Dibenzoxepin Tricycles (Doxepin). Doxepin, the only drug in this class, is marketed as a tricyclic antidepressant (Chapter 16). It also is one of the most potent $H_1$ antagonists and has significant $H_1$ antagonist activity, but this does not translate into greater clinical effectiveness. It can cause drowsiness and is associated with anticholinergic effects. Doxepin is better tolerated by patients with depression than those who are not depressed, where even small doses (e.g., 20 mg) may cause disorientation and confusion.

Ethanolamines (Prototype: Diphenhydramine). These drugs possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated acutely with conventional doses experience somnolence. The incidence of GI side effects, however, is low with this group.
**Ethylenediamines (Prototype: Pyrilamine).** These include some of the most specific H1 antagonists. Although their central effects are relatively feeble, somnolence occurs in a fair proportion of patients. GI side effects are quite common.

**Alkylamines (Prototype: Chlorpheniramine).** These are among the most potent H1 antagonists. The drugs are less prone to produce drowsiness and are more suitable for daytime use, but a significant proportion of patients do experience sedation. Side effects involving CNS stimulation are more common than with other groups.

**First-Generation Piperazines.** The oldest member of this group, chlorcyclizine, has a more prolonged action and produces a comparatively low incidence of drowsiness. Hydroxyzine is a long-acting compound that is used widely for skin allergies; its considerable CNS-depressant activity may contribute to its prominent anti-pruritic action. Cyclizine and meclizine have been used primarily to counter motion sickness, although promethazine and diphenhydramine are more effective (as is the antimuscarnic scopolamine; see “H1 Antihistamines”).

**Second-Generation Piperazines (Cetirizine).** Cetirizine is the only drug in this class. It has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than the other second-generation H1 antagonists. The active enantiomer levocetirizine has somewhat higher incidence of drowsiness than the other second-generation drugs in this class. It has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than the other second-generation H1 antagonists. The active enantiomer levocetirizine has slightly greater potency and may be used at half the dose with less resultant sedation.

**Phenothiazines (Prototype: Promethazine).** Most drugs of this class are H1 antagonists and also possess considerable anticholinergic activity. Promethazine, which has prominent sedative effects, and its many congeners are used primarily for their antiemetic effects (Chapter 37).

**First-Generation Piperdines (Cyproheptadine, Phenindamine).** Cyproheptadine uniquely has both antihistamine and anti-serotonin activity. Cyproheptadine and phenindamine cause drowsiness and also have significant anticholinergic effects and can increase appetite.

**Second-Generation Piperdines (Prototype: Terfenadine).** Terfenadine and astemizole were withdrawn from the market. Current drugs in this class include loratadine, desloratadine, and fexofenadine. These agents are highly selective for H1 receptors, lack significant anticholinergic actions, and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines.

**H2 RECEPTOR ANTAGONISTS**

The pharmacology and clinical utility of H2 antagonists to inhibit gastric acid secretion are described in Chapter 45.

**THE HISTAMINE H3 RECEPTOR AND ITS ANTAGONISTS**

The H3 receptor was characterized as a novel G1-coupled receptor using (R)-α-methylhistamine, a selective H3 agonist, and thioperamide, an antagonist (Arrang et al., 1987). The cloning of its cDNA revealed it to be a GPCR with low sequence identity (~20%) to H1 and H2 receptors (Lovenberg et al., 1999). Further studies on the H3 receptor uncovered a variety of functional isoforms resulting from alternative splicing, many within a pseudo-intron in the third intracellular loop that may control constitutive activity (Arrang et al., 2007); this, combined with the influence of cell type, signaling pathway, and interspecies differences, yields H3 receptors with a variety of binding and signaling properties (Esbenshade et al., 2008).

H3 receptors are presynaptic autoreceptors on histaminergic neurons that originate in the tuberomammillary nucleus in the hypothalamus and project throughout the CNS, most prominently to the hippocampus, amygdala, nucleus accumbens, globus pallidus, striatum, hypothalamus, and cortex (Haas et al., 2008; Sander et al., 2008). The activated H3 receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus, H3 agonists decrease histaminergic transmission, and antagonists increase it. H3 receptors also are presynaptic heteroreceptors on a variety of neurons in brain and peripheral tissues, and their activation inhibits release from noradrenergic, serotonergic, GABA-ergic, cholinergic, and glutamatergic neurons, as well as pain-sensitive C fibers. H3 receptors in the brain have significant constitutive activity in the absence of agonist, which varies according to splicing isoform, cell type, and signaling pathway stimulated; consequently, inverse agonists will activate these neurons.

In the enterochromaffin-like cells of the stomach, H3 receptors inhibit gastrin-induced release of histamine and, therefore, decrease HCl secretion mediated by H2 receptors, but the effect is not large enough to warrant development of therapeutic agents. H3 agonists decrease tachykinin release from capsaicin-sensitive C-fiber terminals and thereby reduce capsaicin-induced plasma extravasation and are antinociceptive. H3 agonists also depress exaggerated catecholamine release in the heart (e.g., during ischemia).

By blocking H3 autoreceptors on histaminergic neurons and H3 heteroreceptors on other neurons, H3 antagonists/inverse agonists have a wide range of central effects; for example, they promote wakefulness, improve cognitive function (e.g., enhance memory, learning, and attention), and reduce food intake (Esbenshade et al., 2008; Sander et al., 2008). As a result, there is considerable interest in developing H3 antagonists for possible treatment of sleeping disorders, attention-deficit hyperactivity disorder (ADHD), epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer’s disease (Esbenshade et al., 2008; Sander et al., 2008). However, this task is complicated by the heterogeneity in receptor isoforms and signaling pathways, varying levels of constitutive H1 activity, species differences in ligand affinities, and the effects of H1 antagonists/inverse agonists on the release of neurotransmitters in addition to histamine (e.g., DA, ACh, NE, GABA, glutamate, and substance P) (Sander et al., 2008; Esbenshade et al., 2008). Although drug development is focused on inverse agonists to block basal and agonist-stimulated H3 activity, it is not yet clear that such drugs will necessarily be clinically superior to neutral antagonists.
Thioperamide was the first “specific” H₃ antagonist/inverse agonist available experimentally, but it turned out to be equally effective on the H₁ receptor. A number of other imidazole derivatives have been developed as H₃ antagonists, including clobenpropit, ciproxifan, and proxyfan. However, the imidazole group can bind to and inhibit CYPs, reduce bioavailability in and penetration into the CNS, and enhance binding to H₁ receptors, prompting efforts to develop more selective H₃-receptor antagonists using non-imidazole-based structures. This has resulted in the generation of numerous antagonists/inverse agonists representing a remarkably broad variety of structural classes (Sander et al., 2008; Esbenshade et al., 2008). Although none is approved for clinical use, several non-imidazole H₃ antagonists/inverse agonists are in phase II clinical trials for treating epilepsy, narcolepsy and other sleep disorders, cognitive impairment, Alzheimer’s disease, schizophrenia, and ADHD; these include tiprolisant (BF2.649), GSK189254, GSK239512, JNJ-17216498, and MK0249.

THE HISTAMINE H₄ RECEPTOR AND ITS ANTAGONISTS

The discovery of a fourth histamine receptor with a unique pharmacology and distribution has further expanded the search for new drugs based on histamine function in inflammation (Leurs et al., 2009; Thurmond et al., 2008). The H₄ receptor has the highest homology with the H₃ receptor and binds many H₃ ligands, especially those with imidazole rings, although sometimes with different effects. For example, thioperamide is an effective inverse agonist at both H₃ and H₄ receptors, whereas H₃ inverse agonist clobenpropit is a partial agonist of the H₄ receptor; impentamine (an H₃ agonist) and iodophenpropit (an H₃ inverse agonist) are both neutral H₄ antagonists (Lim et al., 2005).

Because the H₄ receptor is expressed on cells with inflammatory or immune functions (see the discussion earlier), there is great interest in developing H₄ antagonists to treat various inflammatory conditions (Thurmond et al., 2008). Indeed, H₄ receptors can mediate histamine-induced chemotaxis, induction of cell shape change, secretion of cytokines, and upregulation of adhesion molecules. For example, the H₄ receptor likely accounts for early reports of histamine-dependent eosinophil chemotaxis, which was independent of H₁ receptors and inhibited by H₂ receptors (Clark et al., 1977). The presence of H₄ receptors in the CNS and animal studies with H₄ agonists and antagonists also have indicated a role for this receptor in pruritus and neuropathic pain (Leurs et al., 2009). The first selective H₄ antagonist, JNJ7777120, exhibits ~1000-fold selectivity over other H receptors, has acceptable oral bioavailability, and has in vivo activity; however, its short t₁/₂ (~0.8 hour) limits its potential clinical usefulness. In addition to derivatives of the benzimidazole JNJ7777120, promising H₄ antagonists have been developed using several different scaffolds, including methylpiperazine-substituted 2-quinolinones, quinazolines, and aminopyrimidines (Leurs et al., 2009). Although these are high-affinity ligands, relatively high doses are required for significant anti-inflammatory effects in vivo, possibly due to either their pharmacokinetic properties or competition with endogenous histamine, which also has a high affinity for the receptor (Leurs et al., 2009). No H₄ antagonists have yet been tested in clinical trials.

CLINICAL SUMMARY: ANTI-HISTAMINES

H₁ Antihistamines. These medications are used widely in the treatment of allergic disorders. H₁ antihistamines are most effective in relieving the symptoms of seasonal rhinitis and conjunctivitis (e.g., sneezing; rhinorrhea; itching of the eyes, nose, and throat). In bronchial asthma, they have limited beneficial effects and are not useful as sole therapy. H₁ antagonists are useful adjuncts to epinephrine in the treatment of systemic anaphylaxis or severe angioedema. Certain allergic dermatoses, such as acute urticaria, respond favorably to H₁ antagonists, which help to relieve the itch in atopic or contact dermatitis but have no effect on the rash. Physical and chronic urticaria may require increased dosage to counter the levels of skin histamine generated (Siebenhaar et al., 2009).

Side effects are most prominent with first-generation H₁ antihistamines (e.g., diphenhydramine, chlorpheniramine, doxepin, hydroxyzine), which cross the blood-brain barrier and cause sedation. Some of the first-generation H₁ receptor antagonists also have anticholinergic properties that can be responsible for symptoms such as dryness of the mouth and respiratory passages, urinary retention or frequency, and dysuria. The second-generation drugs (e.g., levocetirizine, cetirizine, loratadine, desloratadine, fexofenadine) are largely devoid of these side effects because they do not penetrate the CNS and do not have antimuscarinic properties. Thus, they usually are the drugs of choice for the treatment of allergic disorders.

The significant sedative effects of some first-generation antihistamines have led to their use in treating insomnia, although better drugs are available. Some first-generation H₁ antagonists (e.g., diphenhydramine, cyclizine, meclizine, and promethazine) can prevent motion sickness, although scopolamine is more effective. Antiemetic effects of these H₁ antihistamines can be beneficial in treating vertigo or postoperative emesis.

Many H₁ antihistamines are metabolized by CYPs. Thus, inhibitors of CYP activity, such as macrolide antibiotics (e.g., erythromycin) or imidazole antifungals (e.g., ketoconazole) can increase H₁ antihistamine levels, leading to toxicity. Some newer antihistamines, such as cetirizine, fexofenadine, levocabastine, and acrivastine, are not subject to these drug interactions.
Caution should be used in treating pregnant or lactating women with certain H₁ antihistamines, especially first-generation drugs, because of their possible teratogenic effects or symptomatic effects on infants resulting from secretion of the drug into breast milk. Cetirizine and loratadine are preferred if H₁ antihistamines are required, but if they are not effective, diphenhydramine can be used safely in pregnant (but not breast-feeding) women.

**H₂ Antihistamines.** These drugs (e.g., cimetidine, ranitidine) primarily are used to inhibit gastric acid secretion in the treatment of GI disorders (Chapter 45).

**H₃ and H₄ Antihistamines.** Although specific H₃ and H₄ receptor antagonists have been developed, no drugs have been approved for clinical use. Based on the functions of H₁ receptors in the CNS, H₃ antagonists have potential in the treatment of sleeping disorders, ADHD, epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer’s disease. Because of the unique localization and function of H₄ receptors, H₄ antagonists are promising candidates to treat inflammatory conditions such as allergic rhinitis, asthma, rheumatoid arthritis, and possibly pruritus and neuropathic pain.

### BRADYKININ, KALLIDIN, AND THEIR ANTAGONISTS

Tissue damage, allergic reactions, viral infections, and other inflammatory events activate a series of proteolytic reactions that generate bradykinin and kallidin in the circulation or tissues. Kinin metabolites released by basic carboxypeptidases, formerly considered inactive degradation products, are agonists of a receptor (B₁) that differs from that of intact kinins (B₂). B₁ receptor expression is induced by tissue injury or inflammation. These peptides contribute to inflammatory responses as autacoids that act locally to produce pain, vasodilation, and increased vascular permeability but can also have beneficial effects, for example in the heart, kidney, and circulation. Much of their activity is due to stimulation of the release of potent mediators such as prostaglandins, NO, or endothelium-derived hyperpolarizing factor (EDHF). Although both B₁ and B₂ receptors are referred to as “bradykinin” receptors, this term properly applies only to the B₂ receptor; the B₁ receptor binds des-Arg metabolites of the kinins (Figure 32–4). These B receptors for kinins must not be confused with β receptors for catecholamines. Current efforts to develop potent non-peptide B₁ and B₂ antagonists may open novel avenues for therapeutic intervention in chronic inflammatory conditions.

**History.** In the 1920s and 1930s, Frey, Kraut, and Werle characterized a hypotensive substance in urine and found a similar material in saliva, plasma, and a variety of tissues. The pancreas also was a rich source, so they named this material *kallikrein* after a Greek synonym for that organ, *kallikrēas*. By 1937, Werle, Götze, and Keppeler had established that kallikreins generate a pharmacologically active substance from an inactive precursor present in plasma; the active substance, *kallidin*, proved to be a polypeptide cleaved from a plasma globulin termed *kallidinogen* (see Werle, 1970).

Interest in the field intensified when Rocha e Silva, Beraldo, and associates reported that trypsin and certain snake venoms acted on plasma globulin to produce a substance that lowered blood pressure and caused a slowly developing contraction of the gut (Rocha e Silva et al., 1949; Beraldo and Andrade, 1997). Because of this slow response, they named the substance *bradykinin*, a term derived from the Greek words *brady*, meaning “slow,” and *kinein*, meaning “to move.” In 1960, the nonapeptide bradykinin was isolated by Elliott and coworkers and synthesized by Boissonnas and associates. Shortly thereafter, kallidin was found to be a decapeptide bradykinin with an additional lysine residue at the amino terminus. These peptides, except for Lys¹, have identical chemical structures (Table 32–3) and quite similar pharmacological properties. For the whole group, the generic term *kinins* has been adopted. The kinins have short half-lives because they are destroyed by plasma and tissue enzymes originally called *kininase I* and *kininase II*. Kininase I releases a single C-terminal amino acid; kininase II releases a dipeptide (Skidgel and Erdös, 1998). Kininase II is identical to angiotensin-converting enzyme (ACE) (Yang et al., 1970).

Ferreira and colleagues (1970) reported the isolation of a bradykinin-potentiating factor from the venom of the Brazilian snake *Bothrops jararaca*. Ondetti and colleagues (1971) subsequently determined the structure of a peptide from the venom that inhibited ACE and lowered blood pressure when given intravenously to hypertensive patients. Synthetic ACE inhibitors, administered orally (Chapter 26), now are widely used in the treatment of hypertension, diabetic nephropathy, congestive heart failure, and after myocardial infarction (Pfeffer and Frolich, 2006).

Regoli and Barabé (1980) divided the kinin receptors into B₁ and B₂ classes based on the rank order of potency of kinin analogs, and this was validated at the molecular level by cloning of the B₁ and B₂ receptors (Bhoola et al., 1992; Hess, 1997). A primary feature that distinguishes peptide ligands of the B₁ and B₂ receptors is the presence of a C-terminal Arg residue; intact kinins (bradykinin and kallidin) are agonists of the B₂ receptor, whereas their des-Arg forms ([des-Arg⁸]-bradykinin and [des-Arg¹⁰]-kallidin) are agonists for the B₁ receptor. First-generation B₂ kinin–receptor antagonists were developed in the mid-1980s (Stewart, 2004), followed by second- and third-generation blockers. These antagonists revealed the role of kinins in the therapeutic effects of ACE/kininase II inhibitors and have led to increased acceptance of the importance of kinins. Studies involving B₁ and B₂ receptor knockout mice (Hess, 1997; Pesquero and Bader, 2006; Jiang et al., 2009) have furthered our understanding of the role of bradykinin in the regulation of cardiovascular homeostasis and inflammatory processes.
Bradykinin is generated by the action of plasma kallikrein on high-molecular-weight (HMW) kininogen, whereas kallidin (Lys1-bradykinin) is released by the hydrolysis of low-molecular-weight (LMW) kininogen by tissue kallikrein. Kallidin and bradykinin are the natural ligands of the B2 receptor but can be converted to corresponding agonists of the B1 receptor by removal of the C-terminal Arg by kininase I–type enzymes: the plasma membrane–bound carboxypeptidase M (CPM) or soluble plasma carboxypeptidase N (CPN). Kallidin or [des-Arg10]-kallidin can be converted to the active peptides bradykinin or to [des-Arg9]-bradykinin by aminopeptidase cleavage of the N-terminal Lys residue. In a parallel fashion, the inactive decapeptide angiotensin I is generated by the action of renin on the plasma substrate angiotensinogen. By removal of the C-terminal His–Leu dipeptide, angiotensin-converting enzyme (ACE) generates the active peptide angiotensin II (AngII). These two systems have opposing effects. AngII is a potent vasoconstrictor that also causes aldosterone release and Na+ retention via activation of the AT1 receptor; bradykinin is a vasodilator that stimulates Na+ excretion by activating the B2 receptor. ACE generates active AngII and, at the same time, inactivates bradykinin and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B2 receptor mediates most of bradykinin’s effects under normal circumstances, whereas synthesis of the B1 receptor is induced by inflammatory mediators in inflammatory conditions. Both B1 and B2 receptors couple through Gq to activate PLC and increase intracellular Ca2+; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For instance, on endothelial cells, activation of B2 receptors results in Ca2+-calmodulin–dependent activation of eNOS and generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, in endothelial cells under inflammatory conditions, B2 receptor stimulation results in prolonged NO production via Gi and MAP kinase–dependent activation of iNOS expression. On smooth muscle cells, activation of kinin receptors coupling through Gi to activate Gs results in an increased [Ca2+]i and contraction. B1 and B2 receptors also can couple through Gi to activate PLA2, causing the release of arachidonic acid and the local generation of prostanoids (PGs) and other metabolites such as endothelium-derived hyperpolarizing factor (EDHF). Kallikrein also plays a role in the intrinsic blood coagulation pathway (see Chapter 30).

Figure 32–4. Synthesis and receptor interactions of active peptides generated by the kallikrein-kinin and renin-angiotensin systems. Bradykinin is generated by the action of plasma kallikrein on high-molecular-weight (HMW) kininogen, whereas kallidin (Lys1-bradykinin) is released by the hydrolysis of low-molecular-weight (LMW) kininogen by tissue kallikrein. Kallidin and bradykinin are the natural ligands of the B2 receptor but can be converted to corresponding agonists of the B1 receptor by removal of the C-terminal Arg by kininase I–type enzymes: the plasma membrane–bound carboxypeptidase M (CPM) or soluble plasma carboxypeptidase N (CPN). Kallidin or [des-Arg10]-kallidin can be converted to the active peptides bradykinin or to [des-Arg9]-bradykinin by aminopeptidase cleavage of the N-terminal Lys residue. In a parallel fashion, the inactive decapeptide angiotensin I is generated by the action of renin on the plasma substrate angiotensinogen. By removal of the C-terminal His–Leu dipeptide, angiotensin-converting enzyme (ACE) generates the active peptide angiotensin II (AngII). These two systems have opposing effects. AngII is a potent vasoconstrictor that also causes aldosterone release and Na+ retention via activation of the AT1 receptor; bradykinin is a vasodilator that stimulates Na+ excretion by activating the B2 receptor. ACE generates active AngII and, at the same time, inactivates bradykinin and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B2 receptor mediates most of bradykinin’s effects under normal circumstances, whereas synthesis of the B1 receptor is induced by inflammatory mediators in inflammatory conditions. Both B1 and B2 receptors couple through Gq to activate PLC and increase intracellular Ca2+; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For instance, on endothelial cells, activation of B2 receptors results in Ca2+-calmodulin–dependent activation of eNOS and generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, in endothelial cells under inflammatory conditions, B2 receptor stimulation results in prolonged NO production via Gi and MAP kinase–dependent activation of iNOS expression. On smooth muscle cells, activation of kinin receptors coupling through Gi to activate Gs results in an increased [Ca2+]i and contraction. B1 and B2 receptors also can couple through Gi to activate PLA2, causing the release of arachidonic acid and the local generation of prostanoids (PGs) and other metabolites such as endothelium-derived hyperpolarizing factor (EDHF). Kallikrein also plays a role in the intrinsic blood coagulation pathway (see Chapter 30).

The Endogenous Kallikrein–Kininogen–Kinin System

Synthesis of Kinins. Bradykinin is a nonapeptide; kallidin, a decapetide containing an additional N-terminal lysine, is sometimes referred to as lysyl-bradykinin (Table 32–3). The two peptides are cleaved from α2 globulins termed kininogens (Figure 32–4). There are two kininogens: high-molecular-weight (HMW) kininogen and low-molecular-weight (LMW) kininogen. A number of serine proteases will generate kinins, but the highly specific proteases that release bradykinin...

ABBREVIATIONS: Hyp, *trans*-4-hydroxy-Pro; Thi, β-(2-thienyl)-Ala; Tic, [d]-1,2,3,4-tetrahydroisoquinolin-3-yl-carbonyl; Oic, (3as,7as)-octahydroindol-2-yl-carbonyl.
and kallidin from the kininogens are termed kallikreins (see “Kallikreins”).

Kallikreins. Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma or tissue kallikrein, respectively (Figure 32–4). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms (Bhoola et al., 1992).

Plasma prekallikrein is an inactive protein of ~88,000 Da that complexes with its substrate, HMW kininogen (Mandle et al., 1976). The ensuing proteolytic cascade is restrained by the protease inhibitors present in plasma. Among the most important of these are the inhibitor of the activated first component of complement (C1-INH) and α2 macroglobulin. Under experimental conditions, the kallikrein–kinin system is activated by the binding of factor XII, also known as Hageman factor, to negatively charged surfaces. Factor XII, a protease that is common to both the kinin and the intrinsic coagulation cascades (Chapter 30), undergoes autoactivation (Silverberg et al., 1980) and, in turn, activates prekallikrein. Importantly, kallikrein further activates factor XII, thereby exerting a positive feedback on the system. In vivo, factor XII may not undergo autoactivation on binding to endothelial cells. Instead, the binding of the HMW kininogen–prekallikrein heterodimer to a multireceptor complex on endothelial cells leads to activation of the prekallikrein-HMW kininogen complex (but not free prekallikrein) by heat shock protein 90 (Joseph et al., 2002) and by a lysosomal enzyme designated prolylcarboxypeptidase, which also is present on endothelial cell membranes (Schmaier, 2008). Kallikrein activates factor XII, cleaves HMW kininogin, and activates prourokinase (Schmaier, 2008; Kaplan et al., 2002; Colman, 1999). Human tissue kallikrein is a member of a large multigene family of 15 members with high sequence identity that are clustered at chromosome 19q13.4 (Emami and Diamandis, 2007). Only the classical (or “true”) tissue kallikrein, hK1, generates kinins from kininogen. Another member, hK3, better known as the prostate-specific antigen (PSA), is an important marker in diagnosing prostate cancer, and several other family members are promising tumor biomarkers (Emami and Diamandis, 2007).

Compared with plasma kallikrein, tissue kallikrein is a smaller protein (29,000 Da). It is synthesized as a preproprotein in the epithelial cells or secretory cells in several tissues, including salivary glands, pancreas, prostate, and distal nephron. Tissue kallikrein also is expressed in human neutrophils. It acts locally near its sites of origin. The synthesis of tissue prokallikrein is controlled by a number of factors, including aldosterone in the kidney and salivary gland and androgens in certain other glands. The secretion of the tissue prokallikrein also may be regulated; for example, its secretion from the pancreas is enhanced by stimulation of the vagus nerve. The activation of tissue prokallikrein to kallikrein requires proteolytic cleavage to remove a 7–amino acid propeptide (Takada et al., 1985).

Kininoges. The two substrates for the kallikreins, HMW kininogen and LMW kininogen, are derived from a single gene by alternative splicing. The HMW kininogen contains 626 amino acid residues: The N-terminal “heavy chain” sequence (362 amino acids) consists of domains 1-3, followed by 9 residue bradykinin sequence (domain 4), connected to a C-terminal “light chain” sequence (255 amino acids) containing domains D5 and D6. LMW kininogen is identical to domains 1–4 of HMW kininogen but is distinguished by its short C-terminal light chain (Takagaki et al., 1985). HMW kininogen is cleaved by plasma and tissue kallikrein to yield bradykinin and kallidin, respectively. LMW kininogen is a substrate only of tissue kallikrein, and the product is kallidin. The kininogens also inhibit cysteine proteinases and thrombin binding and have anti-adhesive and profibrinolytic properties.

Metabolism of Kinins. The decapeptide kallidin is about as active as the nonapeptide bradykinin, even without conversion to bradykinin, which occurs when the N-terminal lysine residue is removed by an aminopeptidase (Skidgel and Erdős, 1998) (Figure 32–4). The nonapeptide has the minimal effective structure for standard responses on B2 receptors (Figure 32–4 and Table 32–3).

The kinins have an evanescent existence—their t1/2 in plasma is only ~15 seconds, and some 80–90% of the kinins may be destroyed in a single passage through the pulmonary vascular bed. Plasma concentrations of bradykinin are difficult to measure because inadequate inhibition of kininogenses or kininases in the blood can lead to artifactual formation or degradation of bradykinin during blood collection. When care is taken to inhibit these processes, the reported physiological concentrations of bradykinin in blood are in the picomolar range.

The principal catabolizing enzyme in the lung and other vascular beds is kininase II, or ACE (Figure 32–4) (Chapter 26). Removal of the C-terminal dipeptide by ACE or neutral endopeptidase 24.11 (neprilysin) inactivates kinins (Skidgel and Erdős, 1998) (Figure 32–5). A slower-acting enzyme, carboxypeptidase N (lysine carboxypeptidase, kininase I), releases the C-terminal arginine residue, producing [desArg9]-bradykinin or [des-Arg10]-kallidin (Table 32–3 and Figures 32–4 and 32–5), which are potent B1 receptor agonists that no longer bind B2 receptors (Bhoola et al., 1992; Skidgel and Erdős, 1998). Carboxypeptidase N is expressed constitutively in blood plasma, where its level is ~10−7 M (Skidgel and Erdős, 1998; Skidgel and Erdős, 2007). Carboxypeptidase M, which also cleaves basic C-terminal amino acids, is a widely distributed plasma membrane–bound enzyme (Skidgel and Erdős, 1998). The recently established crystal structures of the active subunit of carboxypeptidases N and M revealed an overall similarity with unique features consistent with their different localizations and functions (Skidgel and Erdős, 2007). A familial carboxypeptidase N deficiency, due to mutations in the active subunit, causes low plasma levels of this enzyme and is associated with angioedema or urticaria (Skidgel and Erdős, 2007; Matthews et al., 2004). Finally, aminopeptidase P can cleave the N-terminal arginine, rendering bradykinin inactive and susceptible to cleavage by dipeptidyl peptidase IV (Figure 32–5).

Kinin Receptors. The B1 and B2 kinin receptors are both GPCRs, sharing 36% amino acid sequence identity (Hess, 1997; Leeb-Lundberg et al., 2005).

The classical bradykinin B1 receptor is constitutively expressed in most normal tissues, where it selectively binds intact bradykinin and kallidin (Table 32–3 and Figure 32–4) and mediates the majority of their effects. The B1 receptor is activated by the des-Arg metabolites of bradykinin and kallidin produced by the actions of carboxypeptidases N and M (Table 32–3 and Figures 32–4 and 32–5). Interestingly, carboxypeptidase M and the B1 receptor
interact on the cell surface to form an efficient signaling complex; disruption of this interaction decreases the efficiency of generation and delivery of des-Arg-kinin agonist to the B1 receptor and reduces subsequent B1 signaling (Zhang et al., 2008). B1 receptors are normally absent or expressed at low levels in most tissues. B1 receptor expression is upregulated by tissue injury and inflammation and by cytokines, endotoxins, and growth factors (Bhoola et al., 1992; Leeb-Lundberg et al., 2005). Carboxypeptidase M expression also is increased by cytokines (Sangsree et al., 2003), to such a degree that B1 receptor effects may predominate over B2 effects.

The B2 receptor activates PLA2 and PLC via interaction with distinct G proteins. Kinin-induced PLC activation through Gq activates the IP3-Ca2+ pathway, stimulating PKC activity and also enhancing NO synthesis by eNOS/NOS3. Bradykinin activates the pro-inflammatory transcription factor NF-kB through Goq and βγ subunits and also activates the MAP kinase pathway. Coupling of activated B2 receptors to Gq leads to PLA2 activation and the liberation of arachidonate from membrane-bound phospholipids, which is converted to a variety of derivatives, including inflammatory mediators and vasodilator epoxyeicosatrienoic acids (EETs) and prostacyclin (Campbell and Falck, 2007; Leeb-Lundberg et al., 2005) (Chapter 33).

B2 receptors also couple through Gq and G11 to activate many of the same signal transduction pathways as the B2 receptor (Leeb-Lundberg et al., 2005). However, B2 receptor activation enhances NO production by stimulation of the inducible nitric oxide synthase (iNOS) rather than eNOS (Zhang et al., 2007). The B1 and B2 receptors also differ in their time courses of downregulation; the B2 receptor response is rapidly desensitized, whereas the B1 response is not. This likely is due to modification at a Ser/Thr-rich cluster present in the C-terminal tail of the B2 receptor that is not conserved in the B1 receptor sequence (Leeb-Lundberg et al., 2005).

Because B2 receptors are distributed widely and couple to several G proteins, receptor agonists are employed frequently as tools to activate and study signal transduction pathways in a variety of cells. The antagonist icatibant (HOE-140) is commonly used to prove that cellular responses are mediated by B2 receptors. Nevertheless, blocking increased signaling through the B2 receptor does not necessarily indicate enhanced kinin generation because some proteases (e.g., kallikrein) can activate the B2 receptor directly, and this also is blocked by HOE-140 (Biyashev et al., 2006).

Activation of the angiotensin AT2 receptor results in responses (e.g., vasodilation) that oppose those of the activated angiotensin AT1 receptor (e.g., vasoconstriction) (Chapter 26); this can be mediated in part by cross-talk through activation of B2 receptors (Widdop et al., 2003).

**Functions and Pharmacology of Kallikreins and Kinins**

The availability of specific kinin-receptor antagonists and the generation of B1 and B2 receptor knockout mice have advanced our understanding of the roles of the kinins (Leeb-Lundberg et al., 2005; Pesquero and Bader, 2006). Antagonists currently are being investigated in diverse areas such as pain, inflammation, chronic inflammatory diseases and the cardiovascular system. That the beneficial effects of ACE inhibitor therapy rests in part on enhancing bradykinin activity (e.g., on the heart, kidney, blood pressure; see Chapter 26) demonstrates the complexities in interpreting bradykinin’s actions.

**Systems Pharmacology of Kinins**

**Pain.** The kinins are powerful algesic agents that cause an intense burning pain when applied to the exposed base of a blister. Bradykinin excites primary sensory neurons and provokes the release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related peptide. Although there is overlap, B2 receptors generally mediate acute bradykinin algesia, whereas the pain of chronic
inflammation appears to involve increased numbers and activation of B_1_ receptors.

**Inflammation.** Kinins participate in a variety of inflammatory conditions. Plasma kinins increase permeability in the microcirculation, acting on the small venules to cause disruption of the inter-endothelial junctions. This, together with an increased hydrostatic pressure gradient, causes edema. Edema, coupled with stimulation of nerve endings, results in a “wheal and flare” response to intradermal injection.

In hereditary angioedema, bradykinin is formed, and there is depletion of the upstream components of the kinin cascade during episodes of swelling, laryngeal edema, and abdominal pain. B_1_ receptors on inflammatory cells (e.g., macrophages) can elicit production of the inflammatory mediators IL-1 and TNF-α (Bhoola et al., 1992). Kinin levels are increased in a number of chronic inflammatory diseases and may be significant in gout, disseminated intravascular coagulation, inflammatory bowel disease, rheumatoid arthritis, or asthma. Kinins also may contribute to the skeletal changes seen in chronic inflammatory states. Kinins stimulate bone resorption through B_1_ and possibly B_2_ receptors, perhaps by osteoblast-mediated osteoclast activation (Chapter 44).

**Respiratory Disease.** The kinins have been implicated in allergic airway disorders such as asthma and rhinitis (Abraham et al., 2006). Inhalation or intravenous injection of kinins causes bronchospasm in asthmatic patients but not in normal individuals. This bradykinin-induced bronchoconstriction is blocked by anticholinergic agents but not by antihistamines or cyclooxygenase inhibitors. Similarly, nasal challenge with bradykinin is followed by sneezing and glandular secretions in patients with allergic rhinitis. A B_2_ receptor antagonist improved pulmonary function in patients with severe asthma and reduced nasal symptoms in allergic rhinitis (Abraham et al., 2006).

**Cardiovascular System.** In experimental animals and humans, infusion of bradykinin causes vasodilation and lowers blood pressure. Bradykinin causes vasodilation by activating its B_2_ receptor on endothelial cells, resulting in the generation of NO, prostacyclin, and a hyperpolarizing EET that is a CYP-derived metabolite of arachidonic acid (Campbell et al., 1996). In B_2_ antagonist–treated animals or B_2_ receptor knockout mice, basal blood pressure is normal; however, these animals have an exaggerated blood pressure response to salt loading or activation of the renin–angiotensin system. These data suggest that the endogenous kallikrein–kinin system plays a minor role in the regulation of normal blood pressure, but it may be important in hypertensive states. Urinary kallikrein concentrations are decreased in individuals with high blood pressure (Margolius, 1995).

The kallikrein–kinin system is cardioprotective, as revealed by studies showing that many of the beneficial effects of ACE inhibitors on heart function are attributable to enhancement of bradykinin effects, such as their anti-proliferative activity or ability to increase glucose uptake in tissue (Pfeffer and Frolich, 2006; Henriksen et al., 1999; Heitsch, 2003). Bradykinin contributes to the beneficial effect of preconditioning to protect the heart against ischemia and reperfusion injury. Bradykinin also stimulates tissue plasminogen activator (tPA) release from the vascular endothelium (Leeb-Lundberg et al., 2005) and may contribute to the endogenous defense against some cardiovascular events, such as myocardial infarction and stroke. Stimulation of either B_1_ or B_2_ receptors produces cardioprotective effects after myocardial infarction (Leeb-Lundberg et al., 2005; Heitsch, 2003; Jiang et al., 2009).

**Kidney.** Renal kinins act in a paracrine manner to regulate urine volume and composition (Saitoh et al., 1995). Kallikrein is synthesized and secreted by the connecting cells of the distal nephron. Tissue kallikreinogen and kinin receptors are present in the cells of the collecting duct. Like other vasodilators, kinins increase renal blood flow. Bradykinin also causes natriuresis by inhibiting sodium reabsorption at the cortical collecting duct. Treatment with mineralocorticoids, ACE inhibitors, and neutral endopeptidase (neprilysin) inhibitors increases renal kallikrein.

**Other Effects.** Many initial discoveries in the kallikrein–kinin system were made using a bioassay measuring isotonic contractions of the isolated rat uterus in estrus, which is especially sensitive to kinins. Kinins promote dilation of the fetal pulmonary artery, closure of the ductus arteriosus, and constriction of the umbilical vessels, all of which occur in the transition from fetal to neonatal circulation. The kallikrein–kinin system also functions in many other areas in the body, serving to mediate edema formation and smooth muscle contraction. Kinins also affect the CNS, disrupting the blood-brain barrier and allowing increased CNS penetration.

**Potential Therapeutic Uses.** Bradykinin contributes to many of the effects of the ACE inhibitors (Figure 32–4; see the history section under “Bradykinin, Kallidin, and Their Antagonists”). Aprotinin, a kallikrein and plasmin inhibitor, has been administered to patients undergoing coronary bypass to minimize bleeding and blood requirements (see “Kallikrein Inhibitors”, below). Based on the pro-inflammatory and algesic effects of kinins, B_1_ and B_2_ receptor antagonists are being tested for the treatment of inflammatory conditions and certain types of pain (Abraham et al., 2006; Campos et al., 2006).

**Kallikrein Inhibitors**

Aprotinin (TRASYLOL) is a natural protease inhibitor obtained for commercial purposes from bovine lung and is identical to Kunitz’s pancreatic trypsin inhibitor (Waxler and Rabito, 2003). Aprotinin inhibits mediators of the inflammatory response, fibrinolysis, and
thrombin generation following cardiopulmonary bypass surgery, including kallikrein and plasmin. Administration of aprotinin reduces requirements for blood products in patients undergoing coronary artery bypass grafting (Waxler and Rabito, 2003). Recent retrospective meta-analyses and a prospective multicenter trial linked aprotinin use with higher mortality and renal morbidity (Dietrich, 2009). Although there is controversy regarding the validity of these conclusions, the manufacturer has withdrawn the drug from the market (Dietrich, 2009); it remains available through a special investigational treatment protocol. Ecallantide (DX-88), a synthetic plasma kallikrein inhibitor, inhibits acute episodes of angioedema in patients with hereditary angioedema (Schneider et al., 2007).

Bradykinin and the Effects of ACE Inhibitors. ACE inhibitors are widely used in the treatment of hypertension, and they reduce mortality in patients with diabetic nephropathy, left ventricular dysfunction, previous myocardial infarction, or coronary artery disease (Pfeffer and Frohlich, 2006). ACE inhibitors block the conversion of Ang I to Ang II, a potent vasoconstrictor and growth promoter (Figure 32–4) (Chapter 25). Studies with the kinin B$_2$ antagonist HOE-140 demonstrate that bradykinin also contributes to many of the protective effects of ACE inhibitors. For example, administration of HOE-140 in animal models attenuates the favorable effects of ACE inhibitors on blood pressure, myocardial infarct size, and ischemic preconditioning. Bradykinin receptor antagonism also attenuates blood pressure lowering by acute ACE inhibition in humans (Gainer et al., 1998). These effects may result not only from decreased degradation of bradykinin by ACE but also from induction of enhanced receptor sensitivity by ACE inhibitors (Marcic et al., 1999; Biyashev et al., 2006).

A rare side effect of ACE inhibitors is angioedema, which may occur shortly after initiating therapy. This is a class effect of ACE inhibitors and may be connected to the inhibition of kinin metabolism by ACE (Slater et al., 1988). ACE inhibitor–associated angioedema is more common in blacks than in Caucasians. A common side effect of ACE inhibitors is a chronic, nonproductive cough that dissipates when the drug is stopped. The finding that angiotensin AT$_1$ receptor antagonists do not cause cough supports the role of bradykinin in this effect, but the mechanism has not been clearly defined.

Bradykinin also may contribute to the effects of the AT$_1$-receptor antagonists. During AT$_1$ receptor blockade, Ang II concentrations increase, which enhances signaling through the unopposed AT$_2$ subtype receptor, causing an increase in renal bradykinin concentrations (Widdop et al., 2003).

A new class of antihypertensive agent was developed to inhibit two major kinin-degrading enzymes, ACE and neprilysin, and the added inhibition of bradykinin metabolism was expected to enhance therapeutic effectiveness. In phase III clinical trials, the prototype drug omapatrilat was an effective antihypertensive agent but was associated with a 3-fold higher incidence of angioedema than with an ACE inhibitor alone, causing withdrawal of the drug.

**Kinin Receptor Antagonists.** The substitution of a D-Phe for Pro at position 7 in bradykinin conferred weak antagonist activity at the B$_1$ receptor and blocked the action of ACE. The addition of an N-terminal, D-Arg substitution of hydroxyproline in position 3 and thienylalanine at positions 5 and 8 resulted in the first useful and potent B$_1$ antagonist with in vivo activity (NPC-349; Table 32–3) (Stewart, 2004). However, this antagonist had a short $t_{1/2}$ owing to enzymatic degradation by carboxypeptidase N in vivo, which converted it into a B$_2$ antagonist. Based on NPC-349, the longer-acting selective B$_1$ receptor antagonist HOE-140 (icatibant) was developed by substituting synthetic amino acids at positions 7 (D-tetrahydroisoquinoline-3-carboxylic acid (Tic)) and 8 (octahydroindole-2-carboxylic acid (Oic)) (Table 32–3). Icatibant (FIRAZYR) has been approved in the E.U. for treatment of acute episodes of swelling in patients with hereditary angioedema (Bork et al., 2008). It is administered by subcutaneous injection.

Orally active non-peptide receptor antagonists would be preferable for therapeutic use. The first of these for the B$_2$ receptor, WIN64338, had significant muscarinic cholinergic activity. In animals, a newer, more specific non-peptide B$_2$ antagonist, FR173657 (Table 32–3), decreased bradykinin-induced edema, hypotension, pain, bronchoconstriction, and inflammatory responses (Leeb-Lundberg et al., 2005; Abraham et al., 2006). This has led to increased interest by the drug industry and the generation of several new non-peptide B$_2$ antagonists with good oral bioavailability and in vivo stability and activity (Leeb-Lundberg et al., 2005; Abraham et al., 2006). On the other hand, synthetic B$_1$ receptor agonists (such as FR190997; Table 32–3) may be cardioprotective. Synthetic small-molecule bradykinin agonists or antagonists would not necessarily bind to the same regions of the B$_2$ receptor as the peptide (Heitsch, 2003).

Peptide antagonists of the B$_1$ receptor include des-Arg$^{10}$-[Leu$^9$]-kallidin and [des-Arg$^{10}$]-HOE-140 (Table 32–3), among others (Campos et al., 2006). More recently, several non-peptide B$_1$ antagonists with in vivo activity have been developed (Campos et al., 2006; Feng et al., 2008); the most promising of these is SSR240612 (Table 32–3), which is orally active and inhibits inflammation and neuropathic pain in animal studies. None has yet been tested clinically.

**CLINICAL SUMMARY: KININS**

Aprotinin (TRASYLLOL), the potent inhibitor of kallikrein and other serine proteases, has been employed clinically to reduce blood loss in patients undergoing coronary artery bypass surgery, but unfavorable survival statistics in retrospective and prospective studies have resulted in its discontinuation (Dietrich, 2009).

Because kinins and [des-Arg$^{10}$]-kinins enhance pain and inflammation via activation of the two kinin receptors, B$_2$ and B$_1$, antagonists may be useful in treating inflammatory diseases. A peptide-based B$_2$ receptor antagonist, icatibant (FIRAZYR), has been approved in the E.U. for treatment of acute episodes of swelling in patients with hereditary angioedema (Bork et al., 2008).
ACE inhibitors are widely used drugs in the treatment of hypertension, congestive heart failure, and diabetic nephropathy, and they reduce mortality in patients with a variety of cardiovascular risk factors (Chapter 26). One effect of ACE inhibitors is to prevent the degradation of bradykinin. Because bradykinin, by activating its B2 receptor, is responsible for many of the beneficial cardioprotective effects of ACE inhibitors, the search is on to find a suitable stable B2 agonist for clinical evaluation. A major problem for such applications is to establish a safe therapeutic window between potentially protecting the heart and avoiding pro-inflammatory stimulation (Heitsch, 2003).

BIBLIOGRAPHY

Membrane lipids supply the substrate for the synthesis of eicosanoids and platelet-activating factor (PAF). Eicosanoids—arachidonate metabolites, including prostaglandins (PGs), prostacyclin (PGI₂), thromboxane A₂ (TxA₂), leukotrienes (LTs), lipoxins, and hepoxilins—are not stored but are produced, by most cells, when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available. Membrane glycerophosphocholine derivatives can be modified enzymatically to produce PAF. PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids contribute to inflammation, smooth muscle tone, hemostasis, thrombosis, parturition, and gastrointestinal secretion. Several classes of drugs, most notably aspirin, the traditional non-steroidal anti-inflammatory agents (tNSAIDs), and the specific inhibitors of cyclooxygenase-2 (COX-2), such as the coxibs, owe their principal therapeutic effects to blockade of eicosanoid formation. To understand the therapeutic potential of selective inhibitors of eicosanoid synthesis and action, we must first review the synthesis, metabolism, and mechanism of action of eicosanoids and PAF.

**EICOSANOIDS**

**History.** In 1930, Kurzrok and Lieb, two American gynecologists, observed that strips of uterine myometrium relax or contract when exposed to semen. Subsequently, Goldblatt in England and von Euler in Sweden reported independently on smooth muscle-contracting and vasodepressor activities in seminal fluid and accessory reproductive glands. In 1935, von Euler identified the active material as a lipid-soluble acid, which he named prostaglandin, inferring its origin in the prostatic gland. Samuelsson, Bergström, and their colleagues elucidated the structures of prostaglandin E₁ (PGE₁) and prostaglandin F₁α (PGF₁α) in 1962. In 1964, Bergström and coworkers, and van Dorp and associates, independently achieved biosynthesis of PGE₁ from arachidonic acid (AA). Discovery of TxA₂, PGI₂, and the LTs followed. Vane, Smith, and Willis reported that aspirin and NSAIDs act by inhibiting prostaglandin biosynthesis (Vane, 1971). This remarkable period of discovery linked the Nobel Prize of von Euler in 1970 to that of Bergström, Samuelsson, and Vane in 1982.

PGs, LTs, and related compounds are called *eicosanoids*, from the Greek *eikosi* (“twenty”). Precursor essential fatty acids contain 20 carbons and three, four, or five double bonds: 8,11,14-eicosatrienoic acid (dihomo-γ-linolenic acid), 5,8,11,14-eicosatetraenoic acid [AA; Figure 33–1], and 5,8,11,14,17-eicosapentaenoic acid (EPA). In humans, AA, the most abundant precursor, is either derived from dietary linoleic acid (9,12-octadecadienoic acid) or ingested directly as a dietary constituent. EPA is a major constituent of oils from fatty fish such as salmon.

**Biosynthesis.** Biosynthesis of eicosanoids is limited by the availability of substrate and depends primarily on the release of AA, esterified in the *sn*-2 domain of cell membrane phospholipids, or other complex lipids, to the eicosanoid-synthesizing enzymes by acyl hydrolases, most notably phospholipase A₂ (PLA₂). Chemical and physical stimuli activate the Ca²⁺-dependent translocation of group IV_A cytosolic PLA₂ (cPLA₂), which has a high affinity for AA, to the membrane, where it hydrolyzes the *sn*-2 ester bond of membrane phospholipids (particularly phosphatidylcholine and phosphatidylethanolamine), releasing arachidonate. Multiple additional PLA₂ isoforms (secretory [s] and Ca²⁺-independent [i] forms) have been characterized. Under nonstimulated conditions, AA liberated by iPLA₂ is reincorporated into cell membranes, so there is negligible eicosanoid biosynthesis. Although cPLA₂
Figure 33–1. Metabolism of arachidonic acid (AA). The cyclooxygenase (COX) pathway is highlighted in gray. The lipoxygenase (LOX) pathways are expanded in Figure 33–2. Major degradation pathways are shown in Figure 33–3. Cyclic endoperoxides (PGG₂ and PGH₂) arise from the sequential cyclooxygenase and hydroperoxidase actions of COX-1 or COX-2 on AA released from membrane phospholipids. Subsequent products are generated by tissue-specific synthases and transduce their effects via membrane-bound receptors (blue boxes). Dashed lines indicate putative ligand–receptor interactions. Epoxyeicosatrienoic acids (EETs; shaded in blue) and isoprostanes are generated via CYP activity and non-enzymatic free radical attack, respectively. COX-2 can use modified arachidonoylglycerol, an endocannabinoid, to generate the glyceryl prostaglandins. Aspirin and tNSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. Epilipoxins are generated by COX-2 following its acetylation by aspirin (see Figure 33–2). Dual 5-LOX–COX inhibitors interfere with both pathways. See the text for other abbreviations.
cyclopentane rings. Terminal prostanoids distinguished by substitutions on their cyclopentane rings.

Successive metabolism of AA by the COX and hydroperoxidase (HOX) activities of the PG endoperoxide G/H synthases, generate the cyclic endoperoxide PGs G and H (Figure 33–1). Isomerases and synthases affect the transformation of prostaglandin H$_2$ (PGH$_2$) into terminal prostanoids distinguished by substitutions on their cyclopentane rings.

PGs of the E and D series are hydroxyketones, whereas the F$_x$ PGs are 1,3-diols (Figure 33–1). A, B, and C PGs are unsaturated ketones that arise nonenzymatically from PGF during extraction procedures; it is unlikely that they occur biologically. Prostaglandin J$_2$ (PGJ$_2$) and related compounds result from the dehydration of prostaglandin D$_2$ (PGD$_2$). Prostaglandin I$_2$ (PGI$_2$, prostacyclin) has a double-ring structure; in addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. Thromboxanes (TXs) contain a six-member oxirane ring, instead of a double-ring structure; in addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. Thromboxanes (TXs) contain a six-member oxirane ring.

Thromboxanes (TXs) contain a six-member oxirane ring.

Products of Prostaglandin G/H Synthases. Synthesis of the PGs, PGI$_2$, and thromboxane, collectively termed prostanoids, is accomplished in a stepwise manner by a complex of microsomal enzymes. Successive metabolism of AA by the COX and hydroperoxidase (HOX) activities of the PG endoperoxide G/H synthases, generate the cyclic endoperoxide PGs G and H (Figure 33–1). Isomerases and synthases affect the transformation of prostaglandin H$_2$ (PGH$_2$) into terminal prostanoids distinguished by substitutions on their cyclopentane rings.

