperlipidemia should be excluded. Most secondary causes (Table 31–7) can be excluded by ascertaining the patient’s medication history and by measuring serum creatinine, liver function tests, fasting glucose, and thyroid-stimulating hormone levels. Treatment of the disorder causing secondary dyslipidemia may preclude the necessity of treatment with hypolipidemic drugs.

**Arterial Wall Biology and Plaque Stability**

More effective lipid-lowering agents and a better understanding of atherogenesis have helped to prove that
aggressive lipid-lowering therapy has beneficial effects beyond those obtained by simply decreasing lipid deposition in the arterial wall. Aggressive lipid lowering results only in very small increases in lumen diameter but promptly decreases acute coronary events (Cannon et al., 2004). Lesions causing <60% occlusion are responsible for more than two-thirds of the acute events. Aggressive lipid-lowering therapy may prevent acute events through positive effects on the arterial wall; it corrects endothelial dysfunction, corrects abnormal vascular reactivity (spasm), and increases plaque stability.

Atherosclerotic lesions containing a large lipid core, large numbers of macrophages, and a poorly formed fibrous cap are prone to plaque rupture and acute thrombosis. Aggressive lipid lowering appears to alter plaque architecture, resulting in less lipid, fewer macrophages, and a larger collagen and smooth muscle cell–rich fibrous cap. Stabilization of plaque susceptibility to thrombosis appears to be a direct result of LDL-C lowering or an indirect result of changes in cholesterol and lipoprotein metabolism or arterial wall biology (see “Potential Cardioprotective Effects Other Than LDL Lowering,” later in the chapter).

**Whom and When to Treat?**

Large-scale trials with statins have provided new insights into which patients with dyslipidemia should be treated and when treatment should be initiated.

**Gender.** Both men and women with or without a prior vascular disease event benefit from lipid-lowering therapy (Heart Protection Study Collaborative Group, 2002; Ridker et al., 2008). Statins, rather than hormone-replacement therapy, now are the recommended first-line drug therapy for lowering lipids and preventing CHD events in postmenopausal women. This recommendation reflects the increased CHD morbidity in older women with established CHD who were treated with hormone-replacement therapy (see Chapter 40).

**Age.** Age >45 years in men and >55 years in women is considered to be a CHD risk factor. The statin trials have shown that patients >65 years of age benefit from therapy as much as do younger patients. In fact, in those >70 years, the reduction of absolute mortality is stunning compared with individuals 55 years of age (Afilalo et al., 2008; Diamond and Kaul, 2008). Old age *per se* is not a reason to refrain from initiating drug therapy in an otherwise healthy person.

**Cerebrovascular Disease Patients.** In most observational studies, plasma cholesterol levels correlate positively with the risk of ischemic stroke. In clinical trials, statins reduced stroke and transient ischemic attacks in patients with and without CHD (Amarenco and Labreuche, 2009).

**Peripheral Vascular Disease Patients.** Statins prevent CHD events and may improve walking distance in patients with peripheral vascular disease (Aung et al., 2007).

**Hypertensive Patients and Smokers.** The relative risk reduction for coronary events in statin trials of hypertensive patients is similar to that in subjects without hypertension (Franz et al., 2008). Relative risk is reduced more in smokers in statin clinical trials than in nonsmokers (Cheung et al., 2004).

**Type 2 Diabetes Mellitus.** Patients with type 2 diabetes benefit very significantly from aggressive lipid lowering (see “Treatment of Type 2 Diabetes Patients,” later in the chapter) (Cholesterol Treatment Trialists’ Collaborators, 2008; Heart Protection Study Collaborative Group, 2003).

**Post–Myocardial Infarction or Revascularization Patients.** As soon as CHD is diagnosed, it is essential to begin lipid-lowering therapy (NCEP guidelines: LDL-C goal <70 mg/dL for very high-risk patients) (Grundy et al., 2004b). Compliance with drug therapy is greatly enhanced if treatment is initiated in the hospital. Statin therapy administered prior to angioplasty reduces the requirement for procedures related to myocardial infarction risk and the need for repeat revascularization (Ebrahimi et al., 2008; Zhang et al., 2010). Statin therapy also improves the long-term outcome after bypass surgery.

HDL-C, high-density-lipoprotein cholesterol.
Can Cholesterol Levels Be Lowered Too Much? Are there total and LDL cholesterol levels below which adverse health consequences begin to increase? Observational studies initially were confusing. In the U.S. and western Europe, low cholesterol levels were associated with an increase in noncardiac mortality from chronic pulmonary disease, chronic liver disease, cancer (many primary sites), and hemorrhagic stroke; subsequent data indicate that it is the noncardiac diseases that cause the low plasma cholesterol levels and not the reverse. One exception may be hemorrhagic stroke. In the Multiple Risk Factor Intervention Trial (MRFIT), hemorrhagic stroke occurred more frequently in hypertensive patients with total cholesterol levels <160 mg/dL; however, the increased incidence of hemorrhagic stroke was more than offset by reduced CHD risk due to the low cholesterol levels. A recent meta-analysis of statin efficacy in preventing recurrent stroke found an increase in the risk of subsequent hemorrhagic stroke among patients with a prior hemorrhagic stroke who also received a statin. However, the risk of atherothrombotic stroke was reduced in proportion to the degree of cholesterol lowering by statin therapy (Amarenco and Labreuche, 2009).

Abetalipoproteinemia and hypobetalipoproteinemia, two rare disorders associated with extremely low total cholesterol levels, are instructive because affected individuals have reduced CHD risk and no increase in noncardiac mortality. Patients who are homozygous for the mutations that cause these disorders have total cholesterol levels <50 mg/dL and triglyceride levels <25 mg/dL. With the advent of more efficacious cholesterol-lowering agents, it has been possible to test the benefits and risks of lowering LDL-C levels <50 mg/dL (Ridker et al., 2008). Lower LDL-C levels translate into greater reductions in clinical events without any increase in adverse events.

Treatment of Type 2 Diabetes Patients

Diabetes mellitus is an independent predictor of high risk for CHD. CHD morbidity is two to four times higher in patients with diabetes than in nondiabetics. Glucose control is essential but provides only minimal benefit with respect to CHD prevention. Aggressive treatment of diabetic dyslipidemia through diet, weight control, and drugs is critical in reducing risk.

Diabetic dyslipidemia usually is characterized by high triglycerides, low HDL-C, and moderate elevations of total cholesterol and LDL-C. In fact, diabetics without diagnosed CHD have the same level of risk as nondiabetics with established CHD. Thus, the dyslipidemia treatment guidelines for diabetic patients are the same as for patients with CHD, irrespective of whether the diabetic patient has had a CHD event (The Expert Panel, 2002). The American Diabetes Association recommends new lipid therapy targets for diabetics. In addition to targets for LDL-C and non-HDL-C, two targets for total plasma apoB were established based on the level of CVD risk (Brunzell et al., 2008).

Clinical trials with statins have clearly established that total and vascular disease mortality are reduced in diabetics as a consequence of prevention of CVD events (Cholesterol Treatment Trialists’ Collaborators, 2008). A recently completed trial comparing statin therapy to statin plus fenofibrate therapy will provide the first outcome data for statin plus fibrate combination therapy in type 2 diabetes patients (Ginsberg et al., 2007).

The 2001 National Cholesterol Education Program (NCEP) guidelines define the metabolic syndrome as the presence of three or more of these risk factors.

aOverweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body mass index. Therefore, the simple measurement of waist circumference is recommended to identify the body weight component of the metabolic syndrome.

bSome male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased (e.g., 94–102 cm [37–39 inches]). Such patients may have a strong genetic contribution to insulin resistance, and like men with categorical increases in waist circumference, they should benefit from changes in life habits. There is ethnic variation in the values of waist circumference that define abdominal obesity (Alberi et al., 2009). HDL-C, high-density-lipoprotein cholesterol. From The Expert Panel, 2002.

Metabolic Syndrome

There is an increased CHD risk associated with the insulin-resistant, prediabetic state described under the rubric of “metabolic syndrome.” This syndrome consists of a constellation of five CHD risk factors (Table 31–8).

Of the five risk factors, abdominal obesity is defined by ethnic-specific values of abdominal waist circumference (Alberi et al., 2009). An alternative to assessing the five criteria that identify the metabolic syndrome is to determine the ratio of the concentrations of fasting triglycerides divided by the HDL-C. Values >3.5 predict insulin resistance as effectively as meeting the criteria for diagnosing metabolic syndrome (McLaughlin et al., 2005). The prevalence of metabolic syndrome among patients with premature vascular disease may be as high as 50%. Treatment should focus on weight loss and increased physical activity, because being overweight or obese usually precludes optimal risk factor reduction. Specific treatment of increased LDL-C, non-HDL-C, and triglyceride levels and low HDL-C levels also should be undertaken.
Treatment of Hypertriglyceridemia

There is increased CHD risk associated with the presence of triglyceride levels >150 mg/dL. Three categories of hypertriglyceridemia are recognized (Table 31–4), and treatment is recommended based on the degree of elevation. Weight loss, increased exercise, and alcohol restriction are important for all hypertriglyceridemic patients. The LDL-C goal should be ascertained based on each patient’s risk factors or CHD status (Table 31–3). If triglycerides remain >200 mg/dL after the LDL-C goal is reached, further reduction in triglycerides may be achieved by increasing the dose of a statin or of niacin. Combination therapy (statin plus niacin or statin plus fibrate) may be required, but caution is necessary with these combinations to avoid myopathy (see “Statins in Combination with Other Lipid-Lowering Drugs,” later in the chapter).

Treatment of Low HDL-C.

The most frequent risk factor for premature CHD is low HDL-C. In men with angiographically documented CHD, ~60% have HDL-C <35 mg/dL and only 25% have LDL-C >160 mg/dL. In older men with CHD, 38% have HDL-C levels <35 mg/dL and two-thirds have HDL-C <40 mg/dL. Subjects with “normal” cholesterol levels of <200 mg/dL but with low HDL-C (<40 mg/dL) have as much CHD risk as subjects with higher total cholesterol levels (230-260 mg/dL) and more normal HDL-C (40-49 mg/dL). In a recent study of CHD patients admitted to hospitals with acute coronary syndrome between 2000 and 2006, low HDL-C levels were clearly documented as the most prevalent lipid-related risk factor (Sachdeva et al., 2009). In clinical trials employing statins to lower LDL-C, the level of HDL-C has been documented to substantially moderate risk (Jafri et al., 2009).

In patients with low HDL-C, the total cholesterol:HDL-C ratio is a particularly useful predictor of CHD risk (Bersot, 2003). Observational studies suggest that a favorable ratio is ≤3.5 and a ratio of >4.5 is associated with increased risk (Table 31–9). However, results of a post hoc analysis of the relationship between HDL-C levels and treatment benefit of statin therapy suggest that there is substantial additional benefit associated with a total cholesterol:HDL-C ratio <3 (Barter et al., 2007). American men, who are a high-risk group, have a typical ratio of ~4.5. Patients with low HDL-C may have what are considered to be “normal” total and LDL cholesterol levels; however, because of their low HDL-C levels, such patients may be at high risk based on the total cholesterol:HDL-C ratio (e.g., a total cholesterol, 180 mg/dL; HDL-C, 30 mg/dL; ratio, 6). A desirable total cholesterol level in low-HDL-C patients may be considerably lower than 200 mg/dL, especially because low-HDL-C patients also may have moderately elevated triglycerides, which may reflect increased levels of atherogenic remnant lipoproteins. Patients with average or low LDL-C, low HDL-C, and high total cholesterol:HDL-C ratios have benefited from treatment (Barter et al., 2007).

The treatment of low HDL-C patients focuses on lowering LDL-C to the target level based on the patient’s risk factor or CHD status (Table 31–3) and a reduction of VLDL cholesterol (estimated by dividing the plasma triglyceride level by 5) to <30 mg/dL to reach the target for non-HDL-C. Satisfactory treatment results are a ratio of total cholesterol:HDL-C ≤3.5 (Table 3–9). Patients with total cholesterol:HDL-C ratios >4.5 are at risk even if their “non-HDL-C” levels (LDL-C and VLDL cholesterol) are at the goal values recommended by the 2001 NCEP guidelines. Consequently, it is useful to base treatment of patients with low HDL-C levels on both LDL-C and non-HDL-C levels plus the total cholesterol:HDL-C ratio (Tables 31–3 and 31–8) (Bersot et al., 2003).

DRUG THERAPY OF DYSLIPIDEMIA

Statins

The statins are the most effective and best-tolerated agents for treating dyslipidemia. These drugs are competitive inhibitors of HMG-CoA reductase, which
catalyzes an early, rate-limiting step in cholesterol biosynthesis. Higher doses of the more potent statins (e.g., atorvastatin, simvastatin, and rosuvastatin) also can reduce triglyceride levels caused by elevated VLDL levels. Some statins also are indicated for raising HDL-C levels, although the clinical significance of these effects on HDL-C remains to be proven.

Multiple well-controlled clinical trials have documented the efficacy and safety of simvastatin, pravastatin, lovastatin, atorvastatin, and rosuvastatin in reducing fatal and nonfatal CHD events, strokes, and total mortality (Cholesterol Treatment Trials’ Collaborators, 2005; Ridker et al., 2008). Rates of adverse events in statin trials were the same in the placebo groups and in the groups receiving the drug.

**History.** Statins were isolated from a mold, *Penicillium citrinum*, and identified as inhibitors of cholesterol biosynthesis in 1976 by Endo and colleagues. Subsequent studies by Brown and Goldstein established that statins act by inhibiting HMG-CoA reductase. The first statin studied in humans was compactin, renamed mevastatin, which demonstrated the therapeutic potential of this class of drugs. Alberts and colleagues at Merck developed the first statin approved for use in humans, lovastatin (formerly known as mevinolin), which was isolated from *Aspergillus terreus*. Six other statins are also available. Pravastatin and simvastatin are chemically modified derivatives of lovastatin (Figure 31–2). Atorvastatin, fluvastatin, rosuvastatin, and pitavastatin are structurally distinct synthetic compounds.