PGs of the E and D series are hydroxyketones, whereas the F$_x$ PGs are 1,3-diols (Figure 33–1). A, B, and C PGs are unsaturated ketones that arise nonenzymatically from PGF during extraction procedures; it is unlikely that they occur biologically. Prostaglandin J$_2$ (PGJ$_2$) and related compounds result from the dehydration of prostaglandin D$_2$ (PGD$_2$). Prostaglandin I$_2$ (PGI$_2$, prostacyclin) has a double-ring structure; in addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. Thromboxanes (TXs) contain a six-member oxirane ring.

Thromboxanes (TXs) contain a six-member oxirane ring.

Products of Lipoxigenases. LOXs are a family of non-heme iron–containing enzymes that catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides (Brash, 1999). The enzymes require a fatty acid substrate with two cis double bonds separated by a methylene group. AA, which contains several double bonds in this configuration, is metabolized to hydroperoxy eicosatetraenoic acids (HPETEs), which vary in the site of insertion of the hydroperoxy group. Analogous to PGG$_2$ and PGH$_2$, these unstable intermediates, normally with $S$ chirality, are further metabolized by a variety of enzymes. HPETEs are converted to their corresponding hydroxy fatty acid (HETE) either non-enzymatically or by a peroxidase.

There are five active human LOXs—5(S)-LOX, 12(S)-LOX, 12(R)-LOX, 15(S)-LOX-1, and 15(S)-LOX-2—classified according to the site of hydroperoxy group insertion. Human LOX products are of the $S$ stereoconfiguration with the exception of 12(R)-LOX. Their expression is frequently cell specific (Brash, 1999); platelets have only 12(S)-LOX, whereas leukocytes contain both 5(S)- and 12(S)-LOX (Figure 33–2). 12(R)-LOX is restricted in expression mostly to the skin. The epidermal LOXs, which constitute a distinct LOX subgroup, also include 15-LOX-2 and eLOX-3, the most recently identified family member. eLOX-3 has been reported to metabolize further 12(R)-HETE, the product of 12(R)-LOX, to a specific epoxyalcohol product.

The 5-LOX pathway leads to the synthesis of the LTs, which play a major role in the development and persistence of the inflammatory response (Peters-Golden and Henderson, 2007) (Figure 33–2). A nomenclature (e.g., LTB$_4$, LTA$_4$) similar to that of prostanoids applies to the subclassification of the LTs. When eosinophils, mast cells, polymorphonuclear leukocytes, or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with 5-LOX-activating protein (FLAP), an integral membrane protein that facilitates AA to 5-LOX interaction (Evans et al., 2008). Drugs that inhibit FLAP block LT production. A two-step reaction is catalyzed by 5-LOX: oxygenation of AA at C5 to form 5-HPETE, followed by...
Lipoxigenase pathways of arachidonic acid metabolism. 5-LOX-activating protein (FLAP) presents arachidonic acid to 5-LOX, leading to the generation of the LTs. CysLTs are shaded in gray. Lipoxins (shaded in orange) are products of cellular interaction via a 5-LOX–12-LOX pathway or via a 15-LOX–5-LOX pathway. Biological effects are transduced via membrane-bound receptors (blue boxes). The dashed line indicates putative ligand–receptor interactions. Zileuton inhibits 5-LOX but not the COX pathways (expanded in Figure 33–1). Dual 5-LOX–COX inhibitors interfere with both pathways. CysLT antagonists prevent activation of the CysLT1 receptor. See the text for abbreviations.
of epidermal LOXs in normal skin function are not clear, they may be relevant for skin barrier function and adipocyte differentiation. Epidermal accumulation of 12(R)-HETE is a feature of psoriasis and ichthyosis. Inhibitors of 12(R)-LOX are under investigation for the treatment of these proliferative skin disorders.

### Products of CYPs

Multiple CYPs can metabolize AA (Capdevila and Falck, 2002). The epoxyeicosatrienoic acids (EETs), formed by CYP epoxygenases, primarily CYP2C and CYP2J in humans, have been a primary focus of research. Four regioisomers (14,15-; 11,12-; 8,9-; and 5,6-EETs), each containing a mixture of the (R,S) and (S,R) enantiomers, are formed in a CYP isoform–specific manner. EETs are synthesized in endothelial cells, where they function as endothelium-derived hyperpolarizing factors (EDHFs), particularly in the coronary circulation (Campbell and Falck, 2007). Their biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression (see Chapter 6). CYP hydroxylases (primarily CYPs 4A, 4F) generate hydroxyeicosatetraenoic acids (16-, 17-, 18-, 19-, or 20-HETE), with 20-HETE being the principle product. CYP-derived AA metabolite in vascular smooth muscle cells. 20-HETE is generated in response to smooth muscle cell stretch or to vasoactive agents, including angiotensin II (AngII).

EETs are metabolized by numerous pathways. The corresponding biologically less active (or inactive) dihydroxyeicosatetraenoic acids (DHETs) are formed by epoxide hydrolases (EHs), whereas lysolipid acylation results in incorporation of EETs and DHETs into cellular phospholipids, where they can be stored. Inhibitors of EHs currently are under investigation. Glutathione conjugation and oxidation by COX and CYPs generate a series of glutathione conjugates, epoxyprostaglandins, diepoxides, tetrahydrofuran (THF) diols, and epoxyalcohols, whose biological relevance is not known. Similarly, 20-HETE can be converted by the COX pathway to the 20-hydroxy PGs. Intracellular fatty acid–binding proteins (FABPs) may bind EETs and DHETs differentially, thus modulating their metabolism, activities, and targeting.

### Other Pathways

In addition to enzymatic formation of eicosanoids, several families of eicosanoid isomers are generated at significant concentrations in vivo by non-enzymatic free radical catalyzed oxidation of AA. The best characterized of these isoeicosanoids are the F2-isoprostanes (F2-IsoPs) (Lawson et al., 1999; Fam and Morrow, 2003; Milne et al., 2008). Unlike PGs, these compounds are initially formed esterified in phospholipids, after which they are hydrolyzed to their free form by phospholipases, including PAF acetylhydrolase (Stafforini et al., 2006), which then circulate and are metabolized and excreted into urine. Their production is not inhibited in vivo by inhibitors of COX-1 or COX-2, but their formation is suppressed by antioxidants. The PGF2α isomer, 8-iso-PGF2α, was the first F2-IsoP to be identified. Measuring levels of these compounds in plasma and urine is considered the most accurate method to assess oxidative stress status in vivo, and increased levels are found in a large number of clinical conditions. Isoprostanes correlate with cardiovascular risk factors, but their use as predictors of coronary events remains an area of active investigation. Of particular interest is the recent finding that levels of F2-IsoPs predict 30-day outcome in acute coronary syndrome (LeLeiko et al., 2009).

In addition to F2-IsoPs, other PG-like isomers, including D2/E2-IsoPs, isothromboxanes, and isolevuglandins (alternatively termed isoketals), are also formed in vivo by non-enzymatic oxidation of AA (Brame et al., 2004). Isoleukotrienes are also generated non-enzymatically. Because several isoprostanes can activate prostanoid receptors, it has been speculated that they may contribute to the pathophysiology of inflammatory responses in a manner insensitive to COX inhibitors.

In the brain, the endocannabinoids arachidonylethanolamide (anandamide) and 2-arachidonoylglycerol are endogenous ligands of cannabinoid receptors (Bisogno, 2008). They mimic several pharmacological effects of δ9-tetrahydrocannabinol, the active principle of Cannabis sativa preparations such as hashish and marijuana, including inhibition of adenyl cyclase, inhibition of L-type Ca2+ channels, analgesia, and hypothermia. Several pathways have been proposed, but the prevalent one for biosynthesis in vivo remains unclarified. Conversion of anandamide and 2-arachidonoylglycerol by COX-2 generates PG-ethanolamides (prostamides) and PG-glycerol esters (Woodward et al., 2008); their biological significance remains to be clarified.

### Inhibitors of Eicosanoid Biosynthesis

A number of the biosynthetic steps just described can be inhibited by drugs. Inhibition of PLA2 decreases the release of the precursor fatty acid and thus the synthesis of all its metabolites. Because PLA2 is activated by Ca2+ and calmodulin, it may be inhibited by drugs that reduce the availability of Ca2+. Glucocorticoids also inhibit PLA2, but they appear to do so indirectly by inducing the synthesis of a group of proteins termed annexins (formerly lipocortins) that modulate PLA2 activity (see Chapter 42). Glucocorticoids also downregulate induced expression of COX-2 but not of COX-1. Aspirin and tNSAIDs originally were found to prevent the synthesis of PGs from AA in tissue homogenates (Vane, 1971). It is now known that these drugs inhibit the COX, but not the POX, moieties of both PG G/H synthases, and thus the formation of their downstream prostanoid products. In addition, these drugs do not inhibit LOXs and may cause increased formation of LTs by shunting of substrate to the LOX pathway. LTs may contribute to the GI side effects associated with NSAIDs. Dual inhibitors of the COX and 5-LOX pathways, in particular licofelone, are under investigation (Kulkarni and Singh, 2007). However, the exact interplay between these enzyme families remains to be defined.

COX-1 and COX-2 differ in their sensitivity to inhibition by certain anti-inflammatory drugs (Grosser et al., 2006). This observation has led to the recent development of selective inhibitors of COX-2, including the coxibs (see Chapter 34). It was hypothesized that these drugs would have therapeutic advantages over tNSAIDs, many of which are non-selective for COX-1/2. COX-2 is the predominant COX at sites of inflammation, whereas COX-1 is the major source of
cytoprotective PGs in the GI tract. Two randomized trials of selective COX-2 inhibitors reported their superiority in GI safety over NSAID comparators. However, there now is compelling evidence that COX-2 inhibitors confer a spectrum of cardiovascular hazards comprised of myocardial infarction, stroke, systemic and pulmonary hypertension, congestive heart failure, and sudden cardiac death (Grosser et al., 2006). Mechanistically, this hazard can be explained by suppression of cardioprotective COX-2-derived PGs, especially PGI₂, a general restraint on endogenous stimuli—including platelet COX-1-derived TxA₃—for platelet activation, vascular proliferation and remodeling, hypertension, atherogenesis, and cardiac function.

Compounds that preferentially and selectively inhibit the downstream enzymes that metabolize PGH₁ have been considered for some time. For example, agents that inhibit TxA₃ synthase might block platelet aggregation and induce vasodilation. Indeed, such drugs block TxA₃ production in vitro and in vivo; however, they have been disappointing in clinical development, perhaps owing to activation of the TxA₃ receptor by accumulated PGH₃ precursor. Given the problems associated with COX-2 inhibitors, there has been intense interest in developing drugs that might conserve the efficacy of COX-2 selectivity while shedding the cardiovascular risk. Microsomal prostaglandin E synthase-1 (mPGES-1), which catalyzes the isomerization of the COX product-PGH₂ into PGE₂, has emerged as a drug target (Samuelsson et al., 2007). The differential cardiovascular impact of mPGES-1 versus COX-2 inhibition in humans currently is unknown. However, deletion of mPGES-1 does not accelerate the response to a thrombogenic stimulus in vivo in rodents, in contrast to either selective inhibition of COX-2 or deletion of the IP, the I prostanoid receptor for PGI₂ (Cheng et al., 2006b). Indeed, deletion of mPGES-1 depresses systemic production of PGE₂ and augments biosynthesis of PGI₂, by rediversion of the intermediate COX product PGH₂ to PGI synthase. It currently is unclear what contribution elevated PGI₂ makes to the impact on mPGES-1 inhibition and whether this shift in substrate will be seen with pharmacological inhibitors in humans.

Because LTs mediate inflammation, efforts have focused on development of LT-receptor antagonists and selective inhibitors of the LOXs. Zileuton, an inhibitor of 5-LOX, and selective CysLT-receptor antagonists (zafirlukast, pranlukast, and montelukast) have established efficacy in the treatment of mild to moderate asthma (see Chapter 36). These treatments remain, however, less effective than inhaled corticosteroids. A common polymorphism in the gene for LTC₄ synthase that correlates with increased LTC₄ generation is associated with aspirin-intolerant asthma and with the efficacy of anti-LT therapy (Kanaoka and Boyce, 2004). Interestingly, although polymorphisms in the genes encoding 5-LOX or FLAP do not appear to be linked to asthma, studies have demonstrated an association of these genes with myocardial infarction, stroke, and atherosclerosis (Peters-Golden and Henderson, 2007); thus, inhibition of LT biosynthesis may be useful in the prevention of cardiovascular disease.

### Pharmacological Properties of Eicosanoids

The eicosanoids show numerous and diverse effects in biological systems. This discussion highlights those that are thought to be the most important.

### Mechanism of Action

The eicosanoids function through activation of specific cell surface receptors that couple to intracellular second-messenger systems to modulate cellular activity.

**Prostaglandin Receptors.** PGs activate membrane receptors locally near their sites of formation. The diversity of their effects is explained to a large extent by their interaction with a diverse family of distinct receptors (Table 33–1). Eicosanoid receptors interact with Gs, Gi, and Gq to modulate the activities of adenylyl cyclase and phospholipase C (see Chapter 3). Single gene products have been identified for the receptors for PGI₂ (the IP), PGF₂α (the FP), and TxA₃ (the TP). Four distinct PGE₂ receptors (EP₁-₄) and two PGD₂ receptors (DP₁ and DP₂)—also known as CRTH₂—are cloned. Additional isoforms...

of the TP (α and β), FP (A and B), and EP₃ (I-VI, e, f) receptors can arise through differential mRNA splicing (Narumiya et al., 1999; Smyth et al., 2009).

**Cell Signaling Pathways and Expression.** The prostanoid receptors appear to derive from an ancestral EP receptor and share high homology. Phylogenetic comparison of this family reveals three subclusters: The first consists of the relaxant receptors EP₂, EP₄, IP, and DP₁, which increase cellular cyclic AMP generation; the second consists of the contractile receptors EP₁, FP, and TP, which increase cytosolic levels of Ca²⁺; and a third, consisting only of EP₃,

This table lists the major classes of eicosanoid receptors and their signaling characteristics. Splice variants for EP₃, TP, and FP are indicated. Major phenotypes in knockout mouse models are listed. Ca²⁺ᵢ, cytosolic Ca²⁺; cAMP, cyclic AMP; PLC, phospholipase C (activation leads to increased cellular inositol phosphate and diacylglycerol generation and increased Ca²⁺ᵢ); IsoPs, isoprostanes; 15d-PGJ₂, 15-deoxy-Δ¹²,₁⁴-PGJ₂; DP₁ is a member of the fMLP-receptor superfamily; fMLP, formyl-methionyl-leucyl-phenylalanine. See the text for other abbreviations.
can couple to both elevation of intracellular calcium and a decrease in cyclic AMP. The DP₂ receptor is an exception and is unrelated to the other prostanoid receptors; rather, it is a member of the formyl-methionyl-leucyl-phenylalanine (fMLP)-receptor superfamily (Table 33–1).

TPα and TPβ receptors couple via Gq and several other G proteins, to activate the PLC–IP₃–Ca²⁺ pathway (Figure 33–4). Activation of TP receptors also may activate or inhibit adenylyl cyclase via Gs (TPα) or Gi (TPβ), respectively, and signal via Gγ₁₂/₁₃ and Gγ₁₆ to stimulate small G protein–signaling pathways, including ERK and Rho. TP is expressed in platelets, vasculature, lung, kidney, heart, thymus, and spleen. The TPα apparently is the sole isoform expressed in platelets (see Smyth and FitzGerald, 2009). Recognized differences between the splice variants are limited to G protein activation and receptor regulation in heterologous in vitro expression systems.

IP couples with Gs to stimulate adenylyl cyclase activity. It is expressed in many tissues and cells, including human kidney, lung, spine, liver, vasculature, and heart.

DP₁ also couples with adenylyl cyclase through Gi. It is the least abundant of the prostanoid receptors, with expression in mouse ileum, lung, stomach, and uterus. In humans, several subtypes of leukocytes express DP₂, including eosinophils, basophils, monocytes, dendritic cells, and T lymphocytes. DP₁ also is expressed in the central nervous system (CNS), where it appears to be limited specifically to the leptomeninges and the vasculature. DP₂ couples with the Gγ₁₂–PLC–IP₃ pathway to increase intracellular Ca²⁺ (Figure 33–4). Its mRNA is found in many human tissues (brain, heart, thymus, spleen, liver, and intestine). DP₂ is expressed on mast cells, T lymphocytes (Th2 but not Th1), basophils, and eosinophils (Kim and Luster, 2007).

EP₂ and EP₄ receptors activate adenylyl cyclase via Gs. The EP₁ receptor is expressed at much lower levels in most tissues and can be induced in response to inflammatory stimuli, suggesting distinct roles for these two Gs-coupled EP receptors. The EP₁ receptor, via an unclassified G protein, can activate the PLC–IP₃–Ca²⁺ pathway. All human EP₁ isoforms can activate Gi to inhibit adenylyl cyclase; however, certain isoforms can activate G₁₂/₁₃. EP₁ and EP₂...
receptors have limited distribution compared with the distribution of EP<sub>3</sub> and EP<sub>4</sub> receptors.

FP<sub>4</sub> and FP<sub>6</sub> receptors couple via G<sub>q</sub>-PLC–IP<sub>3</sub> to mobilize cellular Ca<sup>2+</sup> and activate PKC. In addition, stimulation of FP activates Rho kinase, leading to the formation of actin stress fibers, phosphorylation of p125 focal adhesion kinase, and cell rounding. The FP receptor is expressed in kidney, heart, lung, stomach, and eye; it is most abundant in the corpus luteum, where its expression pattern varies during the estrus cycle.

**Leukotriene and Lipoxin Receptors.** Several receptors for the LTs and lipoxins have been identified (Peters-Golden and Henderson, 2007) (Table 33–1). Two receptors exist for both LTB<sub>4</sub> (BLT<sub>1</sub> and BLT<sub>2</sub>) and the cysteinyl leukotrienes (CysLT<sub>1</sub> and CysLT<sub>2</sub>). A receptor that binds lipoxin, ALX, is identical to the fMLP-1 receptor; the nomenclature now reflects LXA<sub>4</sub> as a natural and potent ligand (Chiang et al., 2006).

**Cell Signaling Pathways and Expression.** Phylogenetic comparison reveals two clusters of LT/lipoxin receptors: the chemotaxtractant receptors (BLT<sub>1</sub>, BLT<sub>2</sub>, and ALX), which also contain the DP<sub>2</sub> receptor for PGD<sub>2</sub>, and the CysLT<sub>1</sub> and CysLT<sub>2</sub> receptors. All are G protein–coupled receptors (GPCRs) and couple with G<sub>q</sub> and other G proteins (Table 33–1), depending on the cellular context. The BLT<sub>1</sub> is expressed predominantly in leukocytes, thymus, and spleen, whereas BLT<sub>2</sub>, the low-affinity receptor for LTB<sub>4</sub>, is found in spleen, leukocytes, ovary, liver, and intestine. BLT<sub>2</sub> binds 12(S)- and 12(R)-HETE with reasonable affinity, although the biological relevance of this observation is not clear.

CysLT<sub>1</sub> binds LTD<sub>4</sub> with higher affinity than LTC<sub>4</sub>, while CysLT<sub>2</sub> shows equal affinity for both LTs. Both receptors bind LTE<sub>4</sub> with low affinity. Activation of G<sub>q</sub> leading to increased intracellular Ca<sup>2+</sup>, is the primary signaling pathway reported. Studies also have placed G<sub>i</sub> downstream of CysLT<sub>2</sub>. CysLT<sub>1</sub> is expressed in lung and intestinal smooth muscle, spleen, and peripheral blood leukocytes, whereas CysLT<sub>2</sub> is found in heart, spleen, peripheral blood leukocytes, adrenal medulla, and brain.

Responses to ALX-receptor activation vary with cell type. In human neutrophils, AA release is stimulated, whereas Ca<sup>2+</sup> mobilization is blocked; in monocytes, LXA<sub>4</sub> stimulates Ca<sup>2+</sup> mobilization. The ALX receptor is expressed in lung, peripheral blood leukocytes, and spleen.

**Other Agents.** Other AA metabolites (e.g., isoprostanes, epoxyeicosatrienoic acids, hepxolins) have potent biological activities, and there is evidence for distinct receptors for some of these substances. Some isoprostanes appear to act as incidental ligands at the TP (Audoly et al., 2000), which may be important in the pathology of cardiovascular disease. Others activate the FP (Kunapuli et al., 1997).

Certain eicosanoids, most notably 15-deoxy-D<sub>2</sub,14-PGJ<sub>2</sub> (15d-PGJ<sub>2</sub>), a dehydration product of PGD<sub>2</sub>, have been reported as endogenous ligands for a family of nuclear receptors called peroxisome proliferator–activated receptors (PPARs) that regulate lipid metabolism and cellular proliferation and differentiation. However, their affinities for PPARs are significantly lower than for cell surface receptors, raising doubt about the physiological relevance of the ligand–receptor interaction. In vitro 15d-PGJ<sub>2</sub> can bind PPAR<sub>γ</sub>; but the quantities formed in vivo are orders of magnitude lower than those necessary for PPAR activation (Bell-Parikh et al., 2003). Specific receptors for the HETEs and EETs have been proposed but not yet isolated.

**Endogenous Prostaglandins, Thromboxanes, and Leukotrienes: Functions in Physiological and Pathological Processes**

The widespread biosynthesis and myriad of pharmacological actions of eicosanoids are reflected in their complex physiology and pathophysiology. The development of mice with targeted disruptions of genes regulating eicosanoid biosynthesis and eicosanoid receptors has revealed unexpected roles for these autacoids and has clarified hypotheses about their function (Austin and Funk, 1999; Narumiya and FitzGerald, 2001; Matsuoka and Narumiya, 2007; Smyth and FitzGerald, 2009).

**Platelets.** Platelet aggregation leads to activation of membrane phospholipases, with the release of AA and consequent eicosanoid biosynthesis. In human platelets, TX<sub>A</sub> and 12-HETE are the two major eicosanoids formed, although eicosanoids from other sources (e.g., PG<sub>II</sub><sub>2</sub> derived from vascular endothelium) also affect platelet function. A naturally occurring mutation in the first intracellular loop of the TP receptor is associated with a mild bleeding diathesis and resistance of platelet aggregability to TP agonists (Hirata et al., 1994). The importance of the TX<sub>A</sub> pathway is evident from the efficacy of low-dose aspirin in the secondary prevention of myocardial infarction and ischemic stroke. The total biosynthesis of TX<sub>A</sub>, as determined by excretion of its urinary metabolites, is augmented in clinical syndromes of platelet activation, including unstable angina, myocardial infarction, and stroke (Smyth et al., 2009). Deletion of the TP receptor in the mouse prolongs bleeding time, renders platelets unresponsive to TP agonists, modifies their response to collagen but not to ADP, and blunts the response to vasopressors and the proliferative response to vascular injury.

PG<sub>I</sub> inhibits platelet aggregation and disaggregates preformed clumps. Deficiency of the IP receptor in disease-free mice does not alter platelet aggregation significantly ex vivo, although increased responsiveness to thrombin was evident in a mouse model of atherosclerosis (Smyth and FitzGerald, 2009). Augmented biosynthesis of PG<sub>I</sub> in syndromes of platelet activation serves to constrain the effects platelet agonists, vasoconstrictors, and stimuli to platelet activation. However, PG<sub>I</sub> does limit platelet activation by TX<sub>A</sub> in vivo, reducing the thrombotic response to vascular injury (Cheng et al., 2002). The increased incidence of myocardial infarction and stroke in patients receiving selective inhibitors of COX-2, most parsimoniously explained by inhibition of COX-2-dependent PG<sub>I</sub> formation, supports this concept (Grosser et al., 2006b).

Low concentrations of PG<sub>E</sub><sub>2</sub> activate the EP<sub>3</sub> receptor, leading to platelet aggregation (Fabre, 2001). Deletion of the EP<sub>3</sub> in mice leads to an increased bleeding tendency and decreased susceptibility to thromboembolism. Deletion of mPGES-1 did not affect thrombogenesis in vivo, probably due to substrate rediversion and augmented formation of PG<sub>I</sub> (Cheng et al., 2006b).

**Vascular Tone.** Because of their short t<sub>1/2</sub>, prostaglandins do not circulate and generally are considered not to impact directly on systemic vascular tone. They may, however, modulate vascular tone locally.
at their sites of biosynthesis or through renal or other indirect effects. 

PGI₂, the major arachidonate metabolite released from the vascular endothelium, is derived primarily from COX-2 in humans (Catella-Lawson et al., 1999; McAdam et al., 1999). PGI₂ generation and release is regulated by shear stress and by both vasoconstrictor and vasodilator autacoids. Deletion of the IP in mice augments vascular proliferation, remodeling, atherogenesis, and hypertension, while PGI synthesize polymorphisms have been associated with essential hypertension and myocardial infarction (Smyth and FitzGerald, 2009). PGI₂ limits pulmonary hypertension induced by hypoxia and systemic hypertension induced by AngII and lowers pulmonary resistance in patients with pulmonary hypertension.

Deficiency of EP₃ or EP₂ receptors reduces resting blood pressure in male mice; EP₂ receptor deficiency is associated with elevated renin–angiotensin activity. Both EP₂ and EP₃ receptor–deficient animals develop hypertension in response to a high-salt diet, reflecting the importance of PGE₂ in maintenance of renal blood flow and salt excretion. PGI₂ and PGE₂ are implicated in the hypertension associated with septic shock. PGs also may play a role in the maintenance of placental blood flow. Although conflicting data exist, it appears that loss of mPGES-1 in mice is less likely than loss of COX-2 to alter blood pressure (Smyth et al., 2009).

COX-2-derived PGE₂, via the EP₂ receptor, maintains the ductus arteriosus patent until birth, when reduced PGE₂ levels (a consequence of increased PGE₂ metabolism) permit closure. (Coggins et al., 2002). The tNSAIDs induce closure of a patent ductus in neonates (see Chapter 34). Contrary to expectation, animals lacking the EP₂ receptor die with a patent ductus during the perinatal period (Table 33–1) because the mechanism for control of the ductus in utero, and its remodeling at birth, is absent.

Endogenous biosynthesis of EETs is increased in human syndromes of hypertension. An analog of 11,12-EET abrogated the enhanced renal microvascular reactivity to AngII associated with hypertension (Imig et al., 2001), and blood pressure is lower in mice deficient in soluble EH (Sinal et al., 2000); these findings suggest that EH enzyme may be a potential pharmacological target for hypertension. Much indirect evidence suggests the existence of EET receptors, although none has been cloned.

**Inflammatory Vascular Disease.** Studies with knockout mice strongly implicate prostanoids in the development of atherogenesis and abdominal aortic aneurism; both inflammatory cardiovascular diseases (Smyth et al., 2009; Smyth and FitzGerald, 2009). Suppression of TXA₂ biosynthesis, as well as antagonism or deletion of the TP, retards atherogenesis in mice. Deletion of the EP receptor reduces blood pressure and retards atherogenesis, coincident with reduced renin. Conversely, PGI₂ appears atheroprotective and also limits vascular proliferative and remodeling responses. In humans, an arginine to cysteine substitution in the fifth intracellular loop of the IP, which disrupts IP signaling, co-segregated with increased cardiovascular risk in a recent study (Arehart et al., 2008), concordant with a role for this prostanoid in modifying human cardiovascular disease.

The role of PGE₂ effects on inflammatory cardiovascular disease is less clear. Deletion of mPGES-1 does not accelerate the response to a thrombogenic stimulus in vivo in rodents (in contrast to either selective inhibition of COX-2 or deletion of the IP (Cheng et al., 2006b) but does retard atherogenesis in fat-fed hyperlipidemic mice (Wang et al., 2006). It is unclear, however, whether this results from loss of PGE₂ or because of concomitant elevations in PGI₂ biosynthesis. Deletion, or selective inhibition, of COX-2, but not inhibition of COX-1, decreases abdominal aortic aneurism formation in hyperlipidemic mice (King et al., 2006). Similar results were seen in mPGES-1-deficient mice (Wang et al., 2008), although, again, it is unclear to what extent redivision to biosynthesis of other prostanoids (e.g., PGI₂) contributes.

There is growing evidence for a role of the LTs in cardiovascular disease (Peters-Golden and Henderson, 2007). Although conflicting data have been reported in animal studies, human genetic studies have demonstrated a link between cardiovascular disease and polymorphisms in the LT biosynthetic enzymes and FLAP.

**Lung.** A complex mixture of autacoids is released when sensitized lung tissue is challenged by the appropriate antigen. COX-derived bronchodilator (PGE₂) and bronchoconstrictor (e.g., PGF₂α, TXA₂, PGD₂) substances are released. IP deletion in mice exaggerates features of acute and chronic experimental asthma, including increased bronchial hyperresponsiveness. Inhaled iloprost (a PGI₂ analog) suppresses the cardinal features of asthma in mice via inhibition of airway dendritic cell function.

Polymorphisms in the genes for PGD₂ synthase and the TP receptor have been associated with asthma in humans. Deletion of either DP₂ or DP₁ in mice suggests an important role of this prostanoid in asthma (and in other allergic responses), although contradictory findings in DP₂-deficient mice suggest significant complexity in the function of PGD₂ in airway inflammation (Pettipher et al., 2007).

The CysLTs probably dominate during allergic constriction of the airway (Drazen, 1999). Deficiency of 5-LOX leads to reduced influx of eosinophils in airways and attenuates bronchoconstriction. Furthermore, unlike COX inhibitors and histaminergic antagonists, CysLT-receptor antagonists and 5-LOX inhibitors are effective in the treatment of human asthma (see “Inhibitors of Eicosanoid Biosynthesis”). The relatively slow LT metabolism in lung contributes to the long-lasting bronchoconstriction that follows challenge with antigen and may be a factor in the high bronchial tone that is observed in asthmatic patients in periods between acute attacks (see Chapter 36).

**Kidney.** Long-term use of all COX inhibitors is limited by the development of hypertension, edema, and congestive heart failure in a significant number of patients. PGE₂, along with PGI₂, apparently derived from COX-2, plays a critical role in maintaining renal blood flow and salt excretion, whereas there is some evidence that the COX-1-derived vasoconstrictor TXA₂ may play a counterbalancing role. Biosynthesis of PGE₂ and PGI₂ is increased by factors that reduce renal blood flow (e.g., stimulation of sympathetic nerves; AngII).

Barter’s syndrome is an autosomal recessive trait that is manifested as hypokalemic metabolic alkalosis. The syndrome results from inappropriate renal salt absorption caused primarily by dysfunctional mutations in the Na⁺−K⁺−2Cl⁻ co-transporter NKCC2, a target of loop diuretics in the ascending thick limb of the loop of Henle (Simon et al., 1996) (see Chapter 25). The syndrome also can result from dysfunctional alterations in proteins whose activities can limit NKCC2 function: the K⁺ channel ROMK2 (Kir1.1) that recycles K⁺ into the tubular fluid; the basolateral membrane Cl⁻ channel, CIC–Kb; and Barttin, the integral membrane protein that forms the α-subunit of the CIC–Kb heteromer (O’Shaughnessy and Karet, 2004). The antenatal variant of Barter’s syndrome, owing to
dysfunctional ROMK2, also is known as hyperprostaglandin E syndrome. The elevated PGE\textsubscript{2} may exacerbate the symptoms of salt and water loss. The relationship between dysfunctional ROMK2 and elevated PGE\textsubscript{2} synthesis is not clear. However, in patients with antenatal Bartter’s syndrome, inhibition of COX-2 ameliorates many of the clinical symptoms (Nüsing et al., 2001).

**Inflammatory and Immune Responses.** PGs and LTs are synthesized in response to a host of stimuli that elicit inflammatory and immune responses, and contribute significantly to inflammation and immunity (Tilley et al., 2001; Brink et al., 2003; Kim and Luster, 2007). Prostanoids generally promote acute inflammation, although there are some exceptions, such as the inhibitory actions of PGE\textsubscript{2} on mast cell activation (see “Inflammation and Immunity”). Data from animals deficient in either COX-1 or COX-2 yield conflicting results depending on the inflammatory model used, perhaps reflecting the contribution of both isozymes to inflammation. Deletion of mPGES markedly reduced inflammation in several mouse models.

LTs are potent mediators of inflammation. Deletion of either 5-LOX or FLAP reduces inflammatory responses. Generation of BLT\textsubscript{1}-deficient mice confirms the role of LTB\textsubscript{4} in chemotaxis, adhesion, and recruitment of leukocytes to inflamed tissues (Toda et al., 2002). Increased vascular permeability resulting from innate and adaptive immune challenges is offset in mice deficient in CysLT\textsubscript{1} or LTC\textsubscript{4} synthase (Kanaoka and Boyce, 2004) (Table 33–1). Deletion of either LTC\textsubscript{4} synthase (and thus loss of CysLT biosynthesis) or CysLT\textsubscript{2} reduced chronic pulmonary inflammation and fibrosis in response to bleomycin. In contrast, absence of CysLT\textsubscript{1} led to an exaggerated response. These findings demonstrate a role for CysLT\textsubscript{1} in promoting, and an unexpected role for CysLT\textsubscript{1} in counteracting, chronic inflammation.

**Heart.** Studies suggest a role for COX-2 in cardiac function (Smyth et al., 2009). PGI\textsubscript{2} and PGE\textsubscript{2}, acting on the IP or the EP\textsubscript{3}, respectively (Dowd et al., 2001; Shimamura et al., 2005), protect against oxidative injury in cardiac tissue. IP deletion augments myocardial ischemia/reperfusion injury and both mPGES-1 deletion (Degouasse et al., 2008) and cardiomyocyte specific deletion of the EP\textsubscript{3} (Qian et al., 2008) exacerbate the decline in cardiac function after experimental myocardial infarction. COX-2-derived TxA\textsubscript{2} contributed to oxidant stress, isoprostane generation, and activation of the TP, and also possibly the FP, to increase cardiomyocyte apoptosis and fibrosis in a model of heart failure (Zhang et al., 2003). Selective deletion of COX-2 in cardiomyocytes results in mild heart failure and a predisposition to arrhythmogenesis.

**Reproduction and Parturition.** Studies with knockout mice confirm a role for PGs in reproduction and parturition (Smyth and FitzGerald, 2009). COX-1-derived PGF\textsubscript{2\alpha} plays a critical role in maintaining the health of the implantation site. In mice with COX-2 deficiency, PGF\textsubscript{2\alpha} production is increased, and uterine blood flow is decreased over the period of implantation (Cheng et al., 2006a). Subsequent formation of F-ring metabolites from PGD\textsubscript{2} may result in hypertension. PGD\textsubscript{2} is a potent constrictor of both pulmonary arteries and veins in humans. Blood pressure is increased by PGF\textsubscript{2\alpha} in some experimental animals, owing to venoconstriction; however, in humans, PGF\textsubscript{2\alpha} does not alter blood pressure. TxA\textsubscript{2} is a potent vasoconstrictor. It contracts vascular smooth muscle in vitro and is a vasoconstrictor in the whole animal and in isolated vascular beds.

**Cancer.** Pharmacological inhibition or genetic deletion of COX-2 represses tumor formation in models of colon, breast, lung, and other cancers. Large human epidemiological studies report that the incidental use of NSAIDs is associated with significant reductions in relative risk for developing these and other cancers (Harris et al., 2005). PGE\textsubscript{2} has been implicated as the primary pro-oncogenic prostanoid in multiple studies. The pro- and anti-oncogenic roles of other prostanoids remain under investigation, with TxA\textsubscript{2} emerging as another likely COX-2-derived pro-carcinogenic mediator. Studies in mice lacking EP\textsubscript{1}, EP\textsubscript{2}, and EP\textsubscript{3} reduce disease in multiple carcinogenesis models. EP\textsubscript{3} in contrast, may even play a protective role in some cancers. Three randomized controlled trials of COX-2 inhibitors reported a significant reduction in the reoccurrence of adenomas in patients receiving either celecoxib or rofecoxib compared to placebo (Bertagnolli, 2007), while polymorphisms in COX-2 have been associated with an increased risk of colon and other cancers. In mouse mammary tissue, COX-2 is pro-oncogenic (Liu et al., 2001), whereas aspirin use is associated with a reduced risk of breast cancer in women, especially for hormone receptor–positive tumors (Terry et al., 2004). Despite the emphasis on COX-2, studies support a role for both COX enzymes in pro-oncogenic processes, and it remains untested whether selective COX-2 inhibitors will prove superior to nonselective NSAIDs for the prevention or treatment of human cancer. The CysLT and LTB\textsubscript{4} receptors also are implicated in cancer, raising interest in the use of LT inhibitors/antagonists in chemoprevention/therapy.

**Pharmacological Effects**

**Cardiovascular System.** Prostanoids do not circulate and thus do not directly impact systemic vascular tone. They may, however, modulate local vascular tone at the site of their formation and affect systemic blood pressure through their renal actions, including changes of tone of the efferent arteriole. In most vascular beds, PGE\textsubscript{2}, PGI\textsubscript{2}, and PGD\textsubscript{2} elicit vasodilation and a drop in blood pressure (Smyth and FitzGerald, 2009). PGE\textsubscript{2} can cause vasoconstriction through activation of the EP\textsubscript{1} and EP\textsubscript{3}. Infusion of PGD\textsubscript{2} in humans results in flushing, nasal stuffiness, and hypotension. Local subcutaneous release of PGD\textsubscript{2} contributes to dilation of the vasculature in the skin, which causes facial flushing associated with niacin treatment in humans (Cheng et al., 2006a). Subsequent formation of F-ring metabolites from PGD\textsubscript{2} may result in hypertension. PGI\textsubscript{2} relaxes vascular smooth muscle, causing hypotension and reflex tachycardia on intravenous administration. Responses to PGF\textsubscript{2\alpha} vary with species and vascular bed; it is a potent constrictor of both pulmonary arteries and veins in humans. Blood pressure is increased by PGF\textsubscript{2\alpha} in some experimental animals, owing to venoconstriction; however, in humans, PGF\textsubscript{2\alpha} does not alter blood pressure. TxA\textsubscript{2} is a potent vasoconstrictor. It contracts vascular smooth muscle in vitro and is a vasoconstrictor in the whole animal and in isolated vascular beds.
Cardiac output generally is increased by infusion of PGs of the E and F series. Weak, direct inotropic effects have been noted in various isolated preparations. In the intact animal, however, increased force of contraction and increased heart rate are, in large measure, a reflex consequence of a fall in total peripheral resistance. Animal studies suggest direct cardioprotective effects of PGI₂ and PGE₃ (Smyth et al., 2009).

LTC₄ and LTD₄ can constrict or relax isolated vascular smooth muscle preparations, depending on the concentrations used and the vascular bed (Brink et al., 2003). Hypotension in humans may result partly from a decrease in intravascular volume and also from decreased cardiac contractility secondary to a marked LT-induced reduction in coronary blood flow. Although LTC₄ and LTD₄ have little effect on most large arteries or veins, coronary arteries and distal segments of the pulmonary artery are contracted by nanomolar concentrations of these agents. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not. LTC₄ and LTD₄ act in the microvasculature to increase permeability of postcapillary venules; they are approximately 1,000-fold more potent than histamine in this regard. At higher concentrations, LTC₄ and LTD₄ can constrict arterioles and reduce exudation of plasma. Vascular smooth muscle proliferation can be promoted by 12S-HETE and 20-HETE.

EETs cause vasodilation in a number of vascular beds by activating the large conductance Ca²⁺-activated K⁺ channels of smooth muscle cells, thereby hyperpolarizing the smooth muscle and causing relaxation. EETs likely also function as endothelium-derived hyperpolarizing factors (EDHFs), particularly in the coronary circulation (Campbell and Falck, 2007). In contrast to EETs, 20-HETE inhibits large conductance Ca²⁺-activated K⁺ channels, resulting in depolarization of the vascular smooth muscle cell, Ca²⁺ entry, and potent vasoconstriction (Kroetz and Xu, 2005). Evidence supports the role of 20-HETE in the regulation of vascular tone, particularly in renal autoregulation.

Isoprostanes usually are vasoconstrictors, although there are examples of vasodilation in preconstricted vessels.

**Platelets.** Low concentrations of PGE₂, via the EP₃, enhance platelet aggregation. In contrast, higher concentrations of PGE₂, acting via the IP or possibly the Gₛ-coupled EP₂ or EP₄, inhibit platelet aggregation (Smyth et al., 2009). Both PGI₂ and PGD₂ inhibit the aggregation of human platelets in vitro, through cyclic AMP–dependent deactivation of myosin light-chain kinase.

Mature platelets express only COX-1. Megakaryocytes and immature platelet forms, released in clinical conditions of accelerated platelet turnover, also express COX-2 (Rocca et al., 2002), but its role in platelet development and function has yet to be elucidated. TxA₂, the major product of COX-1 in platelets, induces platelet shape change, through Gₛ/G₁₂-mediated Rho/Rho-kinase-dependent regulation of myosin light-chain phosphorylation, and aggregation through Gₛ-dependent activation of PKC. Perhaps more importantly, TxA₂ amplifies the signal for other, more potent platelet agonists, such as thrombin and ADP (FitzGerald, 1991). The actions of TxA₂ on platelets are restrained by its short t½ (~30 seconds), by rapid TP desensitization, and by endogenous inhibitors of platelet function, including NO and PGI₂, which inhibits platelet aggregation by all recognized agonists. The biological importance of 12-HETE formation is poorly understood, although deletion of the platelet 12-LOX augments ADP-induced platelet aggregation and AA-induced sudden death in mice. Some isoprostanes increase the response of platelets to pro-aggregatory agonists in vitro.

**Inflammation and Immunity.** Eicosanoids play a major role in the inflammatory and immune responses, as reflected by the clinical usefulness of the NSAIDs. While LTs generally are pro-inflammatory and lipoxins anti-inflammatory, prostanoids can exert both kinds of activity. A more complete description of inflammation is outlined in Chapter 34.

COX-2 is the major source of prostanoids formed during and after an inflammatory response, although COX-1 also contributes. PGE₂ and PGI₂ are the predominant pro-inflammatory prostanoids, as a result of increased vascular permeability and blood flow in the inflamed region. TxA₂ can increase platelet–leukocyte interaction. Prostanoids, especially PGD₂, also contribute to resolution of inflammation. PGs generally inhibit lymphocyte function and proliferation, suppressing the immune response (Rocca et al., 2002). PGE₂ depresses the humoral antibody response by inhibiting the differentiation of B lymphocytes into antibody-secreting plasma cells. PGE₂ acts on T lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE₂ and TxA₂ also may play a role in T lymphocyte development by regulating apoptosis of immature thymocytes (tilley et al., 2001). PGD₂, a major product of mast cells, is a potent leukocyte chemoattractant (Petipher et al., 2007), primarily through the DP₂. Activation of the DP₂ promotes chemotaxis and activation of the T₉₂ lymphocytes, eosinophils, and basophils. The PGD₂ degradation product, 15d-PGJ₂, also may activate eosinophils via the DP₂. PDG₂-mediated polarization of T cells to the T₉₂ phenotype is DP₂-mediated. A counterregulatory role for DP₂ in leukocyte activation has been proposed, although complementary functions for the two receptors have been reported. The precise interplay between DP₂ and DP₃ in vivo remains to be clarified.

LTB₄ is a potent activator and chemotactic agent for neutrophils, T lymphocytes, eosinophils, monocytes, dendritic cells, and possibly also mast cells (Kim and Luster, 2007). These effects are primarily BLT₁ receptor-mediated and, although BLT₂ expression has been reported in eosinophils, mast cells, and dendritic cells, its contribution to LBT₁ function is unclear. LTB₄ stimulates the aggregation of eosinophils and promotes degranulation and the generation of superoxide. LTB₄ promotes adhesion of neutrophils to vascular endothelial cells and their transepithelial migration and stimulates synthesis of pro-inflammatory cytokines from macrophages and lymphocytes. Mast cell–generated LTB₄ also may contribute significantly to T lymphocyte migration.

The CysLTs are chemotaxins for eosinophils and monocytes through activation of the CysLT₁ receptor. They also induce cytokine generation in eosinophils, mast cells, and dendritic cells. A distinct set of cytokines are produced through activation of mast cell CysLT₁ and CysLT₂. At higher concentrations, these LTs also promote eosinophil adherence, degranulation, cytokine or chemokine release, and oxygen radical formation. In addition, CysLTs contribute to
inflammation by increasing endothelial permeability, thus promoting migration of inflammatory cells to the site of inflammation.

Lipoxins have diverse effects on leukocytes, including activation of monocytes and macrophages and inhibition of neutrophil, eosinophil, and lymphocyte activation (McMahon and Godson, 2004). Both lipoxin A and B inhibit natural killer cell cytotoxicity.

**Smooth Muscle.** PGs also contract or relax smooth muscles in tissues outside the vasculature. The LTs contract most smooth muscles.

**Bronchial and Tracheal Muscle.** In general, TxA$_2$, PGF$_{2\alpha}$, and PGD$_2$ contract, and PGE$_2$ and PGI$_1$ relax, bronchial and tracheal muscle. PGD$_2$ appear to be the primary bronchoconstrictor prostaglandin of relevance in humans. Roughly 10% of people given aspirin or tNSAIDs develop bronchospasm. This appears attributable to a shift in AA metabolism to LT formation, as reflected by an increase in urinary LTE$_4$ in response to aspirin challenge in such individuals. This substrate diversion appears to involve COX-1; such patients do not develop bronchospasm when treated with selective inhibitors of COX-2. The CysLTs are bronchoconstrictors in many species, including humans (Brink et al., 2003). These LTs act principally on smooth muscle in the airways and are a thousand times more potent than histamine both in vitro and in vivo. They also stimulate bronchial mucus secretion and cause mucosal edema.

PGI$_1$ causes bronchodilation in most species; human bronchial tissue is particularly sensitive, and PGI$_2$ antagonizes bronchoconstriction induced by other agents.

**Uterus.** Strips of nonpregnant human uterus are contracted by PGF$_{2\alpha}$ and TxA$_2$, but are relaxed by PGEs. Sensitivity to the contractile response is most prominent before menstruation, whereas relaxation is greatest at midcycle. Uterine strips obtained at hysterectomy from pregnant women are contracted by PGF$_{2\alpha}$ and by low concentrations of PGE$_2$. PGE$_2$, together with oxytocin, is essential for the onset of parturition. PGI$_1$ and high concentrations of PGE$_2$ produce relaxation. The intravenous infusion of PGE$_2$ or PGF$_{2\alpha}$ to pregnant women produces a dose-dependent increase in uterine tone and in the frequency and intensity of rhythmic uterine contractions. PGEs and PGFs are used to terminate pregnancy. Uterine responsiveness to PGs increases as pregnancy progresses but remains smaller than the response to oxytocin.

**Gastrointestinal Muscle.** PGEs and PGFs stimulate contraction of the main longitudinal muscle from stomach to colon. PG endoperoxides, TxA$_2$, and PGI$_1$ also produce contraction but are less active. Circular muscle generally relaxes in response to PGE$_2$ and contracts in response to PGF$_{2\alpha}$. The LTs have potent contractile effects. PGs reduce transit time in the small intestine and colon. Diarrhea, cramps, and reflux of bile have been noted in response to oral PGE$_2$; these are common side effects (along with nausea and vomiting) in patients given PGs for abortion. PGs and PGFs stimulate the movement of water and electrolytes into the intestinal lumen. Such effects may underlie the watery diarrhea that follows their oral or parenteral administration. By contrast, PGI$_1$ does not induce diarrhea; indeed, it prevents that provoked by other PGs.

PGE$_2$ appears to contribute to the water and electrolyte loss in cholera, a disease that is somewhat responsive to therapy with tNSAIDs.

**Gastric and Intestinal Secretions.** In the stomach, PGE$_2$ and PGI$_1$ contribute to increased mucus secretion (cytoprotection), reduced acid secretion, and reduced pepsin content. These effects result from their vasodilatory properties and probable direct effects on secretory cells. PGE$_2$ and its analogs also inhibit gastric damage caused by a variety of ulcerogenic agents and promote healing of duodenal and gastric ulcers (see Chapter 45). Although COX-1 may be the dominant source of such cytoprotective PGs under physiological conditions, COX-2 predominates during ulcer healing. Selective inhibitors of COX-2 and deletion of the enzyme delay ulcer healing in rodents, but the impact of COX-2 inhibitors in humans is unclear. CysLTs, by constricting gastric blood vessels and enhancing production of pro-inflammatory cytokines, may contribute to the gastric damage.

**Kidney.** Renal prostanoids, especially PGE$_2$ and PGI$_2$, but also PGF$_{2\alpha}$ and TxA$_2$, perform complex and intricate functions in the kidney (Hao and Breyer, 2007). Both the renal medulla and cortex synthesize prostanoids, although substantially more are generated in the medulla. COX-2-derived PGE$_2$ and PGI$_2$ increase medullary blood flow and inhibit tubular sodium reabsorption. Expression of medullary COX-2 is increased during high salt intake. COX-1-derived products promote salt excretion in the collecting ducts. Cortical COX-2-derived PGE$_2$ and PGI$_2$ increase renal blood flow and glomerular filtration through their local vasodilating effects, actions that may be particularly relevant to maintaining renal function in marginally functioning kidneys and volume-contracted states. An added layer of complexity is evident from the increased expression of cortical COX-2 expression during low dietary salt intake. Through the action of PGE$_2$ and also possibly PGI$_2$, this results in increased renin release, leading to sodium retention and elevated blood pressure.

TxA$_2$, generated at low levels in the normal kidney, has potent vasoconstrictor effects that reduce renal blood flow and glomerular filtration rate. Infusion of PGF$_{2\alpha}$ causes both natriuresis and diuresis. Conversely, PGF$_{2\alpha}$ may activate the renin–angiotensin system, contributing to elevated blood pressure.

There is substantial evidence for a role of the CYP epoxygenase products in regulating renal function, although their exact role in the human kidney remains unclear. Both 20-HETE and the EETs are generated in renal tissue. 20-HETE constricts the renal arteries, while EETs mediate vasodilation and natriuresis.

**Eye.** Although PGF$_{2\alpha}$ induces constriction of the iris sphincter muscle, its overall effect in the eye is to decrease intraocular pressure (IOP) by increasing the
aqueous humor outflow of the eye via the uveoscleral and trabecular meshwork pathway. A variety of FP receptor agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (see Chapter 64).

**CNS.** Although effects have been reported following injection of several PGs into discrete brain areas, the best established biologically active mediators are PGE₂ and PGD₂. The induction of fever by a range of endogenous and exogenous pyrogens appears to be mediated by PGE₂ (Smyth and FitzGerald, 2009). The hypothalamus regulates the body temperature set point, which is elevated by endogenous pyrogens such as interleukin (IL)-1β, IL-6, tumor necrosis factor-α (TNF-α), and interferons. The initial phase of the thermoregulatory response to pyrogens is thought to be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus, while the late response is mediated by coordinate induction of COX-2 and mPGES-1 in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE₂. PGE₂ can cross the blood-brain barrier and acts on EP₃, and perhaps EP₁, on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. Exogenous PGF₂α and PGI₂ induce fever but do not contribute to the pyretic response. PGD₂ and TxA₂ do not induce fever. PGD₂ also appears to act on arachnoid trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep.

COX-2-derived prostanoids also have been implicated in several CNS degenerative disorders (e.g., Alzheimer’s disease, Parkinson disease; see Chapter 22), although the therapeutic efficacy of blocking their synthesis or action remains to be established.

**Pain.** Inflammatory mediators, including LTs and PGs, increase the sensitivity of nociceptors and potentiate pain perception. Both PGE₂, through the EP₁ and EP₄, and PGI₂, via the IP, reduce the threshold to stimulation of nociceptors, causing “peripheral sensitization”. Centrally, both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli. PGE₂, and perhaps also PGD₂, PGI₂, and PGF₂α, can increase excitability in pain transmission neuronal pathways in the spinal cord, causing hyperalgesia and allodynia. Hyperalgesia also is produced by LTB₄. The release of these eicosanoids during the inflammatory process thus serves as an amplification system for the pain mechanism. The role of PGE₂ and PGI₂ in inflammatory pain is discussed in more detail in Chapter 34.

**Endocrine System.** A number of endocrine tissues respond to PGs. In several species, the systemic administration of PGE₂ increases circulating concentrations of adrenocorticotropic hormone (ACTH), growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and thyrotropin-like effects on the thyroid. The critical role of PGF₂α in parturition relies on its ability to induce an oxytocin-dependent decline in progesterone levels. PGE₂ works as part of a positive-feedback loop to induce oocyte maturation required for fertilization during and after ovulation.

LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by AngII, but not that which occurs in response to ACTH.

**Bone.** PGs are strong modulators of bone metabolism. COX-1 is expressed in normal bone, while COX-2 is upregulated in certain settings, such as inflammation and during mechanical stress. PGE₂ stimulates bone formation by increasing osteoblastogenesis. Bone resorption also is mediated via PGE₂ through activation of osteoclasts.

**Therapeutic Uses**

**Inhibitors and Antagonists.** As a consequence of the important and diverse physiological roles of eicosanoids, mimicking their effects with stable agonists, inhibiting eicosanoid formation, and antagonizing eicosanoid receptors produce therapeutically useful responses. As outlined earlier in “Inhibitors of Eicosanoid Biosynthesis” and in Chapter 34, the nonselective tNSAIDs, and those with selective COX-2 inhibition, are used widely as anti-inflammatory drugs, whereas low-dose aspirin is employed frequently for cardioprotection. LT antagonists are useful clinically in the treatment of asthma, and FP agonists are used in the treatment of open-angle glaucoma (Chapter 64). EP agonists are used to induce labor and to ameliorate gastric irritation owing to tNSAIDs.

There are as of yet no potent selective antagonists of prostanoid receptors in clinical use. TP antagonists were abandoned as antiplatelet agents when it seemed like they would confer nothing superior to aspirin. Now that the clinical implications of suppressing PGI₂ are recognized, the partial suppression by even low doses of aspirin may confer an advantage on TP antagonists, as may blockade of receptor activation by unconventional
ligands such as oxidized lipids. DP₄ antagonists may be useful in offsetting the facial flushing associated with niacin. Orally active antagonists of LTC₄ and D₄, which block the CysLT₁ receptor, are used in the treatment of mild to moderately severe asthma (see Chapter 36). Their effectiveness in patients with aspirin-induced asthma also has been shown.

The use of eicosanoids or eicosanoid derivatives themselves as therapeutic agents is limited in part because systemic administration of prostanoids frequently is associated with significant adverse effects and because of their short t½ in the circulation. Despite these limitations, however, several prostanoids are of clinical utility in the following situations.

**Therapeutic Abortion.** The ability of PGEs, PGFs, and their analogs, to terminate pregnancy at any stage by promoting uterine contractions has been adapted to common clinical use. When given early in pregnancy, their action as abortifacients may be variable and often incomplete and accompanied by adverse effects. PGs appear, however, to be of value in missed abortion and molar gestation, and they have been used widely for the induction of midterm abortion. Dinoprostone, a synthetic preparation of PGE₂, is approved for inducing abortion in the second trimester of pregnancy, for missed abortion, for cervical ripening prior to induction of labor, and for managing benign hydatidiform moles. Several studies have shown that systemic or intravaginal administration of the PGE₂ analog misoprostol in combination with mifepristone (RU486) or methotrexate is highly effective in the termination of early pregnancy. An analog of PGF₂α, carboprost tromethamine, is used to induce second-trimester abortions and to control postpartum hemorrhage that is not responding to conventional methods. PGE₂ or PGF₂α can induce labor at term. However, they may have more value when used to facilitate labor by promoting ripening and dilation of the cervix.

**Gastric Cytoprotection.** The capacity of several PG analogs to suppress gastric ulceration is a property of therapeutic importance. Misoprostol (CYTOTEC), a PGE₁ analog, is approved for prevention of NSAID-induced gastric ulcers. It is about as effective as the proton pump inhibitor omeprazole (Chapter 45).

**Impotence.** PGE₁ (alprostadil), given as an intracavernous injection (CAVERJECT, EDEX) or urethral suppository (MUSE) is a second-line treatment of erectile dysfunction. The erection lasts for 1-3 hours and is sufficient for sexual intercourse. PGE₁ has been superseded largely by the use of phosphodiesterase 5 (PDE5) inhibitors, such as sildenafil, tadalafil, and vardenafil (see Chapters 27 and 28).

**Maintenance of Patent Ductus Arteriosus.** The ductus arteriosus in neonates is highly sensitive to vasodilation by PGE₂. Maintenance of a patent ductus may be important hemodynamically in some neonates with congenital heart disease. PGE₂ (alprostadil, PROSTIN VR PEDIATRIC) is highly effective for palliative, but not definitive, therapy to maintain temporary patency until surgery can be performed. Apnea is observed in ~10% of neonates treated, particularly those who weigh <2 kg at birth.

**Pulmonary Hypertension.** Primary pulmonary hypertension is a rare idiopathic disease that mainly affects young adults. It leads to right-sided heart failure and frequently is fatal. Long-term therapy with PGI₂ (prostacyclin; epoprostenol, FLOLAN), via continuous intravenous infusion, improves symptoms and can delay or preclude the need for lung or heart-lung transplantation in a number of patients. Epoprostenol also has been used successfully to treat portopulmonary hypertension that arises secondary to liver disease, again with a goal of facilitating ultimate transplantation (Krowka et al., 1999). Several PGI₂ analogs with longer t½ have been developed and used clinically. Iloprost can be inhaled (VENTAVIS) or delivered by intravenous administration (not available in the U.S.). Treprostinil (REMODULN) (t½ ~4 hours) may be delivered by continuous subcutaneous or intravenous infusion.

**Glaucoma.** Latanoprost, a stable, long-acting PGF₂α derivative, was the first prostanoid used for glaucoma. The success of latanoprost has stimulated development of similar prostanoids with ocular hypotensive effects, and bimatoprost and travoprost are now available. These drugs act as agonists at the FP receptor and are administered as ophthalmic drops (Chapter 64).

**PLATELET-ACTIVATING FACTOR**

**History.** In 1971, Henson demonstrated that a soluble factor released from leukocytes caused platelets to aggregate. Benveniste and his coworkers characterized the factor as a polar lipid and named it *platelet-activating factor*. During this period, Muirhead described an antihypertensive polar renal lipid (APRL) produced by interstitial cells of the renal medulla that proved to be identical to PAF. Hanahan and coworkers then synthesized acetyl glyceryl ether phosphorylcholine (AGEPC) and determined that this phospholipid had chemical and biological properties identical to those of PAF. Independent determination of the structures of PAF and APRL showed them to be structurally identical to AGEPC. The commonly accepted name for this substance is platelet-activating factor; however, its actions extend far beyond platelets.

**Chemistry and Biosynthesis.** PAF is 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine.

\[
\begin{align*}
\text{CH}_3 - \text{C} & - \text{O} - (\text{CH}_2)_{n} - \text{CH}_3 \\
\text{O} & - \text{CH}_2 - \text{O} - \text{CH}_2 - \text{CH}_2 - \text{N} - \text{CH}_3 \\
\text{CH}_3 & \\
\text{O} & \\
\end{align*}
\]

PAF contains a long-chain alkyl group joined to the glycerol backbone in an ether linkage at position 1 and an acetyl group at position 2. PAF actually represents a family of phospholipids because the alkyl group at position 1 can vary in length from 12-18 carbon atoms. In human neutrophils, PAF consists predominantly of a mixture of the 16- and 18-carbon ethers, but its composition may change when cells are stimulated. The family is expanded by unregulated oxidative production to PAF-like lipids whose mode of action is analogous to PAF (Stafforini et al., 2003).
Analogous to the eicosanoids, PAF is not stored in cells but is synthesized in response to stimulation. The major pathway, termed the remodeling pathway, of PAF generation involves the precursor 1-O-alkyl-2-acyl-glycerophosphocholine, a lipid found in high concentrations in the membranes of many types of cells. The 2-acyl substituents include AA. PAF is synthesized from this substrate in two steps (Figure 33–5). The first involves the action of PLA₂, the initiating enzyme for eicosanoid biosynthesis, with the formation of 1-O-alkyl-2-lyso-glycerophosphocholine (lyso-PAF) and a free fatty acid (usually AA) (Prescott et al., 2000; Honda et al., 2002; Stafforini et al., 2003). Eicosanoid and PAF biosynthesis thus is closely coupled, and deletion of cPLA₂ in mice leads to an almost complete loss of both eicosanoid and PAF generation. The second, rate-limiting step is performed by the acetyl-coenzyme-A-lyso-PAF acetyltransferase. This pathway may contribute to physiological levels of PAF for normal cellular functions. The synthesis of PAF may be stimulated during antigen–antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. Both the phospholipase and acetyltransferase are Ca²⁺-dependent enzymes; thus, PAF synthesis is regulated by the availability of Ca²⁺.

The inactivation of PAF is catalyzed by PAF acetylhydrolases (PAF-AHs) (McIntyre et al., 2009) (Figure 33–5). This is a family of four related Ca²⁺-independent phospholipases A₂ that show marked specificity for phospholipids with short acyl chains at the sn-2 position. Two PAF-AHs, which are group VII enzymes, are commonly known as plasma PAF-AH (or lipoprotein-associated PLA₂) and liver type II PAF-AH. The remaining two are known as type I and II intracellular PAF-AH. PAF is inactivated by PAF-AH-catalyzed hydrolysis of the acetyl group, generating Lyso-PAF, which is then converted to a 1-O-alkyl-2-acyl-glycerophosphocholine by an acyltransferase.

PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. Depending on cell type, PAF can either remain cell associated or be secreted. For example, PAF is released from monocytes but retained by leukocytes and endothelial cells. In endothelial cells, PAF is displayed on the surface for juxtagrane signaling and stimulates adherent leukocytes (Honda et al., 2002).

In addition to these enzymatic routes, PAF-like molecules can be formed from the oxidative fragmentation of membrane phospholipids (oxPLs) (Stafforini et al., 2003). These compounds are increased in settings of oxidant stress, such as cigarette smoking, and differ structurally from PAF in that they contain a fatty acid at the sn-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the sn-2 position. oxPLs mimic the structure of PAF closely enough to bind to its receptor (see “Mechanism of Action of PAF”) and elicit the same responses. Unlike the synthesis of PAF, which is highly controlled, oxPL production is unregulated; degradation by PAF-AH, therefore, is necessary to suppress the toxicity of oxPLs. Levels of plasma PAF-AH are increased in colon cancer, cardiovascular disease, and stroke (Prescott et al., 2002), and polymorphisms have been associated with altered risk of cardiovascular events (Ninio et al., 2004). A common missense mutation in Japanese people is associated disproportionately with more severe asthma.

**Mechanism of Action of PAF.** Extracellular PAF exerts its actions by stimulating a specific GPCR (Honda et al., 2002). The PAF receptor’s strict recognition requirements, including a specific head group and specific atypical sn-2 residue, also are met by oxPLs. The PAF receptor couples to activation of the PLC-IP₃–Ca²⁺ pathway and to inhibition of adenyl cyclase, via G_q and G₁ respectively. Activation of phospholipases A₂, C, and D give rise to second messengers. These include AA-derived PGs, TxA₂, or LTs, which may function as extracellular mediators of the effects of PAF. In addition, p38 MAP kinase is activated downstream of PAF-receptor coupling to G_q, while ERK activation can occur through a number of pathways, including coupling to G_s, G₃, or G₁₀ or via transactivation of the epidermal growth factor receptor, leading to NF-κB activation (Stafforini et al., 2003). Thus, the PAF receptor couples to a variety of downstream signaling cascades in a cell-dependent manner.

PAF exerts many of its important pro-inflammatory actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, polymorphonuclear leukocytes, and monocytes, and acts cooperatively with P selectin to promote adhesion (Prescott et al., 2000). This function of PAF is important for orchestrating the interaction of platelets and circulating inflammatory cells with the inflamed endothelium.

![Figure 33–5. Synthesis and degradation of platelet-activating factor (PAF).](image-url)
Physiological and Pathological Functions of PAF. PAF generally is viewed as a mediator of pathological events and has been implicated in allergic asthma, endotoxic shock, acute pancreatitis, certain cancers, dermal inflammation, and inflammatory cardiovascular diseases such as atherosclerosis. Dysregulation of PAF signaling or degradation has been associated with some human diseases, aided by data from genetically modified animals.

Reproduction and Parturition. A role for PAF in ovulation, implantation, and parturition has been suggested by numerous studies. However, PAF receptor–deficient mice are normal reproductively, indicating that PAF may not be essential for reproduction.

Inflammatory and Allergic Responses. The pro-inflammatory actions of PAF, and its elaboration by endothelial cells, leukocytes, and mast cells under inflammatory conditions, are well characterized. The plasma concentration of PAF is increased in experimental anaphylactic shock, and the administration of PAF reproduces many of its signs and symptoms, suggesting a role for the autacoid in anaphylactic shock. Indeed, studies with PAF receptor–deficient mice confirm the actions of PAF, and PAF-like molecules, as dominant anaphylactic mediators. In addition, mice overexpressing the PAF receptor exhibit bronchial hyperreactivity and increased lethality when treated with endotoxin (Ishii et al., 2002). PAF-receptor knockout mice display milder anaphylactic responses to exogenous antigen challenge, including less cardiac instability, airway constriction, and alveolar edema; they are, however, still susceptible to endotoxic shock. Deletion of the PAF receptor augments the lethality of infection with gram-negative bacteria while improving host defense against gram-positive pneumococcal pneumonia. PAF receptor-overexpressing mice show increased airway responsiveness when challenged, an effect likely mediated through generation of TxA2 and CysLTs (Ishii and Shimizu, 2000). PAF-AH deficiency is associated with asthma in some populations (Stafforini, 2009).

Despite the broad implications of these observations, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. Although PAF antagonists reverse the bronchoconstriction of anaphylactic shock and improve survival in animal models, the impact of these agents on animal models of asthma and inflammation is marginal. Similarly, in patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air. These results may reflect the complexity of these pathological conditions and the likelihood that other mediators contribute to the inflammation associated with these disorders.

Cardiovascular System. PAF is a potent vasodilator in most vascular beds; when administered intravenously, it causes hypotension in all species studied. PAF-induced vasodilation is independent of effects on sympathetic innervation, the renin–angiotensin system, or arachidonate metabolism and likely results from a combination of direct and indirect actions. PAF may, alternatively, induce vasoconstriction depending on the concentration, vascular bed, and involvement of platelets or leukocytes. For example, the intracoronary administration of very low concentrations of PAF increases coronary blood flow by a mechanism that involves the release of a platelet-derived vasodilator. Coronary blood flow is decreased at higher doses by the formation of intravascular aggregates of platelets and/or the formation of TxA2. The pulmonary vasculature also is constricted by PAF, and a similar mechanism is thought to be involved.

Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema in the same manner as histamine and bradykinin. The increase in permeability is due to contraction of venular endothelial cells, but PAF is more potent than histamine or bradykinin by three orders of magnitude.

Platelets. The PAF receptor is constitutively expressed on the surface of platelets. PAF potently stimulates platelet aggregation in vitro and in vivo. Although this is accompanied by the release of TxA2 and the granular contents of the platelet, PAF does not require the presence of TxA2 or other aggregating agents to produce this effect. The intravenous injection of PAF causes formation of intravascular platelet aggregates and thrombocytopenia.

Because PAF is synthesized by platelets and promotes aggregation, it was proposed as the mediator of COX-inhibitor-resistant, thrombin-induced aggregation. However, no bleeding or thrombotic phenotypes have been associated with deletion of the PAF receptor. In addition, PAF antagonists fail to block thrombin-induced aggregation, even though they prolong bleeding time and prevent thrombus formation in some experimental models. Thus, PAF may contribute to thrombus formation, but it does not function as an independent mediator of platelet aggregation.

Leukocytes. PAF is a potent and common activator of inflammatory cells, providing a point of convergence between the hemostatic and innate immune systems (Zimmerman et al., 2002). PAF stimulates a variety of responses in polymorphonuclear leukocytes (eosinophils, neutrophils, and basophils) when it is generated in both physiological and pathological situations. PAF stimulates PMNs to aggregate, degranulate, and generate free radicals and LTs. Because LTB4 is more potent in inducing leukocyte aggregation, it may mediate the aggregatory effects of PAF. PAF is a potent chemotactic for eosinophils, neutrophils, and monocytes and promotes PMN-endothelial adhesion contributing, along with other adhesion molecular systems, to leukocyte rolling, tight adhesion, and migration through the endothelial monolayer. PAF also stimulates basophils to release histamine, activates mast cells, and induces cytokine release from monocytes. In addition, PAF promotes aggregation of monocytes and degranulation of eosinophils. When given systemically, PAF causes leukocytopenia, with neutrophils showing the greatest decline. Intradermal injection causes the accumulation of neutrophils and mononuclear cells at the site of injection. Inhaled PAF increases the infiltration of eosinophils into the airways.

Smooth Muscle. PAF generally contracts GI, uterine, and pulmonary smooth muscle. PAF enhances the amplitude of spontaneous uterine contractions; quiescent muscle contracts rapidly in a phasic fashion. These contractions are inhibited by inhibitors of PG synthesis. PAF does not affect tracheal smooth muscle but contracts airway smooth muscle. Most evidence suggests that another autacoid (e.g., LTC4 or TxA2) mediates this effect of PAF. When given by aerosol, PAF increases airway resistance as well as the responsiveness to other bronchoconstrictors. PAF also increases mucus secretion and the permeability of pulmonary microvessels; this results in fluid accumulation in the mucosal and submucosal regions of the bronchi and trachea.
**Stomach.** In addition to contracting the fundus of the stomach, PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

**Kidney.** When infused intrarenally in animals, PAF decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na⁺ without changes in systemic hemodynamics (Lopez-Novoa, 1999). These effects are the result of a direct action on the renal circulation. PAF exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

**arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.**

**Other.** PAF receptor-overexpressing mice spontaneously develop melanocyte tumors. PAF, a potent mediator of angiogenesis, also has been implicated in breast and prostate cancer. PAF-AH deficiency has been associated with small increases in a range of cardiovascular and thrombotic diseases in some human populations (Stafforini, 2009). Administration of PAF-AH reduces injury-induced neointima formation and atherogenesis in genetically prone mice, suggesting a role for PAF in inflammatory cardiovascular disease.

**Receptor Antagonists.** Several experimental PAF-receptor antagonists exist that selectively inhibit the actions of PAF in vivo and in vitro. One would expect a PAF-receptor antagonist to be a potent anti-inflammatory agent that might be useful in the therapy of disorders such as asthma, sepsis, and other diseases in which PAF is postulated to play a role. However, trials in humans have been disappointing, and the clinical efficacy of PAF antagonists has yet to be realized. Plasma PAF-AH activity modulates the acute and chronic inflammatory response in animal models, indicating that it may provide an alternative inflammatory drug target. However, humans that are homozygous for a mutant PAF-AH, leading to undetectable levels of plasma PAF-AH, do not display rampant inflammation (McIntyre et al., 2009), and thus far, PAF-AH has not been translated into a meaningful therapeutic approach.

**BIBLIOGRAPHY**

This chapter describes the nonsteroidal anti-inflammatory drugs (NSAIDs) used to treat inflammation, pain, and fever and the drugs used for hyperuricemia and gout.

Most currently available traditional NSAIDs (tNSAIDs) act by inhibiting the prostaglandin (PG) G/H synthase enzymes, colloquially known as the cyclooxygenases (COXs; see Chapter 33). The inhibition of cyclooxygenase-2 (COX-2) is thought to mediate, in large part, the antipyretic, analgesic, and anti-inflammatory actions of tNSAIDs, while the simultaneous inhibition of cyclooxygenase-1 (COX-1) largely but not exclusively accounts for unwanted adverse effects in the GI tract. Selective inhibitors of COX-2 (celecoxib, etoricoxib, lumiracoxib) are a subclass of NSAIDs that are also discussed. Aspirin, which irreversibly acetylates COX, is discussed, along with several structural subclasses of tNSAIDs, including propionic acid derivatives (ibuprofen, naproxen), acetic acid derivatives (indomethacin), and enolic acids (piroxicam), all of which compete in a reversible manner with the arachidonic acid (AA) substrate at the active site of COX-1 and COX-2. Acetaminophen (paracetamol) is a weak anti-inflammatory drug; it is effective as an antipyretic and analgesic agent at typical doses that partly inhibit COXs. Acetaminophen has fewer GI side effects than the tNSAIDs.

**History.** The history of aspirin provides an interesting example of the translation of a compound from the realm of herbal folklore to contemporary therapeutics. The use of willow bark and leaves to relieve fever has been attributed to Hippocrates but was most clearly documented by Edmund Stone in a 1763 letter to the president of the Royal Society. Similar properties were attributed to potions from meadowsweet (*Spiraea ulmaria*), from which the name aspirin is derived. Saflacin was crystallized in 1829 by Leroux, and Pina isolated salicylic acid in 1836. In 1859, Kolbe synthesized salicylic acid, and by 1874, it was being produced industrially. It soon was being used for rheumatic fever, gout, and as a general antipyretic. However, its unpleasant taste and adverse GI effects made it difficult to tolerate for more than short periods. In 1899, Hoffmann, a chemist at Bayer Laboratories, sought to improve the adverse-effect profile of salicylic acid (which his father was taking with difficulty for arthritis). Hoffmann came across the earlier work of the French chemist, Gerhardt, who had acetylated salicylic acid in 1853, apparently ameliorating its adverse-effect profile, but without improving its efficacy, and therefore abandoned the project. Hoffmann resumed the quest, and Bayer began testing acetylsalicylic acid (ASA) in animals by 1899—the first time that a drug was tested on animals in an industrial setting—and proceeded soon thereafter to human studies and the marketing of aspirin.

Acetaminophen was first used in medicine by von Mering in 1893. However, it gained popularity only after 1949, when it was recognized as the major active metabolite of both acetanilide and phenacetin. Acetanilide is the parent member of this group of drugs. It was introduced into medicine in 1886 under the name antifebrin by Cahn and Hepp, who had discovered its antipyretic action accidentally. However, acetanilide proved to be excessively toxic. A number of chemical derivatives were developed and tested. One of the more satisfactory of these was phenacetin. It was introduced into therapy in 1887 and was extensively employed in analgesic mixtures until it was implicated in analgesic-abuse nephropathy, hemolytic anemia, and bladder cancer; it was withdrawn in the 1980s. Discussion of its pharmacology can be found in earlier editions of this textbook.

**Inflammation, Pain, and Fever**

**Inflammation.** The inflammatory process is the response to an injurious stimulus. It can be evoked by a wide variety of noxious agents (e.g., infections, antibodies, physical injuries). The ability to mount an inflammatory response is essential for survival in the
face of environmental pathogens and injury; in some situations and diseases, the inflammatory response may be exaggerated and sustained without apparent benefit and even with severe adverse consequences. No matter what the initiating stimulus, the classic inflammatory symptoms include calor (warmth), dolor (pain), rubor (redness), and tumor (swelling). The inflammatory response is characterized mechanistically by a transient local vasodilation and increased capillary permeability, infiltration of leukocytes and phagocytic cells, and tissue degeneration and fibrosis.

Many molecules are involved in the promotion and resolution of the inflammatory process (Nathan, 2002). Histamine was one of the first identified mediators of the inflammatory process. Although several H1 histamine receptor antagonists are available, they are useful only for the treatment of vascular events in the early transient phase of inflammation (see Chapter 32). Bradykinin and 5-hydroxytryptamine (serotonin, 5-HT) also may play a role, but their antagonists ameliorate only certain types of inflammatory response (see Chapter 32). Leukotrienes (LTs) exert pro-inflammatory actions and LT-receptor antagonists (montelukast and zafirlukast) have been approved for the treatment of asthma (see Chapters 33 and 36). Another lipid autacoid, platelet-activating factor (PAF), has been implicated as an important mediator of inflammation; however, inhibitors of PAF synthesis and PAF-receptor antagonists have proven disappointing in the treatment of inflammation (see Chapter 33).

Prostanoid biosynthesis is significantly increased in inflamed tissue. Inhibitors of the COXs, which depress prostanoid formation, are effective and widely used anti-inflammatory agents, highlighting the general role of prostanoids as pro-inflammatory mediators. The rapid induction of COX-2 in inflamed tissue and infiltrating cells provided a rationale for the development of selective COX-2 inhibitors for treatment of inflammation (see Chapter 33). Although COX-2 is the major source of pro-inflammatory prostanooids, COX-1 also contributes (McAdam et al., 2000). Both COX isozymes are expressed in circulating inflammatory cells \textit{ex vivo}, and COX-1 accounts for 10-15\% of the PG formation induced by lipopolysaccharide in volunteers. Impaired inflammatory responses have been reported in both COX-1- and COX-2-deficient mouse models, although they diverge in time course and intensity (Langenbach et al., 1999; Ballou et al., 2000; Yu et al., 2005). Human data are compatible with the concept that COX-1-derived products play a dominant role in the initial phase of an acute inflammatory response, while COX-2 is upregulated within several hours.

Prostaglandin E2 (PGE2) and prostacyclin (PGI2) are the primary prostanoids that mediate inflammation. They increase local blood flow, vascular permeability, and leukocyte infiltration through activation of their respective receptors, EP2 and IP (see Table 33–1 and Figure 33–4). PGD2, a major product of mast cells, contributes to inflammation in allergic responses, particularly in the lung. Activation of its DP1 receptor increases perfusion and vascular permeability and promotes T\textsubscript{H}2 cell differentiation. PGD2 also can activate mature T\textsubscript{H}2 cells and eosinophils via its DP3 receptor (Pettipher et al., 2007). DP3 antagonists may prove useful in the treatment of airway inflammation.

Activation of endothelial cells plays a key role in “targeting” circulating cells to inflammatory sites. Cell adhesion occurs by recognition of cell-surface glycoproteins and carbohydrates on circulating cells due to the augmented expression of adhesion molecules on resident cells. Thus, endothelial activation results in leukocyte adhesion as the leukocytes recognize newly expressed L- and P-selectin; other important interactions include those of endothelial-expressed E-selectin with sialylated Lewis X and other glycoproteins on the leukocyte surface and endothelial intercellular adhesion molecule (ICAM)-1 with leukocyte integrins.

The recruitment of inflammatory cells to sites of injury also involves the concerted interactions of several types of soluble mediators. These include the complement factor C5a, PAF, and the eicosanoid LTB4 (see Chapter 33). All can act as chemotactic agonists. Several cytokines also play essential roles in orchestrating the inflammatory process, especially tumor necrosis factor (TNF) (Dempsey et al., 2003) and interleukin-1 (IL-1) (O’Neill, 2008). They are secreted by monocytes, macrophages, adipocytes, and other cells. Working in concert with each other and various cytokines and growth factors (such as IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor [GM-CSF]; see Chapters 32, 33, and 35), they induce gene expression and protein synthesis—including expression of COX-2, adhesion molecules, and acute-phase proteins—in a variety of cells to mediate and promote inflammation.

TNF is composed of two closely related proteins: mature TNF (TNF-\alpha) and lymphotoxin (TNF-\beta), both of which are recognized by the TNF receptors, a 75-kd type 1 receptor and a 55-kd type 2 receptor (Dempsey et al., 2003). TNF-\alpha blockers (see Chapter 35) are used to treat inflammatory conditions, including rheumatoid arthritis, juvenile idiopathic arthritis, psoriasis and psoriatic arthritis, ankylosing spondylitis, and Crohn’s disease. TNF-\alpha blockers fall into the category of disease-modifying anti-rheumatic drugs (DMARDs) because they reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. NSAIDs generally are not considered DMARDs.
IL-1 comprises two distinct polypeptides (IL-1α and IL-1β) that bind to an 80-kd IL-1 receptor type 1 and a 68-kd IL-1 receptor type 2, which are present on different cell types (O’Neill, 2008). Plasma IL-1 levels are increased in patients with active inflammation. A naturally occurring IL-1 receptor antagonist (IL-1ra) competes with IL-1 for receptor binding and blocks IL-1 activity in vitro and in vivo. IL-1ra often is found in high levels in patients with various infections or inflammatory conditions and may act to limit the extent of an inflammatory response. Clinical studies suggest that the administration of a recombinant form of human IL-1ra (anakinra; see Chapter 35) antagonizes IL-1 action at its receptor and thereby inhibits the progression of structural damage associated with active rheumatoid arthritis and other inflammatory conditions. Canakinumab (ILARIS) is an IL-1β monoclonal antibody recently approved for two forms of the cryopyrin-associated periodic syndrome: familial cold auto-inflammatory syndrome and Muckle-Wells syndrome (see Chapter 35).

Other cytokines and growth factors (e.g., IL-2, IL-6, IL-8, GM-CSF) contribute to manifestations of the inflammatory response. The concentrations of many of these factors are increased in the synovia of patients with inflammatory arthritis. Glucocorticoids interfere with the synthesis and actions of cytokines, such as IL-1 or TNF-α (see Chapter 35). Although some of the actions of these cytokines are accompanied by the release of PGs and thromboxane A2 (TxA2), COX inhibitors appear to block only their pyrogenic effects. In addition, many of the actions of the PGs are inhibitory to the immune response, including suppression of the function of helper T cells and B cells and inhibition of the production of IL-1 (see Chapter 33). Other cytokines and growth factors counter the effects and initiate resolution of inflammation. These include transforming growth factor β1 (TGF-β1), which increases extracellular matrix formation and acts as an immunosuppressant; IL-10, which decreases cytokine and PGE2 formation by inhibiting monocytes; and interferon gamma (IFN-γ), which possesses myelosuppressive activity and inhibits collagen synthesis and collagenase production by macrophages.

Many cytokines, including IL-1 and TNF-α, have been found in the rheumatoid synovium. Rheumatoid arthritis appears to be an autoimmune disease driven largely by activated T cells, giving rise to T cell–derived cytokines, such as IL-1 and TNF-α. Activation of B cells and the humoral response also are evident, although most of the antibodies generated are immunoglobulins G of unknown specificity, apparently elicited by polyclonal activation of B cells rather than from a response to a specific antigen (Brennan and McInnes, 2008).

Pain. Nociceptors, peripheral terminals of primary afferent fibers that sense pain, can be activated by various stimuli, such as heat, acids, or pressure. Inflammatory mediators released from non-neuronal cells during tissue injury increase the sensitivity of nociceptors and potentiate pain perception. Some of the main components of this inflammatory “mélange” are bradykinin, H+, neurotransmitters such as serotonin and ATP, neutrophils (nerve growth factor), LTs, and PGs. Cytokines appear to liberate PGs and some of the other mediators. Neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP), also may be involved in eliciting pain (see Chapter 18).

PGE2 and PGI2 reduce the threshold to stimulation of nociceptors, causing peripheral sensitization (Lopshire and Nicol, 1998; Pulichino et al., 2006). Thus, PGE2 promotes—probably via its receptors, EP1 and EP4—the phosphorylation of transient receptor potential V1 and other ion channels on nociceptors and increases their terminal membrane excitability. Reversal of peripheral sensitization is thought to represent the mechanistic basis for the peripheral component of the analgesic activity of NSAIDs. NSAIDs also have important central actions in the spinal cord and brain. Both COX-1 and COX-2 are expressed in the spinal chord under basal conditions and release PGs in response to peripheral pain stimuli (Vanegas and Schaible, 2001). Centrally active PGE2 and perhaps also PGD2, PGI2, and PGF2α contribute to central sensitization, an increase in excitability of spinal dorsal horn neurons that causes hyperalgesia and allodynia in part by disinhibition of glycnergic pathways (Reinold et al., 2005).

Basal COX-2, expressed in both neurons and glia cells, contributes to central sensitization in the early phase of peripheral inflammation. COX-2 is upregulated widely in the spinal chord within a few hours to contribute to prolonged central sensitization (Samad et al., 2001). A role for COX-1 in nociception has been implicated by COX-1–deleted mice, which show increased tolerance to pain stimuli (Ballou et al., 2000). This isoform is predominant in neurons of dorsal root ganglia. Central sensitization reflects the plasticity of the nociceptive system that is invoked by injury. This usually is reversible within hours to days following adequate responses of the nociceptive system (e.g., postoperative pain). However, chronic inflammatory diseases may cause persistent modification of the architecture of the nociceptive system, which may lead to long-lasting changes in its responsiveness. These mechanisms contribute to chronic pain.

Fever. Regulation of body temperature requires a delicate balance between the production and loss of heat; the hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever, reflecting an infection, or resulting from tissue damage, inflammation, graft rejection, or malignancy. These conditions all enhance formation of cytokines such as IL-1β, IL-6, TNF-α, and interferons, which act as...
endogenous pyrogens. The initial phase of the thermoregulatory response to such pyrogens is thought to be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus (Sanchez-Alavez et al., 2006). The late response is mediated by coordinate induction of COX-2 and microsomal PGE synthase-1 (mPGES-1) in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE₂ (Engblom et al., 2003). PGE₂ can cross the blood-brain barrier and acts on EP₃ and perhaps EP₁ receptors on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. NSAIDs suppress this response by inhibiting PGE₂ synthesis.

**NONSTEROIDAL ANTI-INFLAMMATORY DRUGS**

NSAIDs traditionally are grouped by their chemical characteristics. Following the development of the selective COX-2 inhibitors, the classification into tNSAIDs, which inhibit both COX-1 and COX-2, and COX-2–selective NSAIDs, emerged. Initially, only agents designed specifically for the purpose of COX-2–selective inhibition—colloquially termed the coxibs—were attributed to the group of COX-2–selective NSAIDs. However, some older NSAIDs (e.g., diclofenac, meloxicam, nimesulide) show a degree of selectivity for COX-2 that is similar to that of the first coxib, celecoxib. Thus, these drugs might better be classified as COX-2–selective NSAIDs, although this is not, as yet, commonplace (Figure 34–1). Other classifications of NSAIDs were developed based on t₁/₂, such as those with a shorter (<6 hours) or longer (>10 hours) t₁/₂ (Figure 34–1).

Most NSAIDs are competitive, reversible, active site inhibitors of the COX enzymes. However, aspirin (ASA) acetylates the isozymes and inhibits them irreversibly; thus, aspirin often is distinguished from the tNSAIDs. Similarly, acetaminophen, which is antipyretic

**Figure 34–1.** Classification of NSAIDs by chemical similarity (panel A), cyclooxygenase (COX) isoform selectivity (panel B), and plasma t₁/₂ (panel C). The COX selectivity chart is plotted from data published in Warner et al., 1999, and FitzGerald and Patrono, 2001. tNSAIDs, traditional nonsteroidal anti-inflammatory drugs.
and analgesic but largely devoid of anti-inflammatory activity, also is conventionally segregated from the group, despite sharing many properties with tNSAIDs relevant to its clinical action in vivo.

**Chemistry.** NSAIDs are a chemically heterogeneous group of compounds, which nevertheless share certain therapeutic actions and adverse effects. The class includes derivatives of salicylic acid (e.g., aspirin, diflusinal), propionic acid (e.g., naproxen, ibuprofen, flurbiprofen, ketoprofen), acetic acid (e.g., indomethacin, etodolac, diclofenac, ketorolac), enolic acid (e.g., piroxicam, phenylbutazone), fenamic acid (e.g., mefenamic acid, meclofenamic acid), alkanones (nabumetone), and diaryl heterocyclic compounds (e.g., celecoxib, valdecoxib, rofecoxib, etoricoxib) (Figure 34–1).

The vast majority of tNSAID compounds are organic acids with relatively low $pK_a$ values (Figure 34–1). Even the non-acidic parent drug nabumetone is converted to an active acetic acid derivative in vivo. As organic acids, the compounds generally are well absorbed orally, highly bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, where the pH is lower, potentially confounding the relationship between plasma concentrations and duration of drug effect. Most COX-2–selective NSAIDs are diaryl heterocyclic compounds with a relatively bulky side group, which aligns with a large side pocket in the AA binding channel of COX-2 but hinders its optimal orientation in the smaller binding channel of COX-1 (Figure 34–2) (Smith et al., 2000). Both tNSAIDs and the COX-2–selective NSAIDs generally are hydrophobic drugs, a feature that allows them to access the hydrophobic arachidonate binding channel and results in shared pharmacokinetic characteristics. Again, aspirin and acetaminophen are exceptions to this rule.

**Mechanism of Action**

Cyclooxygenase Inhibition. The principal therapeutic effects of NSAIDs derive from their ability to inhibit PG production. The first enzyme in the PG synthetic pathway is COX, also known as PG G/H synthase. This enzyme converts AA to the unstable intermediates PGG$_2$ and PGH$_2$, and leads to the production of the prostanoids, TxA$_2$, and a variety of PGs (see Chapter 33).

There are two forms of COX, COX-1 and COX-2. COX-1, expressed constitutively in most cells, is the dominant (but not exclusive) source of prostanoids for housekeeping functions, such as gastric epithelial cytoprotection and hemostasis. Conversely, COX-2, induced by cytokines, shear stress, and tumor promoters, is the more important source of prostanoid formation in inflammation and perhaps in cancer (see Chapter 33). However, both enzymes contribute to the generation of autoregulatory and homeostatic prostanoids, and both can contribute to prostanoid formation in syndromes of human inflammation and pain (see “Inflammation and Pain” at the beginning of this chapter). Importantly, COX-1 is expressed as the dominant, constitutive isoform in gastric epithelial cells and is thought to be the major source of cytoprotective PG formation. Inhibition of COX-1 at this site is thought to account largely for the gastric adverse events that complicate therapy with tNSAIDs, thus providing the rationale for the development of NSAIDs specific for inhibition of COX-2 (FitzGerald and Patrono, 2001).

Aspirin and NSAIDs inhibit the COX enzymes and PG production; they do not inhibit the lipoxygenase (LOX) pathways of AA metabolism and hence do not suppress LT formation (see Chapter 33). Glucocorticoids suppress the induced expression of

![Figure 34–2. Structural basis for cyclooxygenase-2 (COX-2)-selective inhibition.](image-url)
COX-2, and thus COX-2–mediated PG production. They also inhibit the action of PLA₂, which releases AA from the cell membrane. These effects contribute to the anti-inflammatory actions of glucocorticoids (see Chapter 35).

At higher concentrations, NSAIDs also are known to reduce production of superoxide radicals, induce apoptosis, inhibit the expression of adhesion molecules, decrease NO synthase, decrease pro-inflammatory cytokines (e.g., TNF-α, IL-1), modify lymphocyte activity, and alter cellular membrane functions in vitro. However, there are differing opinions as to whether any of these actions might contribute to the anti-inflammatory activity of NSAIDs (Vane and Botting, 1998) at the concentrations attained during clinical dosing. The hypothesis that their anti-inflammatory actions in humans derive solely from COX inhibition alone has not been rejected based on current evidence.

Observational studies suggest that acetaminophen, which is a very weak anti-inflammatory agent at the typical dose of 1000 mg, is associated with a reduced incidence of GI adverse effects compared to tNSAIDs. At this dose, acetaminophen inhibits both COXs by ~50%. The ability of acetaminophen to inhibit the enzyme is conditioned by the pKα of the immediate environment (Boutaud et al., 2002). This may partly explain the poor anti-inflammatory activity of acetaminophen, because sites of inflammation usually contain increased concentrations of leukocyte-generated peroxides.

**Irreversible Cyclooxygenase Inhibition by Aspirin.** Aspirin covalently modifies COX-1 and COX-2, irreversibly inhibiting COX activity. This is an important distinction from all the NSAIDs because the duration of aspirin’s effects is related to the turnover rate of COXs in different target tissues. The duration of effect of non-aspirin NSAIDs, which inhibit the active sites of the COX enzymes competitively, relates to the time course of drug disposition. The importance of enzyme turnover in recovery from aspirin action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX-1 (COX-2 is expressed in megakaryocytes and perhaps immature platelet forms) last for the lifetime of the platelet. Inhibition of platelet COX-1–dependent TxA₂ formation therefore is cumulative with repeated doses of aspirin (at least as low as 30 mg/day) and takes ~8-12 days—the platelet turnover time—to recover fully once therapy has been stopped. Importantly, even a partially recovered platelet pool—just a few days after the last aspirin dose—may afford recovery of sufficient hemostatic integrity for some types of elective surgery to be performed. However, such a partial platelet function also may predispose noncompliant patients to thrombotic events.

COXs are configured such that the active site is accessed by the AA substrate via a hydrophobic channel. Aspirin acetylates serine 529 of COX-1, located high up in the hydrophilic channel. Interposition of the bulky acetyl residue prevents the binding of AA to the active site of the enzyme and thus impedes the ability of the enzyme to make PGs. Aspirin acetylates a homologous serine at position 516 in COX-2. Although covalent modification of COX-2 by aspirin also blocks the COX activity of this isoform, an interesting property not shared by COX-1 is that acetylated COX-2 synthesizes 15(R)-hydroxyicosatetraenoic acid [15(R)-HETE]. This may be metabolized, at least in vitro, by 5-LOX to yield 15-epi-lipoxin A₄, which has potent anti-inflammatory properties (see Chapter 33). Repeated doses of aspirin that acutely do not completely inhibit platelet COX-1–derived TxA₂ can exert a cumulative effect with complete blockade. This has been shown in randomized trials for doses as low as 30 mg/day. However, most of the clinical trials demonstrating cardioprotection from low-dose aspirin have used doses in the range of 75-81 mg/day.

The unique sensitivity of platelets to inhibition by such low doses of aspirin is related to their presystemic inhibition in the portal circulation before aspirin is deacetylated to salicylate on first pass through the liver (Pedersen and FitzGerald, 1984). In contrast to aspirin, salicylic acid has no acetylating capacity. It is a weak, reversible, competitive inhibitor of COX. Salicylic acid derivates, rather than the acid, are available for clinical use. The lack of acetylation often is used as justification to prefer trisalicylate or salsalate over aspirin in presurgical patients. High doses of salicylate inhibit the activation of NFκB in vitro, but the relevance of this property to the concentrations attained in vivo is not clear (Yin et al., 1998). Salicylic acid also may inhibit the expression of COX-2 by interfering with the binding of CCAAT/enhancer binding protein (C/EBP) β transcription factor to the COX-2 promoter (Cieslik et al., 2002). This was observed in vitro at concentrations of salicylic acid that are attained in humans.

**Selective Inhibition of Cyclooxygenase-2.** The therapeutic use of the tNSAIDs is limited by their poor GI tolerability. Chronic users are prone to experience GI irritation in ≤20% of cases. Following the discovery of COX-2, it was proposed that the constitutively expressed COX-1 was the predominant source of cytoprotective PGs formed by the GI epithelium. Because its expression is regulated by cytokines and mitogens, COX-2 was thought to be the dominant source of PG formation in inflammation and cancer. Thus, selective inhibitors of COX-2 were developed based on the hypothesis that they would afford efficacy similar to tNSAIDs with better GI tolerability (FitzGerald and Patrono, 2001). Six COX-2 inhibitors specifically designed for such purpose, the coxibs, were initially approved for use in the U.S. or E.U.: celecoxib, rofecoxib, valdecoxib and its prodrug parecoxib, etoricoxib, and lumiracoxib. Most coxibs have been either severely restricted in their use or withdrawn from the market in view of their adverse event profile. Celecoxib
(CELEBREX) currently is the only COX-2 inhibitor licensed for use in the U.S.

The relative degree of selectivity for COX-2 inhibition is lumiracoxib > etoricoxib > valdecoxib > rofecoxib > celecoxib (Figure 34–1). Although there were differences in relative hierarchies, depending on whether screens were performed using recombinantly expressed enzymes, cells, or whole-blood assays, most tNSAIDs expressed similar selectivity for inhibition of the two enzymes. Some compounds, conventionally thought of as tNSAIDs—diclofenac, meloxicam, and nimesulide (not available in the U.S.)—exhibit selectivity for COX-2 that is close to that of celecoxib in vitro (Figure 34–1) (Warner et al., 1999; FitzGerald and Patrono, 2001). Indeed, meloxicam achieved approval in some countries as a selective inhibitor of COX-2. Thus, selectivity for COX-2 should not be viewed as an absolute category; the isof orm selectivity for COX-2 (just like selectivity for β1 adrenergic receptors) is a continuous rather than a discreet variable, as illustrated in Figure 34–1.

Absorption, Distribution, and Elimination

Absorption. Most NSAIDs are rapidly absorbed following oral ingestion, and peak plasma concentrations usually are reached within 2-3 hours. All COX-2–selective NSAIDs are well absorbed, but peak concentrations are achieved with lumiracoxib and etoricoxib in ~1 hour compared to 2-4 hours with the other agents. The poor aqueous solubility of most NSAIDs often is reflected by a less than proportional increase in area under the curve (AUC) of plasma concentration–time curves, due to incomplete dissolution, when the dose is increased. Food intake may delay absorption and sometimes decreases systemic availability (i.e., fenoprofen, sulindac). Antacids, commonly prescribed to patients on NSAID therapy, variably delay, but rarely reduce, absorption. Most interaction studies performed with proton pump inhibitors suggest that relevant changes in NSAID kinetics are unlikely. Little information exists regarding the absolute oral bioavailability of many NSAIDs, as solutions suitable for intravenous administration often are not available. Some compounds (e.g., diclofenac, nabumetone) undergo first-pass or presystemic elimination. Acetaminophen is metabolized to a small extent during absorption. Aspirin begins to acetylate platelets within minutes of reaching the presystemic circulation.

Distribution. Most NSAIDs are extensively bound to plasma proteins (95-99%), usually albumin. Plasma protein binding often is concentration dependent (i.e., naproxen, ibuprofen) and saturable at high concentrations. Conditions that alter plasma protein concentration may result in an increased free drug fraction with potential toxic effects. Highly protein bound NSAIDs have the potential to displace other drugs, if they compete for the same binding sites. Most NSAIDs are distributed widely throughout the body and readily penetrate arthritic joints, yielding synovial fluid concentrations in the range of half the plasma concentration (i.e., ibuprofen, naproxen, piroxicam). Some substances yield synovial drug concentrations similar to (i.e., indomethacin), or even exceeding (i.e., tolmetin), plasma concentrations. Most NSAIDs achieve sufficient concentrations in the CNS to have a central analgesic effect. Celecoxib is particularly lipophilic, so it accumulates in fat and is readily transported into the CNS. Lumiracoxib is more acidic than other COX-2–selective NSAIDs, which may favor its accumulation at sites of inflammation. Multiple NSAIDs are marketed in formulations for topical application on inflamed or injured joints. However, direct transport of topically applied NSAIDs into inflamed tissues and joints appears to be minimal, and detectable concentrations in synovial fluid of some agents (i.e., diclofenac) following topical use are primarily attained via dermal absorption and systemic circulation.

Elimination. Plasma t1/2 varies considerably among NSAIDs. For example, ibuprofen, diclofenac, and acetaminophen have relatively rapid elimination (t1/2 of 1-4 hours), while piroxicam has a t1/2 of ~50 hours at steady state that can increase to up to 75 hours in the elderly. Published estimates of the t1/2 of COX-2–selective NSAIDs vary (2-6 hours for lumiracoxib, 6-12 hours for celecoxib, and 20-26 hours for etoricoxib). However, peak plasma concentrations of lumiracoxib at marketed doses considerably exceed those necessary to inhibit COX-2, suggesting an extended pharmacodynamic t1/2. Hepatic biotransformation and renal excretion is the principal route of elimination of the majority of NSAIDs. Some have active metabolites (e.g., fenbufen, nabumetone, meclofenamic acid, sulindac). Elimination pathways frequently involve oxidation or hydroxylation (Table 34–1). Acetaminophen, at therapeutic doses, is oxidized only to a small fraction to form traces of the highly reactive metabolite, N-acetyl-p-benzoquinone imine (NAPQI). When overdosed (usually >10 g of acetaminophen), however, the principal metabolic pathways are saturated, and hepatotoxic NAPQI concentrations can be formed (see Chapters 4 and 6). Rarely, other NSAIDs also may be complicated by hepatotoxicity (e.g., diclofenac, lumiracoxib). Several NSAIDs or their metabolites are glucuronidated or otherwise conjugated. In some cases, such as the propionic acid derivatives naproxen and ketoprofen, the glucuronide metabolites can hydrolyze back to form the active parent drug when the metabolite is not removed efficiently due to renal insufficiency or competition for renal excretion with other drugs. This may prolong elimination of the NSAID significantly. NSAIDs usually are not removed by hemodialysis due to their extensive plasma protein binding; salicylic acid is an exemption to this rule. In general, NSAIDs are not recommended in the setting of advanced hepatic or renal disease due to their adverse pharmacodynamic effects.