A yeast that grows on rice, *Monascus purpureus*, produces a series of compounds, one of which, monacolin K, is an inhibitor of HMG-CoA reductase and is chemically identical to lovastatin. OTC preparations, known as red yeast rice, contain monacolin K. As with many nutraceuticals, content of the active principle may vary, and such preparations should be used with great caution.

**Chemistry.** The structural formulas of the original statin (mevastatin) and the seven statins currently available in the U.S. are shown in

---

**Figure 31–2. Chemical structures of the statins and the reaction catalyzed by HMG-CoA reductase.**
Figure 31–2 along with the reaction (conversion of HMG-CoA to mevalonate) catalyzed by HMG-CoA reductase, the enzyme they competitively inhibit. The statins possess a side group that is structurally similar to HMG-CoA. Mevastatin, lovastatin, simvastatin, and pravastatin are fungal metabolites, and each contains a hexahydropyranophthalene ring. Lovastatin differs from mevastatin in having a methyl group at carbon 3. There are two major side chains. One is a methylbutyrate ester (lovastatin and pravastatin) or a dimethylbutyrate ester (simvastatin). The other contains a hydroxy acid that forms a six-membered analog of the intermediate compound in the HMG-CoA reductase reaction. Fluvastatin, atorvastatin, rosuvastatin, and pitavastatin are entirely synthetic compounds containing a heptanoic acid side chain that forms a structural analog of the HMG-CoA intermediate. As a result of their structural similarity to HMG-CoA, statins are reversible competitive inhibitors of the enzyme’s natural substrate, HMG-CoA. The inhibition constant (K_i) of the statins is ~1nM; the dissociation constant of HMG-CoA is three orders of magnitude higher.

Lovastatin and simvastatin are lactone prodrugs that are modified in the liver to active hydroxy acid forms. Because they are lactones, they are less soluble in water than are the other statins, a difference that appears to have little if any clinical significance. Pravastatin (an acid in the active form), fluvastatin (sodium salt), and atorvastatin, rosuvastatin, and pitavastatin (calcium salts), are all administered in the active, open-ring form.

Mechanism of Action. Statins exert their major effect—reduction of LDL levels—through a mevalonic acid–like moiety that competitively inhibits HMG-CoA reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit an early and rate-limiting step in cholesterol biosynthesis.

Statins affect blood cholesterol levels by inhibiting hepatic cholesterol synthesis, which results in increased expression of the LDL receptor gene. In response to the reduced free cholesterol content within hepatocytes, membrane-bound SREBPs are cleaved by a protease and translocated to the nucleus. The transcription factors then bind the sterol-responsive element of the LDL receptor gene, enhancing transcription and increasing the synthesis of LDL receptors (Horton et al., 2002). Degradation of LDL receptors also is reduced. The greater number of LDL receptors on the surface of hepatocytes results in increased removal of LDL from the blood, thereby lowering LDL-C levels.

Some studies suggest that statins also can reduce LDL levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production. Because VLDL remnants and IDL are enriched in apoE, a statin-induced increase in the number of LDL receptors, which recognize both apoB-100 and apoE, enhances the clearance of these LDL precursors. The reduction in hepatic VLDL production induced by statins is thought to be mediated by reduced synthesis of cholesterol, a required component of VLDL. This mechanism also likely accounts for the triglyceride-lowering effect of statins and may account for the reduction (~25%) of LDL-C levels in patients with homozgyous familial hypercholesterolemia treated with 80 mg of atorvastatin or simvastatin.

Triglyceride Reduction by Statins. Triglyceride levels (>250 mg/dL) are reduced substantially by statins, and the percent reduction achieved is similar to the percent reduction in LDL-C. Accordingly, hypertriglyceridemic patients taking the highest doses of the most potent statins experience a 35-45% reduction in LDL-C and a similar reduction in fasting triglyceride levels (Hunninghake et al., 2004). The efficacy of triglyceride lowering by pitavastatin in patients with baseline triglyceride levels >250 mg/dL is currently unknown.

Effect of Statins on HDL-C Levels. Most studies of patients treated with statins have systematically excluded patients with low HDL-C levels. In studies of patients with elevated LDL-C levels and gender-appropriate HDL-C levels (~40-50 mg/dL for men; 50-60 mg/dL for women), an increase in HDL-C of 5-10% was observed, irrespective of the dose or statin employed. However, in patients with reduced HDL-C levels (<35 mg/dL), statins may differ in their effects on HDL-C levels. Simvastatin, at its highest dose of 80 mg, increases HDL-C and apoA-I levels more than a comparable dose of atorvastatin (Crouse et al., 2000). In preliminary studies of patients with hypertriglyceridemia and low HDL-C, rosuvastatin appears to raise HDL-C levels by as much as 15-20% (Hunninghake et al., 2004). More studies are needed to ascertain whether the effects of statins on HDL-C in patients with low HDL-C levels are clinically significant.

Effects of Statins on LDL-C Levels. Statins lower LDL-C by 20-55%, depending on the dose and statin used. In large trials comparing the effects of the various statins, equivalent doses appear to be 5 mg of simvastatin = ~15 mg of lovastatin = ~15 mg of pravastatin = ~40 mg of fluvastatin (Pedersen and Tobert, 1996), 20 mg of simvastatin = ~10 mg of atorvastatin (Jones et al., 1998) (Crouse III et al., 1999), and 20 mg of atorvastatin = 10 mg of rosuvastatin (Jones et al., 2003). Analysis of dose-response relationships for all statins demonstrates that the efficacy of LDL-C lowering is log-linear; LDL-C is reduced by ~6% (from baseline) with each doubling of the dose (Jones et al., 1998; Pedersen and Tobert, 1996). Maximal effects on plasma cholesterol levels are achieved within 7-10 days.

Table 31–10 provides information on the statin doses required to reduce LDL-C by 20-55%. The fractional reductions achieved with the various doses are the same regardless of the absolute value of the baseline LDL-C level. The statins are effective in almost all patients with high LDL-C levels. The exception is patients with homozygous familial hypercholesterolemia, who have very attenuated responses to the usual doses of statins because both alleles of the LDL receptor gene code for dysfunctional LDL receptors; the partial response in these patients is due to a reduction in hepatic VLDL synthesis associated with the inhibition of HMG-CoA reductase–mediated cholesterol synthesis. Statin therapy does not reduce Lp(a) levels.

Potential Cardioprotective Effects Other Than LDL Lowering. Although the statins clearly exert their major effects on CHD by lowering LDL-C and improving the lipid profile as reflected in plasma cholesterol levels, a multitude of potentially cardioprotective effects are being ascribed to these drugs (Liao, 2005). However,
the mechanisms of action for non–lipid-lowering roles of statins have not been established, and it is not known whether these potential pleiotropic effects represent a class-action effect, differ among statins, or are biologically or clinically relevant. Until these questions are resolved, selection of a specific statin should not be based on any one of these effects. Nevertheless, the potential importance of the non-lipid roles of statins merits discussion.

**Statins and Endothelial Function.** A variety of studies have established that the vascular endothelium plays a dynamic role in vasoconstriction/relaxation. Hypercholesterolemia adversely affects the processes by which the endothelium modulates arterial tone. Statin therapy enhances endothelial production of the vasodilator nitric oxide, leading to improved endothelial function. Statin therapy improves endothelial function independent of changes in plasma cholesterol levels.

**Statins and Plaque Stability.** The vulnerability of plaques to rupture and thrombosis is of greater clinical relevance than the degree of stenosis they cause (Corti et al., 2003). Statins affect plaque stability in a variety of ways. They inhibit monocyte infiltration into the artery wall and inhibit macrophage secretion of matrix metalloproteinases in vitro. The metalloproteinases degrade extracellular matrix components and thus weaken the fibrous cap of atherosclerotic plaques.

Statins also appear to modulate the cellularity of the artery wall by inhibiting proliferation of smooth muscle cells and enhancing apoptosis. It is debatable whether these effects would be beneficial or harmful if they occurred in vivo. Reduced proliferation of smooth muscle cells and enhanced apoptosis could retard initial hyperplasia and restenosis, but they also could weaken the fibrous cap and destabilize the lesion. Interestingly, statin-induced suppression of cell proliferation and the induction of apoptosis have been extended to tumor biology. The effects of statins on isoprenoid biosynthesis and protein phenylation associated with reduced synthesis of the cholesterol precursor mevalonate may alter the development of malignancies (Li et al., 2003; Wong et al., 2002).

**Statins and Inflammation.** Appreciation of the importance of inflammatory processes in atherogenesis is growing, and statins may have an anti-inflammatory role. Statins decreased the risk of CHD and levels of CRP (an independent marker for inflammation and high CHD risk) independently of cholesterol lowering (Libby and Aikawa, 2003; Libby and Ridker, 2004). Body weight and the metabolic syndrome are associated with elevated levels of highly sensitive CRP, leading some to suggest that the CRP may simply be a marker of obesity and insulin resistance (Pearson et al., 2003). It remains to be determined whether the CRP is simply a marker of inflammation or if it contributes to the pathogenesis of atherosclerosis. The clinical utility of measuring CRP with “highly sensitive” assays appears to be limited to those primary prevention subjects with a moderate (10-20%) 10-year risk of sustaining a CHD event. Values of highly sensitive CRP >3 mg/L suggest that such patients should be managed as secondary prevention patients (Pearson et al., 2003).

**Statins and Lipoprotein Oxidation.** Oxidative modification of LDL appears to play a key role in mediating the uptake of lipoprotein cholesterol by macrophages and in other processes, including cytotoxicity within lesions. Statins reduce the susceptibility of lipoproteins to oxidation both in vitro and ex vivo.

**Statins and Coagulation.** The most compelling evidence of a non–lipid-lowering effect of a statin is the rosuvastatin-mediated reduction in venous thromboembolic events, a prespecified endpoint, in JUPITER. This trial demonstrated a 43% reduction in venous thromboembolic events in patients treated with rosuvastatin, 20 mg daily, compared with placebo during a median follow-up period of 1.9 years (Glynn et al., 2009). Statins reduce platelet aggregation and reduce the deposition of platelet thrombi. In addition, the different statins have variable effects on fibrinogen levels. Elevated plasma fibrinogen levels are associated with an increase in the incidence of CHD.

Absorption, Metabolism, and Excretion

**Absorption from the Small Intestine.** After oral administration, intestinal absorption of the statins is variable (30-85%). All the statins, except simvastatin and lovastatin, are administered in the β-hydroxy acid form, which is the form that inhibits HMG-CoA reductase. Simvastatin and lovastatin are administered as inactive lactones that must be transformed in the liver to their respective β-hydroxy acids, simvastatin acid (SVA) and lovastatin acid (LVA). There is extensive first-pass hepatic uptake of all statins, mediated primarily by the organic anion transporter OATP1B1 (see Chapter 5).
Due to extensive first-pass hepatic uptake, systemic bioavailability of the statins and their hepatic metabolites varies between 5% and 30% of administered doses. The metabolites of all statins, except fluvastatin and pravastatin, have some HMG-CoA reductase inhibitory activity (Bellotta et al., 2004). Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. After the lactones of simvastatin and lovastatin are transformed in the liver to SVA and LVA, small amounts of these active inhibitors of HMG-CoA reductase, as well as small amounts of the lactone forms, can be found in the systemic circulation. In the plasma, >95% of statins and their metabolites are protein bound, with the exception of pravastatin and its metabolites, which are only 50% bound (Schachter, 2005).

After an oral dose, plasma concentrations of statins peak in 1-4 hours. The $t_{1/2}$ of the parent compounds is 1-4 hours, except in the case of atorvastatin and rosuvastatin, which have half-lives of ~20 hours, and simvastatin with a $t_{1/2}$ ~12 hours (Ieiri et al., 2007). The longer $t_{1/2}$ of atorvastatin and rosuvastatin may contribute to their greater cholesterol-lowering efficacy (Corsini et al., 1999). The liver biotransforms all statins, and more than 70% of statin metabolites are excreted by the liver, with subsequent elimination in the feces (Bellotta et al., 2004). Inhibition by other drugs of OATP1B1, which transports several statins into hepatocytes, and inhibition or induction of CYP3A4 by a variety of pharmacological agents provide rationales for drug-drug interactions involving statins (Shitara and Sugiyama, 2006).

**Adverse Effects and Drug Interactions**

**Hepatotoxicity.** Initial post-marketing surveillance studies of the statins revealed an elevation in hepatic transaminase to values greater than three times the upper limit of normal, with an incidence as great as 1%. The incidence appeared to be dose related. However, in the placebo-controlled outcome trials in which 10- to 40-mg doses of simvastatin, lovastatin, fluvastatin, atorvastatin, pravastatin, or rosuvastatin were used, the incidence of 3-fold elevations in hepatic transaminases was 1-3% in the active drug treatment groups and 1.1% in placebo patients (Law et al., 2006; Ridker et al., 2008). No cases of liver failure occurred in these trials. Although serious hepatotoxicity is rare, 30 cases of liver failure associated with statin use were reported to the FDA between 1987 and 2000, a rate of about one case per million person-years of use (Law et al., 2006). It is therefore reasonable to measure alanine aminotransferase (ALT) at baseline and thereafter when clinically indicated.

Observational studies and a prospective trial suggest that transaminase elevations in patients with nonalcoholic fatty liver disease and hepatitis C are not at risk of statin-induced liver toxicity (Alqahtani and Sanchez, 2008; Chalasani et al., 2004; Lewis et al., 2007; Norris et al., 2008). This is important, as many insulin-resistant patients are affected by nonalcoholic fatty liver disease and have elevated transaminases. As insulin resistance is associated with increased CVD risk, insulin-resistant patients, especially those with type 2 diabetes mellitus, benefit from lipid-lowering therapy with statins (Cholesterol Treatment Trailists’ Collaborators, 2008). It is reassuring that these patients with elevated transaminases can safely take statins.