Therapeutic Uses

All NSAIDs, including selective COX-2 inhibitors, are antipyretic, analgesic, and anti-inflammatory, with the exception of acetaminophen, which is antipyretic and analgesic but is largely devoid of anti-inflammatory activity.

Inflammation. NSAIDs find their chief clinical application as anti-inflammatory agents in the treatment of musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. In general, NSAIDs provide mostly symptomatic relief from pain and inflammation associated with the disease and are not considered to be DMARDs. A number of NSAIDs are approved for the treatment of ankylosing spondylitis and gout. The use of NSAIDs for mild arthropathies, together with rest

<sup>a</sup>Time to peak plasma drug concentration (C<sub>p</sub>) after a single dose. In general, food delays absorption but does not decrease peak concentration. <sup>b</sup>The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. <sup>c</sup>Typical t<sub>1/2</sub> is listed for therapeutic doses; if t<sub>1/2</sub> is much different with the toxic dose, this is also given. <sup>d</sup>Limited dosing information given. For additional information, refer to the text and product information literature. Additional references can be found in earlier editions of this textbook. CNS, central nervous system; COX, cyclooxygenase; GI, gastrointestinal; IM, intramuscularly; IV, intravenously.
and physical therapy, generally is effective. When the symptoms are limited either to trouble sleeping because of pain or significant morning stiffness, a single NSAID dose given at night may suffice. Patients with more debilitating disease may not respond adequately to full therapeutic doses of NSAIDs and may require aggressive therapy with second-line agents. Substantial inter- and intraindividual differences in clinical response have been noted.

**Pain.** When employed as analgesics, these drugs usually are effective only against pain of low to moderate intensity, such as dental pain. Although their maximal efficacy is generally much less than the opioids, NSAIDs lack the unwanted adverse effects of opiates in the CNS, including respiratory depression and the potential for development of physical dependence. Co-administration of NSAIDs can reduce the opioid dose needed for sufficient pain control and reduce the likelihood of adverse opioid effects. NSAIDs do not change the perception of sensory modalities other than pain. They are particularly effective when inflammation has caused peripheral and/or central sensitization of pain perception. Thus, postoperative pain or pain arising from inflammation, such as arthritic pain, is controlled well by NSAIDs, whereas pain arising from the hollow viscera usually is not relieved. An exception to this is menstrual pain. The release of PGs by the endometrium during menstruation may cause severe cramps and other symptoms of primary dysmenorrhea; treatment of this condition with NSAIDs has met with considerable success (Marjoribanks et al., 2003). Not surprisingly, the selective COX-2 inhibitors such as rofecoxib and etoricoxib also are efficacious in this condition. NSAIDs are commonly used as first-line therapy to treat migraine attacks and can be combined with second-line drugs, such as the triptans (e.g., TREXIMET, which is a fixed-dose combination of naproxen and sumatriptan), or with antiemetics to aid relief of the associated nausea. NSAIDs lack efficacy in neuropathic pain.

**Fever.** Antipyretic therapy is reserved for patients in whom fever in itself may be deleterious and for those who experience considerable relief when fever is lowered. Little is known about the relationship between fever and the acceleration of inflammatory or immune processes; it may at times be a protective physiological mechanism. The course of the patient’s illness may be obscured by the relief of symptoms and the reduction of fever by the use of antipyretic drugs. NSAIDs reduce fever in most situations, but not the circadian variation in temperature or the rise in response to exercise or increased ambient temperature. Comparative analysis of the impact of tNSAIDs and selective COX-2 inhibitors suggests that COX-2 is the dominant source of PGs that mediate the rise in temperature evoked by bacterial lipopolysaccharide (LPS) administration (McAdam et al., 1999). This is consistent with the antipyretic clinical efficacy of both subclasses of NSAIDs. It seems logical to select an NSAID with rapid onset for the management of fever associated with minor illness in adults.

**Fetal Circulatory System.** PGs have long been implicated in the maintenance of patency of the ductus arteriosus, and indomethacin, ibuprofen, and other tNSAIDs have been used in neonates to close the inappropriately patent ductus. Conversely, infusion of PGE₂ maintains ductal patency after birth. Both COX-1 and COX-2 appear to participate in maintaining patency of the ductus arteriosus in fetal lambs (Clyman et al., 1999), while in mice COX-2 appears to play the dominant role (Loftin et al., 2002). It is not known which isoform or isoforms are involved in maintaining patency of the fetal ductus in utero in humans.

In mice, PGE₂ maintains a low ductal smooth muscle cell tone via the Gₛ-coupled receptor EP₄ that increases intracellular cyclic AMP. In the late gestational period, pulmonary expression of an enzyme that eliminates PGE₂ from the bloodstream, PG 15-OH dehydrogenase (PGDH), is rapidly upregulated (Coggins et al., 2002). At birth, PGE₂ blood concentrations are dramatically reduced by pulmonary PGDH and by additional exposure of circulating PGE₂ to this enzyme with the increase of pulmonary blood flow. Due to reduced EP₄ signaling, intracellular cyclic AMP concentrations in the ductus arteriosus drop, and vasodilating effects are outweighed by vasoconstrictor signals, which initiate remodeling. However, surprisingly little information about the human ductal physiology exists, and a role for PGDH remains to be established in humans.

**Cardioprotection.** Ingestion of aspirin prolongs bleeding time. For example, a single 325-mg dose of aspirin approximately doubles the mean bleeding time of normal persons for 4-7 days. This effect is due to irreversible acetylation of platelet COX and the consequent inhibition of platelet function until sufficient numbers of new, unmodified platelets are released from megakaryocytes. It is the permanent and complete suppression of platelet TxA₂ formation that is thought to underlie the cardioprotective effect of aspirin. Aspirin reduces the risk of serious vascular events in high-risk patients (e.g., those with previous myocardial infarction) by 20-25%. Low-dose (<100 mg/day) aspirin, which is relatively (but not exclusively) selective for COX-1, is as effective as higher doses (e.g., 325 mg/day) but is associated with a lower risk for GI adverse events.
However, low-dose aspirin is not risk free. Placebo-controlled trials reveal that aspirin increases the incidence of serious GI bleeds, reflecting suppression not just of platelet thromboxane, but also reduction of gastroepithelial PGE2 and PGF1α. It also increases the incidence of intracranial bleeds. Although benefit from aspirin outweighs these risks in the case of secondary prevention of cardiovascular disease, the issue is much more nuanced in patients who have never had a serious atherothrombotic event (primary prevention); here, prevention of myocardial infarction by aspirin is numerically balanced by the serious GI bleeds it precipitates (Patrono et al., 2005).

Given their relatively short t1/2 and reversible COX inhibition, most other tNSAIDs are not thought to afford cardioprotection, a view supported by most epidemiological analyses (García Rodríguez et al., 2004). Data suggest that cardioprotection is lost when combining low-dose aspirin with ibuprofen. An exception in some individuals may be naproxen. Although there is considerable between-person variation, a small study suggests that platelet inhibition might be anticipated throughout the dosing interval in some, but not all, individuals on naproxen (Capone et al., 2005). Epidemiological evidence of cardioprotection is less impressive; it suggests an ~10% reduction in myocardial infarction, compared to 20–25% with low-dose aspirin (Antithrombotic Trialists’ Collaboration, 2002). This would fit with heterogeneity of response to naproxen. Reliance on prescription databases may have constrained the ability of this approach to address the question with precision. In the Alzheimer’s Disease Anti-inflammatory Prevention Trial (ADAPT Research Group, 2008), naproxen was associated with a higher rate of cardiac events than celecoxib. Hence, naproxen should not be used as a substitute for aspirin for cardioprotection. COX-2–selective NSAIDs are devoid of antiplatelet activity, as mature platelets do not express COX-2.

Other Clinical Uses

Systemic Mastocytosis. Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, GI system, bones, and skin. In patients with systemic mastocytosis, PGD2, released from mast cells in large amounts, has been found to be the major mediator of severe episodes of flushing, vasodilation, and hypotension; this PGD2 effect is resistant to antihistamines. The addition of aspirin or ketoprofen has provided relief (Worobec, 2000). However, aspirin and tNSAIDs can cause degranulation of mast cells, so blockade with H1 and H2 histamine receptor antagonists should be established before NSAIDs are initiated.

Niacin Tolerability. Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce low-density lipoprotein, and raise high-density lipoprotein (see Chapter 31). However, niacin is tolerated poorly because it induces intense facial flushing. This flushing is mediated largely by release of PGD2 from the skin, which can be inhibited by treatment with aspirin (Jungnickel et al., 1997), and would be susceptible to inhibition of PGD synthesis, or antagonism of its DP1 receptor.

Bartter Syndrome. Bartter syndrome includes a series of rare disorders (frequency ≤1/100,000 persons) characterized by hypokalemic, hypochloremic metabolic alkalosis with normal blood pressure and hyperplasia of the juxtaglomerular apparatus. Fatigue, muscle weakness, diarrhea, and dehydration are the main symptoms. Distinct variants are caused by mutations in a Na+-K+-2Cl− co-transporter, an apical ATP-regulated K+ channel, a basolateral Cl− channel, a protein (barttin) involved in co-transporter trafficking, and the extracellular Ca2+-sensing receptor. Renal COX-2 is induced, and biosynthesis of PGE2 is increased. Treatment with indomethacin, combined with potassium repletion and spironolactone, is associated with improvement in the biochemical derangements and symptoms. Selective COX-2 inhibitors also have been used (Guay-Woodford, 1998).

Cancer Chemoprevention. Chemoprevention of cancer is an area in which the potential use of aspirin and/or NSAIDs is under active investigation. Epidemiological studies suggested that frequent use of aspirin is associated with as much as a 50% decrease in the risk of colon cancer (Kune et al., 2007). Similar observations have been made with NSAID use in this and other cancers (Harris et al., 2005). NSAIDs have been used in patients with familial adenomatous polyposis (FAP), an inherited disorder characterized by multiple adenomatous colon polyps developing during adolescence and the inevitable occurrence of colon cancer by the sixth decade.

Studies in small numbers of patients over short periods of follow-up have shown a decrease in the polyp burden with the use of sulindac, celecoxib, or rofecoxib (Steinbach et al., 2000; Cruz-Correa et al., 2002; Hallak et al., 2003). Celecoxib is approved as an adjunct to endoscopic surveillance and surgery in FAP based on superiority in a short-term, placebo-controlled trial for polyp prevention/regression. However, more recently, the Adenoma Prevention with Celecoxib (APC) Trial showed a significant reduction in the incidence of adenomatous polyps in patients with a history of colorectal adenomas at high doses of celecoxib (200 mg twice a day and 400 mg twice a day versus placebo) (Bertagnolli et al., 2009). The trial was prematurely terminated because of a 2.5 times increase in cardiovascular risk for patients taking 200 mg twice a day of celecoxib and a 3.4 times increase in risk for patients taking 400 mg twice a day (Solomon et al., 2005). Similarly, the Prevention of colorectal Sporadic Adenomatous Polyps (PreSAP) trial found a reduction of polyps at a single daily dose of 400 mg of celecoxib (Arber et al., 2006), which was offset by an increase in cardiovascular risk (Solomon et al., 2006). Finally, the APPROVe trial of 25 mg of rofecoxib showed a reduction in the incidence of adenomatous polyps (Baron et al., 2006) and an increase in cardiovascular adverse events (Bresalier et al., 2005; Baron et al., 2008) that led to the termination of the trial and to rofecoxib’s withdrawal from the market. Controlled evidence is not available to determine if selective COX-2 inhibitors differ from non-COX-2–selective tNSAIDs or aspirin in the extent of adenomatous colorectal polyp reduction in patients with FAP. Likewise, it is unknown whether there is even a clinical benefit from the reduction. Increased expression of COX-2 has been reported in multiple epithelial tumors, and in some cases, the degree of expression has been related to prognosis. Deletion or inhibition of COX-2 dramatically inhibits polyp formation in mouse genetic models of polyposis coli. Although the phenotypes in these models do not completely recapitulate the human disease, deletion of COX-1 had a similar effect. Speculation as to how the two COXs might interact in tumorigenesis includes the possibility that products of COX-1...
might induce expression of COX-2. However, the nature of this interaction is poorly understood, as are its therapeutic consequences. Alzheimer’s Disease. Observational studies have suggested that NSAID use, in particular ibuprofen, is associated with lower risk of developing Alzheimer’s disease. However, more recent prospective studies, including a randomized, controlled clinical trial comparing celecoxib, naproxen, and placebo (ADAPT Research Group, 2008), did not find a significant reduction in Alzheimer’s dementia with the use of NSAIDs.

Adverse Effects of NSAID Therapy

Common adverse events that complicate therapy with aspirin and NSAIDs are outlined in Table 34–2. Age generally is correlated with an increased probability of developing serious adverse reactions to NSAIDs, and caution is warranted in choosing a lower starting dose for elderly patients. NSAIDs are labeled with a black box warning related to cardiovascular risks and are specifically contraindicated following coronary artery bypass graft (CABG) surgery.

Gastrointestinal. The most common symptoms associated with these drugs are gastrointestinal, including anorexia, nausea, dyspepsia, abdominal pain, and diarrhea. These symptoms may be related to the induction of gastric or intestinal ulcers, which is estimated to occur in 15-30% of regular users. Ulceration may range from small superficial erosions to full-thickness perforation of the muscularis mucosa. There may be single or multiple ulcers, and ulceration may be uncomplicated or complicated by bleeding, perforation, or obstruction. Blood loss can be gradual, leading to anemia over time, or acute and life-threatening. The risk is further increased in those with Helicobacter pylori infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids. Although there is a perception that tNSAIDs vary considerably in their tendency to cause erosions and ulcers, this is based on overview analyses of small and heterogeneous studies, often at single doses of individual tNSAIDs.

Large-scale comparative studies of tNSAIDs have not been performed, and there is no reliable information on which to assess the comparative likelihood of GI ulceration on anti-inflammatory doses of aspirin versus tNSAIDs. Thus, most information is derived from the use of surrogate markers or from epidemiological data sets and suggests that the relative risk for serious adverse GI events is elevated about 3-fold in tNSAID users compared to non-users. Epidemiological studies suggest that combining low-dose aspirin (for cardioprotection) with other NSAIDs synergistically increases the likelihood of GI adverse events (see “Drug Interactions”). Similarly, the combination of multiple tNSAIDs and high dosage of a single tNSAID (including inappropriately high dosage in the elderly) has been found to raise the risk for ulcer complications by 7- and 9-fold, respectively. Age >70 years alone increases the likelihood of complications almost 6-fold. The risk of ulcer complications is increased in patients with past uncomplicated (6-fold) or complicated ulcers (13-fold), or concurrent drug therapy including

warfarin (12-fold), glucocorticoids (4-fold), or selective serotonin reuptake inhibitors (SSRIs; 3-fold) (Gabriel et al., 1991; Dalton et al., 2003; García Rodríguez and Barreales Tolosa, 2007).

COX-2–selective NSAIDs were originally designed for a niche indication, to improve treatment safety for patients at high risk for GI complications requiring chronic tNSAIDs—a population of <5% of tNSAID users (Dai et al., 2005). Prescription behavior changed over time, however, and more than one-third of patients at the lowest risk for GI events received a COX-2 inhibitor in 2002. Paradoxically, the incidence of GI adverse events had been falling sharply in the population prior to the introduction of the coxibs—which were developed to reduce the risk of serious GI complication, perhaps reflecting a move away from use of high-dose aspirin as an anti-inflammatory drug strategy. All selective COX-2 inhibitors are less prone to induce endoscopically visualized gastric ulcers than equally efficacious doses of tNSAIDs (Deeks et al., 2002). A more detailed discussion on this topic can be found in the prior edition of this textbook.

Gastric damage by NSAIDs can be brought about by at least two distinct mechanisms (see Chapter 33). Inhibition of COX-1 in gastric epithelial cells depresses mucosal cytoprotective PGs, especially PGI$_2$ and PGE$_2$. These eicosanoids inhibit acid secretion by the stomach, enhance mucosal blood flow, and promote the secretion of cytoprotective mucus in the intestine. Inhibition of PGI$_2$ and PGE$_2$ synthesis may render the stomach more susceptible to damage and can occur with oral, parenteral, or transdermal administration of aspirin or NSAIDs. There is some evidence that COX-2 also contributes to constitutive formation of these PGs by human gastric epithelium; products of COX-2 certainly contribute to ulcer healing in rodents (Mizuno et al., 1997). This may partly reflect an impairment of angiogenesis by the inhibitors (Jones et al., 1999). Indeed, coincidental deletion or inhibition of both COX-1 and COX-2 seems necessary to replicate NSAID-induced gastropathy in mice, and there is some evidence for gastric pathology in the face of prolonged inhibition or deletion of COX-2 alone (Sigthorsson et al., 2002). Another mechanism by which NSAIDs or aspirin may cause ulceration is by local irritation from contact of orally administered drug with the gastric mucosa. Local irritation allows backdiffusion of acid into the gastric mucosa and induces tissue damage. However, the incidence of GI adverse events is not significantly reduced by formulations that reduce drug contact with the gastric mucosa, such as enteric coating or efferent solutions, suggesting that the contribution of direct irritation to the overall risk is minor. It also is possible that enhanced generation of LOX products (e.g., LTs) contributes to ulcerogenicity in patients treated with NSAIDs.

Co-administration of the PGE$_{1}$ analog, misoprostol, or proton pump inhibitors (PPIs) in conjunction with NSAIDs can be beneficial in the prevention of duodenal and gastric ulceration (Rostom et al., 2002).

Several groups have attached NO–donating moieties to NSAIDs and to aspirin in the hope of reducing the incidence of adverse events. Benefit might be attained by abrogation of the inhibition of angiogenesis by tNSAIDs during ulcer healing, as observed in rodents (Ma et al., 2002); however, the clinical benefit of this strategy remains to be established. Similarly, LTs may accumulate in the presence of COX inhibition, and there is some evidence in rodents that combined LOX-COX inhibition may be a useful strategy.

**Cardiovascular.** COX-2–selective NSAIDs were developed to improve the GI safety of anti-inflammatory therapy in patients at elevated risk for GI complications. However, placebo-controlled trials with three structurally distinct compounds—celecoxib, valdecoxib (withdrawn), and rofecoxib (withdrawn)—revealed an increase in the incidence of myocardial infarction, stroke, and thrombosis (Bresalier et al., 2005; Nussmeier et al., 2005; Solomon et al., 2006). The risk appears to also extend to those of the older tNSAIDs, which are quite selective for COX-2, such as diclofenac, meloxicam, and nimesulide (Grosser et al., 2006). Regulatory agencies in the U.S, E.U., and Australia have concluded that all NSAIDs have the potential to increase the risk of heart attack and stroke.

The cardiovascular hazard is plausibly explained by the depression of COX-2-dependent prostanoids formed in vasculature and kidney (Grosser et al., 2006). Vascular PGI$_2$ constrains the effect of prothrombotic and atherogenic stimuli, and renal PGI$_2$ and PGE$_2$ formed by COX-2 contribute to arterial pressure homeostasis (see Chapter 33). Genetic deletion of the PGI$_2$ receptor, IP, in mice augments the thrombotic response to endothelial injury, accelerates experimental atherogenesis, increases vascular proliferation, and adds to the effect of hypertensive stimuli (Cheng et al., 2002; Egan et al., 2004; Kobayashi et al., 2004; Cheng et al., 2006). Genetic deletion or inhibition of COX-2 accelerates the response to thrombotic stimuli and raises blood pressure. Together, these mechanisms would be expected to alter the cardiovascular risk of humans, as COX-2 inhibition in humans depresses PGI$_2$ synthesis (Catella-Lawson et al., 1999; McAdam et al., 1999). Indeed, a human mutation of the IP, which disrupts its signaling, is associated with increased cardiovascular risk (Arehart et al., 2008).

Patients at increased risk of cardiovascular disease or thrombosis are likely to be particularly prone to cardiovascular adverse events while on NSAIDs. This includes patients with rheumatoid arthritis, as the relative risk of myocardial infarction is increased in these patients compared to patients with osteoarthritis or no arthritis. The risk appears to be conditioned by factors influencing drug exposure, such as dose, $t_{1/2}$, degree of COX-2 selectivity, potency, and treatment duration. Thus, the lowest possible dose should be prescribed for the shortest possible period. NSAIDs with selectivity for COX-2 should be reserved for patients at high risk for GI complications.

**Blood Pressure, Renal, and Renovascular Adverse Events.** NSAIDs and COX-2 inhibitors have been associated with renal and renovascular adverse events. NSAIDs have little effect on renal function or blood pressure in normal human subjects. However, in patients with congestive heart failure, hepatic cirrhosis, chronic kidney disease, hypovolemia, and other states of activation of the sympathoadrenal or renin–angiotensin systems, PG formation becomes crucial in model systems and in humans. NSAIDs are associated with loss of the
PG-induced inhibition of both the reabsorption of Cl⁻ and the action of antidiuretic hormone, leading to the retention of salt and water.

Experiments in mice that attribute the generation of vasodilator PGs (PGE₂ and PGD₂) to COX-2 raise the likelihood that the incidence of hypertensive complications (either new onset or worsened control) induced by NSAIDs in patients may correlate with the degree of inhibition of COX-2 in the kidney and the selectivity with which it is attained (Qi et al., 2002). Deletion of receptors for both PGI₂ and PGE₂ elevate blood pressure in mice, mechanistically integrating hypertension with a predisposition to thrombosis. Although this hypothesis has never been addressed directly, epidemiological studies suggest hypertensive complications occur more commonly in patients treated with coxibs than with tNSAIDs.

NSAIDs promote reabsorption of K⁺ as a result of decreased availability of Na⁺ at distal tubular sites and suppression of the PG-induced secretion of renin. The latter effect may account in part for the usefulness of NSAIDs in the treatment of Bartter syndrome (see “Bartter Syndrome”).

**Analgesic Nephropathy.** Analgesic nephropathy is a condition of slowly progressive renal failure, decreased concentrating capacity of the renal tubule, and sterile pyuria. Risk factors are the chronic use of high doses of combinations of NSAIDs and frequent urinary tract infections. If recognized early, discontinuation of NSAIDs permits recovery of renal function.

**Pregnancy and Lactation.** In the hours before parturition, there is induction of myometrial COX-2 expression, and levels of PGE₂ and PGF₂α increase markedly in the myometrium during labor (Slater et al., 2002). Prolongation of gestation by NSAIDs has been demonstrated in model systems and in humans. Some NSAIDs, particularly indomethacin, have been used off-label to terminate preterm labor. However, this use is associated with closure of the ductus arteriosus and impaired fetal circulation in utero, particularly in fetuses older than 32 weeks’ gestation. COX-2-selective inhibitors have been used off-label as tocolytic agents; this use has been associated with stenosis of the ductus arteriosus and oligohydramnios. Finally, the use of NSAIDs and aspirin late in pregnancy may increase the risk of postpartum hemorrhage. Therefore, pregnancy, especially close to term, is a relative contraindication to the use of all NSAIDs. In addition, their use must be weighed against potential fetal risk, even in cases of premature labor, and especially in cases of pregnancy-induced hypertension (Duley et al., 2004).

**Hypersensitivity.** Certain individuals display hypersensitivity to aspirin and NSAIDs, as manifested by symptoms that range from vasomotor rhinitis, generalized urticaria, and bronchial asthma to laryngeal edema, bronchoconstriction, flushing, hypotension, and shock. Aspirin intolerance is a contraindication to therapy with any other NSAID because cross-sensitivity can provoke a life-threatening reaction reminiscent of anaphylactic shock. Despite the resemblance to anaphylaxis, this reaction does not appear to be immunological in nature.

Although less common in children, this cross-sensitivity may occur in 10-25% of patients with asthma, nasal polyps, or chronic urticaria and in 1% of apparently healthy individuals. It is provoked by even low doses (<80 mg) of aspirin and apparently involves COX inhibition. Cross-sensitivity extends to other salicylates, structurally dissimilar NSAIDs, and rarely acetaminophen (see “Adverse Effects” in the “Acetaminophen” section). Treatment of aspirin hypersensitivity is similar to that of other severe hypersensitivity reactions, with support of vital organ function and administration of epinephrine. Aspirin hypersensitivity is associated with an increase in biosynthesis of LTs, perhaps reflecting diversion of AA to LOX metabolism. Indeed, results in a small number of patients suggest that blockade of 5-LOX with the drug zileuton or off-label use of the LT-receptor antagonists may ameliorate the symptoms and signs of aspirin intolerance, albeit incompletely.

**Aspirin Resistance.** All forms of treatment failure with aspirin have been collectively called aspirin resistance. Although this has attracted much attention, there is little information concerning the prevalence of a stable, aspirin-specific resistance or the precise mechanisms that might convey this “resistance.” Genetic variants of COX-1 that co-segregate with resistance have been described, but the relation to clinical outcome is not clear.

**Reye’s Syndrome.** Due to the possible association with Reye’s syndrome, aspirin and other salicylates are contraindicated in children and young adults <20 years of age with viral illness–associated fever. Reye’s syndrome, a severe and often fatal disease, is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera (Glasgow and Middleton, 2001). The etiology and pathophysiology are not clear, nor is it clear whether a causal relationship between aspirin and Reye’s syndrome exists (Schorr, 2007). However, the epidemiologic evidence for an association between aspirin use and Reye’s syndrome seemed sufficiently compelling that labeling of aspirin and aspirin-containing medications to indicate Reye’s syndrome as a risk in children was first mandated in 1986 and extended to bismuth subsalicylate in 2004. Since then, the use of aspirin in children has declined dramatically, and Reye’s syndrome has almost disappeared. Acetaminophen has not been
implicated in Reye’s syndrome and is the drug of choice for antipyresis in children, teens, and young adults.

**Concomitant NSAIDs and Low-Dose Aspirin.** Many patients combine either tNSAIDs or COX-2 inhibitors with “cardioprotective,” low-dose aspirin. Epidemiological studies suggest that this combination therapy increases significantly the likelihood of GI adverse events over either class of NSAID alone.

Prior occupancy of the active site of platelet COX-1 by the commonly consumed NSAID ibuprofen impedes access of aspirin to its target Ser 529 and prevents irreversible inhibition of platelet function (Catella-Lawson et al., 2001). Epidemiological studies have provided conflicting data as to whether this adversely impacts clinical outcomes, but they generally are constrained by the use of prescription databases to examine an interaction between two drug groups commonly obtained without prescription. Evidence in support of this interaction has been observed in comparing ibuprofen-treated patients with and without aspirin in two coxib outcome studies (CLASS and TARGET), but the trials were not powered to address this question definitively. In theory, this interaction should not occur with selective COX-2 inhibitors, because mature human platelets lack COX-2. However, the GI safety advantage of NSAIDs selective for COX-2 is lost when they are combined with low-dose aspirin.

**Drug Interactions**

Angiotensin-converting enzyme (ACE) inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate PG production. Thus, it is logical that NSAIDs might attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic PGs. Due to hyperkalemia, the combination of NSAIDs and ACE inhibitors also can produce marked bradycardia leading to syncope, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. Corticosteroids and SSRIs may increase the frequency or severity of GI complications when combined with NSAIDs. NSAIDs may augment the risk of bleeding in patients receiving warfarin both because almost all tNSAIDs suppress normal platelet function temporarily during the dosing interval and because some NSAIDs also increase warfarin levels by interfering with its metabolism; thus, concurrent administration should be avoided. Many NSAIDs are highly bound to plasma proteins and thus may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with warfarin, sulfonyleurea hypoglycemic agents, or methotrexate; the dosage of such agents may require adjustment to prevent toxicity. Patients taking lithium should be monitored because certain NSAIDs (e.g., piroxicam) can reduce the renal excretion of this drug and lead to toxicity, while others can decrease lithium levels (e.g., sulindac).

**Pediatric and Geriatric Indications and Problems**

**Therapeutic Uses in Children.** Therapeutic indications for NSAID use in children include fever, mild pain, postoperative pain, and inflammatory disorders, such as juvenile arthritis and Kawasaki disease. Inflammation associated with cystic fibrosis has emerged as a potential indication for pediatric NSAID use (Konstan et al., 1995); however, concern about GI adverse effects has limited NSAID use for this indication. The choice of drugs for children is considerably restricted; only drugs that have been extensively tested in children should be used (acetaminophen, ibuprofen, and naproxen).

**Kawasaki Disease.** Aspirin generally is avoided in pediatric populations due to its potential association with Reye’s syndrome (see “Reye’s Syndrome”). However, high doses of aspirin (30-100 mg/kg/day) are used to treat children during the acute phase of Kawasaki disease, followed by low-dose antiplatelet therapy in the subacute phase. Aspirin is thought to reduce the likelihood of aneurysm formation as a consequence of the vasculitis particularly in the coronary arteries. Small randomized studies did not conclusively show whether aspirin adds benefit beyond the standard treatment of Kawasaki disease with intravenous immunoglobulin (Baumer et al., 2006).

**Pharmacokinetics in Children.** Despite the recognition that age-dependent differences in gastric emptying time, plasma protein binding capacity and oxidative liver metabolism affect NSAID pharmacokinetics in children, dosing recommendations frequently are based on extrapolation of pharmacokinetic data from adults. The majority of pharmacokinetic studies that were performed in children involved patients >2 years of age, which often provide insufficient data for dose selection in younger infants. For example, the pharmacokinetics of the most commonly used NSAID in children, acetaminophen, differ substantially between the neonatal period and older children or adults. The systemic bioavailability of rectal acetaminophen formulations in neonates and preterm babies is higher than in older patients. Acetaminophen clearance is reduced in preterm neonates probably due to their immature glucuronide conjugation system (sulphatation is the principal route of biotransformation at this age). Therefore, acetaminophen dosing intervals need to be extended (8-12 hours) or daily doses reduced to avoid accumulation and liver toxicity. Aspirin elimination also is delayed in neonates and young infants compared to adults bearing the risk of accumulation.

Disease also may affect NSAID disposition in children. For example, ibuprofen plasma concentrations are reduced and clearance increased (~80%) in children with cystic fibrosis. This probably
is related to the GI and hepatic pathologies associated with this disease. Aspirin’s kinetics are markedly altered during the febrile phase of rheumatic fever or Kawasaki vasculitis. The reduction in serum albumin associated with these conditions causes an elevation of the free salicylate concentration, which may saturate renal excretion and result in salicylate accumulation to toxic levels. In addition to dose reduction, monitoring of the free drug may be warranted in these situations.

**Pharmacokinetics in the Elderly.** Physiological changes in absorption, distribution, and elimination in aging patients can be expected to affect the pharmacokinetics of most drugs, including NSAIDs. Coincident diseases may further complicate the prediction of the response to the drug. The clearance of many NSAIDs is reduced in the elderly due to changes in hepatic metabolism. Particularly NSAIDs with a long $t_{1/2}$ and primarily oxidative metabolism (i.e., piroxicam, tenoxicam, celecoxib) have elevated plasma concentrations in elderly patients. For example, plasma concentrations after the same dose of celecoxib may rise up to 2-fold higher in patients >65 years of age than in patients <50 years of age (U.S. Food and Drug Administration, 2001), warranting careful dose adjustment. The capacity of plasma albumin to bind drugs is diminished in older patients and may result in higher concentrations of unbound NSAIDs. Free naproxen concentrations, e.g., are markedly increased in older patients, although total plasma concentrations essentially are unchanged. The higher susceptibility of older patients to GI complications may be due to both a reduction in gastric mucosal defense and to elevated total and/or free NSAID concentrations. Generally, it is advisable to start most NSAIDs at a low dosage in the elderly and increase the dosage only if the therapeutic efficacy is insufficient.

**SPECIFIC PROPERTIES OF INDIVIDUAL NSAIDS**

General properties shared by tNSAIDs (including aspirin and acetaminophen) and COX-2–selective NSAIDs were considered in the preceding section, “Nonsteroidal Anti-Inflammatory Drugs.” In the following section, important characteristics of individual substances are discussed. NSAIDs are grouped by their chemical similarity (Figure 34–1).

**ASPIRIN AND OTHER SALICYLATES**

Despite the introduction of many new drugs, aspirin is still the most widely consumed analgesic, antipyretic, and anti-inflammatory agent and is the standard for the comparison and evaluation of the others. Aspirin is the most common household analgesic; yet, because the drug is so generally available, the possibility of misuse and serious toxicity probably is underappreciated, and it remains a cause of fatal poisoning in children.

**Chemistry.** Salicylic acid (orthohydroxybenzoic acid) is so irritating that it can only be used externally; therefore various derivatives of this acid have been synthesized for systemic use. These comprise two large classes, namely esters of salicylic acid obtained from substitutions within the carboxyl group and salicylate esters of organic acids, in which the carboxyl group is retained and substitution is made in the hydroxyl group. For example, aspirin is an ester of acetic acid. In addition, there are sodium, magnesium, and choline salts of salicylic acid. The chemical relationships can be seen from the structural formulas shown in Figure 34–3. Substitutions on the carboxyl or hydroxyl groups change the potency or toxicity of salicylates. The ortho position of the hydroxy group is an important feature for the action of the salicylates. The effects of simple substitutions on the benzene ring have been studied extensively. A difluorophenyl derivative, diflunisal, also is available for clinical use.

**Mechanism of Action**

Salicylates generally act by virtue of their content of salicylic acid. The effects of aspirin are largely caused by its capacity to acetylate proteins, as described in “Irreversible Cyclooxygenase Inhibition by Aspirin;” although high concentrations of aspirin result in therapeutic plasma concentrations of salicylic acid. In addition to their effect on PG biosynthesis (see the NSAIDs section and Chapter 33), the mechanism of action of the salicylates in rheumatic disease also may involve effects on other cellular and immunological processes in mesenchymal and connective tissues. Attention has been directed to the capacity of salicylates to suppress a variety of antigen–antibody reactions. These include the inhibition of antibody production, of antigen–antibody aggregation, and of antigen-induced release of histamine. Salicylates also induce a nonspecific stabilization of
Capillary permeability during immunological insults. The concentrations of salicylates needed to produce these effects are high, and the relationship of these effects to the anti-rheumatic efficacy of salicylates is not clear. Salicylates also can influence the metabolism of connective tissue, and these effects may be involved in their anti-inflammatory action. For example, salicylates can affect the composition, biosynthesis, or metabolism of connective tissue mucopolysaccharides in the ground substance that provides barriers to the spread of infection and inflammation.

Absorption, Distribution, and Elimination

Absorption. Orally ingested salicylates are absorbed rapidly, partly from the stomach but mostly from the upper small intestine. Appreciable concentrations are found in plasma in <30 minutes; after a single dose, a peak value is reached in ~1 hour and then declines gradually. The rate of absorption is determined by many factors, particularly the disintegration and dissolution rates of the tablets administered, the pH at the mucosal surface, and gastric emptying time.

Salicylate absorption occurs by passive diffusion primarily of undissociated salicylic acid or ASA across GI membranes and hence is influenced by gastric pH. Even though salicylate is more ionized as the pH is increased, a rise in pH also increases the solubility of salicylate and thus dissolution of the tablets. The overall effect is to enhance absorption. As a result, there is little meaningful difference between the rates of absorption of sodium salicylate, aspirin, and the numerous buffered preparations of salicylates. The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin. Methyl salicylate likewise is speedily absorbed when applied cutaneously; however, its GI absorption may be delayed many hours, making gastric lavage effective for removal even in poisonings that present late after oral ingestion.

Distribution. After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent passive processes. Salicylates are transported actively by a low-capacity, saturable system out of the cerebrospinal fluid (CSF) across the choroid plexus. The drugs readily cross the placental barrier.

The volume of distribution of usual doses of aspirin and sodium salicylate in normal subjects averages ~170 mL/kg of body weight; at high therapeutic doses, this volume increases to ~500 mL/kg because of saturation of binding sites on plasma proteins. Ingested aspirin mainly is absorbed as such, but some enters the systemic circulation as acetylsalicylic acid after hydrolysis by esterases in the GI mucosa and liver. Aspirin can be detected in the plasma only for a short time as a result of hydrolysis in plasma, liver, and erythrocytes; for example, 30 minutes after a dose of 0.65 g, only 27% of the total plasma salicylate is in the acetylated form. Methyl salicylate also is hydrolyzed rapidly to salicylic acid, mainly in the liver.

Roughly 80-90% of the salicylate in plasma is bound to proteins, especially albumin, at concentrations encountered clinically; the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia, as may occur in rheumatoid arthritis, is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein binding sites; these include thyroxine, triiodothyronine, penicillin, phenytoin, sulfisoxazole, bilirubin, uric acid, and other NSAIDs such as naproxen. Aspirin is bound to a more limited extent; however, it acetylates human plasma albumin in vivo by reaction with the ε-amino group of lysine and may change the binding of other drugs to albumin. Aspirin also acetylates hormones, DNA, and hemoglobin and other proteins.

Elimination. The biotransformation of salicylates takes place in many tissues, but particularly in the hepatic endoplasmic reticulum and mitochondria. The three chief metabolic products are salicylic acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide. In addition, a small fraction is oxidized to gentisic acid (2,5-dihydroxybenzoic acid) and to 2,3-dihydroxybenzoic acid and 2,3,5-trihydroxybenzoic acids; gentisic acid, the glycine conjugate of gentisic acid, also is formed.

Salicylates are excreted in the urine as free salicylic acid (10%), salicylic acid (75%), salicylic phenolic (10%) and acyl glucuronides (5%), and gentisic acid (<1%). However, excretion of free salicylates is extremely variable and depends on the dose and the urinary pH. In alkaline urine, >30% of the ingested drug may be eliminated as free salicylate, whereas in acidic urine, this may be as low as 2%.

The plasma t1/2 for aspirin is ~20 minutes, and for salicylate is 2-3 hours at antiplatelet doses, rising to 12 hours at usual anti-inflammatory doses. The t1/2 of salicylate may be as long as 15-30 hours at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicylic acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses.

Salicylate metabolism shows high intersubject variability due to the variable contribution of different metabolic pathways. Women frequently exhibit higher plasma concentrations, perhaps due to lower intrinsic esterase activity and gender differences in hepatic metabolism. Salicylate clearance is reduced and salicylate exposure is significantly increased in the elderly (see “Pharmacokinetics in the Elderly”). The plasma concentration of salicylate is increased by conditions that decrease glomerular filtration rate or reduce proximal tubule secretion, such as renal disease or the presence of inhibitors that compete for the transport system (e.g., probenecid). Changes in urinary pH also have significant effects on salicylate excretion. For example, the clearance of salicylate is about four times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is true in oliguria. In case of an overdose, hemodialysis and hemofiltration techniques remove salicylic acid effectively from the circulation.

Monitoring of Plasma Salicylate Concentrations. Aspirin is one of the NSAIDs for which plasma salicylate can provide a means to monitor therapy and toxicity. Intermittent analgesic–antipyretic doses of aspirin typically produce plasma aspirin levels of <20 μg/mL and plasma salicylate levels of <60 μg/mL. The daily
ingestion of anti-inflammatory doses of 4-5 g of aspirin produces plasma salicylate levels in the range of 120-350 μg/mL. Optimal anti-inflammatory effects for patients with rheumatic diseases require plasma salicylate concentrations of 150-300 μg/mL. Significant adverse effects can be seen at levels of >300 μg/mL. At lower concentrations, the drug clearance is nearly constant (despite the fact that saturation of metabolic capacity is approached) because the fraction of drug that is free, and thus available for metabolism or excretion, increases as binding sites on plasma proteins are saturated. The total concentration of salicylate in plasma is therefore a relatively linear function of dose at lower concentrations. At higher concentrations, however, as metabolic pathways of disposition become saturated, small increments in dose can disproportionately increase plasma salicylate concentration. Failure to anticipate this phenomenon can lead to toxicity.

**Therapeutic Uses**

**Systemic Uses.** The dose of salicylate depends on the condition being treated.

The analgesic-antipyretic dose of aspirin for adults is 324-1000 mg orally every 4-6 hours. The anti-inflammatory doses of aspirin recommended for arthritis, spondyloarthropathies, and systemic lupus erythematosus (SLE) range from 3-4 g/day in divided doses. Salicylates are contraindicated for fever associated with viral infection in children (see “Reye’s Syndrome”); for nonviral etiologies, 40-60 mg/kg/day given in six divided doses every 4 hours is recommended. The maximum recommended daily dose of aspirin for adults and children >12 years or older is 4 g. The rectal administration of aspirin suppositories may be preferred in infants or when the oral route is unavailable. Although aspirin is regarded as the standard against which other drugs should be compared for the treatment of rheumatoid arthritis, many clinicians favor the use of other NSAIDs perceived to have better GI tolerability, even though this perception remains untested by randomized clinical trials. Salicylates suppress clinical signs and improve tissue inflammation in acute rheumatic fever. Much of the possible subsequent tissue damage, such as cardiac lesions and other visceral involvement, however, is unaffected by salicylate therapy.

Other salicylates available for systemic use include salicylate (salicylsalicylic acid), which is hydrolyzed to salicylic acid during and after absorption, and magnesium salicylate (tablets; DOAN’S, MOMENTUM, others). A combination of choline salicylate and magnesium salicylate (choline magnesium–trisalicylate) also is available.

Diflunisal is a difluorophenyl derivative of salicylic acid that is not converted to salicylic acid in vivo. Diflunisal is more potent than aspirin in anti-inflammatory tests in animals and appears to be a competitive inhibitor of COX. However, it is largely devoid of antipyretic effects, perhaps because of poor penetration into the CNS. The drug has been used primarily as an analgesic in the treatment of osteoarthritis and musculoskeletal strains or sprains; in these circumstances, it is about three to four times more potent than aspirin. The usual initial dose is 1000 mg, followed by 500 mg every 8-12 hours. For rheumatoid arthritis or osteoarthritis, 250-1000 mg/day is administered in two divided doses; maintenance dosage should not exceed 1.5 g/day. Diflunisal produces fewer auditory side effects (see “Otoxic Effects”) and appears to cause fewer and less intense GI and antiplatelet effects than does aspirin.

**Local Uses.** Mesalamine (5-aminosalicylic acid) is a salicylate that is used for its local effects in the treatment of inflammatory bowel disease (see Chapter 47, especially Figure 47-4). The drug as an immediate-release formulation would not be effective orally because it is poorly absorbed and is inactivated before reaching the lower intestine. However, oral formulations that deliver drug to the lower intestine—mesalamine formulated in a pH-sensitive, polymer-coated, delayed-release tablet (ASACOL, LIALDA); an extended-release mesalamine capsule (APRISO); and olsalazine (sodium azosalicylate, a dimer of 5-aminosalicylate linked by an azo bond; DIPENTUM)—are efficacious in the treatment of inflammatory bowel disease (in particular, ulcerative colitis). Mesalamine is available as a rectal enema (ROWASA, others) for treatment of mild to moderate ulcerative colitis, proctitis, and proctosigmoiditis and as a rectal suppository (CANASA) for the treatment of active ulcerative proctitis. Sulfasalazine (salicylazosulfapyridine; AZULFIDINE, others) contains mesalamine linked covalently to sulfapyridine, and balsalazide (COLAZAL, others) contains mesalamine linked to the inert carrier molecule 4-aminobenzoyl-β-alanine. Both drugs are absorbed poorly after oral administration and cleaved to the active moiety by bacteria in the colon. Sulfasalazine and olsalazine have been used in the treatment of rheumatoid arthritis and ankylosing spondylitis. Some over-the-counter medications to relieve indigestion and diarrhea agents contain bismuth subsalicylate (PEPTO-BISMOL, others) and have the potential to cause salicylate intoxication, particularly in children.

The keratolytic action of free salicylic acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, tissue cells swell, soften, and desquamate. Methyl salicylate (oil of wintergreen) is a common ingredient of ointments and deep-heating liniments used in the management of musculoskeletal pain; it also is available in herbal medicines and as a flavoring agent. The cutaneous application of methyl salicylate can result in pharmacologically active, and even toxic, systemic salicylate concentrations and has been reported to increase prothrombin time in patients receiving warfarin.

**Adverse Effects**

**Respiration.** Salicylates increase O₂ consumption and CO₂ production (especially in skeletal muscle) at anti-inflammatory doses; these effects are a result of uncoupling oxidative phosphorylation. The increased production of CO₂ stimulates respiration (mainly by an increase in depth of respiration with only a slight increase in rate). The increased alveolar ventilation balances the increased CO₂ production, and thus plasma CO₂ tension (PCO₂) does not change or may decrease slightly. Salicylates also stimulate the respiratory center directly in the medulla. Respiratory rate and depth increases, the PCO₂ falls, and primary respiratory alkalosis ensues. Both mechanisms can occur in parallel, although the stimulation of ventilation
in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible upon discontinuation of salicylates. However, the use of salicylates is contraindicated in patients with chronic liver disease. Considerable evidence, as discussed earlier in “Reye’s Syndrome,” implicates the use of salicylates as an important factor in the severe hepatic injury and encephalopathy observed in Reye’s syndrome. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen.

**Uricosuric Effects.** The effects of salicylates on uric acid excretion are markedly dependent on dose. Low doses (1 or 2 g/day) may decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g/day) usually do not alter urate excretion. Large doses (>5 g/day) induce uricosuria and lower plasma urate levels; however, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of probenecid and other uricosuric agents that decrease tubular reabsorption of uric acid.

**Effects on the Blood.** Irreversible inhibition of platelet function is the mechanism underlying the cardioprotective effect of aspirin (see “Concomitant NSAIDs and Low-Dose Aspirin”). If possible, aspirin therapy should be stopped at least 1 week before surgery; however, preoperative aspirin often is recommended prior to carotid artery stenting, carotid endarterectomy, infrainguinal arterial bypass, and PCI procedures. Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid aspirin because the inhibition of platelet hemostasis can result in hemorrhage. Care also should be exercised in the use of aspirin during long-term treatment with oral anticoagulant agents because of the combined danger of prolongation of bleeding time coupled with blood loss from the gastric mucosa. On the other hand, aspirin is used widely for the prophylaxis of thromboembolic disease, especially in the coronary and cerebral circulation, and is coupled frequently with oral anticoagulants in patients with bioprosthetic or mechanical heart valves (see Chapter 30).

Salicylates ordinarily do not alter the leukocyte or platelet count, the hematocrit, or the hemoglobin content. However, doses of 3–4 g/day markedly decrease plasma iron concentration and shorten erythrocyte survival time. Aspirin can cause a mild degree of hemolysis in individuals with a deficiency of glucose-6-phosphate dehydrogenase. As noted earlier (see “Cardiovascular Effects”), high doses (>3 g/day) can expand plasma volume and decrease hematocrit by dilution.

**Endocrine Effects.** Long-term administration of salicylates decreases thyroidal uptake and clearance of iodine, but increases $O_2$ consumption and the rate of disappearance of thyroxine and triiodothyronine from the circulation. These effects probably are caused by the competitive displacement by salicylate of thyroxine and triiodothyronine from transthyretin and the thyroxine-binding globulin in plasma (see Chapter 39).

**Ototoxic Effects.** Hearing impairment, alterations of perceived sounds, and tinnitus commonly occur during high-dose salicylate therapy. Tinnitus, historically used as an index of exceeding the acceptable plasma concentration in patients, is not a reliable guide; thus, surveillance for this symptom is no substitute for periodic

---

**Acid–Base and Electrolyte Balance and Renal Effects.** Therapeutic doses of salicylate produce definite changes in the acid–base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis (see “Respiration” in the aspirin section), is achieved by increased renal excretion of bicarbonate, which is accompanied by increased $Na^+$ and $K^+$ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This is the stage of compensatory renal acidosis. This stage is most often seen in adults given intensive salicylate therapy and seldom proceeds further unless toxicity ensues (see “Salicylate Intoxication”). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other NSAIDs can produce papillary necrosis and interstitial nephritis (see “Analgescic Nephropathy”).

**Cardiovascular Effects.** Low doses of aspirin ($\leq 100$ mg daily) are used widely for their cardioprotective effects. At high therapeutic doses ($\geq 23$ g daily), as might be given for acute rheumatic fever, salt and water retention can lead to an increase ($\geq 20\%$) in circulating plasma volume and decreased hematocrit (via a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with carditis or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive cardiac failure and pulmonary edema can occur. High doses of salicylates can produce noncardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

**GI Effects.** The ingestion of salicylates may result in epigastric distress, nausea, and vomiting. Salicylates also may cause gastric ulceration, exacerbation of peptic ulcer symptoms (heartburn, dyspepsia), GI hemorrhage, and erosive gastritis. These effects occur primarily with acetylated salicylates (i.e., aspirin). Because nonacetylated salicylates lack the ability to acetylate COX and thereby irreversibly inhibit its activity, they are weaker inhibitors than aspirin.

Aspirin-induced gastric bleeding sometimes is painless and, if unrecognized, may lead to iron-deficiency anemia. The daily ingestion of anti-inflammatory doses of aspirin (3–4 g) results in an average fecal blood loss of between 3 and 8 mL/day, as compared with ~0.6 mL/day in untreated subjects. Gastroscopic examination of aspirin-treated subjects often reveals discrete ulcerative and hemorrhagic lesions of the gastric mucosa; in many cases, multiple hemorrhagic lesions with sharply demarcated areas of focal necrosis are observed.