**Myopathy.** The major adverse effect associated with statin use is myopathy (Wilke et al., 2007). Between 1987 and 2001, the FDA recorded 42 deaths from rhabdomyolysis induced by statins (excluding cerivastatin, which has been withdrawn from the market worldwide). This is a rate of one death per million prescriptions (30-day supply). In the statin trials described earlier (under “Hepatotoxicity”), rhabdomyolysis occurred in eight active drug recipients versus five placebo subjects. Among active drug recipients, 0.17% had CK values exceeding 10 times the upper limit of normal; among placebo-treated subjects, the incidence was 0.13%. Only 13 out of 55 drug-treated subjects and 4 out of 43 placebo subjects with greater than 10-fold elevations of CK reported any muscle symptoms (Law et al., 2006).

The risk of myopathy and rhabdomyolysis increases in proportion to statin dose and plasma concentrations. Consequently, factors inhibiting statin catabolism are associated with increased myopathy risk, including advanced age (especially >80 years of age), hepatic or renal dysfunction, perioperative periods, multi-system disease (especially in association with diabetes mellitus), small body size, and untreated hypothyroidism (Pasternak et al., 2002; Thompson et al., 2003). Concomitant use of drugs that diminish statin catabolism or interfere with hepatic uptake is associated with myopathy and rhabdomyolysis in 50-60% of all cases (Law and Rudnicka, 2006; Thompson et al., 2003). Thus, avoiding these drug interactions should reduce myopathy and rhabdomyolysis by about one-half (Law and Rudnicka, 2006). The most common statin interactions occurred with fibrates, especially gemfibrozil (38%), cyclosporine (4%), digoxin (5%), warfarin (4%), macrolide antibiotics (3%), mibebradil (2%), and azole antifungals (1%) (Thompson et al., 2003). Other drugs that increase the risk of statin-induced myopathy include niacin (rare), HIV protease inhibitors, amiodarone, and nefazodone (Pasternak et al., 2002).

There are a variety of pharmacokinetic mechanisms by which these drugs increase myopathy risk when administered concomitantly with statins. Gemfibrozil, the drug most commonly associated with statin-induced myopathy, inhibits both uptake of the active hydroxy acid forms of statins into hepatocytes by OATP1B1 and interferes with the transformation of most statins by glucuronidases (Prueksaritanont et al., 2002a; Prueksaritanont et al., 2002b; Prueksaritanont et al., 2002c). Primarily due to inhibition of OATP1B1-mediated hepatic uptake, co-administration of gemfibrozil nearly doubles the plasma concentration of the statin hydroxy acids (Neuvonen et al., 2006). Other fibrates, especially fenofibrate, do not interfere with the glucuronidation of statins and pose less risk of myopathy when used in combination with statin therapy. (For reviews of statin interactions with other drugs, see Bellosta et al., 2004 and Neuvonen et al., 2006). Concomitant therapy with simvastatin, 80 mg daily, and fenofibrate, 160 mg daily, results in no clinically significant pharmacokinetic interaction (Bergman et al., 2004). Similar results were obtained in a study of low-dose rosuvastatin, 10 mg daily, plus fenofibrate, 67 mg three times a day. When statins are administered with niacin, the myopathy probably is caused by an enhanced inhibition of skeletal muscle cholesterol synthesis (a pharmacodynamic interaction).

Drugs that interfere with statin oxidation are those metabolized primarily by CYP3A4 and include certain macrolide antibiotics (e.g., erythromycin); azole antifungals (e.g., itraconazole); cyclosporine; nefazodone, a phenylpiperazine antidepressant; HIV protease inhibitors; and amiodarone (Alsheikh-Ali and Karas, 2005; Bellosta et al., 2004; Corsini, 2003). These pharmacokinetic interactions are associated with increased plasma concentrations of statins.
and their active metabolites. Atorvastatin, lovastatin, and simvastatin are primarily metabolized by CYPs 3A4 and 3A5. Fluvastatin is mostly (50-80%) metabolized by CYP2C9 to inactive metabolites, but CYP3A4 and CYP2C8 also contribute to its metabolism. Pravastatin, however, is not metabolized to any appreciable extent by the CYP system and is excreted unchanged in the urine. Pravastatin, fluvastatin, and rosuvastatin are not extensively metabolized by CYP3A4. Pravastatin and fluvastatin may be less likely to cause myopathy when used with one of the predisposing drugs. However, because cases of myopathy have been reported with both drugs, the benefits of combined therapy with any statin should be carefully weighed against the risk of myopathy. Although rosuvastatin is not transformed to any appreciable extent by oxidation, cases of myopathy have been reported, particularly in association with concomitant use of gemfibrozil (Schneck et al., 2004). Experience with pitavastatin is limited. There are no data regarding myopathy and rhabdomyolysis that might be associated with its use.

Despite the rarity of 10-fold elevations of CK, many patients complain of muscle aches (myalgias) while taking statins. It is unclear if such myalgias are caused by taking a statin. In one clinical trial involving 20,000 subjects randomized to simvastatin (40 mg daily) or placebo, it was observed over the 5 years of the study that one-third of patients complained of myalgia at least once, whether the active drug or the placebo was being taken (Heart Protection Study Collaborative Group, 2002).

Replacing vitamin D in patients with a vitamin D deficiency reportedly reduces statin-associated myalgias and improves statin tolerance (Ahmed et al., 2009). The observation needs to be confirmed, but it is potentially significant because vitamin D deficiency is associated with myopathy, insulin resistance, and increased incidence of CVD (Lee et al., 2008).

**Pregnancy.** The safety of statins during pregnancy has not been established. Women wishing to conceive should not take statins. During their childbearing years, women taking statins should use highly effective contraception (see Chapter 40). Nursing mothers also are advised to avoid taking statins.

**Therapeutic Uses.** Each statin has a low recommended starting dose that reduces LDL-C by 20-30%. Dyslipidemic patients frequently remain on their initial dose, are not titrated to achieve their target LDL-C level, and thus remain undertreated. For this reason, it is advisable to start each patient on a dose that will achieve the patient’s target goal for LDL-C lowering. For example, a patient with a baseline LDL-C of 150 mg/dL and a goal of 100 mg/dL requires a 33% reduction in LDL-C and should be started on a dose expected to provide it (Table 31–10).

**Hepatic cholesterol synthesis is maximal between midnight and 2:00 a.m. Thus, statins with $t_{1/2} \leq 4$ hours (all but atorvastatin and rosuvastatin) should be taken in the evening.**

The initial recommended dose of lovastatin (MEVACOR) is 20 mg and is slightly more effective if taken with the evening meal than if it is taken at bedtime, although bedtime dosing is preferable to missing doses. The dose of lovastatin may be increased every 3-6 weeks up to a maximum of 80 mg/day. The 80-mg dose is slightly (2-3%) more effective if given as 40 mg twice daily. Lovastatin, at 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (ADVICOR). Few patients are appropriate candidates for this fixed-dose combination (see the section on “Nicotinic Acid,” later in the chapter).

The approved starting dose of simvastatin (ZOCOR) for most patients is 20 mg at bedtime unless the required LDL-C reduction exceeds 45% or the patient is a high-risk secondary prevention patient, in which case a 40-mg starting dose is indicated. The maximal dose is 80 mg, and the drug should be taken at bedtime. In patients taking cyclosporine, fibrates, or niacin, the daily dose should not exceed 20 mg. Simvastatin, 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (SIMCOR). See the section on “Nicotinic Acid.”

Pravastatin (PRAVACHOL) therapy is initiated with a 20- or 40-mg dose that may be increased to 80 mg. This drug should be taken at bedtime. Because pravastatin is a hydroxy acid, bile-acid sequestrants will bind it and reduce its absorption. Practically, this is rarely a problem because the resins should be taken before meals and pravastatin should be taken at bedtime. Pravastatin also is marketed in combination with buffered aspirin (PRAVIGARD). The small advantage of combining these two drugs should be weighed against the disadvantages inherent in fixed-dose combinations.

The starting dose of fluvastatin (LESCOL) is 20 or 40 mg, and the maximum is 80 mg/day. Like pravastatin, it is administered as a hydroxy acid and should be taken at bedtime, several hours after ingesting a bile-acid sequestrant (if the combination is used).

Atorvastatin (LIPITOR) has a long $t_{1/2}$ which allows administration of this statin at any time of the day. The starting dose is 10 mg, and the maximum is 80 mg/day. Atorvastatin is marketed in combination with the Ca$^{2+}$-channel blocker amiodipine (CADUET) for patients with hypertension or angina as well as hypercholesterolemia. The physician should weigh any advantage of combination against the associated risks and disadvantages.

Rosuvastatin (CRESTOR) is available in doses ranging between 5 and 40 mg. It has a $t_{1/2}$ of 20-30 hours and may be taken at any time of day. Because experience with rosuvastatin is limited, treatment should be initiated with 5-10 mg daily, increasing stepwise, if needed, until the incidence of myopathy is better defined. If the combination of gemfibrozil with rosvastatin is used, the dose of rosvastatin should not exceed 10 mg.

Pitavastatin (LIVALO) is available in doses of 1, 2, and 4 mg. There is very limited post-marketing experience with this drug.

Gemfibrozil reduces clearance of pitavastatin and raises blood concentrations; consequently, gemfibrozil should be used cautiously, if at all, in combination with pitavastatin.

The choice of statins should be based on efficacy (reduction of LDL-C) and cost. Three drugs (lovastatin, simvastatin, and pravastatin) have been used safely in clinical trials involving thousands of subjects for 5 or more years. The documented safety records of these statins should be considered, especially when initiating therapy in younger patients. Once drug treatment is initiated, it is almost always lifelong. Baseline determinations of ALT and repeat testing at 3-6 months are recommended. If ALT is normal after the initial 3-6 months, then it need not be repeated more than once every 6-12 months. Measurements of CK are not routinely necessary.
unless the patient also is taking a drug that enhances the risk of myopathy. Because myopathy may develop months to years after the start of combined therapy, it is unlikely that routine monitoring for the accompanying rise in CK will consistently herald the onset, even if monitoring is performed every 3-4 months.

**Statin Use by Children.** Some statins have been approved for use in children with heterozygous familial hypercholesterolemia. Atorvastatin, lovastatin, and simvastatin are indicated for children ≥11 years. Pravastatin is approved for children ≥8 years.

**Statins in Combination with Other Lipid-Lowering Drugs.** Statins, in combination with the bile acid-binding resins cholestyramine and colestipol, produce 20-30% greater reductions in LDL-C than can be achieved with statins alone. Preliminary data indicate that colesevelam hydrochloride plus a statin lowers LDL-C by 8-16% more than statins alone. Niacin also can enhance the effect of statins, but the occurrence of myopathy increases when statin doses >25% of maximum (e.g., 20 mg of simvastatin or atorvastatin) are used with niacin. The combination of a fibrate (clofibrate, gemfibrozil, or fenofibrate) with a statin is particularly useful in patients with hypertriglyceridemia and high LDL-C levels. This combination increases the risk of myopathy but usually is safe with a fibrate at its usual maximal dose and a statin at no more than 25% of its maximal dose. Fenofibrate, which is least likely to interfere with statin metabolism, appears to be the safest fibrate to use with statins (Prueksaritanont et al., 2002b). Triple therapy with resins, niacin, and statins can reduce LDL-C by up to 70%. Vytorin, a fixed combination of simvastatin (10, 20, 40, or 80 mg) and ezetimibe (10 mg), decreased LDL-C levels by up to 60% at 24 weeks.

**Bile-Acid Sequestrants**

The two established bile-acid sequestrants or resins (cholestyramine and colestipol) are among the oldest of the hypolipidemic drugs, and they are probably the safest, because they are not absorbed from the intestine. These resins also are recommended for patients 11-20 years of age. Because statins are so effective as monotherapy, the resins are most often used as second agents if statin therapy does not lower LDL-C levels sufficiently. When used with a statin, cholestyramine and colestipol usually are prescribed at submaximal doses. Maximal doses can reduce LDL-C by up to 25% but are associated with unacceptable gastrointestinal side effects (bloating and constipation) that limit compliance. Colesevelam is a newer bile-acid sequestrant that is prepared as an anhydrous gel and taken as a tablet or as a powder that is mixed with water and taken as an oral suspension. It lowers LDL-C by 18% at its maximum dose. The safety and efficacy of colesevelam have not been studied in pediatric patients or pregnant women.

**Chemistry.** Cholestyramine and colestipol (Figure 31–3) are anion-exchange resins. Cholestyramine, a polymer of styrene and divinylbenzene with active sites formed from trimethylbenzylammonium groups, is a quaternary amine. Colestipol, a copolymer of diethyleneetriamine and 1-chloro-2,3-epoxypropane, is a mixture of tertiary and quaternary amines. Cholestyramine and colestipol are hygroscopic powders administered as chloride salts and are insoluble in water. Colesevelam is a polymer, poly(allylamine hydrochloride), cross-linked with epichlorohydlin and alkylated with 1-bromodecane and (6-bromohexyl)-trimethylammonium bromide; it is a hydrophilic gel and insoluble in water.

---

**Figure 31–3. Structures of cholestyramine, colestipol, and colesevelam.**
Mechanism of Action. The bile-acid sequestrants are highly positively charged and bind negatively charged bile acids. Because of their large size, the resins are not absorbed, and the bound bile acids are excreted in the stool. Because more than 95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids, and hepatic bile-acid synthesis increases. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors, an effect similar to that of statins. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol synthesis caused by upregulation of HMG-CoA reductase. Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins.

The resin-induced increase in bile-acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant hypertriglyceridemia (baseline triglyceride level >250 mg/dL). In such patients, bile-acid sequestrant therapy may cause striking increases in triglyceride levels. Use of colesevelam to lower LDL-C levels in hypertriglyceridemic patients should be accompanied by frequent (every 1-2 weeks) monitoring of fasting triglyceride levels until the triglyceride level is stable, or the use of colesevelam in these patients should be avoided.