**Hepatic Effects.** Salicylates can cause hepatic injury, usually in patients treated with high doses of salicylates that result in plasma concentrations of $>150$ $\mu$g/mL. The injury is not an acute effect; rather, the onset characteristically occurs after several months of treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase
monitoring of serum salicylate levels. Ototoxic symptoms sometimes are observed at low doses, and no threshold plasma concentration exists. Symptoms usually resolve within 2 or 3 days after withdrawal of the drug. Ototoxic symptoms are caused by increased labyrinthine pressure or an effect on the hair cells of the cochlea, perhaps secondary to vasoconstriction in the auditory microvasculature. As most competitive COX inhibitors are not associated with hearing loss or tinnitus, a direct effect of salicylic acid rather than suppression of PG synthesis is likely.

Salicylates and Pregnancy. Infants born to women who ingest salicylates for long periods may have significantly reduced birth weights. When administered during the third trimester, there also is an increase in perinatal mortality, anemia, antepartum and postpartum hemorrhage, prolonged gestation, and complicated deliveries; thus, its use during this period should be avoided. As mentioned earlier in “Pregnancy and Lactation,” administration of NSAIDs during the third trimester of pregnancy also can cause premature closure of the ductus arteriosus. The use of aspirin has been advocated for the treatment of women at high risk of preeclampsia, but it is estimated that treatment of 90 women is required to prevent one case of preeclampsia (Villar et al., 2004).

Local Irritant Effects. Salicylic acid is irritating to skin and mucosa and destroys epithelial cells.

Drug Interactions. The plasma concentration of salicylates generally is little affected by other drugs, but concurrent administration of aspirin lowers the concentrations of indomethacin, naproxen, ketoprofen, and fenoprofen, at least in part by displacement from plasma proteins. Important adverse interactions of aspirin with warfarin, sulfonyleurides, and methotrexate are mentioned earlier in “Drug Interactions.” Other interactions of aspirin include the antagonism of spironolactone-induced natriuresis and the blockade of the active transport of penicillin from CSF to blood. Magnesium-aluminum hydroxide antacids can alkalize the urine enough to increase salicylic acid clearance significantly and reduce steady-state concentrations. Conversely, discontinuation of antacid therapy can increase plasma concentrations to toxic levels.

Salicylate Intoxication

Salicylate poisoning or serious intoxication often occurs in children and sometimes is fatal. CNS effects, intense hyperpnea, and hyperpyrexia are prominent symptoms. Salicylate intoxication should be seriously considered in any young child with coma, convulsions, or cardiovascular collapse. The fatal dose varies with the preparation of salicylate. Death has followed use of 10-30 g of sodium salicylate or aspirin in adults, but much larger amounts (130 g of aspirin in one case) have been ingested without a fatal outcome. The lethal dose of methyl salicylate (also known as oil of wintergreen, sweet birch oil, gaultheria oil, betula oil) is considerably less than that of sodium salicylate. As little as a taste of methyl salicylate by children <6 years of age and >4 mL (4.7 g) of methyl salicylate by children ≥6 years of age may cause severe systemic toxicity and warrants referral to an emergency department. Symptoms of poisoning by methyl salicylate differ little from those described earlier for aspirin in “Adverse Effects.” The drug’s odor can be detected easily on the breath and in the urine and vomitus. Poisoning by salicylic acid differs only in the increased prominence of GI symptoms due to the marked local irritation. Mild chronic salicylate intoxication is called salicylism. When fully developed, the syndrome includes headache, dizziness, tinnitus, difficulty hearing, dimness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

Neurological Effects. In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness, delirium, psychosis, stupor, and coma may occur. Salicylates induce nausea and vomiting, which result from stimulation of sites that are accessible from the CSF, probably in the medullary chemoreceptor trigger zone. In humans, centrally induced nausea and vomiting often appear at plasma salicylate concentrations of ~270 μg/mL, but these same effects may occur at much lower plasma levels as a result of local gastric irritation.

Respiration. The respiratory effects of salicylates contribute to the serious acid–base balance disturbances that characterize poisoning by this class of compounds. Salicylates stimulate respiration indirectly by uncoupling of oxidative phosphorylation and directly by stimulation of the respiratory center in the medulla (see “Respiration” in the aspirin section). Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children. Marked hyperventilation occurs when the level approaches 500 μg/mL. However, should salicylate toxicity be associated with the co-administration of a barbiturate or opioid, then central respiratory depression will prevent hyperventilation, and the salicylate-induced uncoupling of oxidative phosphorylation will be associated with a marked increase in plasma PCO₂ and respiratory acidosis. Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO₂ production continues, respiratory acidosis ensues. Respiratory failure is the usual cause of death in fatal cases of salicylate poisoning. Elderly patients with chronic salicylate intoxication often develop noncardiogenic pulmonary edema, which is considered an indication for hemodialysis.

Acid–Base Balance and Electrolytes. As described earlier in “Acid–Base and Electrolyte Balance and Renal Effects” in the aspirin section, high therapeutic doses of salicylate are associated with a primary respiratory alkalosis and compensatory renal acidosis. Subsequent changes in acid–base status generally occur only when toxic doses of salicylates are ingested by infants and children or occasionally after large doses in adults. The phase of primary respiratory alkalosis rarely is recognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and renal acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma PCO₂. Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO₂. Consequently, plasma PCO₂ increases and blood pH decreases. Because the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid–base status at this stage essentially is an uncompensated respiratory acidosis. Superimposed, however, is a true metabolic acidosis caused by accumulation of acids as a
result of three processes. First, toxic concentrations of salicylates displace ~2-3 mEq/L of plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with consequent accumulation of sulfuric and phosphoric acids; renal failure can ensue. Third, salicylates in toxic doses may decrease aerobic metabolism as a result of inhibition of various enzymes. This derangement of carbohydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The same series of events also causes alterations of water and electrolyte balance. The low plasma Pco₂ leads to decreased renal tubular reabsorption of bicarbonate and increased renal excretion of Na⁺, K⁺, and water. Water also is lost by salicylate-induced sweating (especially in the presence of hyperthermia) and hyperventilation; dehydration, which can be profound, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hypernatremia. Prolonged exposure to high doses of salicylate also causes depletion of K⁺ due to both renal and extrarenal factors.

Cardiovascular Effects. Toxic doses of salicylates lead to an exaggeration of the unfavorable cardiovascular responses seen at high therapeutic doses (see “Adverse Effects”), and central vasomotor paralysis occurs. Petechiae may be seen due to defective platelet function.

Metabolic Effects. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen; these effects are partly explained by the release of epinephrine. Such doses also reduce aerobic metabolism of glucose, increase glucose-6-phosphatase activity, and promote the secretion of glucocorticoids. There is a greater risk of hypoglycemia and subsequent permanent brain injury in children. Salicylates in toxic doses cause a significant negative nitrogen balance, characterized by an aminoaciduria. Adrenocortical activation may contribute to the negative nitrogen balance by enhancing protein catabolism. Salicylates reduce lipogenesis by partially blocking incorporation of acetate into fatty acids; they also inhibit epinephrine-stimulated lipolysis in fat cells and displace long-chain fatty acids from binding sites on human plasma proteins. The combination of these effects leads to increased entry and enhanced oxidation of fatty acids in muscle, liver, and other tissues and to decreased plasma concentrations of free fatty acids, phospholipid, and cholesterol; the oxidation of ketone bodies also is increased.

Endocrine Effects. Very large doses of salicylates stimulate steroid secretion by the adrenal cortex through an effect on the hypothalamus and transiently increase plasma concentrations of free corticosteroids by their displacement from plasma proteins. The therapeutic anti-inflammatory effects of salicylate are independent of these effects.

Management of Salicylate Overdose. Salicylate poisoning represents an acute medical emergency, and death may result despite heroic efforts. Monitoring of salicylate levels is a useful guide to therapy but must be used in conjunction with an assessment of the patient’s overall clinical condition, acid–base balance, formulation of salicylate ingested, timing, and dose (O’Malley, 2007).

There is no specific antidote for salicylate poisoning. Management begins with a rapid assessment followed by the ABCD approach to medical emergencies: “A (airway), B (breathing), C (circulation), D (decontamination)”.

### PARA-AMINOPHENOL DERIVATIVES: ACETAMINOPHEN

Acetaminophen (paracetamol; N-acetyl-p-aminophenol; TYLENOL, others) is the active metabolite of phenacetin.

Acetaminophen raises the threshold to painful stimuli, thus exerting an analgesic effect against pain due to a variety of etiologies. It is available without a prescription and is used as a common household analgesic. The drug also is available in fixed-dose combinations containing narcotic and non-narcotic analgesics (including aspirin and other salicylates), barbiturates, caffeine, vascular headache remedies, sleep aids, toothache remedies, antihistamines, antitussives, decongestants, expectorants, cold and flu preparations, and sore throat treatments. Acetaminophen is an effective alternative to aspirin as an analgesic–antipyretic agent; however, its anti-inflammatory effects are much weaker. Although it is indicated for pain relief in patients with osteoarthritis, it is not a suitable substitute for aspirin or other NSAIDs in chronic inflammatory conditions such as rheumatoid arthritis. Acetaminophen is well tolerated and has a low incidence of GI side effects. However, acute overdosage can cause severe hepatic damage, and the number of accidental or deliberate poisonings with acetaminophen continues to grow. Chronic use of <2 g/day is not typically associated with hepatic dysfunction, but overuse of acetaminophen-containing narcotic and over-the-counter combination products marketed in the U.S. has led to heightened awareness of the possibility of toxicity.

### Mechanism of Action

Acetaminophen has analgesic and antipyretic effects similar to those of aspirin. However, as mentioned in the preceding section, it has only weak anti-inflammatory effects, and it has been thought to have a generally poor ability to inhibit COX in the presence of high concentrations of peroxides, as are found at sites of inflammation. This aspect of its action has not been addressed rigorously. A dose of 1000 mg results in ~50% inhibition of both COX-1 and COX-2 in whole blood assays ex vivo in healthy volunteers.
It has been suggested that COX inhibition might be disproportionately pronounced in the brain, explaining its antipyretic efficacy (Ouellet and Percival, 2001; Boutaud et al., 2002). A COX-1 splice variant identified in the canine brain shows some susceptibility for inhibition by acetaminophen in vitro (Chandrasekharan et al., 2002). However, this splice variant does not exist in humans.

Absorption, Distribution, and Elimination

Oral acetaminophen has excellent bioavailability. Peak plasma concentrations occur within 30-60 minutes, and the t1/2 in plasma is ~2 hours after therapeutic doses. Acetaminophen is relatively uniformly distributed throughout most body fluids. Binding of the drug to plasma proteins is variable but less than with other NSAIDs; only 20-50% is bound at the concentrations encountered during acute intoxication. Some 90-100% of the drug may be recovered in the urine within the first day at therapeutic dosing, primarily after hepatic conjugation with glucuronic acid (~60%), sulfuric acid (~35%), or cysteine (~3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (Table 34–1). Children have less capacity for glucuronidation of the drug than do adults. A small proportion of acetaminophen undergoes CYP-mediated N-hydroxylation to form NAPQI, a highly reactive intermediate. This metabolite normally reacts with sulfhydryl groups in glutathione (GSH) and thereby is rendered harmless. However, after ingestion of large doses of acetaminophen, the metabolite is formed in amounts sufficient to deplete hepatic GSH and contributes significantly to the toxic effects of overdose (see “Acetaminophen Intoxication”).

Therapeutic Uses. Acetaminophen is suitable for analgesic or antipyretic uses; it is the first-line analgesic in osteoarthritis and particularly valuable for patients in whom aspirin is contraindicated (e.g., those with peptic ulcer, aspirin hypersensitivity, children with a febrile illness). The conventional oral dose of acetaminophen is 325-650 mg every 4-6 hours; total daily doses should not exceed 4000 mg (2000 mg/day for chronic alcoholics).

In 2009, an FDA advisory panel recommended a lower maximum daily dose of acetaminophen of 2600 mg and a decrease in the maximum single dose from 1000 mg to 650 mg. Single doses for children 2-11 years of age range from 160-480 mg, depending on age and weight; no more than five doses should be administered in 24 hours. A dose of 10 mg/kg also may be used. Particular attention is warranted due to the availability of a wide variety of prescription and nonprescription multi-ingredient medications that represent potentially toxic overlapping sources of acetaminophen.

Adverse Effects. Acetaminophen usually is well tolerated at recommended therapeutic doses. Single or repeated therapeutic doses of acetaminophen have no effect on the cardiovascular and respiratory systems, platelets, or coagulation. Acid–base changes and uricosuric effects do not occur. Epidemiological studies suggest that GI adverse effects are less common than with therapeutic doses of nonsteroidal anti-inflammatory drugs (García Rodríguez et al., 2004). Rash and other allergic reactions occur occasionally. The rash usually is erythematous or urticarial, but sometimes it is more serious and may be accompanied by drug fever and mucosal lesions. Patients who show hypersensitivity reactions to the salicylates only rarely exhibit sensitivity to acetaminophen. The use of acetaminophen has been associated anecdotally with neutropenia, thrombocytopenia, pancytopenia, hemolytic anemia, and methemoglobinemia. Kidney damage has been reported, and liver damage is a prominent feature of overdose.

Acetaminophen Intoxication

Acute ingestion of >7.5 g of acetaminophen, or repeat use of supratherapeutic doses, can result in toxicity. The most serious acute adverse effect of overdosage of acetaminophen is a potentially fatal hepatic necrosis. Renal tubular necrosis and hypoglycemic coma also may occur. The mechanism by which overdosage with acetaminophen leads to hepatocellular injury and death involves its conversion to the toxic metabolite, NAPQI. The glucuronide and sulfate conjugation pathways become saturated, and increasing amounts undergo CYP-mediated N-hydroxylation to form NAPQI. This is eliminated rapidly by conjugation with GSH and then further metabolized to a mercapturic acid and excreted into the urine. In the setting of acetaminophen overdose, hepatocellular levels of GSH become depleted. The highly reactive NAPQI metabolite binds covalently to cell macromolecules, leading to dysfunction of enzymatic systems and structural and metabolic disarray. Furthermore, depletion of intracellular GSH renders the hepatocytes highly susceptible to oxidative stress and apoptosis (see Figure 4–5 and Chapter 6).

Hepatotoxicity. In adults, hepatotoxicity may occur after ingestion of a single dose of 10-15 g (150-250 mg/kg) of acetaminophen; doses of 20-25 g or more are potentially fatal. Conditions of CYP induction (e.g., heavy alcohol consumption) or GSH depletion (e.g., fasting or malnutrition) increase the susceptibility to hepatic injury, which has been documented, albeit uncommonly, with doses in the therapeutic range.

Symptoms that occur during the first 2 days of acute poisoning by acetaminophen reflect gastric distress (e.g., nausea, abdominal pain, anorexia) and belie the potential seriousness of the intoxication. Plasma transaminases become elevated, sometimes markedly so, beginning ~12-36 hours after ingestion. Clinical indications of hepatic damage manifest within 2-4 days of ingestion of toxic doses, with right subcostal pain, tender hepatomegaly, jaundice, and coagulopathy. Renal impairment or frank renal failure may occur. Liver enzyme abnormalities typically peak 72-96 hours after ingestion. The onset of hepatic encephalopathy or worsening coagulopathy beyond this time indicates a poor prognosis. Biopsy of the liver reveals centrilobular necrosis with sparing of the perportal area. In nonfatal cases, the hepatic lesions are reversible over a period of weeks or months.
ACETIC ACID DERIVATIVES

Indomethacin

Indomethacin (INDOCIN, others), a methylated indole derivative, was introduced in 1963 and is indicated for the treatment of moderate to severe rheumatoid arthritis, osteoarthritis, and acute gouty arthritis; ankylosing spondylitis; and acute painful shoulder. Although indomethacin is still used clinically, mainly as a steroid-sparing agent, toxicity and the availability of safer alternatives have limited its use. Indomethacin is available in an injectable form for the closure of patent ductus arteriosus.

Mechanism of Action. Indomethacin is a more potent nonselective inhibitor of the COXs than is aspirin; it also inhibits the motility of polymorphonuclear leukocytes, depresses the biosynthesis of mucopolysaccharides, and may have a direct, COX-independent vasoconstrictor effect. Indomethacin has prominent anti-inflammatory and analgesic–antipyretic properties similar to those of the salicylates.

Absorption, Distribution, and Elimination. Oral indomethacin has excellent bioavailability. Peak concentrations occur 1-2 hours after dosing (Table 34–1). The concentration of the drug in the CSF is low, but its concentration in synovial fluid is equal to that in plasma within 5 hours of administration. There is enterohepatic cycling of the indomethacin metabolites and probably of indomethacin itself. The t½ in plasma is variable, perhaps because of enterohepatic cycling, but averages ~2.5 hours.

Therapeutic Uses. Indomethacin is estimated to be ~20 times more potent than aspirin. A high rate of intolerance limits the long-term analgesic use of indomethacin. Likewise, it is not commonly used as an analgesic or antipyretic unless the fever has been refractory to other agents (e.g., Hodgkin’s disease). When tolerated, indomethacin often is more effective than aspirin.

Indomethacin is FDA approved for closure of persistent patent ductus arteriosus in premature infants who weigh between 500 and 1750 g, who have a hemodynamically significant patent ductus arteriosus, and in whom other supportive maneuvers have been attempted. The regimen involves intravenous administration of 0.1-0.25 mg/kg every 12 hours for three doses, with the course repeated one time if necessary. Successful closure can be expected in >70% of neonates treated. The principal limitation of treating neonates is renal toxicity, and therapy is interrupted if the output of urine falls to <0.6 mL/kg/hr. Renal failure, enterocolitis, thrombocytopenia, or hyperbilirubinemia are contraindications to the use of indomethacin. Treatment with indomethacin also may decrease the incidence and severity of intraventricular hemorrhage in low-birthweight neonates (Ment et al., 1994).
Adverse Effects and Drug Interactions. A very high percentage (35-50%) of patients receiving usual therapeutic doses of indomethacin experience untoward symptoms, and ~20% must discontinue its use because of the side effects. GI adverse events are common and can be fatal; elderly patients are at significantly greater risk. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect (indeed, the most common side effect) is severe frontal headache, occurring in 25-50% of patients who take the drug for long periods. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering indomethacin to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson’s disease, because they are at greater risk for the development of serious CNS adverse effects. Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely aplastic anemia.

The total plasma concentration of indomethacin plus its inactive metabolites is increased by concurrent administration of probenecid, but indomethacin does not interfere with the uricosuric effect of probenecid. Indomethacin antagonizes the natriuretic and antihypertensive effects of furosemide and thiazide diuretics and blunts the antihypertensive effect of β-receptor antagonists, AT1-receptor antagonists, and ACE inhibitors.

Sulindac
Sulindac (CLINORIL, others) is a congener of indomethacin, which was developed in an attempt to find a less toxic but effective alternative (see Haanen, 2001).

Mechanism of Action. Sulindac is a prodrug and appears to be either inactive or relatively weak in vitro. The active sulfide metabolite is >500 times more potent than sulindac as an inhibitor of COX but less than half as potent as indomethacin. The early notion that gastric or intestinal mucosa is not directly exposed to high concentrations of active drug after oral administration of sulindac provided an initial rationale for the claim that sulindac results in a lower incidence of GI toxicity than indomethacin. However, this notion ignores the fact that the mucosa of the GI tract is directly exposed to circulating levels of active drug and no advantage of sulindac over non-indomethacin NSAIDs has materialized in clinical practice. Similarly, early clinical studies suggesting that sulindac, in contrast to other NSAIDs, did not alter renal PG levels and therefore might avoid the association with hypertension in susceptible individuals, have been discredited (Kulling et al., 1995). In short, the same precautions that apply to other NSAIDs regarding patients at risk for GI toxicity, cardiovascular risk, and renal impairment also apply to sulindac.

Absorption, Distribution, and Elimination. The metabolism and pharmacokinetics of sulindac are complex. About 90% of the drug is absorbed in humans after oral administration (Table 34–1). Peak concentrations of sulindac in plasma are attained within 1-2 hours, while those of the sulfide metabolite occur ~8 hours after oral administration. Sulindac undergoes two major biotransformations. It is oxidized to the sulfone and then reversibly reduced to the sulfide, the active metabolite. The sulfide is formed largely by the action of bowel microflora on sulindac excreted in the bile. All three compounds are found in comparable concentrations in human plasma. The t1/2 of sulindac itself is ~7 hours, but the active sulfide has a t1/2 as long as 18 hours. Sulindac and its metabolites undergo extensive enterohepatic circulation, and all are bound highly to plasma protein. Little of the sulfide (or of its conjugates) is found in urine. The principal components excreted in the urine are the sulfone and its conjugates, which account for nearly 30% of an administered dose; sulindac and its conjugates account for ~20%. Up to 25% of an oral dose may appear as metabolites in the feces.

Therapeutic Uses. Sulindac has been used mainly for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, tendonitis, bursitis, acute painful shoulder, and the pain of acute gout. Its analgesic and anti-inflammatory effects are comparable to those achieved with aspirin. The most common dosage for adults is 150-200 mg twice a day. A use proposed for sulindac is to prevent colon cancer in patients with familial adenomatous polyposis (see “Cancer Chemoprevention”).

Adverse Effects. Although the incidence of toxicity is lower than with indomethacin, untoward reactions to sulindac are common. The typical NSAID GI side effects are seen in nearly 20% of patients. CNS side effects as described earlier for indomethacin in “Adverse Effects and Drug Interactions” are seen in ≤10% of patients. Rash and pruritus occur in 5% of patients. Transient elevations of hepatic transaminases in plasma are less common.

Etodolac
Therapeutic Uses. Etodolac is an acetic acid derivative with some degree of COX-2 selectivity (Figure 34–1). Thus, at anti-inflammatory doses, the frequency of gastric irritation may be less than with other NSAIDs (Warner et al., 1999). A single oral dose (200–400 mg) of etodolac provides postoperative analgesia that typically lasts for 6-8 hours. Etodolac also is effective in the treatment of osteoarthritis, rheumatoid arthritis, and mild to moderate pain, and the drug appears to be uricosuric. Sustained-release preparations are available, allowing once-a-day administration.
Adverse Effects. Etodolac appears to be relatively well tolerated. About 5% of patients who have taken the drug for ≤1 year discontinue treatment because of side effects, which include GI intolerance, rashes, and CNS effects.

Tolmetin

Therapeutic Uses. Tolmetin (TOLECTIN, others), a heteroaryl acetic acid derivative, is approved in the U.S. for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis; it also has been used in the treatment of ankylosing spondylitis. Accumulation of the drug in synovial fluid begins within 2 hours and persists for ≤8 hours after a single oral dose. It appears to be approximately equivalent in efficacy to moderate doses of aspirin, in recommended doses (200-600 mg three times/day). The maximum recommended dose is 1.8 g/day, typically given in divided doses with meals, milk, or antacids to lessen abdominal discomfort. However, peak plasma concentrations and bioavailability are reduced when the drug is taken with food. Tolmetin possesses typical tNSAID properties and side effects.

Adverse Effects. Side effects occur in 25-40% of patients who take tolmetin, and 5-10% discontinue use of the drug. GI side effects are the most common (15%), and gastric ulceration has been observed. CNS side effects similar to those seen with indomethacin and aspirin occur, but they are less common and less severe.

Ketorolac

Ketorolac, a heteroaryl acetic acid derivative, is a potent analgesic but only a moderately effective anti-inflammatory drug.

Therapeutic Uses. The use of ketorolac is limited to ≤5 days for acute pain requiring opioid-level analgesia and can be administered intramuscularly, intravenously, or orally. Like other NSAIDs, aspirin sensitivity is a contraindication to the use of ketorolac. Typical doses are 30-60 mg (intramuscular), 15-30 mg (intravenous), and 10-20 mg (oral). Ketorolac has a rapid onset of action and a short duration of action. It is widely used in postoperative patients, but it should not be used for routine obstetric analgesia. Topical (ophthalmic) ketorolac (ACULAR, others) is FDA approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation after cataract extraction and after corneal refractive surgery. The pharmacology of ketorolac has been reviewed (Buckley and Brogden, 1990).

Adverse Effects. Side effects at usual oral doses include somnolence, dizziness, headache, GI pain, dyspepsia, nausea, and pain at the site of injection. The black box warning for ketorolac stresses the possibility of serious adverse GI, renal, bleeding, and hypersensitivity reactions from the use of this potent NSAID analgesic. Patients receiving greater than recommended doses or concomitant NSAID therapy and those at the extremes of age appear to be particularly at risk.

Nabumetone

Nabumetone is the prodrug of 6-methoxy-2-naphthylacetic acid; thus it is a weak inhibitor of COX in vitro but a potent COX inhibitor in vivo.

Therapeutic Uses. Nabumetone is an anti-inflammatory agent approved in 1991 for use in the U.S. It has been reviewed (Davies, 1997). Clinical trials with nabumetone have indicated substantial efficacy in the treatment of rheumatoid arthritis and osteoarthritis, with a relatively low incidence of side effects. The dose typically is 1000 mg given once daily. The drug also has off-label use in the short-term treatment of soft-tissue injuries.

Absorption, Distribution, and Elimination. Nabumetone is absorbed rapidly and is converted in the liver to one or more active metabolites, principally 6-methoxy-2-naphthylacetic acid, a potent nonselective inhibitor of COX. This metabolite, inactivated by O-demethylation in the liver, is then conjugated before excretion and is eliminated with a t1/2 of ~24 hours.

Common Adverse Effects. Nabumetone is associated with crampy lower abdominal pain and diarrhea, but the incidence of GI ulceration appears to be lower than with other tNSAIDs, although randomized, controlled studies directly comparing tolerability and clinical outcomes have not been performed. Other side effects include rash, headache, dizziness, heartburn, tinnitus, and pruritus.

Diclofenac

Diclofenac, a phenylacetic acid derivative, is among the most commonly used NSAIDs in the E.U. (McNeely and Goa, 1999). It is marketed as a potassium salt (ZIPSOR, others) for oral administration, as an epolamine form (FLECTOR) for transdermal administration, and as a sodium salt for topical (SOLARAZE gel; VOLTAREN ophthalmic drops, others) or oral (VOLTAREN, VOLTAREN-XR, others) administration.

Mechanism of Action. Diclofenac has analgesic, antipyretic, and anti-inflammatory activities. Its potency is substantially greater than that of indomethacin, naproxen, or several other tNSAIDs. The selectivity of diclofenac for COX-2 resembles that of celecoxib. In addition, diclofenac appears to reduce intracellular concentrations of free AA in leukocytes, perhaps by altering its release or uptake.
Absorption, Distribution, and Elimination. Diclofenac has rapid absorption, extensive protein binding, and a t1/2 of 1–2 hours (Table 34–1). The short t1/2 makes it necessary to dose diclofenac considerably higher than would be required to inhibit COX-2 fully at peak plasma concentrations to afford inhibition throughout the dosing interval. There is a substantial first-pass effect, such that only ~50% of diclofenac is available systemically. The drug accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than its plasma t1/2. Diclofenac is metabolized in the liver by a member of the CYP2C subfamily to 4-hydroxydiclofenac, the principal metabolite, and other hydroxylated forms; after glucuronidation and sulfation, the metabolites are excreted in the urine (65%) and bile (35%).

Therapeutic Uses. Diclofenac is approved in the U.S. for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, and acute migraine. Four oral formulations are available: immediate-release tablets (CATAFLAM, others) and capsules (ZIPSOR), delayed-release tablets (VOLTAREN, VOLTAROL (U.K.), others), extended-release tablets (VOLTAREN-XR, others), and a powder for oral solution (CAMBIA). The usual daily oral dosage is 100-200 mg, given in several divided doses. For migraine, one packet of powder (50 mg) dissolved in 1-2 oz of water is administered. Diclofenac for topical use is available as a gel (VOLTAREN) and as a transdermal patch (FLECTOR); systemically active concentrations released from these preparations are thought to contribute more to symptom relief than direct transport through the skin into the inflamed tissue. Diclofenac also is available in combination with misoprostol, a PGE1 analog (ARTHROTEC). This combination retains the efficacy of diclofenac while reducing the frequency of GI ulcers and erosions. In addition, an ophthalmic solution of diclofenac (VOLTAREN, others) is available for treatment of postoperative inflammation following cataract extraction and postoperative pain and photophobia following corneal refractive surgery.

Adverse Effects. Diclofenac produces side effects (particularly GI) in ~20% of patients, and ~2% of patients discontinue therapy as a result. The incidence of serious GI adverse effects did not differ between diclofenac and the COX-2-selective inhibitors, celecoxib (Juni et al., 2002) and etoricoxib (Cannon et al., 2006), likely because diclofenac exhibits a degree of COX-2 selectivity that is similar to that of celecoxib. The drug carries the same black box warning as all other tNSAIDs regarding cardiovascular events. Hypersensitivity reactions have occurred following topical application. Modest elevation of hepatic transaminases in plasma occurs in 5-15% of patients. Although usually moderate, transaminase values may increase more than 3-fold in a small percentage of patients. The elevations usually are reversible. Another member of this phenylacetic acid family of NSAIDs, bromfenac, was withdrawn from the market because of its association with severe, irreversible liver injury in some patients. Bromfenac was re-licensed in the U.S. in 2005 as an ophthalmic solution (XIBROM) for postoperative ocular inflammation and pain following cataract extraction. The structurally similar nepafenac (NEVANAC) was licensed as an ophthalmic in the same year for the same indication. Lumiracoxib, another diclofenac analog (see the following section), was withdrawn from the market in several countries due to liver toxicity. Transaminases should be measured during the first 8 weeks of therapy with diclofenac, and the drug should be discontinued if abnormal values persist or if other signs or symptoms develop. Other untoward responses to diclofenac include CNS effects, rashes, allergic reactions, fluid retention, edema, and renal function impairment. The drug is not recommended for children, nursing mothers, or pregnant women. Consistent with its preference for COX-2, and unlike ibuprofen, diclofenac does not interfere with the antiplatelet effect of aspirin (Catella-Lawson et al., 2001).

Lumiracoxib

Lumiracoxib is an analog of diclofenac; it differs only by an additional methyl group and one fluorine substitution for chlorine. Lumiracoxib has greater COX-2 selectivity in vitro than any of the currently available coxibs. Its structural similarity to diclofenac is thought to account for their common hepatic adverse event profiles that may occur via a mechanism independent from COX inhibition. Lumiracoxib’s potency is similar to that of naproxen. It is used at daily doses of 100 or 200 mg for osteoarthritis and 400 mg for acute pain. Lumiracoxib is not approved in the U.S., and marketing authorization was revoked in 2007 in many countries following reports of serious liver toxicity. Refer to earlier editions of this text for further details.

PROPYIONIC ACID DERIVATIVES

Ibuprofen, the most commonly used tNSAID in the U.S., was the first member of the propionic acid class of NSAIDs to come into general use and is available without a prescription in the U.S. Naproxen, also available without prescription, has a longer but variable t1/2, making twice-daily administration feasible (and perhaps once daily in some individuals). Oxaprozin also has a long t1/2 and may be given once daily. Figure 34–4 shows the chemical structures of propionic acid derivatives.

Mechanism of Action. Propionic acid derivatives are nonselective COX inhibitors with the effects and side effects common to other tNSAIDs. Although there is considerable variation in their potency as COX inhibitors, this is not of obvious clinical consequence. Some of the propionic acid derivatives, particularly naproxen, have prominent inhibitory effects on leukocyte function, and some data suggest that naproxen may have slightly better efficacy with regard to analgesia and relief of morning stiffness. This suggestion of benefit accords with the clinical pharmacology of naproxen that suggests that some but not all individuals dosed with 500 mg twice daily sustain platelet inhibition throughout the dosing interval.

Therapeutic Uses. Ibuprofen, naproxen, flurbiprofen, fenoprofen, ketoprofen, and oxaprozin, are available in the U.S. Several additional agents in this class, including fenbufen, carprofen, pirprofen, indobufen, and tiaprofenic acid, are in use or under study in other countries.

Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis and osteoarthritis. Some also are approved for pain, ankylosing spondylitis, acute gouty arthritis, tendinitis, bursitis, and migraine and for primary dysmenorrhea. Small clinical studies suggest that the propionic acid
derivatives are comparable in efficacy to aspirin for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis, perhaps with improved tolerability.

**Drug Interactions.** Ibuprofen also has been shown to interfere with the antiplatelet effects of aspirin (see “Concomitant NSAIDs and Low-Dose Aspirin”). There also is evidence for a similar interaction between aspirin and naproxen. Propionic acid derivatives have not been shown to alter the pharmacokinetics of the oral hypoglycemic drugs or warfarin.

**Ibuprofen**

**Absorption, Distribution, and Elimination.** Ibuprofen is absorbed rapidly, bound avidly to protein, and undergoes hepatic metabolism (90% is metabolized to hydroxylate or carboxylate derivatives) and renal excretion of metabolites. The $t_{1/2}$ is ~2 hours. Slow equilibration with the synovial space means that its anti-arthritic effects may persist after plasma levels decline. In experimental animals, ibuprofen and its metabolites readily cross the placenta.

**Therapeutic Uses.** Ibuprofen [ADVIL, MOTRIN IB, BRUFEN (U.K.), ANADIN ULTRA (U.K.), others] is supplied as tablets, capsules, caplets, and gelcaps containing 50-800 mg; as oral drops; and as an oral suspension. Dosage forms containing $\leq 200$ mg are available without a prescription. Ibuprofen is licensed for marketing in fixed-dose combinations with antihistamines, decongestants, oxycodone (COMBUNOX, others), and hydrocodone (REPREXAIN, IBUDONE, VICOPROFEN, others). An injectable formulation for closure of patent ductus (ibuprofen lysine; NEOPROFEN) has been licensed since 2006, and an injectable formulation for pain that was initially approved in 1974, CALDOLOR, was licensed by the FDA in 2009 for in-hospital use.

Doses of $\leq 800$ mg four times daily can be used in the treatment of rheumatoid arthritis and osteoarthritis, but lower doses often are adequate. The usual dose for mild to moderate pain, such as that of primary dysmenorrhea, is 400 mg every 4-6 hours as needed. For pain or fever, intravenous ibuprofen is administered at a dose of 100-800 mg over 30 minutes every 4-6 hours. Ibuprofen has been reviewed (Davies, 1998a; Rainsford, 2003).

**Adverse Effects.** Ibuprofen is thought to be better tolerated than aspirin and indomethacin and has been used in patients with a history of GI intolerance to other NSAIDs. Nevertheless, 5-15% of patients experience GI side effects.

Epidemiological studies suggest that the relative risk of myocardial infarction is unaltered by ibuprofen or perhaps slightly increased but is considerably less than the risk from COX-2–selective inhibitors. Other adverse effects of ibuprofen have been reported less frequently. They include thrombocytopenia, rashes, headache, dizziness, blurred vision, and in a few cases, toxic amblyopia, fluid retention, and edema. Patients who develop ocular disturbances should discontinue the use of ibuprofen. Ibuprofen can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects, including delay of parturition. Excretion into breast milk is thought to be minimal, so ibuprofen also can be used with caution by women who are breastfeeding.

**Naproxen**

Naproxen (ALEVE, NAPROSYN, others) is supplied as tablets, delayed-release tablets, controlled-release tablets, gelcaps, and caplets containing 200-750 mg of naproxen or naproxen sodium and as an oral suspension. Dosage forms containing $\leq 200$ mg are available without a prescription. Naproxen is licensed for marketing in fixed-dose combinations with pseudoephedrine (ALEVE-D SINUS & COLD, others) and sumatriptan (TREXIMET) and is co-packaged with lansoprazole (PREVACID NAPRA PAC). Naproxen holds more FDA-approved indications than other tNSAIDs. It is indicated for juvenile and rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, tendonitis, bursitis, and acute gout. The pharmacological properties and therapeutic uses of naproxen have been reviewed (Davies and Anderson, 1997b).

**Absorption, Distribution, and Elimination.** Naproxen is absorbed fully when administered orally. Food delays the rate but not the extent of absorption. Peak concentrations in plasma occur within 2-4 hours and are somewhat more rapid after the administration of naproxen sodium. Absorption is accelerated by the concurrent administration of sodium bicarbonate but delayed by magnesium.
Oxaprozin (DAYPRO, others) has similar pharmacological properties, and adverse effects of orally administered flurbiprofen are operative miosis. The pharmacological properties, therapeutic indications, and adverse effects of orally administered flurbiprofen are similar to those of other anti-inflammatory derivatives of propionic acids, and have been reviewed (Davies, 1995). However, its pharmacokinetic properties differ considerably. Peak plasma levels are not achieved until 3-6 hours after an oral dose, while its t1/2 of 40-60 hours allows for once-daily administration.

**THE FENAMATES**

Mefenamic acid and meclofenamate are N-substituted phenylalanthranilic acids. The pharmacological properties of the fenamates are those of typical NSAIDs, and therapeutically, they have no clear advantages over others in the class.

**Available Preparations and Therapeutic Uses.** The fenamates include mefenamic, meclofenamic, and flufenamic acids. Mefenamic acid [PONSTEL, PONSTAN (U.K.), DYSMAN (U.K.)] and meclofenamate sodium have mostly been used in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and rheumatoid and osteoarthritis; flufenamic acid is not licensed for use in the U.S. These drugs are not recommended for use in children or pregnant women.

**Common Adverse Effects.** Approximately 25% of users develop GI side effects at therapeutic doses. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, is also relatively common. Autoimmune hemolytic anemia is a potentially serious but rare side effect.

**ENOLIC ACIDS (OXICAMS)**

The oxicam derivatives are enolic acids that inhibit COX-1 and COX-2 and have anti-inflammatory, analgesic, and antipyretic activity. In general, they are nonselective COX inhibitors, although one member (meloxicam) shows modest COX-2 selectivity comparable to celecoxib in human blood in vitro and was approved as a COX-2–selective NSAID in some countries. The oxicam derivatives are similar in efficacy to aspirin, indomethacin, or naproxen for the long-term treatment of rheumatoid arthritis or osteoarthritis. Controlled trials comparing GI tolerability with aspirin have not been performed. The main advantage suggested for these compounds is their long t1/2, which permits once-a-day dosing.

**Piroxicam**

The pharmacological properties and therapeutic uses of piroxicam (FELDENE, others) have been reviewed (Guttadauria, 1986).

**Mechanism of Action.** Piroxicam can inhibit activation of neutrophils, apparently independently of its ability to inhibit COX; hence, additional modes of anti-inflammatory action have been proposed, including inhibition of proteoglycanase and collagenase in cartilage.

**Absorption, Distribution, and Elimination.** Piroxicam is absorbed completely after oral administration and undergoes enterohepatic recirculation; peak concentrations in plasma occur within 2-4 hours (Table 34–1). Food may delay absorption. Estimates of the t1/2 in plasma have been variable; the average is ~50 hours.
After absorption, piroxicam is extensively (99%) bound to plasma proteins. Concentrations in plasma and synovial fluid are similar at steady state (e.g., after 7-12 days). Less than 5% of the drug is excreted into the urine unchanged. The major metabolic transformation in humans is hydroxylation of the pyridyl ring (predominantly by an isozyme of the CYP2C subfamily), and this inactive metabolite and its glucuronide conjugate account for ~60% of the drug excreted in the urine and feces.

**Therapeutic Uses.** Piroxicam is approved in the U.S. for the treatment of rheumatoid arthritis and osteoarthritis. Due to its slow onset of action and delayed attainment of steady state, it is less suited for acute analgesia but has been used to treat acute gout. The usual daily dose is 20 mg, and because of the long $t_{1/2}$, steady-state blood levels are not reached for 7-12 days.

**Adverse Events.** Approximately 20% of patients experience side effects with piroxicam, and ~5% of patients discontinue use because of these effects. In 2007, the European Medicines Agency reviewed the safety of orally administered piroxicam and concluded that its benefits outweigh its risks, but advised it should no longer be used first-line, nor should it be used for the treatment of acute (short-term) pain and inflammation. Piroxicam was singled out for special review because of signals that it is associated with more GI and serious skin reactions than other nonselective NSAIDs.

**Meloxicam**

**Therapeutic Uses.** Meloxicam (mobic, others) is FDA-approved for use in osteoarthritis. It has been reviewed (Davies and Skjodt, 1999; Fleischmann et al., 2002). The recommended dose for meloxicam is 7.5-15 mg once daily.

**Adverse Events.** On average, meloxicam demonstrates ~10-fold COX-2 selectivity in *ex vivo* assays. However, this is quite variable, and a clinical advantage or hazard has yet to be established for the drug. Indeed, even with surrogate markers, the relationship to dose is nonlinear. There is significantly less gastric injury compared to piroxicam (20 mg/day) in subjects treated with 7.5 mg/day of meloxicam, but the advantage is lost with a dosage of 15 mg/day.

**Other Oxicams**

A number of other oxicam derivatives are under study or in use outside the U.S. These include several prodrugs of piroxicam (amproxicam, dromicam, and pivoxicam), which have been designed to reduce GI irritation. However, as with sulindac, any theoretical diminution in gastric toxicity associated with administration of a prodrug is offset by gastric COX-1 inhibition from active drug circulating systemically. Other oxicams under study or in use outside the U.S. include lornoxicam, cinnoxicam, sudoxicam, and tenoxicam. The efficacy and toxicity of these drugs are similar to those of piroxicam. Lornoxicam is unique among the enolic acid derivatives in that it has a rapid onset of action and a relatively short $t_{1/2}$ (3-5 hours).

**PYRAZOLON DERIVATIVES**

This group of drugs includes phenylbutazone, oxyphenbutazone, antipyrine, aminopyrine, and dipyrone; currently, only antipyrine eardrops are available for human use in the U.S. These drugs were used clinically for many years but have essentially been abandoned because of their propensity to cause irreversible agranulocytosis. Dipyrone was reintroduced in the E.U. a decade ago because epidemiological studies suggested that the risk of adverse effects was similar to that of acetaminophen and lower than that of aspirin. However, the use of dipyrone remains limited. The pyrazolone derivatives are discussed in previous editions of this book and may be accessed on the G&G website.

**DIARYL HETEROCYCLIC COX-2–SELECTIVE NSAIDS**

The first COX-2–selective NSAIDs were diaryl heterocyclic coxibs. Celecoxib is the only such compound still approved in the U.S. Etoricoxib is approved in several countries; rofecoxib and valdecoxib were withdrawn worldwide and have been discussed in previous editions. Parecoxib is a water soluble, injectable prodrug of valdecoxib marketed for treatment of acute pain in several countries. Lumiracoxib, a structural analog of the phenylacetic acid derivative diclofenac, also is not available in the U.S. and has been discussed earlier (see “Lumiracoxib”).

**Chemistry.** Most members of the diaryl heterocyclic family of selective COX-2 inhibitors consist of a central 1,2-diaryl heterocyclic moiety. Celecoxib is a diaryl substituted pyrazole compound; valdecoxib is a diaryl substituted isoxazol derivative. Valdecoxib was made water soluble for parenteral use (parecoxib) by coupling propionic acid via an amide group to its sulfonamide moiety. Etoricoxib is slightly different; it is a monoaryl substituted bipyridine, which results in a three-ring configuration that is superimposable onto the diaryl heterocyclic pharmacophore. Celecoxib, valdecoxib, and its prodrug parecoxib contain a sulfonamide moiety that bares the risk for cross-reactivity in patients with sulfonamide hypersensitivity and, thus, must be avoided in such patients. Etoricoxib has a methylsulfonyl group that is thought to be free of such risk.

**Mechanism of Action.** Compounds with higher affinity for COX-2 than COX-1 were identified in screens of combinatorial libraries. Subsequent crystallography revealed a hydrophobic pocket in the substrate binding channel of COX-2, which is absent in COX-1 (Figure 34–2). Thus, selective inhibitors of COX-2 are molecules with side chains—the third ring—that fit within this hydrophobic pocket but are too large to block COX-1 with equally high affinity. There is considerable difference in response to the coxibs among individuals (Fries et al., 2006), and it is not known how the degree of selectivity may relate to either efficacy or adverse effect profile, although it seems likely to be related to both. No controlled clinical trials comparing outcomes among the coxibs have been performed. Several TNSAIDs (e.g., nimesulide, diclofenac, meloxicam) exhibit relative selectivity for COX-2 inhibition in whole blood assays that resembles that of celecoxib (FitzGerald and Patrono, 2001; Brune and Hinz, 2004).

**Therapeutic Uses.** All COX-2–selective NSAIDs have been shown to afford relief from postextraction dental pain and to afford...
dose-dependent relief from inflammation in osteoarthritis and rheumatoid arthritis. The European Medicines Agency advises that these medicines should not be used in patients with ischemic heart disease or stroke and that prescribers should exercise caution when using selective COX-2 inhibitors in patients with risk factors for heart disease such as hypertension, hyperlipidemia, diabetes, smoking, or peripheral arterial disease. As for all NSAIDs, the agency advises the lowest effective dose for the shortest possible duration of treatment.

Celecoxib

Celecoxib (CELEBREX) was approved for marketing in the U.S. in 1998. Details of its pharmacology have been reviewed (Davies et al., 2000).

Absorption, Distribution, and Elimination. The bioavailability of oral celecoxib is not known, but peak plasma levels occur at 2-4 hours after the dose is taken. The elderly (≥65 years of age) may have up to 2-fold higher peak concentrations and AUC values than younger patients (≤55 years of age). Celecoxib is bound extensively to plasma proteins. Little drug is excreted unchanged; most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination t½ is ~11 hours. The drug commonly is given once or twice per day during chronic treatment. Renal insufficiency is associated with a modest, clinically insignificant decrease in plasma concentration. Celecoxib has not been studied in patients with severe renal insufficiency. Plasma concentrations are increased by ~40% and 180% in patients with mild and moderate hepatic impairment, respectively, and dosages should be reduced by at least 50% in patients with moderate hepatic impairment. Celecoxib is metabolized predominantly by CYP2C9. Although not a substrate, celecoxib is an inhibitor of CYP2D6. Clinical vigilance is necessary during co-administration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6. For example, celecoxib inhibits the metabolism of metoprolol and can result in its accumulation.

Therapeutic Uses. Celecoxib is approved in the U.S. for the management of acute pain in adults, for the treatment of osteoarthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, and primary dysmenorrhea. The recommended dose for treating osteoarthritis is 200 mg/day as a single dose or divided as two 100-mg doses. In the treatment of rheumatoid arthritis, the recommended dose is 100-200 mg twice per day. In the light of its cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible time. Current evidence does not support use of celecoxib as a first choice among the tNSAIDs. Celecoxib also is approved for the chemoprevention of polyposis coli; however, placebo-controlled trials revealed a dose-dependent increase in myocardial infarction and stroke (Solomon et al., 2006).

Adverse Effects. Placebo-controlled trials have established that celecoxib confers a risk of myocardial infarction and stroke and this appears to relate to dose and the underlying risk of cardiovascular disease that anteceded drug administration. Effects attributed to inhibition of PG production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with celecoxib. Studies in mice and some epidemiological evidence suggest that the likelihood of patients’ developing hypertension while on NSAIDs reflects the degree of inhibition of COX-2 and the selectivity with which it is attained. Indeed, the prevalence of hypertension is higher in patients taking etoricoxib than diclofenac, consistent with the greater selectivity for inhibition of COX-2 of the former drug (Cannon et al., 2006; Laime et al., 2007). Thus, the risk of thrombosis, hypertension, and accelerated atherogenesis are mechanistically integrated. The coxibs should be avoided in patients prone to cardiovascular or cerebrovascular disease. None of the coxibs has established superior efficacy over tNSAIDs. Celecoxib carries the same cardiovascular and GI black box warning as tNSAIDs. Although selective COX-2 inhibitors do not interact to prevent the antiplatelet effect of aspirin, it now is thought that they lose their GI advantage over a tNSAID alone when used in conjunction with aspirin. Experience with selective COX-2 inhibitors in patients who exhibit aspirin hypersensitivity is limited, and caution should be observed.

Parecoxib

Parecoxib is the only COX-2–selective NSAID administered by injection and has been shown to be an effective analgesic for the peri-operative period when patients are unable to take oral medication. It is not widely available, and clinical experience is limited.

Absorption, Distribution, and Elimination. Parecoxib is absorbed rapidly (~15 minutes after intramuscular injection) and converted (15-50 minutes) by deoxymethylation to valdecoxib, the active drug (Table 34–1). Valdecoxib undergoes extensive hepatic metabolism by CYPs 3A4 and 2C9 and non–CYP-dependent glucuronidation. It is a weak inhibitor of CYP2C9 and a weak to moderate inhibitor of CYP2C19. The metabolites of valdecoxib are excreted in the urine. The t½ is ~7-8 hours but can be significantly prolonged in the elderly or those with hepatic impairment, with subsequent drug accumulation.

Therapeutic Uses. Parecoxib (DYNASTAT) is available in Germany and Australia, but not in the U.K. or U.S., for management of acute pain, including moderate to severe postsurgical pain. It is supplied as a lyophilized powder equivalent to 20 or 40 mg parecoxib to be reconstituted with sterile saline for injection.

Adverse Effects. The cardiovascular risk of parecoxib and valdecoxib was detected in two postoperative pain management trials of high-risk patients (Grosser et al., 2006). Patients undergoing coronary bypass graft (CABG) surgery were initially treated intravenously with parecoxib or placebo and then switched to oral valdecoxib or placebo. The majority of cardiovascular events occurred within days of treatment initiation in these populations, who were subject to acute hemostatic activation after bypass surgery. Clinical studies suggest that cardiovascular complications
attributable to COX-2–selective NSAIDs is proportional to baseline cardiovascular risk and to the duration of drug exposure (Grosser et al., 2006). All NSAIDs and celecoxib carry a black box warning contraindicating their use for pain following CABG surgery.

Life-threatening skin reactions (including toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme) have been reported in association with valdecoxib, which contains a sulfonamide group. The risk of hypersensitivity or skin reactions applies also to parecoxib. The drug must be discontinued at the first sign of rash, mucosal lesion, or any other sign of hypersensitivity. This additional hazard renders valdecoxib an unlikely therapeutic choice.

**Etoricoxib**

Etoricoxib is a COX-2–selective inhibitor with selectivity second only to that of lumiracoxib.

**Absorption, Distribution, and Elimination.** Etoricoxib is incompletely (~80%) absorbed and has a long t1/2 of ~20-26 hours (Table 34–1). It is extensively metabolized before excretion. Small studies suggest that those with moderate hepatic impairment are prone to drug accumulation, and the dosing interval should be adjusted. Renal insufficiency does not affect drug clearance.

**Therapeutic Uses.** Etoricoxib (ARCOXIA) is approved in some countries (not in U.S.) as a once-daily medicine for symptomatic relief of the treatment of osteoarthritis, rheumatoid arthritis, and acute gouty arthritis, as well as for the short-term treatment of musculoskeletal pain, postoperative pain, and primary dysmenorrhea (Patrignani et al., 2003).

**Common Adverse Effects.** In keeping with other coxibs, etoricoxib shows decreased GI injury as assessed endoscopically. The European regulatory agency concluded that etoricoxib, along with other coxibs, increased the risk of heart attack and stroke; the agency specifically restricted its use in patients with uncontrolled hypertension.

**Rofecoxib**

Rofecoxib (VIOXX) was introduced in 1999. Details of its pharmacodynamics, pharmacokinetics, therapeutic efficacy, and toxicity have been reviewed (Davies et al., 2003). Based on interim analysis of data from the Adenomatous Polyp Prevention on Vioxx (APPROVe) study, which showed a significant (2-fold) increase in the incidence of serious thromboembolic events in subjects receiving 25 mg of rofecoxib relative to placebo (Bresalier et al., 2005), rofecoxib was withdrawn from the market worldwide in 2004.

**OTHER NONSTEROIDAL ANTI-INFLAMMATORY DRUGS**

**Apazone (Azapropazone)**

Apazone is a tNSAID that has anti-inflammatory, analgesic, and antipyretic activity and is a potent uricosuric agent. It is available in E.U. but not in U.S. Some of its efficacy may arise from its capacity to inhibit neutrophil migration, degranulation, and superoxide production.

Apazone has been used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and gout but usually is restricted to cases where other tNSAIDs have failed. Typical doses are 600 mg three times per day for acute gout. Once symptoms have abated, or for non-gout indications, typical dosage is 300 mg three to four times per day. Clinical experience to date suggests that apazone is well tolerated. Mild GI side effects (nausea, epigastric pain, dyspepsia) and rashes occur in ~3% of patients, while CNS effects (headache, vertigo) are reported less frequently. Precautions appropriate to other nonselective COX inhibitors also apply to apazone.

**Nimesulide**

Nimesulide is a sulfonanilide compound available in Europe that demonstrates COX-2 selectivity similar to celecoxib in whole-blood assays. Additional effects include inhibition of neutrophil activation, decrease in cytokine production, decrease in degradative enzyme production, and possibly activation of glucocorticoid receptors (Bennett, 1999).

Nimesulide is administered orally in doses ≤100 mg twice daily as an anti-inflammatory, analgesic, and antipyretic. Its use in the E.U. is limited to ≤15 days due to the risk of hepatotoxicity.

**CLINICAL SUMMARY: NSAIDs**

Both tNSAIDs and COX-2–selective NSAIDs have anti-inflammatory, analgesic, and antipyretic activity by virtue of inhibition of PG biosynthesis. Selective inhibitors of COX-2 were developed to reduce GI adverse effects but have never been shown to exhibit an efficacy advantage over tNSAIDs, and most have been eliminated from the market due to cardiovascular and hepatic toxicities. Choice and dosing of an NSAID are usually guided by multiple considerations, including the therapeutic indication, patient age, coincident diseases or allergies, the drug’s safety and interaction profile, and cost considerations. Drugs with more rapid onset of action and shorter duration of action (sometimes marketed as rapid release or liquid formulations that facilitate absorption) probably are preferable for fever accompanying minor viral illnesses, pain after minor musculoskeletal injuries, or headache, whereas a longer duration of action may be preferable for management of postoperative or arthritic pain.

The choice among tNSAIDs for the treatment of chronic arthritic conditions such as rheumatoid arthritis largely is empirical. Substantial differences in response have been noted among individuals treated with the same tNSAID and within an individual treated with different tNSAIDs, even when the drugs are structurally related. It is reasonable to give a drug for a week or two as a therapeutic trial and to continue it if the response is satisfactory. Initially, all patients should be asked about previous hypersensitivity to aspirin or any member of the NSAID class. Thereafter, low doses of
the chosen agent should be prescribed to determine initial patient tolerance. Older patients may require lower doses than younger patients to reduce the risk of toxicity. Regulatory agencies stress use of the lowest effective dose for the shortest possible duration of treatment. Alterations in dosing may take several days (>3–4 t1/2) to translate into clinically detectable changes. Delayed distribution into the synovial compartment may extend this interval. Indeed, some NSAIDs that are short lived in plasma are sustained in synovial fluid and may afford sufficient relief even when administered at intervals longer than their plasma t1/2 time. If the patient does not achieve therapeutic benefit from one NSAID, another may be tried. For mild arthropathies, the scheme outlined earlier in this paragraph, together with rest and physical therapy, probably will be sufficiently effective. When the patient has sleeping problems because of pain or morning stiffness, a larger proportion of the daily dose may be given at night. However, patients with more debilitating disease may not respond adequately, prompting the initiation of more aggressive therapy with disease-modifying anti-rheumatic drugs (see below). The experience in children is limited to a small number of drugs, which are dosed by age and body weight.

Some adverse effects may manifest in the first weeks of therapy; however, the risk of gastric ulceration and bleeding accumulates with the duration of dosing. Combination therapy with more than one NSAID is to be avoided. A number of risk factors for GI complications have been determined in epidemiological studies. Patients at high risk for GI complications should be prescribed a gastroprotective agent. These patients also are potential candidates for a COX-2–selective NSAID.

Placebo-controlled trials have established that selective inhibition of COX-2 confers an increased risk of heart attack and stroke. The likelihood of hazard would be expected to be related to selectivity attained in vivo, dose, potency and duration of action, and duration of dosing, as well as the underlying cardiovascular risk profile of an individual patient. It seems likely that some of the older drugs with COX-2 selectivity (e.g., diclofenac) may closely resemble celecoxib. The cardiovascular hazard from both celecoxib and rofecoxib, the two inhibitors for which data are available from placebo-controlled trials lasting >1 year, appeared to increase with chronicity of dosing. This is consistent with a mechanism-based acceleration of atherogenesis directly via inhibition of PGI2 and indirectly due to the rise in blood pressure consequent to inhibition of COX-2–derived PGE2 and PGI2. Similarly, the increased risk conferred by rofecoxib has been shown to dissipate slowly, if at all, in the year after drug cessation. If a COX-2–selective inhibitor is prescribed, it should be used at the lowest possible dose for the shortest period of time.

Patients at risk of cardiovascular disease or prone to thrombosis should not be treated with COX-2–selective NSAIDs. Small absolute risks of thrombosis attributable to these drugs may interact geometrically with small absolute risks from genetic variants like factor V Leiden or concomitant therapies, such as anovulant oral contraceptives. Some tNSAIDs (ibuprofen, naproxen) have been shown to interfere with the antiplatelet activity of low-dose aspirin, and aspirin’s cardioprotective effect may be diminished in patients who take low-dose aspirin and a tNSAID concomitantly. The administration of immediate-release (not enteric-coated) aspirin should be separated from the dose of tNSAID to avoid the interaction. For example, ibuprofen should not be taken within 30 minutes of the ingestion of low-dose aspirin and low-dose aspirin should not be ingested within 8 hours of a dose of ibuprofen. Patients at high risk for cardiovascular events should preferentially use analgesics that do not interfere with platelet action.

DISEASE-MODIFYING ANTI-RHEUMATIC DRUGS

Rheumatoid arthritis is an autoimmune disease that affects ~1% of the population. The pharmacological management of rheumatoid arthritis includes symptomatic relief through the use of NSAIDs. However, although they have anti-inflammatory effects, NSAIDs have minimal, if any effect on progression of joint deformity. DMARDs (disease-modifying anti-rheumatic drugs), on the other hand, reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. DMARDs include a diverse group of small molecule non-biologicals and biological agents (mainly antibodies or binding proteins), as summarized in Table 34–3.

Treatment with single non-biological DMARDs can achieve remission or at least a state of very low disease activity in a large number of rheumatoid arthritis patients (Saag et al., 2008). Combinations of non-biological DMARDs (e.g., methotrexate + sulfasalazine, methotrexate + hydroxychloroquine, methotrexate + leflunomide, methotrexate + sulfasalazine + hydroxychloroquine) are indicated for patients with moderate or high disease activity or prolonged disease duration or for those who fail to respond to a single compound. Biological DMARDs remain reserved for patients...
with persistent moderate or high disease activity and indicators of poor prognosis such as functional impairment, radiographic bony erosions, extra-articular disease, and rheumatoid factor positivity. Therapy is tailored to the individual patient, and the use of these agents must be weighed against their potentially serious adverse effects. The combination of NSAIDs with these agents is common. Short-term glucocorticoids often are used to bring the level of inflammation quickly under control. Glucocorticoids are not suitable for long-term use because of adrenal suppression. The older agents (gold, penicillamine) have unclear mechanisms of action and tend to have slight efficacy and significant side effects. Their pharmacology is described in more detail in previous editions of this book.

**PHARMACOTHERAPY OF GOUT**

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response (Terkeltaub et al., 2006). Acute gout usually causes an exquisitely painful distal monoarthritis, but it also can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects ~0.5-1% of the population of Western countries. Once considered a disease of kings and the rich, gout is no respecter of class and is found at all socioeconomic strata. Indeed, gout is the most common form of inflammatory arthritis in the elderly.

The pathophysiology of gout is understood incompletely. Hyperuricemia, while a prerequisite, does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels (~5 mg/dL, or 0.3 mM) approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Mutations of one of the renal urate transporters, URAT-1, are associated with hypouricemia (Enomo et al., 2002); the uricosuric effect of benzbromarone and probenecid can be explained by inhibition of this transporter. Urate tends to crystallize as monosodium urate in colder or more acidic conditions. Monosodium urate crystals activate monocytes/macrophages via the Toll-like receptor pathway mounting an innate immune response. This results in the secretion of cytokines, including IL-1β and TNF-α; endothelial activation; and attraction of neutrophils to the site of inflammation (Terkeltaub et al., 2006). Neutrophils secrete...
inflammatory mediators that lower the local pH and lead to further urate precipitation.

The aims of treatment are to:

• decrease the symptoms of an acute attack
• decrease the risk of recurrent attacks
• lower serum urate levels

The substances available for these purposes are:

• drugs that relieve inflammation and pain (NSAIDs, colchicine, glucocorticoids)
• drugs that prevent inflammatory responses to crystals (colchicine and NSAIDs)
• drugs that act by inhibition of urate formation (allopurinol, febuxostat) or to augment urate excretion (probenecid)

NSAIDs have been discussed earlier. Glucocorticoids are discussed in Chapter 42. This section focuses on colchicine, allopurinol, febuxostat and the uricosuric agents probenecid and benz bromarone.

Colchicine

Colchicine is one of the oldest available therapies for acute gout. Plant extracts containing colchicine were used for joint pain in the sixth century. Colchicine is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses. There no longer is a role for colchicine in the treatment of primary biliary cirrhosis, psoriasis, or Behçet’s disease.

Mechanism of Action. Colchicine exerts a variety of pharmacological effects, but how these occur or how they relate to its activity in gout is not well understood. Its structure-activity relationship has been discussed (Levy et al., 1991). It has antimitotic effects, arresting cell division in G1 by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (e.g., neutrophils, GI epithelium). Colchicine may alter neutrophil motility in ex vivo assays (Levy et al., 1991). Experimental data suggest that colchicine decreases the crystal-induced secretion of chemotactic factors and superoxide anions by activated neutrophils. It also limits neutrophil adhesion to endothelium by modulating the expression of endothelial adhesion molecules. Higher concentrations inhibit IL-1β processing and release from neutrophils in vitro.

Colchicine inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melanin granules in melanophores. These processes also may involve interference with the microtubular system, but whether this occurs at clinically relevant concentrations is questionable.

Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances GI activity by neurogenic stimulation but depresses it by a direct effect, and alters neuromuscular function.

Absorption, Distribution, and Elimination. The absorption of oral colchicine is rapid but variable. Peak plasma concentrations occur 0.5-2 hours after dosing. In plasma, 50% of colchicine is protein bound. The formation of colchicine-tubulin complexes in many tissues contributes to its large volume of distribution. There is significant enterohepatic circulation. The exact metabolism of colchicine in humans is unknown, but in vitro studies indicate that it may undergo oxidative demethylation by CYP3A4. Indeed, other CYP3A4 substrates, such as cimetidine, have been associated with an increase in colchicine plasma t1/2 and the emergence of colchicine toxicity. The drug is contraindicated in patients with hepatic or renal impairment requiring concomitant therapy with CYP3A4 or P-glycoprotein inhibitors. Only 10-20% is excreted in the urine, although this increases in patients with liver disease. The kidney, liver, and spleen also contain high concentrations of colchicine, but it apparently is largely excluded from heart, skeletal muscle, and brain. The plasma t1/2 of colchicine is ~9 hours, but the drug can be detected in leukocytes and in the urine for at least 9 days after a single intravenous dose.

Therapeutic Uses. A minimum of 3 days, but preferably 7 or 14 days, should elapse between courses of gout treatment with colchicine to avoid cumulative toxicity. Patients with hepatic or renal disease and dialysis patients should receive reduced doses and/or less frequent therapy. Great care should be exercised in prescribing colchicine for elderly patients, for whom the dose should be based on renal function. For those with cardiac, renal, hepatic, or GI disease, NSAIDs or glucocorticoids may be preferred.

Acute Gout. Colchicine dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 hours of attack onset. Pain, swelling, and redness abate within 12 hours and are completely gone within 48-72 hours. In the past, the typical dosing regimen was 0.6 mg each hour until pain was relieved or diarrhea developed; the typical course of therapy ranged from 4-8 mg. The new regimen approved by the FDA in 2009 for adults recommends a total of only two doses taken 1 hour apart: 1.2 mg (two tablets) at the first sign of a gout flare followed by 0.6 mg (one tablet) 1 hour later. The dose must be adjusted in patients exposed to inhibitors of P-glycoprotein or CYP3A4 within the previous 14 days.

Prevention of Acute Gout. The main off-label indication for colchicine is in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose for prophylaxis is 0.6 mg taken orally 3 or 4 days/wk for patients who have <1 attack per year, 0.6 mg daily for patients who have >1 attack per
year, and 0.6 mg two or three times daily for patients who have severe attacks. The dose must be decreased for patients with impaired renal function.

**Familial Mediterranean Fever.** The administration of daily colchicine is useful for the prevention of attacks of familial Mediterranean fever and prevention of amyloidosis, which may complicate this disease. The dose for adults and children >12 years of age is 1.2-2.4 mg daily. The dose for patients as young as 4 years is reduced on the basis of age.

**Adverse Effects.** Exposure of the GI tract to large amounts of colchicine and its metabolites via enterohepatic circulation and the rapid rate of turnover of the GI mucosa may explain why the GI tract is particularly susceptible to colchicine toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects and the earliest signs of impending colchicine toxicity. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose or route of administration, of several hours or more between the administration of the drug and the onset of symptoms. A dosing study required as part of FDA approval demonstrated that one dose initially and a single additional dose after 1 hour was much less toxic than traditional hourly dosing for acute gout flares. Acute intoxication causes hemorrhagic gastropathy. Intravenous colchicine was previously used to treat acute gouty arthritis; however, this route obviates early GI side effects that can be a harbinger of serious systemic toxicity. The FDA suspended the U.S. marketing of all injectable dosage forms of colchicine in 2008. Other serious side effects of colchicine therapy include myelosuppression, leukopenia, granulocytopenia, thrombocytopenia, aplastic anemia, and rhabdomyolysis. Life-threatening effects include myelosuppression, leukopenia, granulocytopenia, thrombocytopenia, aplastic anemia, and rhabdomyolysis. Life-threatening toxicities are associated with administration of concomitant therapy with P-glycoprotein or CYP3A4 inhibitors.

### Allopurinol

Allopurinol inhibits xanthine oxidase and prevents the synthesis of urate from hypoxanthine and xanthine. Allopurinol is used to treat hyperuricemia in patients with gout and to prevent it in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction is the underlying defect in most gout patients, allopurinol remains effective therapy.

**History.** Allopurinol initially was synthesized as a candidate antineoplastic agent but was found to lack antineoplastic activity. Subsequent testing showed it to be an inhibitor of xanthine oxidase that was useful clinically for the treatment of gout.

**Chemistry.** Allopurinol is an analog of hypoxanthine. Its active metabolite, oxygenpurinol, is an analog of xanthine.

**Mechanism of Action.** Both allopurinol and its primary metabolite, oxypurinol (alloxanthine), inhibit xanthine oxidase and reduce urate production. Allopurinol competitively inhibits xanthine oxidase at low concentrations and is a noncompetitive inhibitor at high concentrations. Allopurinol also is a substrate for xanthine oxidase; the product of this reaction, oxygenpurinol, also is a noncompetitive inhibitor of the enzyme. The formation of oxygenpurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of allopurinol.

In the absence of allopurinol, the dominant urinary purine is uric acid. During allopurinol treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Because each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during allopurinol therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients with a very high urate load before allopurinol therapy, which can be minimized by liberal fluid intake and alkalization of the urine with sodium bicarbonate, potassium citrate, or citrate combinations such as modified Shohl’s solution.

Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, allopurinol cannot restore renal function but may delay disease progression.

The incidence of acute attacks of gouty arthritis may increase during the early months of allopurinol therapy as a consequence of mobilization of tissue stores of uric acid. Co-administration of colchicine helps suppress such acute attacks. After reduction of excess tissue stores of uric acid, the incidence of acute attacks decreases and colchicine can be discontinued.

In some patients, the allopurinol-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of re-utilization of oxypurines and feedback inhibition of de novo purine biosynthesis.

**Absorption, Distribution, and Elimination.** Allopurinol is absorbed relatively rapidly after oral ingestion, and peak plasma concentrations are reached within 60-90 minutes. About 20% is excreted in the feces in 48-72 hours, presumably as unabsorbed drug, and 10-30% is excreted unchanged in the urine. The remainder undergoes metabolism, mostly to oxypurinol apparently by the catalytic activity of aldehyde oxidoreductase. Oxypurinol is excreted slowly in the urine by glomerular filtration, counterbalanced by some tubular reabsorption. The plasma t_{1/2} of allopurinol and oxypurinol is ~1-2 hours and ~18-30 hours (longer in those with renal impairment), respectively. This allows for once-daily dosing and makes allopurinol the most commonly used antihyperuricemic agent.

Allopurinol and its active metabolite oxypurinol are distributed in total tissue water, with the exception of brain, where their concentrations are about one-third of those in other tissues. Neither compound is bound to plasma proteins. The plasma concentrations of the two compounds do not correlate well with therapeutic or toxic effects. The clinical pharmacology of allopurinol and its metabolite have been reviewed (Day et al., 2007).
Drug Interactions. Allopurinol increases the \( t_{1/2} \) of probenecid and enhances its uricosuric effect, while probenecid increases the clearance of oxypurinol, thereby increasing dose requirements of allopurinol.

Allopurinol inhibits the enzymatic inactivation of mercaptopurine and its derivative azathioprine by xanthine oxidase. Thus, when allopurinol is used concomitantly with oral mercaptopurine or azathioprine, dosage of the antineoplastic agent must be reduced to one-fourth to one-third of the usual dose (see Chapters 35 and 61). This is of importance when treating gout in the transplant recipient. The risk of bone marrow suppression also is increased when allopurinol is administered with cytotoxic agents that are not metabolized by xanthine oxidase, particularly cyclophosphamide.

Allopurinol also may interfere with the hepatic inactivation of other drugs, including warfarin. Although the effect is variable, increased monitoring of prothrombin activity is recommended in patients receiving both medications.

It remains to be established whether the increased incidence of rash in patients receiving concurrent allopurinol and ampicillin should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 36).

Therapeutic Uses. Allopurinol (ZYLORIM, ALOPRIM, others) is available for oral and intravenous use. Oral therapy provides effective therapy for primary and secondary gout, hyperuricemia secondary to malignancies, and calcium oxalate calculi. Intravenous therapy is indicated for hyperuricemia secondary to cancer chemotherapy for patients unable to tolerate oral therapy.

Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). Allopurinol generally is used in complicated hyperuricemia post-transplantation, to prevent acute tumor lysis syndrome, or in patients with hyperuricemia post-transplantation. If necessary, it can be used in conjunction with a uricosuric agent such as probenecid.

The goal of therapy is to reduce the plasma uric acid concentration to <6 mg/dL (<360 μmol/L). In the management of gout, it is customary to anteced allopurinol therapy with colchicine and to avoid starting allopurinol during an acute attack. Fluid intake should be sufficient to maintain daily urinary volume of >2 L; slightly alkaline urine is preferred. An initial daily dose of 100 mg in patients with estimated glomerular filtration rates >40 mg/min is increased by 100-mg increments at weekly intervals according to the antihyperuricemic effect achieved. Plasma uric acid concentration <6 mg/dL (<360 μmol/L) are attained in less than half of the patients on 300 mg/day, the most commonly prescribed dose. Achieving sufficient reduction of uric acid serum levels may require 400-600 mg/day. Those with hematological malignancies may need up to 800 mg/day beginning 2-3 days before the start of chemotherapy. Interindividually variability in drug response is high. Daily doses >300 mg should be divided. Dosage must be reduced in patients in proportion to the reduction in glomerular filtration (e.g., 300 mg/day if creatinine clearance is >90 mL/min, 200 mg/day if creatinine clearance is between 60 and 90 mL/min, 100 mg/day if creatinine clearance is 30-60 mL/min, and 50-100 mg/day if creatinine clearance is <30 mL/min) (Terkeltaub, 2003).

The usual daily dose in children with secondary hyperuricemia associated with malignancies is 150-300 mg, depending on age.

Allopurinol also is useful in lowering the high plasma concentrations of uric acid in patients with Lesch-Nyhan syndrome and thereby prevents the complications resulting from hyperuricemia; there is no evidence that it alters the progressive neurological and behavioral abnormalities that are characteristic of the disease.

Adverse Effects. Allopurinol generally is well tolerated, but the drug occasionally induces drowsiness. The most common adverse effects are hypersensitivity reactions that may manifest after months or years of therapy. Serious hypersensitivity reactions preclude further use of the drug.

The cutaneous reaction caused by allopurinol is predominantly a pruritic, erythematous, or maculopapular eruption. Rarely, toxic epidermal necrolysis or Stevens-Johnson syndrome occurs, which can be fatal. The risk for Stevens-Johnson syndrome is limited primarily to the first 2 months of treatment. Because the rash may precede severe hypersensitivity reactions, patients who develop a rash should discontinue allopurinol. If indicated, desensitization to allopurinol can be carried out starting at 10-25 μg/day, with the drug diluted in oral suspension and doubled every 3-14 days until the desired dose is reached. This is successful in approximately half of patients (Terkeltaub, 2003). Oxypurinol has orphan drug status and is available for compassionate use in the U.S. for patients intolerant of allopurinol.

Fever, malaise, and myalgias also may occur. Such effects are noted in ~3% of patients with normal renal function and more frequently in those with renal impairment. Transient leukopenia or leukocytosis and eosinophilia are rare reactions that may require cessation of therapy. Hepatomegaly and elevated levels of transaminases in plasma and progressive renal insufficiency also may occur.

Febuxostat

Febuxostat is a novel xanthine oxidase inhibitor that was recently approved for treatment of hyperuricemia in patients with gout (Pascual et al., 2009).

Chemistry. Febuxostat is a two-ring molecule with substituted phenyl and thiazole rings.

Mechanism of Action. Febuxostat is a non-purine inhibitor of xanthine oxidase. While oxypurinol, the active metabolite of allopurinol, inhibits the reduced form of the enzyme, febuxostat forms a stable
complex with both the reduced and oxidized enzyme and inhibits catalytic function in both states.

Absorption, Distribution, and Elimination. Febuxostat is rapidly absorbed with maximum plasma concentrations between 1-1.5 hours post-dose. The absorption of radiolabeled compound was estimated to be at least 49%, however, the absolute bioavailability is unknown. Magnesium hydroxide and aluminum hydroxide delay absorption ~1 hour. Food reduces absorption slightly, but has no clinically significant effect on the reduction of serum uric acid concentration. Febuxostat is highly plasma protein bound and has a volume of distribution of 50 L. It is extensively metabolized by oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes conjugation via UGTs 1A1, 1A3, 1A9 and 2B7. The relative contribution of each metabolic route is not known. The oxidation of the isobutyl side chain leads to the formation of four pharmacologically active hydroxy metabolites, all of which occur in plasma at markedly lower concentrations than febuxostat. Febuxostat has a t₁/₂ of 5-8 hours and is eliminated by both hepatic and renal pathways. Mild to moderate renal or hepatic impairment does not affect its elimination kinetics relevantly.

Therapeutic Use. Febuxostat (ULORIC; ADNEURIC [EUROPE]) is approved for hyperuric patients with gout attacks, but not recommended for treatment of asymptomatic hyperuricemia. It is available in 40 and 80-mg oral tablets. Three randomized controlled clinical trials that compared febuxostat with allopurinol showed that 40 mg/day febuxostat lowered serum uric acid to similar levels as 300 mg/day allopurinol. More patients reached the target concentration of 6.0 mg/dL (360 μmol/L) on 80 mg/day febuxostat than on 300 mg/day allopurinol (Becker et al., 2005a; Becker et al., 2005b; Schumacher et al., 2008). Thus, therapy should be initiated with 40 mg/day and the dose increased if the target serum uric acid concentration is not reached within 2 weeks.

Common Adverse Events. The most common adverse reactions in clinical studies were liver function abnormalities, nausea, joint pain, and rash. Liver function should be monitored periodically. An increase in gout flares was frequently observed after initiation of therapy, due to reduction in serum uric acid levels resulting in mobilization of urate from tissue deposits. Concurrent prophylactic treatment with an NSAID or colchicine is usually required. There was also a numerically higher rate of myocardial infarction and stroke in patients on febuxostat than on allopurinol. It is currently unknown whether there is a causal relationship between the cardiovascular events and febuxostat therapy or whether these were due to chance. The FDA has imposed as a condition for approval that a prospective study designed to assess the drug’s cardiovascular safety be performed. Meanwhile patients should be monitored for cardiovascular complications.

Drug Interactions. Plasma levels of drugs that are metabolized by xanthine oxidase (e.g., theophylline, mercaptourine, azathioprine) can be expected to increase—possibly to toxic levels—when administered concurrently with febuxostat, although drug interaction studies with these drugs have not been conducted. Thus, febuxostat is contraindicated in patients on azathioprine, mercaptourine, or theophylline. Based on in vitro studies, interactions between febuxostat and CYP inhibitors are likely, but interactions studies have not been performed in humans.

### Rasburicase

Rasburicase (ELITEK) is a recombinant urate oxidase that catalyzes the enzymatic oxidation of uric acid into the soluble and inactive metabolite allantoin. It has been shown to lower urate levels more effectively than allopurinol (Bosly et al., 2003). It is indicated for the initial management of elevated plasma uric acid levels in pediatric patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia.

Produced by a genetically modified Saccharomyces cerevisiae strain, the therapeutic efficacy may be hampered by the production of antibodies against the drug. Hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis have been associated with the use of rasburicase. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. Rasburicase causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug. The recommended dose of rasburicase is 0.15 mg/kg or 0.2 mg/kg as a single daily dose for 5 days, with chemotherapy initiated 4-24 hours after infusion of the first rasburicase dose.

### Uricosuric Agents

Uricosuric agents increase the rate of excretion of uric acid. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption predominates, such that the net the amount excreted usually is ~10% of that filtered. Reabsorption is mediated by an organic anion transporter family member, URAT-1, which can be inhibited. A number of other organic acid transporters, may also participate in urate exchange at the basolateral membrane of proximal tubule epithelial cells (Terkeltaub et al., 2006).

URAT-1 exchanges urate for either an organic anion such as lactate or nicotinate or less potent for an inorganic anion such as chloride. The monocarboxylate metabolite of the anti-tuberculous drug pyrazinamide, an organic anion, is a potent stimulator of urate reuptake. Uricosuric drugs such as probenecid, sulfinpyrazone, benz bromarone, and losartan compete with urate for the transporter, thereby inhibiting its reabsorption via the urate–anion exchanger system. However, transport is bidirectional, and depending on dosage, some drugs, including salicylates, may either decrease or increase the excretion of uric acid. Decreased excretion usually occurs at a low dosage, while increased excretion is observed at a higher dosage. Not all agents show this phenomenon, and one uricosuric drug may either add to or inhibit the action of another.

Two mechanisms for a drug-induced decrease in urinary excretion of urate have been advanced; they are not mutually exclusive. The
The transport of drugs such as penicillin G also may be affected by very low concentrations of the drug. Higher concentrations may inhibit urate reabsorption in the usual manner. The second proposal suggests that the urate-retaining anionic drug gains access to the intracellular fluid by an independent mechanism and promotes reabsorption of urate across the brush border by anion exchange.

There are also two mechanisms by which one drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by one drug may counterbalance the inhibition of urate reabsorption by the other.

Many compounds have incidental uricosuric activity by acting as exchangeable anions, but only probenecid is prescribed routinely for this purpose. Sulfinpyrazone has been withdrawn from the U.S. market (see the previous edition of this book for the pharmacology of sulfinpyrazone). Benzbromarone is an alternative uricosuric agent that is available in the E.U. Conversely, a number of drugs and toxins cause retention of urate; these have been reviewed elsewhere (Maalouf et al., 2004). The angiotensin II–receptor antagonist, losartan, has a modest uricosuric effect and may be an option for those who are intolerant to probenecid and are hypertensive.

**Probenecid.** Probenecid is a highly lipid-soluble benzoic acid derivative (pKₐ 3.4).

![Chemical Structure of Probenecid]

**Mechanism of Action**

**Inhibition of Organic Acid Transport.** The actions of probenecid are confined largely to inhibition of the transport of organic acids across epithelial barriers. When tubular secretion of a substance is inhibited, its final concentration in the urine is determined by the degree of filtration, which in turn is a function of binding to plasma protein, and by the degree of reabsorption. The significance of each of these factors varies widely with different compounds. Usually, the end result is decreased tubular secretion of the compound, leading to decreased urinary and increased plasma concentration. Probenecid inhibits the reabsorption of uric acid by organic anion transporters, principally URAT-1. Uric acid is the only important endogenous compound whose excretion is known to be increased by probenecid. The uricosuric action of probenecid is blunted by the co-administration of salicylates.

**Inhibition of Transport of Miscellaneous Substances.** Probenecid inhibits the tubular secretion of a number of drugs, such as methotrexate and the active metabolite of clofibrate. It inhibits renal secretion of the inactive glucuronide metabolites of NSAIDs such as naproxen, ketoprofen, and indomethacin, and thereby can increase their plasma concentrations.

**Inhibition of Monoamine Transport to CSF.** Probenecid inhibits the transport of 5-hydroxyindoleacetic acid (5-HIAA) and other acidic metabolites of cerebral monoamines from the CSF to the plasma. The transport of drugs such as penicillin G also may be affected.

**Inhibition of Biliary Excretion.** Probenecid depresses the biliary secretion of certain compounds, including the diagnostic agents indocyanine green and bromosulfophthalein (BSP). It also decreases the biliary secretion of rifampin, leading to higher plasma concentrations.

**Absorption, Distribution, and Elimination.** Probenecid is absorbed completely after oral administration. Peak concentrations in plasma are reached in 2–4 hours. The t½ of the drug in plasma is dose dependent and varies from <5 hours to >8 hours over the therapeutic range. Between 85% and 95% of the drug is bound to plasma albumin. The 5-15% of unbound drug is cleared by glomerular filtration. The majority of the drug is secreted actively by the proximal tubule. The high lipid solubility of the undissociated form results in virtually complete absorption by back diffusion unless the urine is markedly alkaline. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

**Therapeutic Uses (Gout).** Probenecid (PROBALAN, BENURYL (U.K.)) is marketed for oral administration. The starting dose is 250 mg twice daily, increasing over 1-2 weeks to 500-1000 mg twice daily. Probenecid increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. Probenecid should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant colchicine or NSAIDs are indicated early in the course of therapy to avoid precipitating an attack of gout, which may occur in ≤20% of gouty patients treated with probenecid alone.

**Combination with Penicillin.** Probenecid was developed for the purpose of delaying the excretion of penicillin. Higher doses of probenecid are used as an adjuvant to prolong penicillin concentrations. This dosing method usually is confined to those being treated for gonorrhea or neurosyphilis infections or to cases in which penicillin resistance may be an issue (see Chapter 53).

**Common Adverse Effects.** Probenecid is well tolerated. Approximately 2% of patients develop mild GI irritation. The risk is increased at higher doses, and caution should be used in those with a history of peptic ulcer. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of <50 mL/min. Hypersensitivity reactions usually are mild and occur in 2-4% of patients. Serious hypersensitivity is extremely rare. The appearance of a rash during the concurrent administration of probenecid and penicillin G presents the physician with an awkward diagnostic dilemma. Substantial overdosage with probenecid results in CNS stimulation, convulsions, and death from respiratory failure.

**Benzbromarone**

Benzbromarone is a potent uricosuric agent that is used in Europe. It was withdrawn from the market in Europe in 2003, but was registered again with restrictions in some countries in 2004. Hepatotoxicity has been reported in conjunction with its use. The drug is absorbed readily after oral ingestion, and peak concentrations in blood are achieved in ~4 hours. It is metabolized to monobromine and dehalogenated derivatives, both of which have uricosuric activity, and is excreted primarily in the bile. The uricosuric action is blunted by aspirin or sulfinpyrazone. No paradoxical retention of urate has been observed.

It is a potent and reversible inhibitor of the urate–anion exchanger in the proximal tubule. As the micronized powder, it is effective in a single daily dose of 40–80 mg. It is effective in patients with renal insufficiency and may be prescribed to patients who are either allergic or
refractory to other drugs used for the treatment of gout. Preparations that combine allopurinol and benzbromarone are more effective than either drug alone in lowering serum uric acid levels, in spite of the fact that benzbromarone lowers plasma levels of oxypurinol, the active metabolite of allopurinol.

**CLINICAL SUMMARY: TREATMENT OF GOUT**

Gout is an inflammatory response to the precipitation of monosodium urate crystals in tissues. Although distal joints are typically affected, deposition of crystals can principally occur in any tissue and present as tophaceous gout or urate nephropathy if crystallization is localized in the renal medulla.

**Treatment of Acute Gout.** Acute gouty arthritis resolves spontaneously within a few days to several weeks. Anti-inflammatory therapy with NSAIDs, colchicines, and intra-articular or systemic glucocorticoids alleviates symptoms more quickly. The IL-1β antagonist, anakinra, is under investigation for this indication.

Several NSAIDs reportedly are effective in the treatment of acute gout, particularly if treatment is initiated within 24 hours of symptom onset. When effective, NSAIDs should be given at relatively high doses for 3-4 days and then tapered for a total of 7-10 days. Indomethacin, naproxen, sulindac, celecoxib, and etoricoxib all have been found to alleviate inflammatory symptoms, although the first three are the only NSAIDs that have received FDA approval for the treatment of gout. Aspirin is not used because it can inhibit urate excretion at low doses, and through its uricosuric actions, can increase the risk of renal calculi at higher doses. In addition, aspirin can inhibit the actions of uricosuric agents. Likewise, apazone should not be used in acute gout because of the concern that its uricosuric effects may promote nephrolithiasis.

Glucocorticoids give rapid relief within hours of therapy. Systemic therapy is initiated with high doses that are then tapered rapidly (e.g., prednisone 30-60 mg/day for 3 days, then tapered over 10-14 days), depending on the size and number of affected joints. Intra-articular glucocorticoids are useful if only a few joints are involved and septic arthritis has been ruled out. Further information on these agents is available in Chapter 42.

Colchicine is thought to alleviate inflammation rapidly through multiple mechanisms, including the inhibition of neutrophil chemotaxis and activation. Symptoms resolve usually within 2-3 days, but adverse GI events are frequent, and toxicity may include bone marrow depression. The therapeutic index of colchicine is narrow—especially in the elderly.

**Prevention of Recurrent Attacks.** Recurrent attacks of gout can be prevented with the use of NSAIDs or colchicine (e.g., 0.6 mg daily or on alternate days). These agents are used early in the course of uricosuric therapy when mobilization of urate is associated with a temporary increase in the risk of acute gouty arthritis.

**Antihyperuricemic Therapy.** Isolated hyperuricemia is not necessarily an indication for therapy, as not all of these patients develop gout. Persistently elevated uric acid levels, complicated by recurrent gouty arthritis, nephropathy, or subcutaneous tophi, can be lowered by allopurinol or febuxostat, which inhibit the formation of urate, or by uricosuric agents. Some physicians recommend measuring 24-hour urinary urate levels in patients who are on a low-purine diet to distinguish underexcretors from overproducers. However, tailored and empirical therapies have similar outcomes (Terkeltaub, 2003).

Probenecid and other uricosuric agents increase the rate of uric acid excretion by inhibiting its tubular reabsorption. They compete with uric acid for organic acid transporters, primarily URAT-1, which mediate urate exchange in the proximal tubule. Certain drugs, particularly thiazide diuretics (see Chapter 25) and immunosuppressant agents (especially cyclosporine) may impair urate excretion and thereby increase the risk of gout attacks. Probenecid generally is well tolerated but causes mild GI irritation in some patients. Other uricosuric agents, sulfinpyrazone and benzbromarone, are not available in the U.S.

Rasburicase lowers urate levels by enzymatic oxidation of uric acid into the soluble and inactive metabolite allantoin. It is approved for management of hyperuricemia in children secondary to malignancies. Routine use for hyperuricemia in adults would be limited by the risk of antibody development to uricase, which may result in hypersensitivity. A pegylated uricase form is under development.

THE IMMUNE RESPONSE

The immune system evolved to discriminate self from nonself. Multicellular organisms were faced with the problem of destroying infectious invaders (microbes) or dysregulated self (tumors) while leaving normal cells intact. These organisms responded by developing a robust array of receptor-mediated sensing and effector mechanisms broadly described as innate and adaptive. Innate, or natural, immunity is primitive, does not require priming, and is of relatively low affinity, but is broadly reactive. Adaptive, or learned, immunity is antigen specific, depends on antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system being most active early in an immune response and adaptive immunity becoming progressively dominant over time. The major effectors of innate immunity are complement, granulocytes, monocytes/macrophages, natural killer cells, mast cells, and basophils. The major effectors of adaptive immunity are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells are important in the normal immune response to infection and tumors but also mediate transplant rejection and auto-immunity. Immunoglobulins (antibodies) on the B-lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of self major histocompatibility complex (MHC) antigens (called human leukocyte antigens [HLAs] in humans) on the surface of antigen-presenting cells, such as dendritic cells, macrophages, and other cell types expressing MHC class I (HLA-A, -B, and -C) and class II antigens (HLA-DR, -DP, and -DQ) in humans. Once activated by specific antigen recognition via their respective clonally restricted cell-surface receptors, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that perform as effectors and regulators of the immune response.

The impact of the immune system in human disease is enormous. Developing vaccines against emerging infectious agents such as human immunodeficiency virus (HIV) and Ebola virus is among the most critical challenges facing the research community. Immune system–mediated diseases are significant medical problems. Immunological diseases are growing at epidemic proportions that require aggressive and innovative approaches to develop new treatments. These diseases include a broad spectrum of auto-immune diseases, such as rheumatoid arthritis, type I diabetes mellitus, systemic lupus erythematosus, and multiple sclerosis (MS); solid tumors and hematological malignancies; infectious diseases; asthma; and various allergic conditions. Furthermore, one of the great therapeutic opportunities for the treatment of many disorders is organ transplantation. However, immune system–mediated graft rejection remains the single greatest barrier to widespread use of this technology. An improved understanding of the immune system has led to the development of new therapies to treat immune system–mediated diseases.

This chapter briefly reviews drugs used to modulate the immune response in three ways: immunosuppression, tolerance, and immunostimulation. Four major classes of immunosuppressive drugs are discussed: glucocorticoids (Chapter 42), calcineurin inhibitors, antiproliferative and antimetabolic agents (Chapter 61), and antibodies. The “holy grail” of immunomodulation is
the induction and maintenance of immune tolerance, the active state of antigen-specific nonresponsiveness. Approaches expected to overcome the risks of infections and tumors with immunosuppression are reviewed. These include co-stimulatory blockade, donor-cell chimerism, soluble HLAs, and antigen-based therapies. A general discussion of the limited number of immunostimulant agents is presented, followed by an overview of active and passive immunization, and concluding with a brief case study of immunotherapy for MS.

IMMUNOSUPPRESSION

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are:

- glucocorticoids
- calcineurin inhibitors
- anti-proliferative/antimetabolic agents
- biologicals (antibodies)

These drugs have met with a high degree of clinical success in treating conditions such as acute immune rejection of organ transplants and severe autoimmune diseases. However, such therapies require lifelong use and nonspecifically suppress the entire immune system, exposing patients to considerably higher risks of infection and cancer. The calcineurin inhibitors and glucocorticoids, in particular, are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibody preparations directed at reactive T cells are important adjunct therapies and provide a unique opportunity to target specifically immune-reactive cells. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mammalian target of rapamycin (mTOR) inhibitors (sirolimus, everolimus) and anti-CD25 (interleukin-2 receptor [IL-2R]) antibodies (basiliximab, daclizumab) target growth-factor pathways, substantially limiting clonal expansion and thus potentially promoting tolerance. Immunosuppressive drugs used more commonly today are described in the rest of this section. Many more selective therapeutic agents under development are expected to revolutionize immunotherapy in the next decade.

General Approach to Organ Transplantation Therapy

Organ transplantation therapy is organized around five general principles. The first principle is careful patient preparation and selection of the best available ABO blood type–compatible HLA match for organ donation. Second, a multitiered approach to immunosuppressive drug therapy, similar to that in cancer chemotherapy, is employed. Several agents, each of which is directed at a different molecular target within the allograft response (Table 35–1; Hong and Kahan, 2000), are used simultaneously. Synergistic effects permit use of the various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect. The third principle is that greater immunosuppression is required to gain early engraftment and/or to treat established rejection than to maintain long-term immunosuppression. Therefore, intensive induction and lower-dose maintenance drug protocols are employed. Fourth, careful investigation of each episode of transplant dysfunction is required, including evaluation for rejection, drug toxicity, and infection, keeping in mind that these various problems can and often do co-exist. Organ-specific problems (e.g., obstruction in the case of kidney transplants) also must be considered. The fifth principle, which is common to all drugs, is that a drug should be reduced or withdrawn if its toxicity exceeds its benefit.

Biological Induction Therapy

Induction therapy with polyclonal and monoclonal antibodies (mAbs) has been an important component of immunosuppression dating back to the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection in renal transplant recipients. Over the past 40 years, several polyclonal antilymphocyte preparations have been used in renal transplantation; however, only two preparations currently are approved by the FDA for use in transplantation: lymphocyte immune globulin (ATGAM) and antithymocyte globulin (ATG; THYMOCLOBULIN) (Howard et al., 1997). Another important milestone in biological therapy was the development

of mAbs and the introduction of the murine anti-CD3 mAb (muromonab-CD3 or OKT3) (Ortho Multicenter Transplant Study Group, 1985). ATG is the most frequently used depleting agent. Lymphocyte immune globulin and OKT3 are rarely used because of poorer efficacy and acute side effects, respectively. Alemtuzumab, a humanized anti-CD52 monoclonal antibody that produces prolonged lymphocyte depletion, is approved for use in chronic lymphocytic leukemia but is increasingly used off label as induction therapy in transplantation.

In many transplant centers, induction therapy with biological agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly pre-sensitized patients, African-American patients, or pediatric patients). Most of the limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have a prolonged serum half-life. Antibodies derived from transgenic mice carrying human antibody genes are labeled “humanized” (90-95% human) or “fully human” (100% human); antibodies derived from human cells are labeled “human.” However, all three types of antibodies probably are of equal efficacy and safety. Chimeric antibodies generally contain ~33% mouse protein and 67% human protein and can still produce an antibody response, resulting in reduced efficacy and t1/2 compared to humanized antibodies. The anti–IL-2R mAbs (frequently referred to as anti-CD25) were the first biologicals proven to be effective as induction agents in randomized double-blind prospective trials (Vincenti et al., 1998).

Biological agents for induction therapy in the prophylaxis of rejection currently are used in ~70% of de novo transplant patients and have been propelled by several factors, including the introduction of the relatively safe anti–IL-2R antibodies and the emergence of ATG as a safer and more effective alternative to lymphocyte immune globulin or muromonab-CD3. Biologicals for induction can be divided into two groups: the depleting agents and the immune modulators. The depleting agents consist of lymphocyte immune globulin, ATG, and muromonab-CD3 mAb (the latter also produces immune modulation); their efficacy derives from their ability to deplete the recipient’s CD3-positive cells at the time of transplantation and antigen presentation. The second group of biological agents, the anti–IL-2R mAbs, do not deplete T lymphocytes, with the possible exception of T regulatory cells, but rather block IL-2–mediated T-cell activation by binding to the α chain of IL-2R.

More aggressive approaches have been recently utilized in patients with high levels of anti-HLA antibodies, donor-specific antibodies detected by cytotoxicity cross-match, or flow cytometry and humoral rejection. These therapies include plasmapheresis, intravenous immunoglobulin, and rituximab, a chimeric anti-CD20 monoclonal antibody (Akalin et al., 2003; Zachary et al., 2003; Vo et al., 2008).

Maintenance Immunotherapy. The basic immunosuppressive protocols use multiple drugs simultaneously. Therapy typically involves a calcineurin inhibitor, glucocorticoids, and mycophenolate (a purine metabolism inhibitor; see “Mycophenolate Mofetil”), each directed at a discrete site in T-cell activation (Suthanthiran et al., 1996). Glucocorticoids, azathioprine, cyclosporine, tacrolimus, mycophenolate, sirolimus, and various monoclonal and polyclonal antibodies all are approved for use in transplantation. Glucocorticoid-free regimens have achieved special prominence in recent successes in using pancreatic islet transplants to treat patients with type I diabetes mellitus. Protocols employing rapid steroid withdrawal (within 1 week after transplantation) are being utilized in more than a third of renal transplant recipients. Short-term results are good, but the effects on long-term graft function are unknown (Vincenti et al., 2008). Recent data suggest that calcineurin inhibitors may shorten graft t1/2 by their nephrotoxic effects (Nankivell et al., 2003). Protocols under evaluation include calcineurin dose reduction or switching from calcineurin to sirolimus-based immunosuppressive therapy at 3-4 months.

**Therapy for Established Rejection.** Although low doses of prednisone, calcineurin inhibitors, purine metabolism inhibitors, or sirolimus are effective in preventing acute cellular rejection, they are less effective in blocking activated T lymphocytes and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection (Monaco et al., 1999). Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy), polyclonal antilymphocyte antibodies, or muromonab-CD3.

**Adrenocortical Steroids**

The introduction of glucocorticoids as immunosuppressive drugs in the 1960s played a key role in making organ transplantation possible. Their chemistry, pharmacokinetics, and drug interactions are described in Chapter 42. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and auto-immune disorders.

**Mechanism of Action.** The immunosuppressive effects of glucocorticoids have long been known, but the specific mechanisms of their immunosuppressive actions somewhat elusive. Glucocorticoids lyse (in some species) and induce the redistribution of lymphocytes, causing a rapid, transient decrease in peripheral blood lymphocyte counts. To effect longer-term responses, steroids bind to receptors inside cells; either these receptors, glucocorticoid-induced proteins, or interacting proteins regulate the transcription of numerous other genes (Chapter 42). Additionally, glucocorticoids curtail activation of NF-κB, which increases apoptosis of activated cells (Auphan et al., 1995). Of central importance, key pro-inflammatory cytokines such as IL-1 and IL-6 are downregulated. T cells are inhibited from making IL-2 and proliferating. The activation of cytotoxic T lymphocytes is inhibited. Neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release. Therefore, glucocorticoids have broad anti-inflammatory effects on multiple components of cellular immunity. In contrast, they have relatively little effect on humoral immunity.

** Therapeutic Uses.** There are numerous indications for glucocorticoids. They commonly are combined with...
other immunosuppressive agents to prevent and treat transplant rejection. High-dose pulses of intravenous methylprednisolone sodium succinate (SOLU-MEDROL, others) are used to reverse acute transplant rejection and acute exacerbations of selected auto-immune disorders. Glucocorticoids also are efficacious for treatment of graft-versus-host disease in bone-marrow transplantation. Glucocorticoids are routinely used to treat auto-immune disorders such as rheumatoid and other arthritides, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, auto-immune hematological disorders, and acute exacerbations of MS (see “Multiple Sclerosis”). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonab-CD3 and to a lesser extent ATG (see “Antithymocyte Globulin”).

**Calcineurin Inhibitors**

Perhaps the most effective immunosuppressive drugs in routine use are the calcineurin inhibitors, cyclosporine and tacrolimus, which target intracellular signaling pathways induced as a consequence of T cell–receptor activation. Although they are structurally unrelated (Figure 35-1) and bind to distinct (albeit related) molecular targets, they inhibit normal T-cell signal transduction essentially by the same mechanism (Figure 35–2). Cyclosporine and tacrolimus do not act **per se** as immunosuppressive agents. Instead, these drugs bind to an immunophilin (cyclophilin for cyclosporine [see “Cyclosporine”] or FKBP-12 for tacrolimus [see “Tacrolimus”]), resulting in subsequent interaction with calcineurin to block its phosphatase activity. Calcineurin-catalyzed dephosphorylation is required for movement of a component of the nuclear factor of activated T lymphocytes (NFAT) into the nucleus (Figure 35–2). NFAT, in turn, is required to induce a number of cytokine genes, including that for interleukin-2 (IL-2), a prototypic T-cell growth and differentiation factor.

**Tacrolimus.** Tacrolimus (PROGRAF, FK506) is a macrolide antibiotic produced by *Streptomyces tsukubaensis* (Goto et al., 1987). Because of perceived slightly greater efficacy and ease of blood level monitoring, tacrolimus has become the preferred calcineurin inhibitor in most transplant centers (Ekberg et al., 2008).