Effects on Lipoprotein Levels. The reduction in LDL-C by resins is dose dependent. Doses of 8-12 g of cholestyramine or 10-15 g of colestipol are associated with 12-18% reductions in LDL-C. Maximal doses (24 g of cholestyramine, 30 g of colestipol) may reduce LDL-C by as much as 25% but will cause gastrointestinal side effects that are poorly tolerated by most patients. One to two weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. HDL-C levels increase 4-5%. Statins plus resins or niacin plus resins can reduce LDL-C by as much as 40-60%. Colesevelam, in doses of 3-3.75 g, reduces LDL-C levels by 9-19%.

Adverse Effects and Drug Interactions. The resins are generally safe, as they are not systemically absorbed. Because they are administered as chloride salts, rare instances of hyperchloremia have been reported. Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol because these resins increase triglyceride levels. At present, there are insufficient data on the effect of colesevelam on triglyceride levels.

Cholestyramine and colestipol both are available as a powder that must be mixed with water and drunk as a slurry. The gritty sensation is unpleasant to patients initially but can be tolerated. Colestipol is available in a tablet form that reduces the complaint of grittiness but not the gastrointestinal symptoms. Colesevelam is available as a hard capsule that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for gastrointestinal irritation.

Patients taking cholestyramine and colestipol complain of bloating and dyspepsia. These symptoms can be substantially reduced if the drug is completely suspended in liquid several hours before ingestion (e.g., evening doses can be mixed in the morning and refrigerated; morning doses can be mixed the previous evening and refrigerated). Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium, if necessary. Colesevelam may be less likely to cause the dyspepsia, bloating, and constipation observed in patients treated with cholestyramine or colestipol.

Cholestyramine and colestipol bind and interfere with the absorption of many drugs, including some thiazides, furosemide, propranolol, L-thyroxine, digoxin, warfarin, and some of the statins. The effect of cholestyramine and colestipol on the absorption of most drugs has not been studied. For this reason, it is wise to administer all drugs either 1 hour before or 3-4 hours after a dose of cholestyramine or colestipol. Colesevelam does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as digoxin, lovastatin, warfarin, metoprolol, quinidine, and valproic acid. The maximum concentration and the AUC of sustained-release verapamil are reduced by 31% and 11%, respectively, when the drug is co-administered with colesevelam. The effect of colesevelam on the absorption of other drugs has not been tested, but it seems prudent to recommend that patients take other medications 1 hour before or 3-4 hours after a dose of colesevelam.

Preparations and Use. Cholestyramine resin (QUESTRAN, others) is available in bulk (with scoops that measure a 4-g dose) or in individual packets of 4 g. Additional flavorings are added to increase palatability. The “light” preparations contain artificial sweeteners rather than sucrose. Colestipol hydrochloride (COLESTID, others) is available in bulk, in individual packets containing 5 g of colestipol, or as 1-g tablets. Resins should never be taken in the dry form. The powdered forms of cholestyramine (4 g/dose) and colestipol (5 g/dose) are either mixed with a fluid (water or juice) and drunk as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with one scoop or packet twice daily, and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than two doses (scoops or packets) twice a day.

Colesevelam hydrochloride (WELCHOL) is available as a solid tablet containing 0.625 g of colesevelam and as a powder in packets of 3.75 g or 1.875 g. The starting dose is either three tablets taken twice daily with meals or all six tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is seven tablets (4.375 g). The powder in the packets is first suspended in 4-8 oz of water and should be taken with meals. Dosing of the packet containing 3.75 g is once daily; the packet containing 1.875 g is taken twice daily.

Niacin (Nicotinic Acid) Niacin, nicotinic acid (pyridine-3-carboxylic acid), one of the oldest drugs used to treat dyslipidemia, favorably affects virtually all lipid parameters.
Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after its conversion to NAD or NADP, in which it occurs as an amide. Both niacin and its amide may be given orally as a source of niacin for its functions as a vitamin, but only niacin affects lipid levels. The hypolipidemic effects of niacin require larger doses than are required for its vitamin effects. Niacin is the best agent available for increasing HDL-C (30-40%); it also lowers triglycerides by 35-45% (as effectively as fibrates and the more effective statins) and reduces LDL-C levels by 20-30%. Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly. Despite its salutary effect on lipids, niacin has side effects that limit its use (see “Adverse Effects,” later in the chapter).

**Mechanism of Action.** In adipose tissue, niacin inhibits the lipolysis of triglycerides by hormone-sensitive lipase, which reduces transport of free fatty acids to the liver and decreases hepatic triglyceride synthesis. Niacin and related compounds (e.g., 5-methylpyrazine-2-carboxylic-4-oxide, acipimox) may exert their effects on lipolysis by inhibiting adipocyte adenylyl cyclase. A GPCR for niacin has been identified and designated as GPR109A; it couples to Gi (Wise et al., 2003); its mRNA is highly expressed in the adipose tissue and spleen, sites of high-affinity nicotinic acid binding (Lorenzen et al., 2001). Acting on this receptor, niacin stimulates the G_{i}-adenyllyl cyclase pathway in adipocytes, inhibiting cyclic AMP production and decreasing hormone-sensitive lipase activity, triglyceride lipolysis, and release of free fatty acids. Niacin also may inhibit a rate-limiting enzyme of triglyceride synthesis, diacylglycerol acyltransferase-2 (Ganji et al., 2004).

In the liver, niacin reduces triglyceride synthesis by inhibiting both the synthesis and esterification of fatty acids, effects that increase apoB degradation. Reduction of triglyceride synthesis reduces hepatic VLDL Production, which accounts for the reduced LDL levels. Niacin also enhances LPL activity, which promotes the clearance of chylomicrons and VLDL triglycerides. Niacin raises HDL-C levels by decreasing the fractional clearance of apoA-I in HDL rather than by enhancing HDL synthesis. This effect is due to a reduction in the hepatic clearance of HDL-apoA-I, but not of cholesterol esters, thereby increasing the apoA-I content of plasma and augmenting reverse cholesterol transport. In macrophages, niacin stimulates expression of the scavenger receptor CD36 and the cholesterol exporter ABCA1. The net effect of niacin on mononuclear cells (“foam cells”) is HDL-mediated reduction of cellular cholesterol content (Rubic et al., 2004).

**Effects on Plasma Lipoprotein Levels.** Regular or crystalline niacin in doses of 2-6 g/day reduces triglycerides by 35-50%; the maximal effect occurs within 4-7 days. Reductions of 25% in LDL-C levels are possible with doses of 4.5-6 g/day, but 3-6 weeks are required for maximal effect. HDL-C increases less in patients with low HDL-C levels (<35 mg/dL) than in those with higher levels.

**Absorption, Fate, and Excretion.** The pharmacological doses of regular (crystalline) niacin used to treat dyslipidemia are almost completely absorbed, and peak plasma concentrations (up to 0.24 mmol) are achieved within 30-60 minutes. The t1/2 is about 60 minutes, which accounts for the necessity of dosing two to three times daily. At lower doses, most niacin is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of the drug is excreted in the urine as unchanged nicotinic acid.

**Adverse Effects.** Two of niacin’s side effects, flushing and dyspepsia, limit patient compliance. The cutaneous effects include flushing and pruritus of the face and upper trunk, skin rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin mediated. Flushing is worse when therapy is initiated or the dosage is increased but ceases in most patients after 1-2 weeks of a stable dose. Taking an aspirin each day alleviates the flushing in many patients. Flushing recurs if only one or two doses are missed, and the flushing is more likely to occur when niacin is consumed with hot beverages (coffee, tea) or with ethanol-containing beverages. Flushing is minimized if therapy is initiated with low doses (100-250 mg twice daily) and if the drug is taken after breakfast or supper. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions or creams containing salicylic acid. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease should not take niacin because it can reactivate ulcer disease.

The most common, medically serious side effects are hepatotoxicity, manifested as elevated serum transaminases, and hyperglycemia. Both regular (crystalline) niacin and sustained-release niacin, which was developed to reduce flushing and itching, have been reported to cause severe liver toxicity. An extended-release niacin (Niaspan) appears to be less likely to cause severe hepatotoxicity, perhaps simply because it is administered once daily instead of more frequently. The incidence of flushing and pruritus with this preparation is not substantially different from that with regular niacin. Severe hepatotoxicity is more likely to occur when patients take more than 2 g of sustained-release, over-the-counter preparations. Affected patients experience flu-like fatigue and weakness. Usually, aspartate transaminase and ALT are elevated, serum albumin levels decline, and total cholesterol and LDL-C levels decline substantially. In fact, reductions in LDL-C of 50% or more in a patient taking niacin should be viewed as a sign of niacin toxicity.

In patients with diabetes mellitus, niacin should be used cautiously because niacin-induced insulin resistance can cause severe hyperglycemia. Niacin use in patients with diabetes mellitus often mandates a change to insulin therapy. In a study of patients with type 2 diabetes taking niaspan, 4% stopped taking the drug because of inadequate glycemic control (Grundy et al., 2002). If niacin is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. Niacin also elevates uric acid levels and may reactivate gout. A history of gout is a relative contraindication for niacin use. Rarer
reversible side effects include toxic amblyopia and toxic maculopapathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. *Niacin, at doses used in humans, has been associated with birth defects in experimental animals and should not be taken by pregnant women.*

**Therapeutic Use.** Niacin is indicated for hypertriglyceridemia and elevated LDL-C; it is especially useful in patients with both hypertriglyceridemia and low HDL-C levels. There are two commonly available forms of niacin. Crystalline niacin (immediate-release or regular) refers to niacin tablets that dissolve quickly after ingestion. Sustained-release niacin refers to preparations that continuously release niacin for 6-8 hours after ingestion. NIASPAN is the only preparation of niacin that is FDA-approved for treating dyslipidemia and that requires a prescription.

Crystalline niacin tablets are available over the counter in a variety of strengths from 50- to 500-mg tablets. To minimize the flushing and pruritus, it is best to start with a low dose (e.g., 100 mg twice daily taken after breakfast and supper). The dose may be increased stepwise every 7 days by 100-200 mg to a total daily dose of 1.5-2 g. After 2-4 weeks at this dose, transaminases, serum albumin, fasting glucose, and uric acid levels should be measured. Lipid levels should be checked and the dose increased further until the desired effect on plasma lipids is achieved. After a stable dose is attained, blood should be drawn every 3-6 months to monitor for the various toxicities.

Because concurrent use of niacin and a statin can cause myopathy, the statin should be administered at no more than 25% of its maximal dose. Patients also should be instructed to discontinue therapy if flu-like muscle aches occur. Routine measurement of CK in patients taking niacin and statins does not assure that severe myopathy will be detected before onset of symptoms, as patients have developed myopathy after several years of concomitant use of niacin with a statin.

Over-the-counter, sustained-release niacin preparations and NIASPAN are effective up to a total daily dose of 2 g. All doses of sustained-release niacin, but particularly doses above 2 g/day, have been reported to cause hepatotoxicity, which may occur soon after beginning therapy or after several years of use (Knopp et al., 2009). The potential for severe liver damage should preclude use of OTC preparations in most patients, including those who have taken an equivalent dose of crystalline niacin safely for many years and are considering switching to a sustained-release preparation. NIASPAN may be less likely to cause hepatotoxicity.

**Fibric Acid Derivatives: PPAR Activators**

**History.** In 1962, Throp and Waring reported that ethyl chlorophenoxyisobutyrate lowered lipid levels in rats. In 1967, the ester form (clofibrate) was approved for use in the U.S. and became the most widely prescribed hypolipidemic drug. Its use declined dramatically, however, after the World Health Organization (WHO) reported that, despite a 9% reduction in cholesterol levels, clofibrate treatment did not reduce fatal cardiovascular events, although nonfatal infarcts were reduced. Total mortality was significantly greater in the clofibrate group. The increased mortality was due to multiple causes, including cholelithiasis. Interpretation of these negative results was clouded by failure to analyze the data according to the intention-to-treat principle. A later analysis demonstrated that the apparent increase in noncardiac mortality did not persist in the clofibrate-treated patients after discontinuation of the drug (Heady et al., 1992). Clofibrate use was virtually abandoned after publication of the results of the 1978 WHO trial. Clofibrate as well as two other fibrates, gemfibrozil and fenofibrate, remain available in the U.S.

Two subsequent trials involving only men have reported favorable effects of gemfibrozil therapy on fatal and nonfatal cardiovascular events without an increase in morbidity or mortality (Frick et al., 1987; Rubins et al., 1999). A third trial of men and women reported fewer events in a subgroup characterized by high triglyceride and low HDL-C levels (Haim et al., 1999).

**Chemistry.** Clofibrate, the prototype of the fibric acid derivatives, is the ethyl ester of *p*-chlorophenoxyisobutyrate. Gemfibrozil is a nonhalogenated phenoxypentanoic acid and thus is distinct from the halogenated fibrates. A number of fibric acid analogs (e.g., fenofibrate, bezafibrate, ciprofibrate) have been developed and are used in Europe and elsewhere (see Figure 31–4 for their structural formulas).

Figure 31–4. Structures of the fibric acids.
**Mechanism of Action.** Despite extensive studies in humans, the mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear. Recent studies suggest that many of the effects of these compounds on blood lipids are mediated by their interaction with peroxisome proliferator-activated receptors (PPARs) (Kersten et al., 2000), which regulate gene transcription. Three PPAR isotypes (α, β, and γ) have been identified. Fibrates bind to PPARα, which is expressed primarily in the liver and brown adipose tissue and to a lesser extent in kidney, heart, and skeletal muscle. Fibrates reduce triglycerides through PPARα-mediated stimulation of fatty acid oxidation, increased LPL synthesis, and reduced expression of apoC-III. An increase in LPL would enhance the clearance of triglyceride-rich lipoproteins. A reduction in hepatic production of apoC-III, which serves as an inhibitor of triglyceride-rich lipoproteins. A reduction in hepatic synthesis, and reduced expression of apoC-III. An increase in LPL would enhance the clearance of triglyceride-rich lipoproteins. A reduction in hepatic production of apoC-III, which serves as an inhibitor of triglyceride-rich lipoproteins. A reduction in hepatic production of apoC-III, which serves as an inhibitor of triglyceride-rich lipoproteins. A reduction in hepatic production of apoC-III, which serves as an inhibitor of triglyceride-rich lipoproteins. A reduction in hepatic production of apoC-III, which serves as an inhibitor of triglyceride-rich lipoproteins. been reported to potentiate the action of oral anticoagulants, in part by displacing them from their binding sites on albumin. Careful monitoring of the prothrombin time and reduction in dosage of the anticoagulant may be appropriate when treatment with a fibrate is begun.