**Mechanism of Action.** Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin. Tacrolimus binds to an intracellular protein, FK506-binding protein–12 (FKBP-12), an immunophilin structurally related to cyclophilin. A complex of tacrolimus-FKBP-12, Ca\(^{2+}\), calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited. As described for cyclosporine and depicted in Figure 35–2, the inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression.

**Disposition and Pharmacokinetics.** Tacrolimus is available for oral administration as capsules (0.5, 1, and 5 mg) and as a solution for injection (5 mg/mL). Immunosuppressive activity resides primarily in the parent drug. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy. Whole blood, rather than plasma, is the most appropriate sampling compartment to describe tacrolimus pharmacokinetics. For tacrolimus, the trough drug level seems to correlate better with clinical events than it does for cyclosporine. Target concentrations in most centers are 10-15 ng/mL in the early preoperative period and 100-200 ng/mL 3 months after transplantation. Gastrointestinal absorption is incomplete and variable. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75-99%, involving primarily \(\alpha_1\)-acid glycoprotein. The \(t_{1/2}\) of tacrolimus is \(~12\) hours. Tacrolimus is extensively metabolized in the liver by CYP3A; at least some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces. Less than 1% of administered tacrolimus is excreted unchanged in the urine.

**Therapeutic Uses.** Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to cyclosporine (see “Cyclosporine”) and is used off label as rescue therapy in patients with rejection episodes despite “therapeutic” levels of cyclosporine.

Recommended initial oral doses are 0.2 mg/kg/day for adult kidney transplant patients, 0.1-0.15 mg/kg/day for adult liver transplant patients, 0.075 mg/kg/day for adult heart transplant patients, and 0.15-0.2 mg/kg/day for pediatric liver transplant patients in two divided doses 12 hours apart. These dosages are intended to achieve typical blood trough levels in the 5- to 20-ng/mL range.

**Toxicity.** Nephrotoxicity, neurotoxicity (e.g., tremor, headache, motor disturbances, seizures), GI complaints, hypertension, hyperkalemia, hyperglycemia, and diabetes all are associated with tacrolimus use. As with cyclosporine, nephrotoxicity is limiting. Tacrolimus has a negative effect on pancreatic islet \(\beta\) cells, and glucose intolerance and diabetes mellitus are well-recognized complications of tacrolimus-based immunosuppression. As with other immunosuppressive agents,
there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol. Diarrhea and alopecia are commonly noted in patients on concomitant mycophenolate therapy.

**Drug Interactions.** Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely, especially when tacrolimus is used with other potentially nephrotoxic drugs. Co-administration with cyclosporine results in additive or synergistic nephrotoxicity; therefore, a delay of at least 24 hours is required when switching a patient from cyclosporine to tacrolimus. Because tacrolimus is metabolized mainly by CYP3A, the potential interactions described in the following section for cyclosporine also apply for tacrolimus.

**Cyclosporine**

**Chemistry.** Cyclosporine (cyclosporin A), a cyclic polypeptide of 11 amino acids, is produced by the fungus *Beauveria nivea*. Because cyclosporine is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to ensure solubilization.

**Mechanism of Action.** Cyclosporine suppresses some humoral immunity but is more effective against T cell–dependent immune...
mechanisms such as those underlying transplant rejection and some forms of auto-immunity. It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines, including IL-2, and the expression of anti-apoptotic proteins. Cyclosporine forms a complex with cyclophilin, a cytoplasmic-receptor protein present in target cells (Figure 35-2). This complex binds to calcineurin, inhibiting Ca\(^{2+}\)-stimulated dephosphorylation of the cytosolic component of NFAT (Schreiber and Crabtree, 1992). When cytoplasmic NFAT is dephosphorylated, it translocates to the nucleus and complexes with nuclear components required for complete T-cell activation, including transactivation of IL-2 and other lymphokine genes. Calcineurin phosphatase activity is inhibited after physical interaction with the cyclosporine/cyclophilin complex. This prevents NFAT dephosphorylation such that NFAT does not enter the nucleus, gene transcription is not activated, and the T lymphocyte fails to respond to specific antigenic stimulation. Cyclosporine also increases expression of transforming growth factor \(\beta\) (TGF-\(\beta\)), a potent inhibitor of IL-2–stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (CTLs) (Khanna et al., 1994).

**Disposition and Pharmacokinetics.** Cyclosporine can be administered intravenously or orally. The intravenous preparation (Sandimmune, others) is provided as a solution in an ethanol-polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule is absorbed slowly, with 20-50% bioavailability. A modified microemulsion formulation (Neoral) has become the most widely used preparation. It has more uniform and slightly increased bioavailability compared to the original formulation. It is provided as 25-mg and 100-mg soft gelatin...
capsules and a 100-mg/mL oral solution. Because the original and microemulsion formulations are not bioequivalent, they cannot be used interchangeably without supervision by a physician and monitoring of drug concentrations in plasma. Generic preparations of both NEORAL and SANDIMMUNE, now widely available, are bioequivalent by FDA criteria. When switching between formulations, increased surveillance is recommended to ensure that drug levels remain in the therapeutic range. This need for increased monitoring is based on anecdotal experience rather than validated differences. Because SANDIMMUNE and NEORAL differ in terms of their pharmacokinetics and definitely are not bioequivalent, their generic versions cannot be used interchangeably. This has been a source of confusion to pharmacists and patients. Transplant units need to educate patients that SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity.

Blood is most conveniently sampled before the next dose (a C₀, or trough level). Although convenient to obtain, C₀ concentrations do not reflect the area under the drug concentration curve (AUC) as a measure of cyclosporine exposure in individual patients. As a practical solution to this problem and to better measure the overall exposure of a patient to the drug, it has been proposed that levels be taken 2 hours after a dose administration (so-called C₂ levels) (Cole et al., 2003). Some studies have shown a better correlation of C₂ with the AUC, but no single time point can simulate the exposure as measured by more frequent drug sampling. In complex patients with delayed absorption, such as diabetics, the C₀ level may underestimate the peak cyclosporine level obtained, and in others who are rapid absorbers, the C₂ level may have peaked before the blood sample is drawn. In practice, if a patient has clinical signs or symptoms of toxicity, or if there is unexplained rejection or renal dysfunction, a pharmacokinetic profile can be used to estimate that person’s exposure to the drug. Many clinicians, particularly those caring for transplant patients some time after the transplant, monitor cyclosporine blood levels only when a clinical event (e.g., renal dysfunction or rejection) occurs. In that setting, either a C₀ or C₂ level helps to ascertain whether inadequate immunosuppression or drug toxicity is present. As described above, cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. The elimination of cyclosporine from the blood generally is biphasic, with a terminal t₁/₂ of 5-18 hours (Noble and Markham, 1995). After intravenous infusion, clearance is ~5-7 mL/min/kg in adult recipients of renal transplants, but results differ by age and patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the intersubject variability is so large that individual monitoring is required.

After oral administration of cyclosporine (as NEORAL), the time to peak blood concentrations is 1.5-2 hours (Noble and Markham, 1995). Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 minutes of administration decrease the AUC by ~13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients.

Cyclosporine is distributed extensively outside the vascular compartment. After intravenous dosing, the steady-state volume of distribution reportedly is as high as 3-5 L/kg in solid-organ transplant recipients.

Only 0.1% of cyclosporine is excreted unchanged in urine. Cyclosporine is extensively metabolized in the liver by CYP3A and to a lesser degree by the GI tract and kidneys. At least 25 metabolites have been identified in human bile, feces, blood, and urine. All of the metabolites have reduced biological activity and toxicity compared to the parent drug. Cyclosporine and its metabolites are excreted principally through the bile into the feces, with ~6% being excreted in the urine. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for dialysis or renal failure patients.

**Therapeutic Uses.** Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; and psoriasis. Its use in dermatology is discussed in Chapter 65. Cyclosporine generally is recognized as the agent that ushered in the modern era of organ transplantation, increasing the rates of early engraftment, extending kidney graft survival, and making cardiac and liver transplantation possible. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate and, most recently, sirolimus.

The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. Especially for renal transplant patients, therapeutic algorithms have been developed to delay cyclosporine or tacrolimus introduction until a threshold renal function has been attained. The amount of the initial dose and reduction to maintenance dosing is sufficiently variable that no specific recommendation is provided here. Dosing is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the reason for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient can take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to methotrexate. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely. In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies have failed. Because of its mechanism of action, there is a theoretical basis for the use of cyclosporine in a variety of other T cell–mediated diseases. Cyclosporine reportedly is effective in Behçet’s acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nphrotic syndrome, even when standard therapies have failed.

**Toxicity.** The principal adverse reactions to cyclosporine therapy are renal dysfunction and hypertension; tremor, hirsutism, hyperlipidemia, and gum hyperplasia also are frequently encountered. Hypertension occurs in ~50% of renal transplant and almost all cardiac transplant patients. Hyperuricemia may lead to worsening of
gout, increased P-glycoprotein activity, and hypercholesterolemia. Nephrotoxicity occurs in the majority of patients and is the major reason for cessation or modification of therapy (Nankivell et al., 2003). Recent reviews of calcineurin inhibitor nephrotoxicity are available (Burdman et al., 2003). Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this apparently is more problematic in patients treated with tacrolimus (see “Tacrolimus” section earlier). Especially at risk are obese patients, African-American or Hispanic transplant recipients, or those with a family history of type II diabetes or obesity. Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in LDL cholesterol (Artz et al., 2003).

**Drug Interactions.** Cyclosporine interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects microsomal enzymes, especially CYP3A, may impact cyclosporine blood concentrations.

Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include Ca²⁺ channel blockers (e.g., verapamil, nicardipine), antifungal agents (e.g., fluconazole, ketoconazole), antibiotics (e.g., erythromycin), glucocorticoids (e.g., methylprednisolone), HIV-protease inhibitors (e.g., indinavir), and other drugs (e.g., allopurinol, metoclopramide). Grapefruit juice inhibits CYP3A and the P-glycoprotein multidrug efflux pump and should be minimized by patients taking cyclosporine because these effects can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (e.g., nafcillin, rifampin), anticonvulsants (e.g., phenobarbital, phenytoin), and others (e.g., octreotide, ticlopidine). In general, close monitoring of cyclosporine blood levels and the levels of other drugs is required when such combinations are used.

Interactions between cyclosporine and sirolimus (also see “Drug Interactions” in the sirolimus section) have led to the recommendation that administration of the two drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Other drug interactions of concern include additive nephrotoxicity when cyclosporine is co-administered with nonsteroidal anti-inflammatory drugs (NSAIDs) and other drugs that cause renal dysfunction; elevation of methotrexate levels when the two drugs are co-administered; and reduced clearance of other drugs, including prednisolone, digoxin, and statins.

**ISATX247.** This is a new oral semisynthetic structural analog of cyclosporine. The cyclosporine molecule is modified at the first amino acid residue. It is more potent on a weight basis than cyclosporine in vitro for calcineurin inhibition. Some preclinical studies show reduced nephrotoxicity, and thus the drug is in clinical development as a primary immunosuppressive drug. Phase 2 clinical trials are in process and thus far show similar or less nephrotoxicity with less frequent glucose intolerance compared to tacrolimus-treated patients (Vincenti and Kirk, 2008).

**Janus Kinase Inhibitors/CP-690550.** Cytokine receptors are enticing targets for modulation by new small immunosuppressive molecules. Janus kinase (JAK) inhibitors are a class of drugs that inhibit important cytoplasmic tyrosine kinases that are involved in cell signaling. The molecule CP-690550 currently is in clinical trials. As an immunosuppressive drug, this compound inhibits JAK3, which is found primarily on hematopoietic cells. In preclinical studies, this JAK3 inhibitor has been tolerated without nephrotoxicity, malignancy, or other important side effects. To date, all studies have shown non-inferiority with other standard immunosuppressive regimens (Vincenti and Kirk, 2008).

**Protein Kinase C Inhibitors/AEB071.** Various isoforms of PKC are important mediators in signaling pathways distal to the T-cell receptor and co-stimulators. AEB071 is a low-molecular-weight compound that blocks T-cell activation by inhibition of PKC, thus producing immunosuppression by a different mechanism than calcineurin inhibitors. Clinical studies are ongoing. Early trials using PKC inhibitors in combination with calcineurin inhibitors (CNIs) followed by discontinuation of the CNI had to be stopped because acute rejections occurred when the CNIs were discontinued (Vincenti and Kirk, 2008).

**Anti-Proliferative and Antimetabolic Drugs**

**Sirolimus**

Sirolimus (rapamycin; RAPAMUNE) is a macrocyclic lactone (Figure 35–1) produced by Streptomyces hygroscopicus.

**Mechanism of Action.** Sirolimus inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (Figure 35–2). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKBP-12. However, the sirolimus–FKBP-12 complex does not affect calcineurin activity. It binds to and inhibits a protein kinase, designated mTOR, which is a key enzyme in cell-cycle progression. Inhibition of mTOR blocks cell-cycle progression at the G₁ → S phase transition. In animal models, sirolimus not only inhibits transplant rejection, graft-versus-host disease, and a variety of auto-immune diseases, but its effect also lasts several months after discontinuing therapy, suggesting a tolerizing effect (see “Tolerance”) (Groth et al., 1999). A newer indication for sirolimus is the avoidance of calcineurin inhibitors, even when patients are stable, to protect kidney function (Flechner et al., 2008).

**Disposition and Pharmacokinetics.** After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within ~1 hour after a single dose in healthy subjects and within ~2 hours after multiple oral doses in renal transplant patients. Systemic availability is ~15%, and blood concentrations are proportional to doses between 3 and 12 mg/m². A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood, with a blood-to-plasma ratio of 38 in renal transplant patients. Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. Seven major metabolites have been identified in whole blood. Metabolites also are detectable in feces and urine, with the bulk of total excretion being in feces. Although some of its metabolites are active, sirolimus itself is the major active
component in whole blood and contributes >90% of the immunosuppressive effect. The blood \( t_{1/2} \) after multiple doses in stable renal transplant patients is 62 hours (Zimmerman and Kahan, 1997). A loading dose of three times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.

**Therapeutic Uses.** Sirolimus is indicated for prophylaxis of organ transplant rejection usually in combination with a reduced dose of calcineurin inhibitor and glucocorticoids. In patients experiencing or at high risk for calcineurin inhibitor–associated nephrotoxicity, sirolimus has been used with glucocorticoids and mycophenolate to avoid permanent renal damage. Sirolimus dosing regimens are relatively complex with blood levels generally targeted between 5-15 ng/mL. It is recommended that the daily maintenance dose be reduced by approximately one-third in patients with hepatic impairment (Watson et al., 1999). Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion.

**Toxicity.** The use of sirolimus in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides that may require treatment. Although immunotherapy with sirolimus per se is not nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine and either azathioprine or placebo. Sirolimus also may prolong delayed graft function in deceased donor kidney transplants, presumably because of its antiproliferative action (Smith et al., 2003). Renal function therefore must be monitored closely in such patients. Lymphocele, a known complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up. Other adverse effects include anemia, leukopenia, thrombocytopenia, mouth ulcer, hypokalemia, proteinuria, and GI effects. Delayed wound healing may occur with sirolimus use. As with other immunosuppressive agents, there is an increased risk of neoplasms, especially lymphomas, and infections. Sirolimus is not recommended in liver and lung transplants due to the risk of hepatic artery thrombosis and bronchial anastomotic dehiscence, respectively.

**Drug Interactions.** Because sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required. As noted above, cyclosporine and sirolimus interact, and their administration should be separated by time. Dose adjustment may be required when sirolimus is co-administered with diltiazem or rifampin. Dose adjustment apparently is not required when sirolimus is co-administered with acyclovir, digoxin, glyburide, nifedipine, norgestrel/ethinyl estradiol, prednisolone, or trimethoprim–sulfamethoxazole. This list is incomplete, and blood levels and potential drug interactions must be monitored closely.

**Everolimus**

Everolimus [40-O-(2-hydroxyethyl)-rapamycin] is closely related chemically and clinically to sirolimus but has distinct pharmacokinetics. The main difference is a shorter \( t_{1/2} \) and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to that of sirolimus. Aside from the shorter \( t_{1/2} \), no studies have compared everolimus with sirolimus in standard immunosuppressive regimens (Eisen et al., 2003). As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors that enhances toxicity and reduces rejection. The toxicity of everolimus and the drug interactions reported to date seem to be the same as with sirolimus.

**Azathioprine**

Azathioprine (IMURAN, others) is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine (see Figure 61–11).

**Mechanism of Action.** Following exposure to nucleophiles such as glutathione, azathioprine is cleaved to 6-mercaptopurine, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (Chapter 61). A fraudulent nucleotide, 6-thio-IMP, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation thereby is inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-mercaptopurine, which may reflect differences in drug uptake or pharmacokinetic differences in the resulting metabolites.

**Disposition and Pharmacokinetics.** Azathioprine is well absorbed orally and reaches maximum blood levels within 1-2 hours after administration. The \( t_{1/2} \) of azathioprine is ~10 minutes, while that of its metabolite, 6-mercaptopurine, is ~1 hour. Other metabolites have a \( t_{1/2} \) of up to 5 hours. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and mercaptopurine are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver and/or erythrocytes. Renal clearance has little impact on biological effectiveness or toxicity.

**Therapeutic Uses.** Azathioprine was first introduced as an immunosuppressive agent in 1961, helping to make allogeneic kidney transplantation possible. It is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis. Although the dose of azathioprine required to prevent organ rejection and minimize toxicity varies, 3-5 mg/kg/day is the usual starting dose. Lower initial doses (1 mg/kg/day) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

**Toxicity.** The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less
common), and/or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

**Drug Interactions.** Xanthine oxidase, an enzyme of major importance in the catabolism of azathioprine metabolites, is blocked by allopurinol. If azathioprine and allopurinol are used concurrently, the azathioprine dose must be decreased to 25-33% of the usual dose; it is best not to use these two drugs together. Adverse effects resulting from co-administration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

**Mycophenolate Mofetil**

Mycophenolate mofetil (MMF; CELL-CEPT) is the 2-morpholinoethyl ester of mycophenolic acid (MPA).

**Mechanism of Action.** MMF is a prodrug that is rapidly hydrolyzed to the active drug, MPA, a selective, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), an important enzyme in the de novo pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation, while other cell types can use salvage pathways; MPA therefore selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

**Disposition and Pharmacokinetics.** MMF undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA, in turn, is metabolized to the inactive phenolic glucuronide MPAG. The parent drug is cleared from the blood within a few minutes. The t1/2 of MPA is ~16 hours. Negligible (<1%) amounts of MPA are excreted in the urine. Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency. In early renal transplant patients (<40 days after transplant), plasma concentrations of MPA after a single dose of MMF are about half of those found in healthy volunteers or stable renal transplant patients.

**Therapeutic Uses.** MMF is indicated for prophylaxis of transplant rejection, and it is typically used in combination with glucocorticoids and a calcineurin inhibitor but not with azathioprine. Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels.

For renal transplants, 1 g is administered orally or intravenously (over 2 hours) twice daily (2 g/day). A higher dose, 1.5 g twice daily (3 g/day), may be recommended for African-American renal transplant patients and all liver and cardiac transplant patients. MMF is increasingly used off label in systemic lupus.

**Toxicity.** The principal toxicities of MMF are gastrointestinal and hematologic. These include leukopenia, pure red cell aplasia, diarrhea, and vomiting. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus; progressive multifocal leukoencephalopathy also has been reported in conjunction with the administration of MMF. Tacrolimus in combination with MMF has been associated with activation of polyoma viruses such as BK virus, which can cause interstitial nephritis difficult to distinguish from acute rejection (Hirsch et al., 2002). Excessive immunosuppression is suspected to be responsible for this adverse effect, not necessarily this widely used drug combination. The use of mycophenolate in pregnancy is associated with congenital anomalies and increased risk of pregnancy loss. Women of childbearing potential taking mycophenolate must use effective contraception.

**Drug Interactions.** Potential drug interactions between MMF and several other drugs commonly used by transplant patients have been studied. There appear to be no untoward effects produced by combination therapy with cyclosporine, trimethoprim–sulfamethoxazole, or oral contraceptives. Unlike cyclosporine, tacrolimus delays elimination of MMF by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Co-administration with antacids containing aluminum or magnesium hydroxide leads to decreased absorption of MMF; thus, these drugs should not be administered simultaneously. MMF should not be administered with cholestyramine or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. Acyclovir and ganciclovir may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency.

A delayed-release tablet form of MPA (MYFOR-TIC) also is available. It does not release MPA under acidic conditions (pH <5) such as in the stomach but is highly soluble in neutral pH present in the intestine. The enteric coating results in a delay in the time to reach maximum MPA concentrations and may improve GI tolerability, although data are sparse and not convincing (Darji et al., 2008).

**Other Anti-Proliferative and Cytotoxic Agents.** Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (Chapter 61) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used off label as immunosuppressive agents include methotrexate, cyclophosphamide, thalidomide (THALOMID), and chlorambucil (LEUKERAN). Methotrexate is used for treatment of graft-versus-host disease, rheumatoid arthritis, psoriasis, and some cancers. Cyclophosphamide and chlorambucil are used in leukemia and lymphomas and a variety of other malignancies. Cyclophosphamide also is FDA approved for childhood nephrotic syndrome and is used widely for treatment of severe systemic lupus erythematosus and other vasculitides such as Wegener’s granulomatosis. Leflunomide (ARAVA, others) is a pyrimidine-synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis (Prakash and Jarvis, 1999). This drug has found increasing empirical use in
the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients. There are no controlled studies showing efficacy compared with control patients treated with only withdrawal or reduction of immunosuppression alone in BK virus nephropathy. The drug inhibits dihydroorotate dehydrogenase in the de novo pathway of pyrimidine synthesis. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

**Fingolimod** (FTY720). This is the first agent in a new class of small molecules, sphingosine-1-phosphate receptor (S1P-R) agonists (Figure 35–1). This S1P receptor prodrug reduces recirculation of lymphocytes from the lymphatic system to the blood and peripheral tissues, including inflammatory lesions and organ grafts.

**Therapeutic Uses.** The drug has not been as effective as standard regimens in phase III trials, and further drug development has been limited (Vincenti and Kirk, 2008).

**Mechanism of Action.** Unlike other immunosuppressive agents, FTY720 acts via “lymphocyte homing.” It specifically and reversibly sequesters host lymphocytes into the lymph nodes and Peyer’s patches and thus away from the circulation. This protects the graft from T cell–mediated attack. Although FTY720 sequesters lymphocytes, it does not impair either T- or B-cell functions. FTY720 is phosphorylated by sphingosine kinase-2, and the FTY720-phosphate product is a potent agonist of S1P receptors. Altered lymphocyte traffic induced by FTY720 clearly results from its effect on S1P receptors.

**Toxicity.** Lymphopenia, the most common side effect of FTY720, is predicted from its pharmacological effect and is fully reversible upon drug discontinuation. Of greater concern is the negative chronotropic effect of FTY720 on the heart, which has been observed with the first dose in up to 30% of patients. In most patients, the heart rate returns to baseline within 48 hours, with the remainder returning to baseline thereafter.

**Biological Immunosuppression Antibodies and Fusion Receptor Protein**

Both polyclonal and monoclonal antibodies against lymphocyte cell-surface antigens are widely used for prevention and treatment of organ transplant rejection. Polyclonal antisera are generated by repeated injections of human thymocytes (ATG) or lymphocytes (antilymphocyte globulin, ALG) into animals such as horses, rabbits, sheep, or goats and then purifying the serum immunoglobulin fraction. Although highly effective immunosuppressive agents, these preparations vary in efficacy and toxicity from batch to batch. The advent of hybridoma technology to produce monoclonal antibodies was a major advance in immunology (Kohler and Milstein, 1975). It now is possible to make essentially unlimited amounts of a single antibody of a defined specificity (Figure 35–3). These monoclonal reagents

![Figure 35–3. Generation of monoclonal antibodies.](image-url)
have overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but they are more limited in their target specificity.

The first-generation murine monoclonal antibodies have been replaced by newer humanized or fully human monoclonal antibodies that lack antigenicity, have a prolonged t\(_1/2\), and can be mutagenized to alter their affinity to Fc receptors. Another class of biological agents being developed for both auto-immunity and transplantation are fusion receptor proteins. These agents usually consist of the ligand-binding domains of receptors bound to the Fc region of an immunoglobulin (usually IgG\(_1\)) to provide a longer t\(_1/2\). Examples of such agents include abatacept (CTLA4-Ig) and belatacept (a second-generation CTLA4-Ig), discussed later in “Co-stimulatory Blockade.” Thus, polyclonal and monoclonal antibodies as well as fusion receptor proteins have a place in immunosuppressive therapy. 

### Antithymocyte Globulin

ATG is a purified gamma globulin from the serum of rabbits immunized with human thymocytes (Regan et al., 1999). It is provided as a sterile, freeze-dried product for intravenous administration after reconstitution with sterile water.

**Mechanism of Action.** ATG contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes (Bourdage and Hamlin, 1995). The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

**Therapeutic Uses.** ATG is used for induction immunosuppression, although the only approved indication is in the treatment of acute renal transplant rejection in combination with other immunosuppressive agents (Mariat et al., 1998). Antilymphocyte-depleting agents (THYMOGLOBULIN, ATGAM, and OKT3) have been neither rigorously tested in clinical trials nor registered for use as induction immunosuppression. However, a meta-analysis (Szczech et al., 1997) showed that antilymphocyte induction improves graft survival. A course of antithymocyte-globulin treatment often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors and thereby aid in recovery from ischemic reperfusion injury. The recommended dose for acute rejection of renal grafts is 1.5 mg/kg/day (over 4-6 hours) for 7-14 days. Mean T-cell counts fall by day 2 of therapy. ATG also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection (Wall, 1999).

### Toxicity

Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, acetaminophen, and/or an antihistamine and administration of the antiserum by slow infusion (over 4-6 hours) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is a rare event. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop, although they do not limit repeated use.

### Monoclonal Antibodies

#### Anti-CD3 Monoclonal Antibodies

Antibodies directed at the ε chain of CD3, a trimeric molecule adjacent to the T-cell receptor on the surface of human T lymphocytes, have been used with considerable efficacy since the early 1980s in human transplantation. The original mouse IgG\(_2a\) antihuman CD3 monoclonal antibody, muromonab-CD3 (OKT3, ORTHOCLONE OKT3), still is used to reverse glucocorticoid-resistant rejection episodes (Cosimi et al., 1981).

**Mechanism of Action.** Muromonab-CD3 binds to the ε chain of CD3, a monomorphic component of the T-cell receptor complex involved in antigen recognition, cell signaling, and proliferation. Antibody treatment induces rapid internalization of the T-cell receptor, thereby preventing subsequent antigen recognition. Administration of the antibody is followed rapidly by depletion and extravasation of a majority of T cells from the bloodstream and peripheral lymphoid organs such as lymph nodes and spleen. This absence of detectable T cells from the usual lymphoid regions is secondary both to complement activation-induced cell death and to margination of T cells onto vascular endothelial walls and redistribution of T cells to non-lymphoid organs such as the lungs. Muromonab-CD3 also reduces function of the remaining T cells, as defined by lack of IL-2 production and great reduction in the production of multiple cytokines, perhaps with the exception of IL-4 and IL-10.

**Therapeutic Uses.** Muromonab-CD3 is indicated for treatment of acute organ transplant rejection (Ortho Multicenter Transplant Study Group, 1985).

Muromonab-CD3 is provided as a sterile solution containing 5 mg per ampule. The recommended dose is 5 mg/day (in adults; less for children) in a single intravenous bolus (<1 minute) for 10-14 days. Antibody levels increase over the first 3 days and then plateau. Circulating T cells disappear from the blood within minutes of administration and return within ~1 week after termination of therapy. Repeated use of muromonab-CD3 results in the immunization of the patient against the mouse determinants of the antibody, which can neutralize and prevent its immunosuppressive efficacy. Thus, repeated treatment with the muromonab-CD3 or other mouse monoclonal antibodies generally is contraindicated. The use of muromonab-CD3 for induction and rejection therapy has diminished substantially in the past 5 years because of its toxicity and the availability of ATG.
Toxicity. The major side effect of anti-CD3 therapy is the “cytokine release syndrome” (Ortho Multicenter Transplant Study Group, 1985). The syndrome typically begins 30 minutes after infusion of the antibody (but can occur later) and may persist for hours. Antibody binding to the T-cell receptor complex combined with Fc receptor-mediated cross-linking is the basis for the initial activating properties of this agent. The syndrome is associated with and attributed to increased serum levels of cytokines (including tumor necrosis factor-α [TNF-α], IL-2, IL-6, and interferon-γ [IFN-γ]), which are released by activated T cells and/or monocytes. In several studies, the production of TNF-α has been shown to be the major cause of the toxicity (Herbelin et al., 1995). The symptoms usually are worst with the first dose; frequency and severity decrease with subsequent doses. Common clinical manifestations include high fever, chills/rigor, headache, tremor, nausea, vomiting, diarrhea, abdominal pain, malaise, myalgias, arthralgias, and generalized weakness. Less common complaints include skin reactions and cardiorespiratory and central nervous system (CNS) disorders, including aseptic meningitis. Potentially fatal pulmonary edema, acute respiratory distress syndrome, cardiovascular collapse, cardiac arrest, and arrhythmias have been described.

Administration of glucocorticoids before the injection of muromonab-CD3 prevents the release of cytokines, reduces first-dose reactions considerably, and now is a standard procedure. Volume status of patients also must be monitored carefully before therapy; steroids and other premedications should be given, and a fully competent resuscitation facility must be immediately available for patients receiving their first several doses of this therapy.

Other toxicities associated with anti-CD3 therapy include anaphylaxis and the usual infections and neoplasms associated with immunosuppressive therapy. “Rebound” rejection has been observed when muromonab-CD3 treatment is stopped. Anti-CD3 therapies may be limited by anti-idiotypic or antimurine antibodies in the recipient. When muromonab-CD3 treatment is stopped. Anti-CD3 therapies may be limited by anti-idiotypic or antimurine antibodies in the recipient.

Currently, muromonab-CD3 rarely is used in transplantation. It has been replaced by ATG and alemtuzumab.

New-Generation Anti-CD3 Antibodies. Recently, genetically altered anti-CD3 monoclonal antibodies have been developed that are “humanized” to minimize the occurrence of anti-antibody responses and mutated to prevent binding to Fc receptors (Friend et al., 1999). The rationale for developing this new generation of anti-CD3 monoclonal antibodies is that they could induce selective immunomodulation in the absence of toxicity associated with conventional anti-CD3 monoclonal antibody therapy. In initial clinical trials, a humanized anti-CD3 monoclonal antibody that does not bind to Fc receptors reversed acute renal allograft rejection without causing the first-dose cytokine-release syndrome. Clinical efficacy of these agents in auto-immune diseases is being evaluated (Herold et al., 2002).

It is not clear whether any of the new generation of anti-CD3s will be developed for use in transplantation.

Anti-IL-2 Receptor (Anti-CD25) Antibodies. Daclizumab (ZENAPAX), a humanized murine complementarity-determining region (CDR)/human IgG1 chimeric monoclonal antibody, and basiliximab (SIMULLECT), a murine-human chimeric monoclonal antibody, have been produced by recombinant DNA technology (Wiseman and Faulds, 1999). The composite daclizumab antibody consists of human (90%) constant domains of IgG1, and variable framework regions of the Eu myeloma antibody and murine (10%) CDR of the anti-Tac antibody.

Mechanism of Action. Daclizumab has a somewhat lower affinity but a longer t1/2 (20 days) than basiliximab. The exact mechanism of action of the anti-CD25 mAbs is not completely understood but likely results from the binding of the anti-CD25 mAbs to the IL-2 receptor on the surface of activated, but not resting, T cells (Vincenti et al., 1998; Amlot et al., 1995).

Significant depletion of T cells does not appear to play a major role in the mechanism of action of these mAbs. However, other mechanisms of action may mediate the effect of these antibodies. In a study of daclizumab-treated patients, there was a moderate decrease in circulating lymphocytes staining with 7G7, a fluorescein-conjugated antibody that binds a different α-chain epitope than that recognized and bound by daclizumab (Vincenti et al., 1998). Similar results were obtained in studies with basiliximab (Amlot et al., 1995). These findings indicate that therapy with the anti IL-2R mAbs results in a relative decrease of the expression of the α chain, either from depletion of coated lymphocytes or modulation of the α chain secondary to decreased expression or increased shedding. There also is recent evidence that the β chain may be downregulated by the anti-CD25 antibody. Recent evidence suggests that T-regulatory cells are transiently depleted during anti-CD25 therapy (Bluestone et al., 2008).

Therapeutic Uses. Anti–IL-2-receptor monoclonal antibodies are used for prophylaxis of acute organ rejection in adult patients. There are two anti–IL-2R preparations for use in clinical transplantation: daclizumab and basiliximab (Vincenti et al., 1998).

In phase III trials, daclizumab was administered in five doses (1 mg/kg given intravenously over 15 minutes in 50-100 mL of normal saline) starting immediately preoperatively, and subsequently at biweekly intervals. The t1/2 of daclizumab was 20 days, resulting in saturation of the IL-2Rα on circulating lymphocytes for up to 120 days after transplantation. In these trials, daclizumab was used with maintenance immunosuppressive regimens (cyclosporine, azathioprine, and steroids; cyclosporine and steroids). Subsequently, daclizumab was successfully used with a maintenance triple-therapy regimen—either with cyclosporine or tacrolimus, steroids, and MMF substituting for azathioprine (Pescovitz et al., 2003). In phase III trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation (Kahan et al., 1999). This regimen of basiliximab resulted in a concentration of ≥0.2 μg/mL, sufficient to saturate IL-2R on circulating lymphocytes for 25-35 days after transplantation.

The t1/2 of basiliximab was 7 days. In the phase III trials, basiliximab was used with a maintenance regimen consisting of...
cyclosporine and prednisone. In one randomized trial, basiliximab was found to be safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone (Lawen et al., 2000).

There presently is no marker or test to monitor the effectiveness of anti–IL-2R therapy. Saturation of an α chain on circulating lymphocytes during anti–IL-2R mAb therapy does not predict rejection. The duration of IL-2R blockade by basiliximab was similar in patients with or without acute rejection episodes (34 ± 14 days versus 37 ± 14 days, mean ± SD) (Kovarik et al., 1999). In another daclizumab trial, patients with acute rejection were found to have circulating and intragraft lymphocytes with saturated IL-2R (Vincenti et al., 2001). A possible explanation is that those patients who reject despite anti–IL-2R blockade do so through a mechanism that bypasses the IL-2 pathway due to cytokine–cytokine receptor redundancy (i.e., IL-7, IL-15).

**Toxicity.** No cytokine-release syndrome has been observed with these antibodies, but anaphylactic reactions can occur. Although lymphoproliferative disorders and opportunistic infections may occur, as with the depleting antilymphocyte agents, the incidence ascribed to anti-CD25 treatment appears remarkably low. No significant drug interactions with anti–IL-2R receptor antibodies have been described (Hong and Kahan, 1999).

**Alemtuzumab.** Alemtuzumab (CAMPATH) is a humanized mAb that has been approved for use in chronic lymphocytic leukemia. The antibody targets CD52, a glycoprotein expressed on lymphocytes, monocytes, macrophages, and natural killer cells; thus, the drug causes extensive lympholysis by inducing apoptosis of targeted cells. It has achieved some use in renal transplantation because it produces prolonged T- and B-cell depletion and allows drug minimization. Large controlled studies of efficacy or safety are not available. Although short-term results are promising, further clinical experience is needed before alemtuzumab is accepted into the clinical armamentarium for transplantation.

**Anti-TNF Reagents.** TNF has been implicated in the pathogenesis of several immune-mediated intestinal, skin, and joint diseases. For example, patients with rheumatoid arthritis have elevated levels of TNF-α in their joints, while patients with Crohn’s disease have elevated levels of TNF-α in their stools. As a result, a number of anti-TNF agents have been developed for the treatment of these disorders.

Infliximab (REMICADE) is a chimeric anti–TNF-α monoclonal antibody containing a human constant region and a murine variable region. It binds with high affinity to TNF-α and prevents the cytokine from binding to its receptors.

In one trial, infliximab plus methotrexate improved the signs and symptoms of rheumatoid arthritis more than methotrexate alone. Patients with active Crohn’s disease who had not responded to other immunosuppressive therapies also improved when treated with infliximab, including those with Crohn’s-related fistulae. Infliximab is approved in the U.S. for treating the symptoms of rheumatoid arthritis and is typically used in combination with methotrexate in patients who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of moderate to severe Crohn’s disease in patients who have failed to respond to conventional therapy and in treatment to reduce the number of draining fistulae in Crohn’s disease patients (Chapter 47). Other FDA-approved indications include ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis. About one of six patients receiving infliximab experiences an infusion reaction characterized by fever, urticaria, hypotension, and dyspnea within 1-2 hours after antibody administration. The development of antinuclear antibodies, and rarely a lupus-like syndrome, has been reported after treatment with infliximab.

Although not a monoclonal antibody, etanercept (ENBREL) is mechanistically related to infliximab because it also targets TNF-α. Etanercept contains the ligand-binding portion of a human TNF-α receptor fused to the Fc portion of human IgG1, and binds to TNF-α and prevents it from interacting with its receptors. It is approved in the U.S. for treatment of the symptoms of rheumatoid arthritis in patients who have not responded to other treatments, as well as for treatment of ankylosing spondylitis, plaque psoriasis, polychrdrular juvenile idiopathic arthritis, and psoriatic arthritis. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

Adalimumab (HUMIRA) is another anti-TNF product for intravenous use. This recombinant human IgG1 monoclonal antibody was created by phage display technology and is approved for use in rheumatoid arthritis, ankylosing spondylitis, Crohn’s disease, juvenile idiopathic arthritis, and psoriatic arthritis. Although not a monoclonal antibody, etanercept (ENBREL) is mechanistically related to infliximab because it also targets TNF-α. Etanercept contains the ligand-binding portion of a human TNF-α receptor fused to the Fc portion of human IgG1, and binds to TNF-α and prevents it from interacting with its receptors. It is approved in the U.S. for treatment of the symptoms of rheumatoid arthritis in patients who have not responded to other treatments, as well as for treatment of ankylosing spondylitis, plaque psoriasis, polychrdrular juvenile idiopathic arthritis, and psoriatic arthritis. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

Adalimumab (HUMIRA) is another anti-TNF product for intravenous use. This recombinant human IgG1 monoclonal antibody was created by phage display technology and is approved for use in rheumatoid arthritis, ankylosing spondylitis, Crohn’s disease, juvenile idiopathic arthritis, and psoriatic arthritis. Although not a monoclonal antibody, etanercept (ENBREL) is mechanistically related to infliximab because it also targets TNF-α. Etanercept contains the ligand-binding portion of a human TNF-α receptor fused to the Fc portion of human IgG1, and binds to TNF-α and prevents it from interacting with its receptors. It is approved in the U.S. for treatment of the symptoms of rheumatoid arthritis in patients who have not responded to other treatments, as well as for treatment of ankylosing spondylitis, plaque psoriasis, polychrdrular juvenile idiopathic arthritis, and psoriatic arthritis. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

**IL-1 Inhibition.**

Plasma IL-1 levels are increased in patients with active inflammation (Moltó and Olivé, 2009; see also Chapter 34). In addition to the naturally occurring IL-1 receptor antagonist (IL-1RA), several IL-1 receptor...
antagonists are in development and a few have been approved for clinical use. Anakinra is an FDA-approved recombinant, non-glycosylated form of human IL-1RA for the management of joint disease in rheumatoid arthritis. It can be used alone or in combination with anti-TNF agents such as etanercept (ENBREL), infliximab (REMICADE), or adalimumab (HUMIRA). Canakinumab (ILARIS) is an IL-1β monoclonal antibody approved by the FDA in June 2009 for Cryoprin-associated periodic syndromes (CAPS), a group of rare inherited inflammatory diseases associated with overproduction of IL-1 that includes Familial Cold Autoinflammatory and Muckle-Wells Syndromes (Lachmann et al., 2009). Canakinumab is also being evaluated for use in chronic obstructive pulmonary disease (Church et al., 2009). Rilonacept (IL-1 Trap) is another IL-1 blocker (a fusion protein that binds IL-1) that is now being evaluated in a phase 3 study for gout (Terkeltaub et al., 2009). IL-1 is an inflammatory mediator of joint pain associated with elevated uric acid crystals.

### Lymphocyte Function–Associated Antigen-1 (LFA-1) Inhibition

**Efalizumab** (RAPTIVA) is a humanized IgG1 mAb targeting the CD11a chain of lymphocyte function–associated antigen-1 (LFA-1). Efalizumab binds to LFA-1 and prevents the LFA-1–intercellular adhesion molecule (ICAM) interaction to block T-cell adhesion, trafficking, and activation.

Pretransplant therapy with anti-CD11a prolonged survival of murine skin and heart allografts and monkey heart allografts (Nakakura et al., 1996). A randomized, multicenter trial of a murine anti–ICAM-1 mAb (enlimomab) failed to reduce the rate of acute rejection or to improve delayed graft function of cadaveric renal transplants (Salmela et al., 1999). This may have been due to either the murine nature of the mAb or the redundancy of the ICAMs. Efalizumab also is approved for use in patients with psoriasis. In a phase I/II open-label, dose-ranging, multidose, multicenter trial, efalizumab (dose, 0.5 mg/kg or 2 mg/kg) was administered subcutaneously for 12 weeks after renal transplantation (Vincenti et al., 2001; Vincenti et al., 2007). Both doses of efalizumab decreased the incidence of acute rejection. Pharmacokinetic and pharmacodynamic studies showed that efalizumab produced saturation and 80% modulation of CD11a within 24 hours of therapy. In a subset of 10 patients who received the higher dose efalizumab (2 mg/kg) with full-dose cyclosporine, MMF, and steroids, three patients developed post-transplant lymphoproliferative diseases. Progressive multifocal leukoencephalopathy (PML) also has occurred during therapy with efalizumab. Although efalizumab appears to be an effective immunosuppressive agent, it may be best used in a lower dose and with an immunosuppressive regimen that spares calcineurin inhibitors. Several trials are being conducted with efalizumab in renal, liver, and islet cell transplantation.

### Alefacept

(AMEVIVE) is a human LFA-3-IgG1 fusion protein. The LFA-3 portion of alefacept binds to CD2 on T lymphocytes, blocking the interaction between LFA-3 and CD2 and interfering with T-cell activation. Alefacept is FDA approved for use in psoriasis.

Treatment with alefacept has been shown to produce a dose-dependent reduction in T-effector memory cells (CD45, RO+ but not in naive cells (CD45, RA+). This effect has been related to its efficacy in psoriatic disease and is of significant interest in transplantation because T-effector memory cells have been associated with co-stimulation blockade resistant and depletion resistant rejection. Alefacept will delay rejection in non-human primate (NHP) cardiac transplantation and has recently been shown to have synergistic potential when used with co-stimulation blockade and/or sirolimus-based regimens in NHPs (Vincenti and Kirk, 2008). A phase II randomized, open-label, parallel-group, multicenter study to assess the safety and efficacy of maintenance therapy with alefacept in kidney transplant recipients currently is under way.

### Targeting B Cells

Most of the advances in transplantation can be attributed to drugs designed to inhibit T-cell responses. As a result, T cell–mediated acute rejection has become much less of a problem, while B cell–mediated responses such as antibody-mediated rejection and other effects of donor-specific antibodies have become more evident. Thus, several agents, both biologicals and small molecules with B-cell specific effects now are being considered for development in transplantation, including humanized monoclonal antibodies to CD20 and inhibitors of the two B cell–activation factors BLYS and APRIL and their respective receptors.

### TOLERANCE

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and auto-immune diseases is to induce and maintain immunological tolerance, the active state of antigen-specific nonresponsiveness (Krensky and Clayberger, 1994). Tolerance, if attainable, would represent a true cure for conditions discussed earlier in this section without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models (Van Parijs and Abbas, 1998). In these same model systems, sirolimus does not prevent tolerance and may even promote tolerance induction (Li et al., 1998). Several other promising approaches are being evaluated in clinical...
trials. Because they remain experimental, they are discussed only briefly here.

**Co-stimulatory Blockade.** Induction of specific immune responses by T lymphocytes requires two signals: an antigen-specific signal via the T-cell receptor and a co-stimulatory signal provided by the interaction of molecules such as CD28 on the T lymphocyte and CD80 and CD86 on the antigen-presenting cell (Figure 35–4; Khoury et al., 1999).

In preclinical studies, inhibition of the co-stimulatory signal has been shown to induce tolerance (Weaver et al., 2008). Experimental approaches to inhibit co-stimulation include a recombinant fusion protein molecule, CTLA4-Ig, and anti-CD80 and/or anti-CD86 mAbs. The antibodies h1F1 and h3D1 are humanized anti-CD80 and anti-CD86 mAbs, respectively. _In vitro_, h1F1 and h3D1 block CD28-dependent T-cell proliferation and decrease mixed lymphocyte reactions. These mAbs must be used in tandem, because either CD80 or CD86 is sufficient to stimulate T cells via CD28. In nonhuman primates, anti-CD80 and anti-CD86 mAbs were proven effective in renal transplantation, either as monotherapy or in combination with steroids or cyclosporine (Weaver et al., 2008), but did not induce durable tolerance. A phase I study of h1F1 and h3D1 in renal transplant recipients was performed in patients receiving maintenance therapy consisting of cyclosporine, MMF, and steroids (Vincenti, 2002). Although the results of this study showed that h1F1 and h3D1 are relatively safe and possibly effective, clinical development was not further pursued.

CTLA4-Ig (abatacept) contains the binding region of CTLA4, which is a CD28 homolog, and the constant region of the human IgG1. CTLA4-Ig competitively inhibits CD28. Numerous animal studies have confirmed the efficacy of CTLA4-Ig in inhibiting alloimmune responses, resulting in successful organ transplantation. More recently, CTLA4-Ig was shown to be effective in the treatment of rheumatoid arthritis. However, CTLA4-Ig was less effective when utilized in nonhuman primate models of renal transplantation. Belatacept (LEA29Y) (Figure 35–5) is a second-generation CTLA4-Ig with two amino acid substitutions. Belatacept has higher affinity for CD80 (2-fold) and CD86 (4-fold), yielding a 10-fold increase in potency _in vitro_ as compared to CTLA4-Ig. Preclinical renal transplant studies in nonhuman primates showed that belatacept did not induce tolerance but did prolong graft survival.

---

**Figure 35–4. Co-stimulation.** A. Two signals are required for T-cell activation. Signal 1 is via the T-cell receptor (TCR), and signal 2 is via a co-stimulatory receptor–ligand pair. Both signals are required for T-cell activation. Signal 1 in the absence of signal 2 results in an inactivated T cell. B. One important co-stimulatory pathway involves CD28 on the T cell and B7-1 (CD80) and B7-2 (CD86) on the antigen-presenting cell (APC). After a T cell is activated, it expresses additional co-stimulatory molecules. CD152 is CD40 ligand, which interacts with CD40 as a co-stimulatory pair. CD154 (CTLA4) interacts with CD80 and CD86 to dampen or downregulate an immune response. Antibodies against CD80, CD86, and CD152 are being evaluated as potential therapeutic agents. CTLA4-Ig, a chimeric protein consisting of part of an immunoglobulin molecule and part of CD154, also has been tested as a therapeutic agent. (Adapted with permission from Clayberger, C., and Krensky, A.M. Mechanisms of allograft rejection. In, *Immunologic Renal Diseases*. (Nielson, E.G., and Couser, W.G., eds) Lippincott-Raven, Philadelphia, 2001. (http://lww.com).)

**Figure 35–5. Structure of belatacept, a CTLaIg congener.** For details, see the text and Figure 35–4.
In a large phase II clinical trial, belatacept was administered intravenously initially every 2 weeks then every 4 or 8 weeks without calcineurin inhibitors and compared to a cyclosporine-based regimen (Vincenti et al., 2005). Belatacept showed comparable efficacy to cyclosporine but was associated with better renal function. Recent reports from phase III trials show similar results to phase II except that the more intense regimen was no more efficacious than the lower intensity regimen but was associated with more infections and posttransplant lymphoproliferative disease (PTLD) (Emamaullee et al., 2009). Because of the risk of PTLD, EBV negative patients should not be treated with belatacept. Belatacept may be approved for maintenance biologic therapy in renal transplantation soon.

A second co-stimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, and/or antigen-presenting cells (Figure 35–4). Among the purported activities of anti-CD154 antibody treatment is the blockade of B7 expression induced by immune activation. Two humanized anti-CD154 monoclonal antibodies have been used in clinical trials in renal transplantation and auto-immune diseases. The development of these antibodies, however, is on hold because of associated thromboembolic events. An alternative approach to block the CD154-CD40 pathway is to target CD40 with monoclonal antibodies. These antibodies are undergoing trials in non-Hodgkin’s lymphoma but are also likely to be developed for auto-immunity and transplantation.

**Donor Cell Chimerism**

Another promising approach is induction of chimerism (co-existence of cells from two genetic lineages in a single individual) by any of a variety of protocols that first dampen or eliminate immune function in the recipient with ionizing radiation, drugs such as cyclophosphamide, and/or antibody treatment and then provide a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells (Starzl et al., 1997). Upon reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as “nonself.” Such tolerance is long lived and is less likely to be complicated by the use of calcineurin inhibitors. Although the most promising approaches in this arena have been therapies that promote the development of mixed or macrochimerism, in which substantial numbers of donor cells are present in the circulation, some microchimerization approaches also have shown promise in the development of long-term unresponsiveness.