A myopathy syndrome occasionally occurs in subjects taking clofibrate, gemfibrozil, or fenofibrate and may occur in up to 5% of patients treated with a combination of gemfibrozil and higher doses of statins. To diminish the risk of myopathy, statin doses should be reduced when combination therapy of a statin plus a fibrate is employed. Several drug interactions may contribute to this adverse response. Gemfibrozil inhibits hepatic uptake of statins by OATP1B1. Gemfibrozil also competes for the same glucuronosyl transferases that metabolize most statins. As a consequence, levels of both drugs may be increased when they are co-administered (Pruksaritanont et al., 2002b; Pruksaritanont et al., 2002c). Patients taking this combination should be instructed to be aware of the potential symptoms and should be followed at 3-month intervals with careful history and determination of CK values until a stable pattern is established. Patients taking fibrates with rosuvastatin should be followed especially closely even if low doses (5-10 mg) of rosuvastatin are employed during therapy. There is more experience with and knowledge of the safety of this specific combination. Fenofibrate is glucuronidated by enzymes that are not involved in statin glucuronidation. Thus, fenofibrate-statin combinations are less likely to cause myopathy than combination therapy with gemfibrozil and statins.

All of the fibrates increase the lithogenicity of bile. Clofibrate use has been associated with increased risk of gallstone formation. Renal failure is a relative contraindication to the use of fibrates. As is hepatic dysfunction. Combined statin-fibrate therapy should be avoided in patients with compromised renal function. Gemfibrozil should be used with caution and at a reduced dosage to treat the hyperlipidemia of renal failure. Fibrates should not be used by children or pregnant women.

**Therapeutic Use.** Clofibrate is available for oral administration. The usual dose is 2 g/day in divided doses. This compound is little used but may be useful in patients who do not tolerate gemfibrozil or fenofibrate. Gemfibrozil (LOFIBRA) usually is administered as a 600-mg dose taken twice a day, 30 minutes before the morning and evening meals. Fenofibrate is available in two different formulations. The first preparation developed is the dimethylethyl ester of fenofibric acid, which is poorly water soluble and poorly absorbed. After uptake by the liver, this compound is hydrolyzed to produce fenofibrin acid, which is the active moiety. Recently, a choline salt of fenofibrin acid that is highly soluble in water and readily absorbed was developed. The effects of both formulations, however, are similar with respect to changes in plasma lipid concentrations (Grundy et al., 2005; Jones et al., 2009). The dimethylethyl ester preparations of fenofibrin acid include TRICOR and LOFIBRA. The tricor brand of fenofibrate is available in tablets of 48 and 145 mg. The usual daily dose is 145 mg. Generic fenofibrate (LOFIBRA) is available in capsules containing 67, 134, and 200 mg. TRICOR, 145 mg, and LOFIBRA, 200 mg, are equivalent doses. The choline salt of fenofibrin acid (TRILIPIX) is available in capsules of 135 and 45 mg. TRILIPIX, 135 mg, is equivalent to TRICOR, 145 mg, and LOFIBRA, 200 mg. Choline fenofibrate is indicated for combination therapy with statins (Jones et al., 2009). Fibrates are the drugs of choice for treating hyperlipidemic subjects with type III hyperlipoproteinemia as well as subjects with severe hypertriglyceridemia (triglycerides >1000 mg/dL) who are at risk for pancreatitis. Fibrates appear to have an important role in subjects with high triglycerides and low HDL-C levels associated with the metabolic syndrome or type 2 diabetes mellitus (Robins, 2001). When fibrates are used in such patients, the LDL levels need to be monitored; if LDL levels rise, the addition of a low dose of a statin may be needed. Many experts now treat such patients first with a statin (Heart Protection Study Collaborative Group, 2003) and then add a fibrate, based on the reported benefit of gemfibrozil therapy. However, statin-fibrate combination therapy has not been evaluated in outcome studies (American Diabetes Association, 2004). If this combination is used, there should be careful monitoring for myopathy.

**Ezetimibe and the Inhibition of Dietary Cholesterol Uptake**

Ezetimibe is the first compound approved for lowering total and LDL-C levels that inhibits cholesterol absorption by enterocytes in the small intestine. It lowers LDL-C levels by ~20% and is used primarily as adjunctive therapy with statins.

**History.** Ezetimibe (SCH58235) was developed by pharmaceutical chemists studying inhibition of intestinal ACAT. Several compounds were found to inhibit cholesterol absorption, but by inhibiting intestinal cholesterol transport rather than ACAT.

**Mechanism of Action.** Ezetimibe inhibits luminal cholesterol uptake by jejunal enterocytes, by inhibiting the transport protein NPC1L1 (Altmann et al., 2004; Davis et al., 2004).

In wild-type mice, ezetimibe inhibits cholesterol absorption by about 70%; in NPC1L1 knockout mice, cholesterol absorption is 86% lower than in wild-type mice, and ezetimibe has no effect on cholesterol absorption (Altmann et al., 2004). Ezetimibe does not affect intestinal triglyceride absorption. In human subjects, ezetimibe reduced cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis that can be inhibited with a cholesterol synthesis inhibitor such as a statin (Sudhop et al., 2002). There also is a substantial reduction of plasma levels of plant sterols (campesterol and sitosterol concentrations are reduced by 48% and 41%, respectively), indicating that ezetimibe also inhibits intestinal absorption of plant sterols.

The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons. The reduced cholesterol content of chylomicrons diminishes the delivery of cholesterol to the liver by chylomicron remnants. The
diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins. In experimental animal models of remnant dyslipidemia, ezetimibe profoundly diminished diet-induced atherosclerosis (Davis et al., 2001a).

Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma. Indeed, ezetimibe reduces LDL-C levels by 15-20% (Gagné et al., 2002; Knopp et al., 2003).

**Combination Therapy (Ezetimibe plus Statins).** The maximal efficacy of ezetimibe for lowering LDL-C is 15-20% when used as monotherapy (Knopp et al., 2003). This reduction is equivalent to, or less than, that attained with 10- to 20-mg doses of most statins. Consequently, the role of ezetimibe as monotherapy of patients with elevated LDL-C levels appears to be limited to the small group of statin-intolerant patients.

The actions of ezetimibe are complementary to those of statins. Statins, which inhibit cholesterol biosynthesis, increase intestinal cholesterol absorption (Miettinen and Gylling, 2003). Ezetimibe, which inhibits intestinal cholesterol absorption, enhances cholesterol biosynthesis by as much as 3.5 times in experimental animals (Davis et al., 2001b). Dual therapy with these two classes of drugs prevents both the enhanced cholesterol synthesis induced by ezetimibe and the increase in cholesterol absorption induced by statins. This combination provides additive reductions in LDL-C levels irrespective of the statin employed (Ballantyne et al., 2004; Ballantyne et al., 2003; Melani et al., 2003).

A combination tablet containing ezetimibe, 10 mg, and various doses of simvastatin (10, 20, 40, and 80 mg) has been approved (VYTORIN). At the highest simvastatin dose (80 mg), plus ezetimibe (10 mg), average LDL-C reduction was 60%, which is greater than can be attained with any statin as monotherapy (Feldman et al., 2004). Despite the robust laboratory-based efficacy of this combination, the clinical cardiovascular benefits remain controversial when the combination is compared to effects of statins alone (Kastelein et al., 2008; Mitka, 2009).

**Absorption, Fate, and Excretion.** Ezetimibe is highly water insoluble, precluding studies of its bioavailability. After ingestion, it is glucuronidated in the intestinal epithelium and absorbed and then enters an enterohepatic recirculation (Patrick et al., 2002). Pharmacokinetic studies indicate that about 70% is excreted in the feces and about 10% in the urine (as a glucuronide conjugate) (Patrick et al., 2002). Bile-acid sequestrants inhibit absorption of ezetimibe, and the two agents should not be administered together. Otherwise, no significant drug interactions have been reported.

**Adverse Effects and Drug Interactions.** Other than rare allergic reactions, specific adverse effects have not been observed in patients taking ezetimibe. The safety of ezetimibe during pregnancy has not been established. With doses of ezetimibe sufficient to increase exposure 10-150 times compared with a 10-mg dose in humans, fetal skeletal abnormalities were noted in rats and rabbits. Since all statins are contraindicated in pregnant and nursing women, combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.

**Therapeutic Use.** Ezetimibe (ZETIA) is available as a 10-mg tablet that may be taken at any time during the day, with or without food. Ezetimibe may be taken with any medication other than bile-acid sequestrants, which inhibit its absorption.

**CLINICAL SUMMARY**

Patients with any type of dyslipidemia (e.g., elevated levels of cholesterol, low levels of HDL-C with or without hypercholesterolemia, or moderately elevated triglyceride levels with low HDL-C levels) are at risk of developing atherosclerosis-induced vascular disease. Maintaining ideal body weight, eating a diet low in saturated fat and cholesterol, and regular exercise are the cornerstones of managing dyslipidemia. In the absence of vascular disease, type 2 diabetes mellitus, or metabolic syndrome, adoption of these behaviors will alleviate the need for cholesterol-lowering medications in many subjects. Following assessment of their future risk for a vascular disease event, patients should be treated to achieve target lipid values. In virtually every type of dyslipidemic patient, statins have been proven to reduce the risk of subsequent CHD events and nonhemorrhagic stroke. For this reason, statin therapy should be the first-line choice when choosing between classes of lipid-lowering agents.

A second principle is to treat with statin doses adequate to reduce the patient’s lipid values to goal levels. Most patients are not adequately treated and do not reach goal values. Safety is greatly enhanced if doctors discuss with their patients the rare but serious side effects of hepatotoxicity and rhabdomyolysis with associated renal failure.

Finally, patients with low HDL-C levels may not receive the maximum benefit of lipid-lowering therapy as prescribed by the ATP III guidelines based on levels of LDL-C or non-HDL-C. For this reason, treatment of patients with low HDL-C levels should be based on both LDL-C levels and the ratio of total cholesterol:HDLC (Table 31–9).

The biogenic amine, histamine, is a major mediator of inflammation, anaphylaxis, and gastric acid secretion; in addition, histamine plays a role in neurotransmission. Our understanding of the physiological and pathophysiological roles of histamine has been enhanced by the development of subtype-specific receptor antagonists and by the cloning of four receptors for histamine. Competitive antagonists of H₁ receptors have diverse actions and are used therapeutically in treating allergies, urticaria, anaphylactic reactions, nausea, motion sickness, insomnia, and some symptoms of asthma. Antagonists of the H₂ receptor are effective in reducing gastric acid secretion. The peptide, bradykinin, has cardiovascular effects similar to those of histamine and plays prominent roles in inflammation and nociception.

This chapter presents the physiology and pathophysiology of histamine and kinins and the pharmacology of the antagonists that inhibit responses to these mediators.

**HISTAMINE**

**History.** The history of histamine (β-aminoethylimidazole) parallels that of acetylcholine (ACh). Both were chemically synthesized before their biological significance was recognized; they were first detected as uterine stimulants in, and isolated from, extracts of ergot, where they proved to be contaminants derived from bacterial action (Dale, 1953).

Dale and Laidlaw subjected histamine to intensive pharmacological study (Dale, 1953), discovering that it stimulated a host of smooth muscles and had an intense vasodepressor action. Importantly, they observed that when a sensitized animal was injected with a normally inert protein, the immediate responses closely resembled those of poisoning by histamine. These observations anticipated by many years the finding that endogenous histamine contributes to immediate hypersensitivity reactions and to responses to cellular injury. Best and colleagues (1927) isolated histamine from fresh samples of liver and lung, thereby establishing it as a natural constituent of mammalian tissues, hence the name histamine after the Greek word for tissue, histos. The presence of histamine in tissue extracts delayed the acceptance of the discovery of some peptide and protein hormones (e.g., gastrin) until the technology for separating the naturally occurring substances was sufficiently advanced (Grossman, 1966).

Lewis and colleagues (Lewis, 1927) proposed that a substance with the properties of histamine (“H substance”) was liberated from the cells of the skin by injurious stimuli, including the reaction of antigen with antibody. We now know that endogenous histamine plays a role in the immediate allergic response and is an important regulator of gastric acid secretion. More recently, a role for histamine as a modulator of neurotransmitter release in the central and peripheral nervous systems has emerged.

Early suspicions that histamine acts through more than one receptor have been borne out by the elucidation of four classes of receptors, designated H₁ (Ash and Schild, 1966), H₂ (Black et al., 1972), H₃ (Arrang et al., 1987), and H₄ (Leurs et al., 2009). H₁ receptors are blocked selectively by the classical “antihistamines.” Second-generation H₁ antagonists are collectively referred to as nonsedating antihistamines. The term third generation has been applied to some recently developed antihistamines, such as active metabolites of first- or second-generation antihistamines that are not further metabolized (e.g., cetirizine derived from hydroxyzine or fexofenadine from terfenadine) or to antihistamines that have additional therapeutic effects. However, the Consensus Group on New-Generation Antihistamines concluded that none of the currently available antihistamines can be classified as true third-generation drugs, defined as lacking in cardiotoxicity, drug-drug interactions, and CNS effects or with possible additional beneficial effects (e.g., anti-inflammatory) (Holgate et al., 2003). The discovery of H₂ antagonists and their ability to inhibit gastric secretion has contributed greatly to the resurgence of interest in histamine in biology and clinical medicine (Chapter 45). H₂ receptors were discovered as presynaptic autoreceptors on histamine-containing neurons that mediate feedback inhibition of the release and synthesis of histamine. The development of selective H₃ receptor agonists and antagonists has led to an increased understanding of the importance of H₃ receptors in histaminergic neurons in vivo. None of these H₃ agonists or
antagonists has yet emerged as a therapeutic agent (Sander et al., 2008). The \( H_4 \) receptor is most similar to the \( H_3 \) receptor but is expressed in cells of hematopoietic lineage; the availability of \( H_4 \)-specific antagonists with anti-inflammatory properties should help to define the biological roles of the \( H_4 \) receptor (Thurmond et al., 2008).

**Chemistry.** Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by two methylene groups. The pharmacologically active form is the monocationic \( \gamma \)-\( H \) tautomer, which is the charged form of the species depicted in Figure 32–1 (Ganellin and Parsons, 1982). \( H_1 \) and \( H_4 \) receptors have a much higher affinity for histamine than \( H_3 \) and \( H_2 \) receptors, and the four histamine receptors can be activated differently by analogs of histamine (Venable and Thurmond, 2006) (Figure 32–1 and Table 32–1). The specificities of histamine analogs were re-evaluated after the discovery of the \( H_4 \) receptor. Thus, 4-methylhistamine and dimaprit, originally classified as \( H_2 \) receptors (Black et al., 1972), are full \( H_4 \) agonists with a ~100-fold higher affinity for the \( H_4 \) receptor. A number of \( H_3 \) agonists also are weaker agonists of the \( H_4 \) receptor (Lim et al., 2005; Venable and Thurmond, 2006).

**Distribution and Biosynthesis of Histamine**

**Distribution.** Histamine is widely, if unevenly, distributed throughout the animal kingdom and is present in many venoms, bacteria, and plants. Almost all mammalian tissues contain histamine in amounts ranging from <1 to >100 \( \mu g/g \). Concentrations in plasma and other body fluids generally are very low, but human cerebrospinal fluid (CSF) contains significant amounts. The mast cell is the predominant storage site for histamine in most tissues; the concentration of histamine is particularly high in tissues that contain large numbers of mast cells, such as skin, bronchial mucosa, and intestinal mucosa.

**Synthesis, Storage, and Metabolism.** Histamine is formed by the decarboxylation of the amino acid histidine by the enzyme L-histidine decarboxylase (Figure 32-2), found in every mammalian tissue that contains histamine. The chief site of histamine storage in most tissues is the mast cell; in the blood, it is the basophil. These cells synthesize histamine and store it in secretory granules.

At the secretory granule pH of ~5.5, histamine is positively charged and ionicly complexed with negatively charged acidic groups on other granule constituents, primarily proteases and heparin or chondroitin sulfate proteoglycans. The turnover rate of

Figure 32–1. Structure of histamine and some \( H_1 \), \( H_2 \), \( H_3 \), and \( H_4 \) agonists. Dimaprit and 4-methylhistamine, originally identified as specific \( H_2 \) agonists, have a much higher affinity for the \( H_4 \) receptor; 4-methylhistamine is the most specific available \( H_4 \) agonist, with ~10-fold higher affinity than dimaprit, a partial \( H_4 \) agonist. Impromidine is among the most potent \( H_2 \) agonists but also is an antagonist at \( H_1 \) and \( H_4 \) receptors and a partial agonist at \( H_3 \) receptors. \( (R)\-\alpha\)-Methylhistamine and imetit are high-affinity agonists of \( H_3 \) receptors and lower-affinity full agonists at \( H_4 \) receptors.
histamine in secretory granules is slow, and when tissues rich in mast cells are depleted of their histamine stores, it may take weeks before concentrations return to normal levels. Non–mast cell sites of histamine formation include the epidermis, the gastric mucosa, neurons within the CNS, and cells in regenerating or rapidly growing tissues. Turnover is rapid at these non–mast cell sites because the histamine is released continuously rather than stored. Non–mast cell sites of histamine production contribute significantly to the daily excretion of histamine metabolites in the urine. Because L-histidine decarboxylase is an inducible enzyme, the histamine-forming capacity at such sites is subject to regulation. Histamine that is ingested or formed by bacteria in the gastrointestinal (GI) tract does not contribute to the body’s stores; rather, it is rapidly metabolized, and the metabolites are eliminated in the urine.

There are two major paths of histamine metabolism in humans (Figure 32–2). The more important is ring methylation to form N-methylhistamine, catalyzed by histamine-N-methyltransferase, which is distributed widely. Most of the N-methylhistamine formed is then converted to N-methylimidazole acetic acid by monoamine oxidase (MAO), and this reaction can be blocked by MAO inhibitors (Chapters 8, 15, and 22). Alternatively, histamine may undergo oxidative deamination catalyzed mainly by the nonspecific enzyme diamine oxidase, yielding imidazole acetic acid, which is then converted to imidazole acetic acid riboside. These metabolites have little or no activity and are excreted in the urine. Measurement of N-methylhistamine in urine affords a more reliable index of histamine production than assessment of histamine itself. Artfactually elevated levels of histamine in urine arise from genitourinary tract bacteria that can decarboxylate histidine. In addition, the metabolism of histamine appears to be altered in patients with mastocytosis such that determination of histamine metabolites is a more sensitive diagnostic indicator of the disease than histamine.

*At least 20 alternately spliced H₃ isoforms have been detected at the mRNA level. Eight of these isoforms, ranging in size from 329-445 residues, were found to be functionally competent by binding or signaling assays (see Esbenshade et al., 2008)

Figure 32–2. Pathways of histamine synthesis and metabolism in humans. Histamine is synthesized from histidine by decarboxylation. Histamine is metabolized via two pathways, predominantly by methylation of the ring followed by oxidative deamination (left side of figure), and secondarily by oxidative deamination and then conjugation with ribose.
Release and Functions of Endogenous Histamine

Histamine has important physiological roles. After its release from storage granules as a result of the interaction of antigen with immunoglobulin E (IgE) antibodies on the mast cell surface, histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and blood vessels account for many of the symptoms of the allergic response. In addition, some drugs act directly on mast cells to release histamine, causing untoward effects. Histamine has a major role in regulating gastric acid secretion and also modulates neurotransmitter release.

Role in Allergic Responses. The principal target cells of immediate hypersensitivity reactions are mast cells and basophils (Schwartz, 1994). As part of the allergic response to an antigen, IgE antibodies are generated and bind to the surfaces of mast cells and basophils via specific high-affinity Fc receptors. This receptor, FcεRI, consists of α, β, and two γ chains (Chapter 35). Atopic individuals develop IgE antibodies to commonly inhaled antigens. This is a heritable trait, conferring a predilection to rhinitis, asthma, and atopic dermatitis.

Antigen bridges the IgE molecules and via FcεRI activates signaling pathways in mast cells or basophils involving tyrosine kinases and subsequent phosphorylation of multiple protein substrates within 5-15 seconds of contact with antigen. Protein kinases implicated include the Src-related kinases Lyn and Syk. Prominent among the phosphorylated proteins are the β and γ subunits of FcεRI, itself, and phospholipase C (PLC)γ and PLCγ2, with consequent production of inositol trisphosphate (IP3) and mobilization of intracellular Ca2+ (Chapter 3). These events trigger the exocytosis of the contents of secretory granules.

Release of Other Autacoids. The release of histamine only partially explains the biological effects that ensue from immediate hypersensitivity reactions because a broad spectrum of other inflammatory mediators is released on mast cell activation.

Stimulation of IgE receptors also activates phospholipase A2 (PLA2), leading to the production of a host of mediators, including platelet-activating factor (PAF) and metabolites of arachidonic acid such as leukotrienes C4 and D4, which contract the smooth muscles of the bronchial tree (Chapters 33 and 36). Kinins also are generated during some allergic responses. Thus, the mast cell secretes a variety of inflammatory mediators in addition to histamine, each contributing to the major symptoms of the allergic response (see below).

Regulation of Mediator Release. The wide variety of mediators released during the allergic response can explain the ineffectiveness of drug therapy focused on a single mediator. Agents that act at muscarinic or α-adrenergic receptors increase the release of mediators, an effect of little clinical significance. Epinephrine and related drugs that act through β2 adrenergic receptors increase cellular cyclic AMP and thereby inhibit the secretory activities of mast cells. However, the beneficial effects of β adrenergic agonists in allergic states such as asthma are due mainly to relaxing bronchial smooth muscle (Chapters 12 and 36).

Histamine Release by Drugs, Peptides, Venoms, and Other Agents. Many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization. Responses of this sort are most likely to occur following intravenous injections of certain categories of substances, particularly organic bases such as amides, amidines, quaternary ammonium compounds, pyridinium compounds, piperidines, and alkaloids (Rothschild, 1966). Tubocurarine, succinylcholine, morphine, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders also may elicit the response. The phenomenon is one of clinical concern, and may account for unexpected anaphylactoid reactions. For example, vancomycin-induced red-man syndrome, involving hypotension and flushing in the upper body and face, may be mediated through histamine release.

In addition to therapeutic agents, certain experimental compounds stimulate the release of histamine as their dominant pharmacological characteristic. The archetype is the polybasic substance known as compound 48/80. This is a mixture of low-molecular-weight polymers of p-methoxy-N-methylphenethylamine, of which the hexamer is most active.

Basic polypeptides often are effective histamine releasers, and over a limited range, their potency generally increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (Lys-bradykinin) and substance P, with more positively charged amino acids, are more active. Some venom, such as that of the wasp, contain potent histamine-releasing peptides (Johnson and Erdös, 1973). Polymyxin B also is very active. Basic polypeptides released upon tissue injury constitute pathophysiological stimuli to secretion for mast cells and basophils.

Within seconds of the intravenous injection of a histamine liberator, human subjects experience a burning, itching sensation. This effect, most marked in the palms of the hand and in the face, scalp, and ears, is soon followed by a feeling of intense warmth. The skin reddens, and the color rapidly spreads over the trunk. Blood pressure falls, the heart rate accelerates, and the subject usually complains of headache. After a few minutes, blood pressure recovers, and crops of hives usually appear on the skin. Colic, nausea, hypersecretion
of acid, and moderate bronchospasm also frequently occur. The effect becomes less intense with successive injections as the mast cell stores of histamine are depleted. Histamine liberators do not deplete tissues of non–mast cell histamine.

**Mechanism of Histamine-Releasing Agents.** Histamine-releasing substances activate the secretory responses of mast cells and basophils by causing a rise in intracellular Ca\(^{2+}\). Some are ionophores and directly facilitate the entry of Ca\(^{2+}\) into the cell; others, such as neurotensin, act on specific G protein–coupled receptors (GPCRs). In contrast, the precise mechanism by which basic secretagogues (e.g., substance P, mastoparan, kallidin, compound 48/80, and polymyxin B) release histamine still is unclear. These agents can directly activate G\(_i\) proteins after being taken up by the cell (Ferry et al., 2002), but more recent evidence indicates the involvement of a cell-surface GPCR in the Mas-related gene family or integrin-associated protein CD47 coupled to G\(_i\) (Sick et al., 2009). The downstream effectors appear to be \(\beta\gamma\) subunits released from G\(_{\alpha}\), which activate the PLC\(\beta\)–IP\(_3\)–Ca\(^{2+}\) pathway. Antigen–IgE complexes lead to mobilization of stored Ca\(^{2+}\) and activation of isoforms of PLC\(\gamma\), as described in “Role in Allergic Responses.”

**Histamine Release by Other Means.** Clinical conditions related to histamine release include cold, cholinergic, and solar urticaria. Some of these involve specific secretory responses of the mast cells and cell-fixed IgE. However, nonspecific cellular damage from any cause can release histamine. The redness and urticaria that follow scratching of the skin is a familiar example.

**Increased Proliferation of Mast Cells and Basophils and Gastric Carcinoid Tumors.** In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that sting when stroked. In systemic mastocytosis, overproliferation of mast cells also is found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of GI effects, such as diarrhea or peptic ulceration. Episodes of mast cell activation with attendant systemic histamine release are precipitated by a variety of stimuli, including exertion, insect stings, exposure to heat, and exposure to drugs that release histamine directly or to which patients are allergic. In myelogenous leukemia, excessive numbers of basophils are present in the blood, raising its histamine content to high levels that may contribute to chronic pruritus. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy “geographical” flush.

**Gastric Acid Secretion.** Histamine acting at H\(_2\) receptors is a powerful gastric secretagogue, evoking a copious secretion of acid from parietal cells (see Figure 45–1); it also increases the output of pepsin and intrinsic factor. The secretion of gastric acid from parietal cells also is caused by stimulation of the vagus nerve and by the enteric hormone gastrin. However, histamine undoubtedly is the dominant physiological mediator of acid secretion; blockade of H\(_2\) receptors not only antagonizes acid secretion in response to histamine but also inhibits responses to gastrin and vagal stimulation. (For regulation of gastric acid secretion and the clinical utility of H\(_2\) antagonists, see Chapter 45.)

**Central Nervous System.** There is substantial evidence that histamine functions as a neurotransmitter in the CNS. Histamine-containing neurons control both homeostatic and higher brain functions, including regulation of the sleep-wake cycle, circadian and feeding rhythms, immunity, learning, memory, drinking, and body temperature (see Haas et al., 2008). However, knockout animals lacking histamine or its receptors exhibit only subtle defects unless challenged, and no human disease has yet been directly linked to dysfunction of the brain histamine system. Histamine, histidine decarboxylase, enzymes that metabolize histamine, and H\(_1\), H\(_3\), and H\(_4\) receptors are distributed widely but not uniformly in the CNS (see Haas et al., 2008). H\(_1\) receptors are associated with both neuronal and nonneuronal elements (e.g., glia, blood cells, vessels) and are concentrated in regions that control neuroendocrine function, behavior, and nutritional state. Distribution of H\(_2\) receptors is more consistent with histaminergic projections than H\(_1\) receptors, suggesting that they mediate many of the postsynaptic actions of histamine. H\(_3\) receptors also are heterogeneously concentrated in areas known to receive histaminergic projections, consistent with their function as presynaptic autoreceptors. Histamine inhibits appetite and increases wakefulness via H\(_1\) receptors, explaining sedation by classical antihistamines (Haas et al., 2008).

**Pharmacological Effects**

**Receptor–Effector Coupling and Mechanisms of Action.** Histamine receptors are GPCRs (Leurs et al., 2009; Haas et al., 2008; Thurmond et al., 2008) (Table 32–1). H\(_1\) receptors couple to G\(_{i/1}\) and activate the PLC–IP\(_3\)–Ca\(^{2+}\) pathway and its many possible sequelae, including activation of PKC, Ca\(^{2+}\)–calmodulin–dependent enzymes (eNOS and various protein kinases), and PLA\(_2\). H\(_2\) receptors link to G\(_i\) to activate the adenylyl cyclase–cyclic AMP–PKA pathway, whereas H\(_3\) and H\(_4\) receptors couple to G\(_{\beta\gamma}\) to inhibit adenylyl cyclase and decrease cellular cyclic AMP. Activation of H\(_3\) receptors also can activate MAP kinase and inhibit the Na\(^+\)/H\(^+\) exchanger, and activation of H\(_4\) receptors mobilizes stored Ca\(^{2+}\) in some cells (Leurs et al., 2009; Haas et al., 2008; Thurmond et al., 2008; Esbenshade et al., 2008). Armed with this information, knowledge of the cellular expression of H receptor subtypes, and an understanding of the differentiated functions of a particular cell type, one can predict a cell’s response to histamine. Of course, in a physiological setting, a cell is exposed to a myriad of hormones simultaneously, and significant interactions may occur between signaling pathways, such as the G\(_q\) \(\rightarrow\) G\(_s\) cross-talk described in a number of systems (Meszaros et al., 2000). Furthermore, the differential expression
of H receptor subtypes on neighboring cells and the unequal sensitivities of H receptor–effector response pathways can cause parallel and opposing cellular responses to occur together, complicating interpretation of the overall response of a tissue. For example, activation of H4 receptors on vascular endothelium stimulates the Ca2+-mobilizing pathway \((G_q-PLC-IP_3)\) and activates eNOS to produce nitric oxide (NO), which diffuses to nearby smooth muscle cells to increase cyclic GMP and cause relaxation. Stimulation of H1 receptors on smooth muscle also will mobilize Ca2+ but cause contraction, whereas activation of H2 receptors on the same smooth muscle cell will link via \(G_s\) to enhanced cyclic AMP accumulation, activation of PKA, and thence to relaxation.

The existence of multiple histamine receptors was predicted by the studies of Ash and Schild (1966) and Black and colleagues (1972) a generation before the cloning of histamine receptors. Similarly, heterogeneity of H1 receptors, predicted by kinetic and radioligand-binding studies, has been confirmed by cloning, which revealed H3 isoforms differing in the third intracellular loop, transmembrane helices 6 and 7, and C-terminal tail, and in their capacity to couple \(G_i\), inhibit adenyl cyclase, and activate MAP kinase. Molecular cloning studies also identified the H4 receptor.

As Figure 32–1 and Table 32–1 indicate, the pharmacological definition of H1, H2, and H3 receptors is clear because relatively specific agonists and antagonists are available. However, the H4 receptor exhibits 35-40% homology to isoforms of the H3 receptor, and the two were harder to distinguish pharmacologically because many high-affinity H1 ligands also interact with H2 receptors. Several non-imidazole compounds that are more selective H4 antagonists have been developed (Sander et al., 2008), and there are now several selective H4 antagonists (Leurs et al., 2009; Venable and Thurmond, 2006). 4-Methylhistamine and dimaprit, previously identified as specific H2 agonists (Black et al., 1972), are actually more potent H4 agonists (Venable and Thurmond, 2006).

**H1 and H2 Receptors.** H1 and H2 receptors are distributed widely in the periphery and in the CNS. Histamine can exert local or widespread effects on smooth muscles and glands. It causes itching and stimulates secretion from nasal mucosa. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. Histamine also is a potent stimulus of gastric acid secretion (see “Gastric Acid Secretion”). Other, less prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated by H1 receptors. Gastric secretion results from the activation of H2 receptors and, accordingly, can be inhibited by H2 receptor antagonists. Some responses, such as vascular dilation, are mediated by both H1 and H2 receptor stimulation.

**H3 and H4 Receptors.** H3 receptors are expressed mainly in the CNS (Arrang et al., 1987), especially in the basal ganglia, hippocampus, and cortex. H4 receptors function as autoreceptors on histaminergic neurons, much like presynaptic \(\alpha_2\) receptors, inhibiting histamine release and modulating the release of other neurotransmitters. Because H3 receptors have high constitutive activity, histamine release is tonically inhibited, and inverse agonists will thus reduce receptor activation and increase histamine release from histaminergic neurons. H3 agonists promote sleep; thus, H3 antagonists promote wakefulness. H4 receptors primarily are found in cells of hematopoietic origin such as eosinophils, dendritic cells, mast cells, monocytes, basophils, and T cells but has also been detected in the GI tract, dermal fibroblasts, CNS, and primary sensory afferent neurons (Leurs et al., 2009). Activation of H4 receptors in some of these cell types has been associated with induction of cellular shape change, chemotaxis, secretion of cytokines and upregulation of adhesion molecules, suggesting that H4 antagonists may be useful inhibitors of allergic and inflammatory responses (Thurmond et al., 2008).

**Effects on Histamine Release.** H2 receptor stimulation increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils, whereas activation of H3 and H4 receptors has the opposite effect by decreasing cellular cyclic AMP (Oda et al., 2000). Activation of presynaptic H3 receptors also inhibits histamine release from histaminergic neurons.

**Histamine Toxicity from Ingestion.** Histamine is the toxin in food poisoning from spoiled scombroid fish such as tuna (Morrow et al., 1991). The high histidine content combines with a large bacterial capacity to decarboxylate histidine, generating a lot of histamine. Ingestion of the fish causes severe nausea, vomiting, headache, flushing, and sweating. Histamine toxicity, manifested by headache and other symptoms, also can follow red wine consumption in persons with a diminished ability to degrade histamine. The symptoms of histamine poisoning can be suppressed by H2 antagonists.

**Cardiovascular System.** Histamine characteristically dilates resistance vessels, increases capillary permeability, and lowers systemic blood pressure. In some vascular beds, histamine constricts veins, contributing to the extravasation of fluid and edema formation upstream in capillaries and postcapillary venules.

**Vasodilation.** This is the most important vascular effect of histamine in humans. Vasodilation involves both H1 and H2 receptors distributed throughout the resistance vessels in most vascular beds; however, quantitative differences are apparent in the degree of dilation that occurs in various beds. Activation of either the H1 or H2
Histamine's effect on small vessels results in efflux of plasma protein and fluid into the extracellular spaces and an increase in lymph flow, causing edema. H₁ receptors on endothelial cells are the major mediators of this response; the role of H₂ receptors is uncertain.

Increased permeability results from histamine activation of H₁ receptors on postcapillary venules. This contracts the endothelial cells, disrupts interendothelial junctions, and exposes the basement membrane, which is freely permeable to plasma proteins and fluid. The gaps between endothelial cells also may permit passage of circulating cells recruited to tissues during the mast cell response. Recruitment of circulating leukocytes is enhanced by H₁ receptor–mediated expression of adhesion molecules (e.g., P-selectin) on endothelial cells (Thurmond et al., 2008).

**Triple Response of Lewis.** If histamine is injected intradermally, it elicits a characteristic phenomenon known as the *triple response* (Lewis, 1927). This consists of:

- a localized red spot extending for a few millimeters around the site of injection that appears within a few seconds and reaches a maximum in ~1 minute
- a brighter red flush, or “flare,” extending ~1 cm beyond the original red spot and developing more slowly
- a wheal that is discernible in 1-2 minutes and occupies the same area as the original small red spot at the injection site.

The initial red spot results from the direct vasodilating effect of histamine (H₁ receptor–mediated NO production), the flare is due to histamine-induced stimulation of axon reflexes that cause vasodilation indirectly, and the wheal reflects histamine’s capacity to increase capillary permeability (edema formation).

**Constriction of Larger Vessels.** Histamine tends to constrict larger blood vessels, in some species more than in others. In rodents, the effect extends to the arterioles and may overshadow dilation of the finer blood vessels, leading to an elevation in blood pressure. As noted earlier, H₁ receptor–mediated constriction may occur in some veins and in conduit coronary arteries.

**Heart.** Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and ventricular muscle by promoting the influx of Ca²⁺, and it speeds heart rate by hastening diastolic depolarization in the sinoatrial (SA) node. It also directly slows atrioventricular (AV) conduction to increase automaticity and, in high doses, can elicit arrhythmias. The slowed AV conduction involves mainly H₁ receptors, while the other effects are largely attributable to H₂ receptors and cyclic AMP accumulation. The direct cardiac effects of histamine given intravenously are overshadowed by baroreceptor reflexes due to reduced blood pressure.

**Histamine Shock.** Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, their permeability increases, and plasma escapes from the circulation. Resembling surgical or traumatic shock, these effects diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

**Extravascular Smooth Muscle.** Histamine directly contracts or, more rarely, relaxes various extravascular smooth muscles. Contraction is due to activation of H₁ receptors on smooth muscle to increase intracellular Ca²⁺ (in contrast to intact vessels, where endothelium-derived NO causes vasodilation; see “Vasodilation”), and relaxation is mainly due to activation of H₂ receptors. Responses vary widely among species and even among humans. Bronchial smooth muscle of guinea pigs is exquisitely sensitive. Minute doses of histamine also will evoke intense bronchoconstriction in patients with bronchial asthma and certain other pulmonary diseases, but in normal humans, the effect is much less. Although the spasmogenic influence of H₁ receptors is dominant in human bronchial muscle, H₂ receptors with dilator function also are present. Thus, histamine-induced bronchospasm *in vitro* is potentiated slightly
by H₂ blockade. In asthmatic subjects in particular, histamine-induced bronchospasm may involve an additional reflex component that arises from irritation of afferent vagal nerve endings (Nadel and Barnes, 1984).

The uterus of some species is contracted by histamine; in the human uterus, gravid or not, the response is negligible. Responses of intestinal muscle also vary with species and region, but the classical effect is contraction. Bladder, ureter, gallbladder, iris, and many other smooth muscle preparations are affected little or inconsistently by histamine.

Peripheral Nerve Endings: Pain, Itch, and Indirect Effects. Histamine stimulates various nerve endings and sensory effects. In the epidermis, it causes itch; in the dermis, it evokes pain, sometimes accompanied by itching. Stimulant actions on nerve endings, including autonomic afferents and efferents, contribute to the “flare” component of the triple response and to indirect effects of histamine on the bronchi and other organs. In the periphery, neuronal receptors for histamine are generally of the H₁ type (see Rocha e Silva, 1978; Ganellin and Parsons, 1982).

Clinical Uses

The practical application of histamine is limited to use as a diagnostic agent, such as to assess nonspecific bronchial hyperreactivity in asthmatics or as a positive control injection during allergy skin testing.

H₁ RECEPTOR ANTAGONISTS

History. Antihistamine activity was first demonstrated by Bovet and Staub in 1937 with one of a series of amines with a phenolic ether moiety. The substance 2-isopropyl-5-methylphenoxy-ethyl-diethyl-amine protected guinea pigs against several lethal doses of histamine but was too toxic for clinical use. By 1944, Bovet and his colleagues had described pyrilamine maleate, an effective histamine antagonist of this category. The discovery of the highly effective diphenhydramine and tripelellamine soon followed (Ganellin and Parsons, 1982). In the 1980s, non-sedating H₁ histamine receptor antagonists were developed for treatment of allergic diseases. Despite success in blocking allergic responses to histamine, the H₁ antihistamines failed to inhibit a number of other diseases, notably gastric acid secretion. The discovery of H₂ receptors and H₂ antagonists by Black and colleagues provided a new class of agents that antagonized histamine-induced acid secretion (Black et al., 1972). The pharmacology of these drugs (e.g., cimetidine, famotidine) is described in Chapter 45.

Pharmacological Properties

Chemistry. All the available H₁ receptor “antagonists” are actually inverse agonists (see Chapter 3) that reduce constitutive activity of the receptor and compete with histamine (Haas et al., 2008): Whereas histamine binding to the receptor induces a fully active conformation, antihistamine binding yields an inactive conformation. At the tissue level, the effect seen is proportional to receptor occupancy by the antihistamine. Like histamine, many H₁ antagonists contain a substituted ethylamine moiety.

Unlike histamine, which has a primary amino group and a single aromatic ring, most H₁ antagonists have a tertiary amino group linked by a two-or three-atom chain to two aromatic substituents and conform to the general formula

\[
\text{Ar}_1 - \underset{\beta}{\text{N}} - \underset{\text{C}}{\text{C}} - \text{Ar}_2
\]

where Ar is aryl and X is a nitrogen or carbon atom or a —C—O— ether linkage to the β-aminoethyl side chain. Sometimes the two aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine may be part of a ring structure (Figure 32–3) (Ganellin and Parsons, 1982).

Mechanism of Action. Most H₁ antagonists have similar pharmacological actions and therapeutic applications. Their effects are largely predictable from knowledge of the consequences of the activation of H₁ receptors by histamine.

Effects on Physiological Systems.

Smooth Muscle. H₁ antagonists inhibit most of the effects of histamine on smooth muscles, especially the constriction of respiratory smooth muscle. For example, a small dose of histamine causes death by asphyxia in guinea pigs, yet the animal may survive a hundred lethal doses of histamine if given an H₁ antagonist. In the same species, striking protection also is afforded against anaphylactic bronchospasm. This is not so in humans, where allergic bronchoconstriction appears to be caused by a variety of alternative mediators, such as leukotrienes (Chapter 33).

H₁ antagonists inhibit both the vasoconstrictor effects of histamine and, to a degree, the more rapid vasodilator effects mediated by activation of H₁ receptors on endothelial cells (synthesis/release of NO and other mediators). Residual vasodilation is due to H₂ receptors on smooth muscle; administration of an H₂ antagonist suppresses the effect. The efficacy of the histamine antagonists on histamine-induced changes in systemic blood pressure parallels these vascular effects.

Capillary Permeability. H₁ antagonists strongly block the increased capillary permeability and formation of edema and wheal caused by histamine.
Flare and Itch. H₁ antagonists suppress the action of histamine on nerve endings, including the flare component of the triple response and the itching caused by intradermal injection.

Exocrine Glands. H₁ antagonists do not suppress gastric secretion; they do inhibit histamine-evoked salivary, lacrimal, and other exocrine secretions, but with variable success. However, the antimuscarinic properties of many H₁ antagonists may contribute to lessened secretion in cholinergically innervated glands and reduce ongoing secretion in, e.g., the respiratory tree. Nasal sprays of some H₁ antagonists can be used to treat allergic rhinitis.

Immediate Hypersensitivity Reactions: Anaphylaxis and Allergy. During hypersensitivity reactions, histamine is one of the many potent autacoids released (see “Release of Other Autacoids”), and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by H₁ antagonists thus also varies accordingly. In humans, edema formation and itch are effectively suppressed. Other effects, such as hypotension, are less well antagonized. This may be explained by the participation of other types of H receptors and by effects of other mast cell mediators, chiefly eicosanoids (Thurmond et al., 2008; Campbell and Falck, 2007) (Chapter 25). Bronchoconstriction is reduced little, if at all.

Central Nervous System. The first-generation H₁ antagonists can both stimulate and depress the CNS. Stimulation occasionally is encountered in patients given conventional doses; they become restless, nervous, and unable to sleep. Central excitation also is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, usually accompanies therapeutic doses of the older H₁ antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Patients vary in their susceptibility and responses to individual drugs. The ethanolamines (e.g., diphenhydramine; Figure 32–3) are particularly prone to causing sedation. Because of the sedation that occurs with first-generation antihistamines, these drugs cannot be tolerated or used safely by many patients except at bedtime. Even then, patients may experience an antihistamine “hangover” in the morning, resulting in sedation with or without psychomotor impairment (Simons, 2003). Whether tolerance to such adverse effects results from protracted use when administered in divided doses to patients with chronic urticarial syndromes is unclear (Richardson
INFLAMMATION, IMMUNOMODULATION, AND HEMATOPOIESIS

SECTION IV

Many antipsychotic agents are H₁ and H₄ receptor antagonists, but it is unclear whether this property plays a role in the anti-psychotic effects of these agents. The atypical anti-psychotic agent clozapine is an effective H₁ antagonist and a weak H₄ receptor antagonist but an H₃ receptor agonist in the rat. The H₄ antagonist activity of typical and atypical antipsychotic drugs is responsible for the effect of these agents to cause weight gain (see Haas et al., 2008).

Anticholinergic Effects. Many of the first-generation H₁ antagonists tend to inhibit responses to ACh that are mediated by muscarinic receptors and may be manifest during clinical use (see below). Some H₁ antagonists also can be used to treat motion sickness (Chapters 9 and 46). Because scopolamine potently prevents motion sickness, the anticholinergic properties of H₁ antagonists may be largely responsible for this effect. Indeed, promethazine has perhaps the strongest muscarinic-blocking activity among these agents and is the most effective H₁ antagonist in combating motion sickness. The second-generation H₁ antagonists have no effect on muscarinic receptors.

Local Anesthetic Effect. Some H₁ antagonists have local anesthetic activity, and a few are more potent than procaine. Promethazine (phenergan) is especially active. However, the concentrations required for this effect are much higher than those that antagonize histamine’s interactions with its receptors.

Absorption, Distribution, and Elimination. The H₁ antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 2-3 hours, and effects usually last 4-6 hours; however, some of the drugs are much longer acting (Table 32–2).

Studies of the metabolic fate of the older H₁ antagonists are limited. Diphenhydramine, given orally, reaches a maximal concentration in the blood in ~2 hours, remains there for another 2 hours, then falls exponentially with a plasma elimination t₁/₂ of ~4-8 hours. The drug is distributed widely throughout the body, including the CNS. Little, if any, is excreted unchanged in the urine; most appears there as metabolites. Other first-generation H₁ antagonists can be eliminated in much the same way (see Paton and Webster, 1985).

Peak concentrations of these drugs in the skin may persist after plasma levels have declined. Thus, inhibition of “wheal and flare” responses to the intradermal injection of histamine or allergen can persist for ≥36 hours after treatment, even when the concentration in plasma is low.

Like other extensively metabolized drugs, H₁ antagonists are eliminated more rapidly by children than by adults and more slowly in those with severe liver disease. H₁-receptor antagonists also induce hepatic CYPs and thus may facilitate their own metabolism (Paton and Webster, 1985).

The second-generation H₁ antagonist loratadine is absorbed rapidly from the GI tract and metabolized in the liver to an active metabolite by CYPs (Chapter 6). Consequently, metabolism of loratadine can be affected by other drugs that compete for the P450 enzymes. Two other second-generation H₁ antagonists that were marketed previously, terfenadine and astemizole, also were converted by CYPs to active metabolites. Both of these drugs were found in rare cases to induce a potentially fatal arrhythmia, torsades de pointes, when their metabolism was impaired, such as by liver disease or drugs that inhibit the CYP3A family (Chapter 29). This led to the withdrawal of terfenadine and astemizole from the market in 1998 and 1999, respectively. The active metabolite of terfenadine, fexofenadine, is its replacement. Fexofenadine lacks the toxic side effects of terfenadine, is not sedating, and retains the anti-allergic properties of the parent compound (Meeves and Appajosyula, 2003). Another antihistamine developed using this strategy is desloratadine, an active metabolite of loratadine. Cetirizine, loratadine, and fexofenadine are all well absorbed and are excreted mainly in the unmetabolized form. Cetirizine and loratadine are excreted primarily into the urine, whereas fexofenadine is excreted primarily in the feces. Levocetirizine represents the active enantiomer of cetirizine.

Therapeutic Uses

H₁ antagonists have an established place in the symptomatic treatment of various immediate hypersensitivity reactions. The central properties of some of the drugs also are of therapeutic value for suppressing motion sickness or for sedation.

Allergic Diseases. H₁ antagonists are most useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis. Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, histamine antagonists have limited efficacy and are not used as sole therapy (Chapter 36). In the treatment of systemic anaphylaxis, where autacoids other than histamine are important, the mainstay of therapy is epinephrine; histamine antagonists have only a subordinate and adjuvant role. The same is true for severe angioedema, in which laryngeal swelling constitutes a threat to life.

Other allergies of the respiratory tract are more amenable to therapy with H₁ antagonists. The best results are obtained in seasonal rhinitis and conjunctivitis (hay fever, pollinosis), in which these drugs relieve the sneezing, rhinorrhea, and itching of eyes, nose, and throat. A gratifying response is obtained in most patients, especially at the beginning of the season when pollen counts are low; however, the drugs are less effective when the allergens are most abundant, when exposure to them is prolonged, and when nasal congestion is prominent. Nasal sprays or topical ophthalmic preparations of antihistamines such as levocabastine (discontinued in the

(Continued)
U.S.), azelastine (ASTELIN, ASTEPRO, nasal spray; OPTIVAR, ophthalmic drops), emedastine (EMADINE, drops), epinastine (ELESTAT, drops), ketotifen (ZADITOR, drops), and olopatadine (PATANOL, drops; PATANASE, spray) are effective in allergic conjunctivitis and rhinitis. H1 antihistamines have been investigated for potential anti-inflammatory properties because histamine releases inflammatory cytokines and eicosanoids, increases expression of endothelial adhesion molecules, and activates the pro-inflammatory transcription factor NF-κB (Holgate et al., 2003; Thurmond et al., 2008).

Although H1 antihistamines do exhibit a variety of anti-inflammatory effects in vitro and in animal models, in many cases the doses required are higher than those normally achieved therapeutically, and clinical effectiveness has not been proven (Holgate et al., 2003; Thurmond et al., 2008). Rupatadine is a second-generation H1 antagonist (available in many countries outside the U.S.) that also blocks receptors for the inflammatory phospholipid, PAF (Mullol et al., 2008). Although rupatadine appears to have broader anti-inflammatory effects than other antihistamines, the clinical relevance of these properties is unclear.

Certain allergic dermatoses respond favorably to H1 antagonists. The benefit is most striking in acute urticaria. Chronic urticaria can be less responsive but also may require higher doses than has been approved for rhinitis (Siebenhaar et al., 2009; Kaplan, 2002). Furthermore, the combined use of H1 and H2 antagonists sometimes is effective when therapy with an H1 antagonist alone has failed. Angioedema also responds to treatment with H1 antagonists, but the paramount importance of epinephrine in the severe attack must be re-emphasized, especially in life-threatening laryngeal edema (Chapter 12). In this setting, it may be appropriate to also administer an H1 antagonist intravenously.

H1 antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients with atopic and contact dermatitis (although topical corticosteroids are more effective) and in such diverse conditions as insect bites and poison ivy. Pruritus without an allergic basis sometimes responds to antihistamine therapy. The urticarial and edematous lesions of serum sickness respond to H1 antagonists, but fever and arthralgia often do not.

Many drug reactions attributable to allergic phenomena respond to therapy with H1 antagonists, particularly those characterized by itch, urticaria, and angioedema. However, explosive release of histamine generally calls for treatment with epinephrine, with H1 antagonists being accorded a subsidiary role. Nevertheless, prophylactic treatment with an H1 antagonist may reduce symptoms to a tolerable level when a drug known to be a histamine liberator is to be given.

Common Cold. H1 antagonists are without value in combating the common cold. The weak anticholinergic effects of the older agents may tend to lessen rhinorrhea, but this drying effect may do more harm than good, as may their tendency to induce somnolence.
Motion Sickness, Vertigo, and Sedation. Scopolamine, the muscarinic antagonist, given orally, parenterally, or transdermally, is the most effective drug for the prophylaxis and treatment of motion sickness. Some $H_1$ antagonists are useful for milder cases and have fewer adverse effects. These drugs include dimenhydrinate and the piperazines (e.g., cyclizine, meclizine). Promethazine, a phenothiazine, is more potent and more effective; its additional antiemetic properties may be of value in reducing vomiting, but its pronounced sedative action usually is disadvantageous. Whenever possible, the various drugs should be administered ~1 hour before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial.

Some $H_1$ antagonists, notably dimenhydrinate and meclizine, often are of benefit in vestibular disturbances such as Meniere’s disease and in other types of true vertigo. Only promethazine is useful in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other, more effective anti-emetic drugs (e.g., 5-HT3 antagonists) are available (Chapter 46). Diphenhydramine can reverse the extrapyramidal side effects caused by phenothiazines (Chapter 16).

The tendency of some $H_1$ receptor antagonists to produce somnolence has led to their use as hypnotics. $H_1$ antagonists, principally diphenhydramine, often are present in various proprietary over-the-counter remedies for insomnia. Although these drugs generally are ineffective in the recommended doses, some sensitive individuals may derive benefit. The sedative and mild anti-anxiety activities of hydroxyzine contribute to its use as a weak anxiolytic.

Adverse Effects. The most frequent side effect in first-generation $H_1$ antagonists is sedation. Although sedation may be a desirable adjunct in the treatment of some patients, it may interfere with the patient’s daytime activities. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors.

The next most frequent side effects involve the digestive tract and include loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea. Taking the drug with meals may reduce their incidence. $H_1$ antagonists such as cyproheptadine may increase appetite and cause weight gain. Other side effects, owing to the antimuscarinic actions of some first-generation $H_1$ antagonists, include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation $H_1$ antagonists.

Drug allergy may develop when $H_1$ antagonists are given orally but occurs more commonly after topical application. Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications, such as leukopenia, agranulocytosis, and hemolytic anemia, are very rare. Because $H_1$ antihistamines cross the placenta, caution is advised for women who are or may become pregnant. Several antihistamines (e.g., azelastine, hydroxyzine, fexofenadine) had teratogenic effects in animal studies, whereas others (e.g., chlorpheniramine, diphenhydramine, cetirizine, loratadine) did not (see Simons, 2003). Antihistamines can be excreted in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms such as irritability, drowsiness, or respiratory depression in the nursing infant (Simons, 2003). Because $H_1$ antagonists interfere with skin tests for allergy, they must be withdrawn well before such tests are performed.

In acute poisoning with $H_1$ antagonists, their central excitatory effects constitute the greatest danger. The syndrome includes hallucinations, excitement, ataxia, incoordination, atetosis, and convulsions. Fixed, dilated pupils with a flushed face, together with sinus tachycardia, urinary retention, dry mouth, and fever, lend the syndrome a remarkable similarity to that of atropine poisoning. Terminally, there is deepening coma with cardiorespiratory collapse and death usually within 2-18 hours. Treatment is along general symptomatic and supportive lines.

Pediatric and Geriatric Indications and Problems. Although little clinical testing has been done, second-generation antihistamines are recommended for elderly patients (>65 years of age), especially those with impaired cognitive function, because of the sedative and anti-cholinergic effects of first-generation drugs. Therapy should be approached cautiously, possibly at reduced dosages, because of the greater likelihood of compromised renal and hepatic function in these patients, which can reduce drug elimination.

First-generation antihistamines are not recommended for use in children because their sedative effects can impair learning and school performance. The second-generation drugs loratadine, desloratadine, fexofenadine, cetirizine, levocetirizine, and azelastine (intranasal) have been approved by the FDA for use in children and are available in appropriate lower-dose formulations (e.g., chewable or rapidly dissolving tablets, syrup).

Use of over-the-counter cough and cold medicines (containing mixtures of antihistamines, decongestants, antitussives, expectorants) in young children has been associated with serious side effects and deaths (Kuehn, 2008). In 2008, the FDA recommended that they not be used in children <2 years of age, and drug manufacturers affiliated with the Consumer Healthcare Products Association voluntarily re-labeled products “do not use” for children <4 years of age. The FDA is reviewing the safety of these medicines in children aged 2-11 years.

Available $H_1$ Antagonists. Summarized below are the therapeutic side effects of a number of $H_1$ antagonists, grouped by their chemical structures. Representative preparations are listed in Table 32–2.