**Soluble HLA**

In the pre-cyclosporine era, blood transfusions were shown to be associated with improved outcomes in renal transplant patients (Opelz and Terasaki, 1978). These findings gave rise to donor-specific transfusion protocols that improved outcomes (Opelz et al., 1997). After the introduction of cyclosporine, however, these effects of blood transfusions disappeared, presumably due to the efficacy of this drug in blocking T-cell activation. Nevertheless, the existence of tolerance-promoting effects of transfusions is irrefutable. It is possible that this effect is due to HLA molecules on the surface of cells or in soluble forms. Recently, soluble HLA and peptides corresponding to linear sequences of HLA molecules have been shown to induce immunological tolerance in animal models via a variety of mechanisms (Murphy and Krensky, 1999).

**Antigens**

Specific antigens provided in a variety of forms (generally as peptides) induce immunological tolerance in preclinical models of diabetes mellitus, arthritis, and MS. Clinical trials of such approaches are under way. The past decade has witnessed a revolution in our understanding of the basis of immune tolerance. It is now well established that antigen/MHC complex binding to the T cell–receptor/CD3 complex coupled with soluble and membrane-bound co-stimulatory signals initiates a cascade of signaling events that lead to productive immunity. In addition, the immune response is regulated by a number of negative signaling events that control cell survival and expansion. In vitro and preclinical in vivo studies have demonstrated that one can selectively inhibit immune responses to specific antigens without the associated toxicity of established immunosuppressive therapies (Van Parijs and Abbas, 1998). With these insights comes the promise of specific immune therapies to treat the vast array of immune disorders from auto-immunity to transplant rejection. These new therapies will take advantage of a combination of drugs that target the primary T-cell receptor–mediated signal, either by blocking cell-surface receptor interactions or inhibiting early signal transduction events. The drugs will be combined with therapies that effectively block co-stimulation to prevent cell expansion and differentiation of those cells that have engaged antigen while maintaining a non-inflammatory milieu.

**IMMUNOSTIMULATION**

**General Principles**

In contrast to immunosuppressive agents that inhibit the immune response in transplant rejection and auto-immunity, a few immunostimulatory drugs have been developed with applicability to infection, immunodeficiency, and cancer. Problems with such drugs include systemic (generalized) effects at one extreme or limited efficacy at the other.

**Immunostimulants**

**Levamisole.** Levamisole (ERGAMISOL) was synthesized originally as an anthelmintic but appears to “restore” depressed immune function of B lymphocytes, T lymphocytes, monocytes, and macrophages. Its only clinical indication was as adjuvant therapy with 5-fluorouracil after surgical resection in patients with Dukes’ stage C colon cancer (Moertel et al., 1990). Because of its risk for fatal agranulocytosis, levamisole was withdrawn from the U.S. market in 2005.

**Thalidomide.** Thalidomide (THALOMID) is best known for the severe, life-threatening birth defects it caused when administered to pregnant women. For this reason, it is available only under a restricted distribution program and can be prescribed only by specially registered physicians who understand the risk of teratogenicity if thalidomide is used during pregnancy. *Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.* Nevertheless, it is indicated for the treatment of patients...
with erythema nodosum leprosum (Chapter 56) and multiple myeloma. In addition, it has orphan drug status for mycobacterial infections, Crohn's disease, HIV-associated wasting, Kaposi sarcoma, lupus, myelofibrosis, brain malignancies, leprosy, graft-versus-host disease, and aphthous ulcers.

Its mechanism of action is unclear (see Figure 62–4). Reported immunological effects vary substantially under different conditions. For example, thalidomide has been reported to decrease circulating TNF-α in patients with erythema nodosum leprosum but to increase it in patients who are HIV seropositive. Alternatively, it has been suggested that the drug affects angiogenesis (Paravar and Lee, 2008). The anti–TNF-α effect has led to its evaluation as a treatment for severe, refractory rheumatoid arthritis.

**Lenalidomide.** Lenalidomide (REVLIMID), 3-(4-amino-1-oxo 1, 3-dihydro-2H-isindo1-2-yl) piperidine-2,6-dione, is a thalidomide analog with immunomodulatory and anti-angiogenic properties. Lenalidomide is FDA approved for the treatment of patients with transfusion-dependent anemia due to low- or intermediate risk myelodysplastic syndromes associated with a deletion 5q cytogenetic abnormality with or without additional cytogenetic abnormalities.

The usual starting dose is 10 mg/day. Because lenalidomide causes significant neutropenia and thrombocytopenia in almost all patients, patients have to be closely monitored with weekly blood counts and lenalidomide dose adjusted according to the labeling information. Lenalidomide also is associated with a significant risk for deep vein thrombosis. Lenalidomide carries the same risk of teratogenicity as thalidomide, and pregnancy has to be avoided. Lenalidomide’s availability is limited to a special distribution program administered by the manufacturer.

**Bacillus Calmette-Guérin (BCG).** Live BCG (TICE BCG, THERACYS) is an attenuated, live culture of the bacillus of Calmette and Guérin strain of *Mycobacterium bovis* that induces a granulomatous reaction at the site of administration. By unclear mechanisms, this preparation is active against tumors and is indicated for the treatment and prophylaxis of carcinoma in situ of the urinary bladder and for prophylaxis of primary and recurrent stage Ta and/or T1 papillary tumors after transurethral resection (Patard et al., 1998). Adverse effects include hypersensitivity, shock, chills, fever, malaise, and immune complex disease.

**Recombinant Cytokines**

**Interferons.** Although interferons (α, β, and γ) initially were identified by their antiviral activity, these agents also have important immunomodulatory activities (Ransohoff, 1998). The interferons bind to specific cell-surface receptors that initiate a series of intracellular events: induction of certain enzymes, inhibition of cell proliferation, and enhancement of immune activities, including increased phagocytosis by macrophages and augmentation of specific cytotoxicity by T lymphocytes.

Recombinant IFN-α-2b (INTRON A) is obtained from *Escherichia coli* by recombinant expression. It is a member of a family of naturally occurring small proteins with molecular weights of 15,000–27,600 Da, produced and secreted by cells in response to viral infections and other inducers. IFN-α-2b is indicated in the treatment of a variety of tumors, including hairy cell leukemia, malignant melanoma, follicular lymphoma, and AIDS-related Kaposi sarcoma (Sinkovics and Horvath, 2000). It also is indicated for infectious diseases, chronic hepatitis B, and condylomata acuminata. In addition, it is supplied in combination with ribavirin (REBETRON) for treatment of chronic hepatitis C in patients with compensated liver function not treated previously with IFN-α-2b or who have relapsed after IFN-α-2b therapy (Lo Iacono et al., 2000).

Flu-like symptoms, including fever, chills, and headache, are the most common adverse effects after IFN-α-2b administration. Adverse experiences involving the cardiovascular system (e.g., hypotension, arrhythmias, and rarely cardiomyopathy and myocardial infarction) and CNS (e.g., depression, confusion) are less frequent side effects. All α interferons carry a boxed warning regarding development of pulmonary hypertension.

IFN-γ-1b (ACTIMMUNE) is a recombinant polypeptide that activates phagocytes and induces their generation of oxygen metabolites that are toxic to a number of microorganisms. It is indicated to reduce the frequency and severity of serious infections associated with chronic granulomatous disease and to delay the time to progression in severe malignant osteopetrosis. IFN-γ-1b is not effective and may increase mortality in patients with idiopathic pulmonary fibrosis. Adverse reactions include fever, headache, rash, fatigue, GI distress, anorexia, weight loss, myalgia, and depression.

IFN-β-1a (AVONEX, REBIF), a 166–amino acid recombinant glycoprotein, and IFN-β-1b (BETASERON), a 165–amino acid recombinant protein, have antiviral and immunomodulatory properties. They are FDA-approved for the treatment of relapsing MS to reduce the frequency of clinical exacerbations (see “Multiple Sclerosis”). The mechanism of their action in MS is unclear. Flu-like symptoms (e.g., fever, chills, myalgia) and injection-site reactions have been common adverse effects.

Further discussion of the use of these and other interferons in the treatment of viral diseases can be found in Chapter 58.
**Interleukin-2.** Human recombinant IL-2 (aldesleukin, PROLEUKIN; des-alanyl-1, serine-125 human IL-2) is produced by recombinant DNA technology in *E. coli* (Taniguchi and Minami, 1993). This recombinant form differs from native IL-2 in that it is not glycosylated, has no amino-terminal alanine, and has a serine substituted for the cysteine at amino acid 125 (Doyle et al., 1985). The potency of the preparation is represented in International Units in a lymphocyte proliferation assay such that 1.1 mg of recombinant IL-2 protein equals 18 million IU. Aldesleukin has the following *in vitro* biological activities of native IL-2: enhancement of lymphocyte proliferation and growth of IL-2-dependent cell lines, enhancement of lymphocyte-mediated cytotoxicity and killer cell activity, and induction of IFN-γ activity (Whittington and Faulds, 1993). *In vivo* administration of aldesleukin in animals produces multiple immunological effects in a dose-dependent manner. Cellular immunity is profoundly activated with lympho-immunological effects in a dose-dependent manner. Although most vaccines have targeted infectious diseases, a new generation of vaccines may provide complete or limited protection from specific cancers or auto-immune diseases. Because T cells optimally are activated by peptides and co-stimulatory ligands that are present on antigen-presenting cells (APCs), one approach for vaccination has consisted of immunizing patients with APCs expressing a tumor antigen. The first generation of anticancer vaccines used whole cancer cells or tumor-cell lysates as a source of antigen in combination with various adjuvants, relying on host APCs to process and present tumor-specific antigens (Sinkovics and Horvath, 2000). These anticancer vaccines resulted in occasional clinical responses and are being tested in prospective clinical trials. Second-generation anticancer vaccines utilized specific APCs incubated *ex vivo* with antigen or transduced to express antigen and subsequently reinfused into patients. In laboratory animals, immunization with dendritic cells previously pulsed with MHC class I–restricted peptides derived from tumor-specific antigens led to pronounced antitumor cytotoxic T-lymphocyte responses and protective tumor immunity (Tarte and Klein, 1999). Finally, multiple studies have demonstrated the efficacy of DNA vaccines in small- and large-animal models of infectious diseases and cancer (Lewis and Babiuk, 1999). The advantage of DNA vaccination over peptide immunization is that it permits generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. However, a safety concern about this technique is the potential for integration of the plasmid DNA into the host genome, possibly disrupting important genes and thereby leading to phenotypic mutations or carcinogenicity. A final approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest. Different types of viral vectors that can infect mammalian cells, such as vaccinia, avipox, lentivirus, adenovirus, or adenovirus-associated virus, have been used.

**Immunization**

Immunization may be active or passive. Active immunization involves stimulation with an antigen to develop immunological defenses against a future exposure. Passive immunization involves administration of preformed antibodies to an individual who is already exposed or is about to be exposed to an antigen.

**Vaccines.** Active immunization, vaccination, involves administration of an antigen as a whole, killed (inactivated) organism; attenuated (live) organism; or a specific protein or peptide constituent of an organism. Booster doses often are required, especially when killed organisms are used as the immunogen. In the U.S., vaccination has sharply curtailed or practically eliminated a variety of major infections, including diphtheria, measles, mumps, pertussis, rubella, tetanus, *Haemophilus influenzae* type b, and pneumococcus.

Although most vaccines have targeted infectious diseases, a new generation of vaccines may provide complete or limited protection from specific cancers or auto-immune diseases. Because T cells optimally are activated by peptides and co-stimulatory ligands that are present on antigen-presenting cells (APCs), one approach for vaccination has consisted of immunizing patients with APCs expressing a tumor antigen. The first generation of anticancer vaccines used whole cancer cells or tumor-cell lysates as a source of antigen in combination with various adjuvants, relying on host APCs to process and present tumor-specific antigens (Sinkovics and Horvath, 2000). These anticancer vaccines resulted in occasional clinical responses and are being tested in prospective clinical trials. Second-generation anticancer vaccines utilized specific APCs incubated *ex vivo* with antigen or transduced to express antigen and subsequently reinfused into patients. In laboratory animals, immunization with dendritic cells previously pulsed with MHC class I–restricted peptides derived from tumor-specific antigens led to pronounced antitumor cytotoxic T-lymphocyte responses and protective tumor immunity (Tarte and Klein, 1999). Finally, multiple studies have demonstrated the efficacy of DNA vaccines in small- and large-animal models of infectious diseases and cancer (Lewis and Babiuk, 1999). The advantage of DNA vaccination over peptide immunization is that it permits generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. However, a safety concern about this technique is the potential for integration of the plasmid DNA into the host genome, possibly disrupting important genes and thereby leading to phenotypic mutations or carcinogenicity. A final approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest. Different types of viral vectors that can infect mammalian cells, such as vaccinia, avipox, lentivirus, adenovirus, or adenovirus-associated virus, have been used.

**Immune Globulin.** Passive immunization is indicated when an individual is deficient in antibodies because of a congenital or acquired immunodeficiency, when an individual with a high degree of risk is exposed to an agent and there is inadequate time for active immunization (e.g., measles, rabies, hepatitis B), or when a disease is already present but can be ameliorated by passive antibodies (e.g., botulism, diphtheria, tetanus). Passive immunization may be provided by several different products (Table 35–2). Nonspecific immunoglobulins or highly specific immunoglobulins may be provided based on the indication. The protection provided usually lasts 1-3 months. Immune globulin is derived from pooled plasma of adults by an alcohol-fractionation procedure. It contains largely IgG (95%) and is indicated for antibody-deficiency disorders, exposure to infections such as hepatitis A and measles, and specific immunological diseases such as immune thrombocytopenic purpura and Guillain-Barré syndrome. In contrast, specific immune globulins (“hyperimmune”) differ from other immune globulin preparations in that donors are selected for high titers of the desired antibodies.
Specific immune globulin preparations are available for hepatitis B, rabies, varicella-zoster, cytomegalovirus, botulism, and respiratory syncytial virus. Rho(D) immune globulin is a specific hyperimmune globulin for prophylaxis against hemolytic disease of the newborn due to Rh incompatibility between mother and fetus. All such plasma-derived products carry the theoretical risk of transmission of infectious disease.

**Rho(D) Immune Globulin.** The commercial forms of Rho(D) immune globulin (Table 35–2) consist of IgG containing a high titer of antibodies against the Rh(D) antigen on the surface of red blood cells. All donors are carefully screened to reduce the risk of transmitting infectious diseases. Fractionation of the plasma is performed by precipitation with cold alcohol followed by passage through a viral clearance system (Bowman, 1998).

**Mechanism of Action.** Rho(D) immune globulin binds Rh antigens, thereby preventing sensitization (Peterec, 1995). Rh-negative women may be sensitized to the “foreign” Rh antigen on red blood cells via the fetus at the time of birth, miscarriage, ectopic pregnancy, or any transplacental hemorrhage. If the women go on to have a primary immune response, they will make antibodies to Rh antigen that can cross the placenta and damage subsequent fetuses by lysing red blood cells. This syndrome, called hemolytic disease of the newborn, is life-threatening. The form due to Rh incompatibility is largely preventable by Rho(D) immune globulin.

**Therapeutic Use.** Rho(D) immune globulin is indicated whenever fetal red blood cells are known or suspected to have entered the circulation of an Rh-negative mother unless the fetus is known to also be Rh negative. The drug is given intramuscularly. The $t_{1/2}$ of circulating immunoglobulin is ~21–29 days.

**Toxicity.** Injection-site discomfort and low-grade fever have been reported. Systemic reactions are extremely rare, but myalgia, lethargy, and anaphylactic shock have been reported. As with all plasma-derived products, there is a theoretical risk of transmission of infectious diseases.

**Intravenous Immunoglobulin (IVIG).** In recent years, indications for the use of IVIG have expanded beyond replacement therapy for agammaglobulinemia and other immunodeficiencies to include a variety of bacterial and viral infections, and an array of autoimmune and inflammatory diseases as diverse as thrombocytopenic purpura, Kawasaki disease, and autoimmune skin, neuromuscular, and neurological diseases.

Although the mechanism of action of IVIG in immune modulation remains largely unknown, proposed mechanisms include modulation of expression and function of Fc receptors on leukocytes and endothelial cells, interference with complement activation and cytokine production, provision of anti-idiotypic antibodies (Jerne’s network theory), and effects on the activation and effector function of T and B lymphocytes. Although IVIG is effective in many autoimmune diseases, its spectrum of efficacy and appropriate dosing (especially duration of therapy) are unknown. Additional controlled studies of IVIG are needed to identify proper dosing, cost-benefit, and quality-of-life parameters.
MS is a demyelinating inflammatory disease of the CNS white matter that displays a triad of pathogenic symptoms: mononuclear cell infiltration, demyelination, and scarring (gliosis). The peripheral nervous system is uninvolved. The disease, which may be episodic or progressive, occurs in early to middle adulthood with prevalence increasing from late adolescence to 35 years of age and then declining. MS is roughly 3-fold more common in females than in males and occurs mainly in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS; despite many suggestions, associations with infectious agents have proven inconclusive, even though several viruses can cause similar demyelinating diseases in laboratory animals and humans. A stronger linkage is the genetic one: people of northern European ancestry have a higher susceptibility to MS, and studies in twins and siblings suggest a strong genetic component of susceptibility to MS.

Specifically, MS is a complex genetic disease in which multiple allelic variants lead to disease susceptibility. Although there is long-range linkage disequilibrium in the MHC region, HLA-DR2 clearly is associated with risk of developing MS (p = 10^{-228}), as is HLA-B*4402. Genome-wide association studies have identified predominantly immune-related variants associated with disease risk, including the IL-2RA chain (p = 10^{-27}), IL-7R chain (p = 10^{-20}), CLEC16A (p = 10^{-15}), CD58 (LFA-3, p = 10^{-10}), and CD226 (p = 10^{-8}) (IMSGC, 2007; IMSGC, 2008; Hafler, 2008). It is estimated that >200 common allelic variants will be uncovered as genome-wide association studies become properly powered. Interestingly, these variants are strikingly common among the different auto-immune diseases.

There also is substantial evidence of an autoimmune component to MS: in MS patients, there are activated T cells that are reactive to different myelin antigens, including myelin basic protein (MBP). In addition, there is evidence for the presence of auto-antibodies to myelin oligodendrocyte glycoprotein (MOG) and to MBP that can be eluted from the CNS plaque tissue, although it appears unlikely that high-affinity auto-antibodies are present in the circulation. These antibodies may act with pathogenic T cells to produce some of the cellular pathology of MS. The neurophysiological result is altered conduction (both positive and negative) in myelinated fibers within the CNS (cerebral white matter, brain stem, cerebellar tracts, optic nerves, spinal cord); some alterations appear to result from exposure of voltage-dependent K^+ channels that normally are covered by myelin.

Attacks are classified by type and severity and likely correspond to specific degrees of CNS damage and pathological processes. Thus, physicians refer to relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurological deterioration following a long period of relapsing-remitting disease), and primary progressive MS (~15% of patients, wherein deterioration with relatively little inflammation is apparent at onset). De Jager and Hafler (2007) have reviewed current concepts of the etiology, natural history, and current therapy of MS.

**Pharmacotherapy for MS.** Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability (Table 35–3). Nonspecific therapies focus on maintaining function and quality of life. For acute attacks, pulse glucocorticoids often are employed (typically, 1 g/day of methylprednisolone administered intravenously for 3-5 days). There is no evidence that tapered doses of oral prednisone are useful or even desirable.

For reducing the recurrence of relapsing-remitting attacks, immunomodulatory therapies are approved: β-1 interferons [IFN-β-1a, IFN-β-1b], and glatiramer acetate (GA; COPAXONE). The interferons suppress the proliferation of T lymphocytes, inhibit their movement into the CNS from the periphery, and shift the cytokine profile from pro- to anti-inflammatory types.

Random polymers that contain amino acids commonly used as MHC anchors and T cell–receptor contact residues have been proposed as possible “universal APLs (altered peptide ligands).” GA is a random-sequence polypeptide consisting of four amino acids [alanine (A), lysine (K), glutamate (E), and tyrosine (Y)] at a molar ratio of A:K:E:Y of 4.5:3.6:1.5:1 with an average length of 40-100 amino acids. Directly labeled GA binds efficiently to different murine H2 I-A molecules, as well as to their human counterparts, the MHC class II DR molecules, but does not bind MHC class I-A molecules in vitro. In phase III clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by ~30% (De Jager and Hafler, 2007). In vivo administration of GA induces highly cross-reactive CD4+ T cells that are immune deviated to secrete Th2 cytokines and prevents the appearance of new lesions detectable by magnetic resonance imaging. This represents one of the first successful uses of an
agent that ameliorates auto-immune disease by altering signals through the T cell–receptor complex.

For relapsing-remitting attacks and for secondary progressive MS, the alkylating agent cyclophosphamide (De Jager and Hafler, 2007) and the anthracenedione-derivative mitoxantrone (Novantrone, others) currently are used in patients refractory to other immunomodulators. These agents, primarily used for cancer chemotherapy, have significant toxicities (see Chapter 61 for structures and pharmacology). Although cyclophosphamide in patients with MS may not be limited by an accumulated dose exposure, mitoxantrone generally can be tolerated only up to an accumulated dose of 100-140 mg/m² (Crossley, 1984). However, because decreases in left-ventricular ejection fraction (LVEF) and frank congestive heart failure have occurred in patients who have received <100 mg/m², the FDA now recommends that LVEF be evaluated before initiating therapy, prior to each dose, and annually after patients have finished treatment to detect late-occurring cardiac toxicity. The utility of interferon therapy in patients with secondary progressive MS is unclear. In primary progressive MS, with no discrete attacks and less observed inflammation, suppression of inflammation seems to be less helpful. A minority of patients at this stage will respond to high doses of glucocorticoids. Table 35–3 summarizes current immunomodulatory therapies for MS.

EDSS, Expanded Disability Status Scale, a neurologic assessment scale for MS pathology. Gd, gadolinium, used in Gd-enhanced MRI to assess the number and size of inflammatory brain lesions; IFN, interferon; IM, intramuscularly; IV, intravenously; MMP, matrix metalloprotease; MS, multiple sclerosis; RRMS, relapsing-remitting MS; SC, subcutaneously; SPMS, secondary progressive MS; MRI, magnetic resonance imaging.
Each of the agents mentioned in this section has side effects and contraindications that may be limiting: infections (for glucocorticoids), hypersensitivity and pregnancy (for immunomodulators), and prior anti-tuberculosis/anthracycline use, mediastinal irradiation, or cardiac disease (mitoxantrone). With all of these agents, it is clear that the earlier they are used, the more effective they are in preventing disease relapses. What is not clear is whether any of these agents will prevent or diminish the later onset of secondary progressive disease, which causes the more severe form of disability. Given the fluctuating nature of this disease, only long-term studies lasting decades will answer this question.

A number of other new immunomodulatory therapies have either recently been approved by the FDA or are completing phase III trials. The monoclonal antibody, natalizumab (TYSABRI), directed against the adhesion molecule α4 integrin, antagonizes interactions with integrin heterodimers containing α4 integrin, such as α4β1 integrin that is expressed on the surface of activated lymphocytes and monocytes. Preclinical data suggest that an interaction of α4β1 integrin with vascular-cellular adhesion molecule (VCAM)-1 is critical for T-cell trafficking from the periphery into the CNS (Steinman, 2004); thus, blocking this interaction would hypothetically inhibit disease exacerbations. Phase III clinical trials demonstrated a significant decrease in the number of new lesions as determined by magnetic resonance imaging and clinical attacks in MS patients receiving natalizumab (Polman et al., 2006). Postmarketing use of natalizumab has been associated with the development of progressive multifocal leukoencephalopathy, and availability has been limited to a special distribution program (TOUCH) administered by the manufacturer. Monoclonal antibodies directed against the IL-2 receptor and against CD52 (alemtuzumab; CAMPATH) are also in phase III clinical trials. The pharmacotherapy of MS has been reviewed by De Jager and Hafler (2007); the utility of immunotherapy for auto-immune diseases has been reviewed by Steinman (2004).

CLINICAL SUMMARY

Most transplant centers employ some combination of immunosuppressive drugs with antilymphocyte induction therapy with either a monoclonal or polyclonal antibody agent. Maintenance immunosuppression consists of a calcineurin inhibitor (cyclosporine or tacrolimus), glucocorticoids, and an antimetabolite (azathioprine or mycophenolate). Mycophenolate has largely replaced azathioprine as part of the standard immunosuppressive regimen after transplantation. At present, a number of centers are conducting trials with new drug combinations including either cyclosporine or tacrolimus in combination with glucocorticoids and mycophenolate, with or without antibody-induction therapy or fingolimod with cyclosporine. Sirolimus is being used to limit exposure to the nephrotoxic calcineurin inhibitors, while steroid avoidance or minimization strategies are used increasingly. Newer immunosuppressive agents are providing more effective control of rejection and permitting transplantation to become an accepted procedure with a number of different organs, including kidney, liver, pancreas, and heart. The apparent effectiveness of new drug combinations has resulted in a resurgence of interest in reducing or avoiding glucocorticoids and calcineum inhibitors.

INTRODUCTION

Pulmonary pharmacology concerns understanding how drugs act on the lung and the pharmacological therapy of pulmonary diseases. Much of pulmonary pharmacology is concerned with the effects of drugs on the airways and the therapy of airway obstruction, particularly asthma and chronic obstructive pulmonary disease (COPD), which are among the most common chronic diseases in the world. Both asthma and COPD are characterized by chronic inflammation of the airways, although there are marked differences in inflammatory mechanisms and response to therapy between these diseases (Barnes, 2008b). After a brief introduction to asthma and COPD, this chapter discusses the pharmacotherapy of obstructive airways disease, particularly bronchodilators, which act mainly by reversing airway smooth muscle contraction, and anti-inflammatory drugs, which suppress the inflammatory response in the airways. This chapter focuses on the pulmonary pharmacology of β2 agonists and corticosteroids; the basic pharmacology of these classes of agents is presented elsewhere (Chapters 12 and 42). In presenting the details of pharmacotherapy of asthma and COPD, the chapter also covers the physiology and molecular pathology surrounding these conditions, deriving knowledge of the diseases by assessing their responses to various classes of drugs.

This chapter also discusses other drugs used to treat obstructive airway diseases, such as mucolytics and respiratory stimulants, and covers the drug therapy of cough, the most common respiratory symptom, as well as drugs used to treat pulmonary hypertension. Drugs used in the treatment of lung infections, including tuberculosis (Chapter 56), are covered elsewhere.

MECHANISMS OF ASTHMA

Asthma is a chronic inflammatory disease of the airways that is characterized by activation of mast cells, infiltration of eosinophils, and T helper 2 (Th2) lymphocytes (Figure 36–1) (Barnes, 2008b). Mast cell activation by allergens and physical stimuli releases bronchoconstrictor mediators, such as histamine, leukotriene D4, and prostaglandin D2, which cause bronchoconstriction, microvascular leakage, and plasma exudation (Chapters 32 and 33). Increased numbers of mast cells in airway smooth muscle are a characteristic of asthma. Many of the symptoms of asthma are due to airway smooth muscle contraction, and therefore bronchodilators are important as symptom relievers. Whether airway smooth muscle is intrinsically abnormal in asthma is not clear, but increased contractility of airway smooth muscle may contribute to airway hyperresponsiveness, the physiological hallmark of asthma. The mechanism of chronic inflammation in asthma is still not well understood. It may initially be driven by allergen exposure, but it appears to become autonomous so that asthma is essentially incurable. The inflammation may be orchestrated by dendritic cells that regulate Th2 cells that drive eosinophilic inflammation and also IgE formation by B lymphocytes. Airway epithelium plays an important role through the release of multiple inflammatory mediators and through the release of growth factors in an attempt to repair the damage caused by inflammation. The inflammatory process in asthma is mediated through the release of >100 inflammatory mediators (Barnes et al., 1998a). Complex cytokine networks, including chemokines and growth factors, play important roles in orchestrating the inflammation process (Barnes, 2008a).
Chronic inflammation may lead to structural changes in the airways, including an increase in the number and size of airway smooth muscle cells, blood vessels, and mucus-secreting cells. A characteristic histological feature of asthma is collagen deposition (fibrosis) below the basement membrane of the airway epithelium (Figure 36–1). This appears to be the result of eosinophilic inflammation and is found even at the onset of asthmatic symptoms. The complex inflammation of asthma is suppressed by corticosteroids in most patients, but even if asthma is well controlled, the inflammation and symptoms return if corticosteroids are discontinued. Asthma usually starts in early childhood, then may disappear during adolescence and reappear in adulthood. It is characterized by variable airflow obstruction and typically shows a good therapeutic response to bronchodilators and corticosteroids. Asthma severity usually does not change, so that patients with mild asthma rarely progress to severe asthma and patients with severe asthma usually have this from the onset, although some patients, particularly with late-onset asthma, show a progressive loss of lung function like patients with COPD. Patients with severe asthma may have a pattern of inflammation more similar to COPD and are characterized by reduced responsiveness to corticosteroids (Wenzel and Busse, 2007).

**MECHANISMS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE**

Chronic obstructive pulmonary disease involves inflammation of the respiratory tract with a pattern that differs from that of asthma. In COPD, there is a predominance of neutrophils, macrophages, and cytotoxic...

T-lymphocytes (Tc1 cells). The inflammation predominantly affects small airways, resulting in progressive small airway narrowing and fibrosis (chronic obstructive bronchiolitis) and destruction of the lung parenchyma with destruction of the alveolar walls (emphysema) (Figure 36–2) (Barnes, 2008b). These pathological changes result in airway closure on expiration, leading to air trapping and hyperinflation, particularly on exercise (dynamic hyperinflation). This accounts for shortness of breath on exertion and exercise limitation that are characteristic symptoms of COPD.

Bronchodilators reduce air trapping by dilating peripheral airways and are the mainstay of treatment in COPD. In contrast to asthma, the airflow obstruction of COPD tends to be progressive. The inflammation in the peripheral lung of COPD patients is mediated by multiple inflammatory mediators and cytokines, although the pattern of mediators differs from that of asthma (Barnes, 2004; Barnes, 2008a). In marked contrast to asthma, the inflammation in COPD patients is largely corticosteroid resistant, and there are currently no effective anti-inflammatory treatments for this disease. In addition to pulmonary disease, many patients with COPD have systemic manifestations (skeletal muscle wasting, weight loss, depression, osteoporosis, anemia) and comorbid diseases (ischemic heart disease, hypertension, congestive heart failure, diabetes) (Barnes and Celli, 2009). Whether these are due to spillover of inflammatory mediators from the lung or due to common causal mechanisms (such as smoking) is not yet clear, but it may be important to treat the systemic components in the overall management of COPD.
Drug delivery to the lungs

Drugs may be delivered to the lungs by oral or parenteral routes and also by inhalation. The choice depends on the drug and on the respiratory disease.

Inhaled Route

Inhalation (Figure 36–3) is the preferred mode of delivery of many drugs with a direct effect on airways, particularly for asthma and COPD (Berger, 2009). It is the only way to deliver some drugs such as cromolyn sodium and anticholinergic drugs and is the preferred route of delivery for \( \beta_2 \) agonists and corticosteroids to reduce systemic side effects. Antibiotics may be delivered by inhalation in patients with chronic respiratory sepsis (e.g., in cystic fibrosis). Inhalation is also used to facilitate systemic drug delivery in other diseases (e.g., to avoid daily injections with insulin; see Chapter 43).

The major advantage of inhalation is the delivery of drug to the airways in doses that are effective with a much lower risk of systemic side effects. This is particularly important with the use of inhaled corticosteroids (ICS), which largely avoids systemic side effects. In addition, drugs such as inhaled bronchodilators have a more rapid onset of action than when taken orally so that more rapid control of symptoms is possible.

Particle Size

The size of particles for inhalation is of critical importance in determining the site of deposition in the respiratory tract. The optimum size for particles to settle in the airways is 2-5 \( \mu \text{m} \) mass median aerodynamic diameter (MMAD). Larger particles settle out in the upper airways, whereas smaller particles remain suspended and are therefore exhaled. There is increasing interest in delivering drugs to small airways, particularly in COPD and severe asthma (Sturton et al., 2008). This involves delivering drug particles of \( \sim 1 \mu \text{m} \) MMAD, which is now possible using drugs formulated in hydrofluoroalkane (HFA) propellant.

Pharmacokinetics

Of the total drug delivered, only 10-20% enters the lower airways with a conventional pressurized metered-dose inhaler (pMDI). The fate of the inhaled drug is poorly understood. Drugs are absorbed from the airway lumen and have direct effects on target cells of the airway. Drugs may also be absorbed into the bronchial circulation and then distributed to more peripheral airways. Whether drugs are metabolized in the airways is often uncertain, and there is little understanding of the factors that may influence local absorption and metabolism of inhaled drugs. Drugs with higher molecular weights tend to be retained to a greater extent in the airways. Nevertheless, several drugs have greater therapeutic efficacy when given by the inhaled route. The inhaled corticosteroid ciclesonide is a prodrug activated by esterases in the respiratory tract to the active principle des-ciclesonide. More extensive pulmonary distribution of a drug with a smaller MMAD increases alveolar deposition and thus is likely to increase absorption from the lungs into the general circulation resulting in more systemic side effects. Thus, although HFA pMDIs deliver more inhaled corticosteroid to smaller airways, there is also increased systemic absorption, so that the therapeutic ratio may not be changed.

Figure 36–3. Schematic representation of the deposition of inhaled drugs (e.g., corticosteroids, \( \beta_2 \) agonists). Inhalation therapy deposits drugs directly, but not exclusively, in the lungs. Distribution between lungs and oropharynx depends mostly on the particle size and the efficiency of the delivery method. Most material will be swallowed and absorbed, entering systemic circulation after undergoing the first-pass effect in the liver. Some drug will also be absorbed into the systemic circulation from the lungs. Use of a large-volume spacer will reduce the amount of drug deposited on oropharynx, thereby reducing amount swallowed and absorbed from GI tract, thus limiting systemic effects. MDI, metered-dose inhaler.
Delivery Devices

Several ways of delivering inhaled drugs are possible (Virchow et al., 2008).

Pressurized Metered-Dose Inhalers. Drugs are propelled from a canister with the aid of a propellant, previously with a chlorofluorocarbon (Freon) but now replaced by a hydrofluoroalkane (HFA) that is “ozone friendly.” These devices are convenient, portable, and typically deliver 100-400 doses of drug. It is necessary to coordinate inhalation with activation of the device, so it is important that patients are taught to use these devices correctly. Many patients find this difficult despite instruction.

Spacer Chambers. Large-volume spacer devices between the pMDI and the patient reduce the velocity of particles entering the upper airways and the size of the particles by allowing evaporation of liquid propellant. This reduces the amount of drug that impinges on the oropharynx and increases the proportion of drug inhaled into the lower airways. The need for careful coordination between activation and inhalation is also reduced because the pMDI can be activated into the chamber and the aerosol subsequently inhaled from the one-way valve. Perhaps the most useful application of spacer chambers is in the reduction of the oropharyngeal deposition of inhaled corticosteroids and the consequent reduction in the local side effects of these drugs. Large-volume spacers also reduce the systemic side effects of drugs because less is deposited in the oropharynx, and therefore swallowed. It is the swallowed fraction of the drug absorbed from the GI tract that makes the greatest contribution to the systemic fraction. This is of particular importance in the use of certain inhaled steroids, such as beclomethasone dipropionate, which can be absorbed from the GI tract. Spacer devices are also useful in delivering inhaled drugs to small children who are not able to use a pMDI. Children as young as 3 years of age are able to use a spacer device fitted with a face mask.

Dry Powder Inhalers. Drugs may also be delivered as a dry powder using devices that scatter a fine powder dispersed by air turbulence on inhalation. These devices may be preferred by some patients (Chan, 2006) because careful coordination is not as necessary as with the pMDI, but some patients find that the dry powder is an irritant. Children <7 years of age find it difficult to use a dry powder inhaler (DPI) because they may not be able to generate sufficient inspiratory flow. DPIs have been developed to deliver peptides and proteins, such as insulin (e.g., EXUBERA, APRESA), systemically.

Nebulizers. Two types of nebulizer are available. Jet nebulizers are driven by a stream of gas (air or oxygen), whereas ultrasonic nebulizers use a rapidly vibrating piezoelectric crystal and thus do not require a source of compressed gas. The nebulized drug may be inspired during tidal breathing, and it is possible to deliver much higher doses of drug compared with pMDI. Nebulizers are therefore useful in treating acute exacerbations of asthma and COPD, for delivering drugs when airway obstruction is extreme (e.g., in severe COPD), for delivering inhaled drugs to infants and small children who cannot use the other inhalation devices, and for giving drugs such as antibiotics when relatively high doses must be delivered. Small handheld nebulizers (soft mist inhalers) are now also available.

Oral Route

Drugs for treatment of pulmonary diseases may also be given orally. The oral dose is much higher than the inhaled dose required to achieve the same effect (typically by a ratio of ~20:1), so that systemic side effects are more common. When there is a choice of inhaled or oral route for a drug (e.g., β2 agonist or corticosteroid), the inhaled route is always preferable, and the oral route should be reserved for the few patients unable to use inhalers (e.g., small children, patients with physical problems such as severe arthritis of the hands). Theophylline is ineffective by the inhaled route and therefore must be given systemically. Corticosteroids may have to be given orally for parenchymal lung diseases (e.g., in interstitial lung diseases), although it may be possible in the future to deliver such drugs into alveoli using specially designed inhalation devices with a small particle size.

Parenteral Route

The intravenous route should be reserved for delivery of drugs in the severely ill patient who is unable to absorb drugs from the GI tract. Side effects are generally frequent due to the high plasma concentrations.

BRONCHODILATORS

Bronchodilator drugs relax constricted airway smooth muscle in vitro and cause immediate reversal of airway obstruction in asthma in vivo. They also prevent bronchoconstriction (and thereby provide bronchoprotection). Three main classes of bronchodilator are in current clinical use:

- β2 Adrenergic agonists (sympathomimetics)
- Theophylline (a methylxanthine)
- Anticholinergic agents (muscarinic receptor antagonists)

Drugs such as cromolyn sodium, which prevent bronchoconstriction, have no direct bronchodilator action and are ineffective once bronchoconstriction has occurred. Anti-leukotrienes (leukotriene receptor antagonists and 5-lipoxygenase inhibitors) have a small bronchodilator effect in some asthmatic patients and appear to prevent bronchoconstriction. Corticosteroids, although gradually improving airway obstruction, have no direct effect on contraction of airway smooth muscle and are not therefore considered to be bronchodilators.

β2 ADRENERGIC AGONISTS

Inhaled β2 agonists are the bronchodilator treatment of choice in asthma because they are the most effective bronchodilators and have minimal side effects when used correctly. Systemic, short-acting, and nonselective β agonists, such as isoproterenol (isoprenaline) or metaproterenol, should only be used as a last resort.

Chemistry. The development of β2 agonists is based on substitutions in the catecholamine structure of norepinephrine and epinephrine (Chapter 12). The catechol ring consists of hydroxyl groups in the 3 and 4 positions of the benzene ring (Figure 36–4). Norepinephrine
differ from epinephrine only in the terminal amine group; in general, further modification at this site confers \( \beta \) receptor selectivity. Further substitution of the terminal amine resulted in \( \beta_2 \) receptor selectivity, as in albuterol (salbutamol) and terbutaline. Exogenous catecholamines are rapidly metabolized by catechol-O-methyl transferase (COMT), which methylates in the 3-hydroxyl position, and accounts for the short duration of action of catecholamines. Modification of the catechol ring, as in albuterol and terbutaline, prevents this degradation and therefore prolongs the effect. Catecholamines are also broken down in sympathetic nerve terminals and in the GI tract by monoamine oxidase (MAO), which cleaves the side chain. Isoproterenol, which is a substrate for MAO, is metabolized in the gut, making absorption variable. Substitution in the amine group confers resistance to MAO and ensures reliable absorption. Many other \( \beta_2 \)-selective agonists have now been introduced and, although there may be differences in potency, there are no clinically significant differences in selectivity. Inhaled \( \beta_2 \)-selective drugs in current clinical use (apart from rimiterol [not available in the U.S.] that is broken down by COMT) have a similar duration of action (3-6 hours). The inhaled long-acting inhaled \( \beta_2 \) agonists salmeterol and formoterol have a much longer duration of effect, providing bronchodilation and bronchoprotection for >12 hours (Kips and Pauwels, 2001). Formoterol has a bulky substitution in the aliphatic chain and has a moderate lipophilicity, which appears to keep the drug in the membrane close to the receptor, so it behaves as a slow-release drug. Salmeterol has a long aliphatic chain, and its long duration may be due to binding within the receptor binding cleft ("exosite") that anchors the drug in the binding cleft. Once-daily \( \beta_2 \) agonists, such as indacaterol, with a duration of action >24 hours, are now in development (Cazzola and Matera, 2008).

### Mode of Action

Occupation of \( \beta_2 \) receptors by agonists results in the activation of the \( G_s \)-adenyl cyclase-cAMP-PKA pathway, resulting in phosphorylative events leading to bronchial smooth muscle relaxation (Figure 36–5). \( \beta \) Agonists produce bronchodilation by directly stimulating \( \beta_2 \) receptors in airway smooth muscle, and \textit{in vitro} relax human bronchi and lung strips (indicating an effect on peripheral airways). \textit{In vivo} there is a rapid decrease in airway resistance. \( \beta_2 \) Receptors have been localized to airway smooth muscle of all airways by direct receptor binding techniques and autoradiographic mapping studies.

The molecular mechanisms by which \( \beta \) agonists induce relaxation of airway smooth muscle include:

- Lowering of \([Ca^{2+}]_i\) concentration by active removal of Ca\(^{2+}\) from the cytosol into intracellular stores and out of the cell
- Acute inhibition of the PLC-IP\(_3\) pathway and its mobilization of cellular Ca\(^{2+}\) (prolonged use can upregulate expression of PLC\(_{\beta1}\))
- Inhibition of myosin light chain kinase activation
- Activation of myosin light chain phosphatase
- Opening of a large conductance Ca\(^{2+}\)-activated K\(^+\) channel (K\(_{Ca}\)), which repolarizes the smooth muscle cell and may stimulate the sequestration of Ca\(^{2+}\) into intracellular stores. \( \beta_2 \) Receptors may also couple to K\(_{Ca}\) via G\(_{s}\) so that relaxation of airway smooth muscle may occur independently of an increase in cAMP.

Several actions of \( \beta_2 \) agonists are mediated not by PKA but by other cAMP-regulated proteins, such as the exchange protein activated by cAMP (EPAC) (Holz et al., 2006). \( \beta_2 \) Agonists act as \textit{functional antagonists} and reverse bronchoconstriction irrespective of

---

**Figure 36–4.** Chemical structure of some adrenergic agonists showing development from catecholamines by substitutions on the catechol nucleus and side chain.
the contractile agent. This is an important property for the treatment of asthma because many bronchoconstrictor mechanisms (neurotransmitters and mediators) are likely to be contributory. In COPD the major mechanism of action is likely to be reduction of cholinergic neural bronchoconstriction.

β₂ Receptors are localized to several different airway cells, where they may have additional effects. Thus, β₂ agonists may cause bronchodilation in vivo not only via a direct action on airways smooth muscle, but also indirectly by inhibiting the release of bronchoconstrictor mediators from inflammatory cells and of bronchoconstrictor neurotransmitters from airway nerves. These mechanisms include:

- Prevention of mediator release from isolated human lung mast cells (via β₂ receptors).
- Prevention of microvascular leakage and thus the development of bronchial mucosal edema after exposure to mediators, such as histamine and leukotriene D₄.
- Increase in mucus secretion from submucosal glands and ion transport across airway epithelium; these effects may enhance mucociliary clearance, and thereby reverse the defective clearance found in asthma.
- Reduction in neurotransmission in human airway cholinergic nerves by an action at presynaptic β₂ receptors to inhibit acetylcholine release. This may contribute to their bronchodilator effect by reducing reflex cholinergic bronchoconstriction.

Although these additional effects of β₂ agonists may be relevant to the prophylactic use of these drugs against various challenges, their rapid bronchodilator action is probably attributable to a direct effect on airway smooth muscle.

Anti-Inflammatory Effects

Whether β₂ agonists have anti-inflammatory effects in asthma is controversial. The inhibitory effects of β₂ agonists on mast cell mediator release and microvascular leakage are clearly anti-inflammatory, suggesting that β₂ agonists may modify acute inflammation. However, β₂ agonists do not appear to have a significant inhibitory effect on the chronic inflammation of asthmatic airways, which is suppressed by corticosteroids. This has now been confirmed by several biopsy and bronchoalveolar lavage studies in patients with asthma who are taking regular β₂ agonists (including long-acting inhaled β₂ agonists), that demonstrate no significant reduction in the number or activation in inflammatory cells in the airways, in contrast to resolution of the inflammation that occurs with ICS. This may be related to the fact that effects of β₂ agonists on macrophages, eosinophils, and lymphocytes are rapidly desensitized.

Clinical Use

Short-Acting β₂ Agonists. Inhaled short-acting β₂ agonists are the most widely used and effective bronchodilators in
the treatment of asthma due to their functional antagonism of bronchoconstriction. When inhaled from pMDI or DPI, they are convenient, easy to use, rapid in onset, and without significant systemic side effects. In addition to their acute bronchodilator effect, these agents are effective in protecting against various challenges, such as exercise, cold air, and allergens. Short-acting β₂ agonists are the bronchodilators of choice in treating acute severe asthma. The nebulized route of administration is easier and safer than intravenous administration and just as effective. Inhalation is preferable to the oral administration because systemic side effects are less, and inhalation may be more effective. Short-acting inhaled β₂ agonists, such as albuterol, should be used "as required" by symptoms and not on a regular basis in the treatment of mild asthma; increased use indicates the need for more anti-inflammatory therapy.

Oral β₂ agonists are occasionally indicated as an additional bronchodilator. Slow-release preparations (e.g., slow-release albuterol and bambuterol [a prodrug that slowly releases terbutaline but is not commercially available in the U.S.]) may be indicated in nocturnal asthma; however, these agents are less useful than inhaled βagonists because of an increased risk of side effects. Several short-acting β₂ agonists are available. With the exception of rimiterol (which retains the catechol ring structure and is therefore susceptible to rapid enzymatic degradation), they are resistant to uptake and enzymatic degradation by COMT and MAO. There is little to choose between the various short-acting β₂ agonists currently available; all are usable by inhalation and orally, have a similar duration of action (~3-4 hours; less in severe asthma), and similar side effects. Differences in β₂ selectivity have been claimed but are not clinically important. Drugs in clinical use include salbutamol, leva-albuterol, metaproterenol, terbutaline, as well as several not available in the U.S., fenoterol, tulobuterol, rimiterol, and pirbuterol.

Long-Acting Inhaled β₂ Agonists. The long-acting inhaled β₂ agonists (LABA) salmeterol, formoterol, and arformoterol have proved to be a significant advance in asthma and COPD therapy. These drugs have a bronchodilator action of >12 hours and also protect against bronchoconstriction for a similar period (Kips and Pawels, 2001). They improve asthma control (when given twice daily) compared with regular treatment with short-acting β₂ agonists (four to six times daily).

Tolerance to the bronchodilator effect of formoterol and the bronchoprotective effects of formoterol and salmeterol have been demonstrated, but this is a small loss of protection that does not appear to be progressive and is of doubtful clinical significance. Although both drugs have a similar duration of effect in clinical studies, there are differences. Formoterol has a more rapid onset of action and is an almost full agonist, whereas salmeterol is a partial agonist with a slower onset of action. These differences might confer a theoretical advantage for formoterol in more severe asthma, whereas it may also make it more likely to induce tolerance. However, no significant clinical differences between salmeterol and formoterol have been found in the treatment of patients with severe asthma (Nightingale et al., 2002).

In COPD, LABA are effective bronchodilators that may be used alone or in combination with anticholinergics or ICS. LABA improve symptoms and exercise tolerance by reducing both air trapping and exacerbations. In asthma patients, LABA should never be used alone because they do not treat the underlying chronic inflammation; rather, LABA should always be used in combination with ICS (preferably in a fixed-dose combination inhaler). LABA are an effective add-on therapy to ICS and are more effective than increasing the dose of ICS when asthma is not controlled at low doses.

Combination Inhaled β₂ Agonists. Combination inhalers containing a LABA and a corticosteroid (e.g., fluticasone/salmeterol [Advair], budesonide/formoterol [Symbicort]) are now widely used in the treatment of asthma and COPD. In asthma there is a strong scientific rationale for combining a LABA with a corticosteroid because these treatments have complementary synergistic actions (Barnes, 2002). The combination inhaler is more convenient for patients, simplifies therapy, and improves compliance with ICS because the patients perceive clinical benefit, but there may be an additional advantage because delivering the two drugs in the same inhaler ensures they are delivered simultaneously to the same cells in the airways, allowing the beneficial molecular interactions between LABA and corticosteroids to occur. It is likely that these inhalers will become the preferred therapy for all patients with persistent asthma. These combination inhalers are also more effective in COPD patients than LABA and ICS alone, but the mechanisms accounting for this beneficial interaction are less well understood than in patients with asthma.

Recently, a combination inhaler that contains formoterol and budesonide was shown to be more effective for relieving acute symptoms than either terbutaline or formoterol alone, suggesting that the inhaled corticosteroids may also be contributing to the benefit (Rabe et al., 2006). This may make it possible to control asthma with a single inhaler both for maintenance and relief of symptoms.

Steroselective β₂ Agonists. Albuterol is a racemic mixture of active R- and inactive S-isomers. Animal studies suggest that the S-isomer may increase airway responsiveness, providing a rationale for the development of R-albuterol (leva-albuterol). Although the R-isomer is more potent than racemic R/S-albuterol in some studies, careful dose responses show no advantage in terms of efficacy and no evidence that the S-albuterol is detrimental in asthmatic patients (Lotvall et al., 2001). Because leva-albuterol is more expensive than normally used racemic albuterol, this therapy has no clear clinical advantage (Barnes, 2006b). Steroselective formoterol (R, R-formoterol, arformoterol) has now been developed as a nebulized solution but also appears to offer no clinical advantage over racemic formoterol (Madaan, 2009).
**β₂ Receptor Polymorphisms.** Several single nucleotide polymorphisms and haplotypes of the human β₂ adrenergic receptor gene (*ADRB2*), which affect the structure of β₂ receptors, have been described. The common variants are Gly¹⁶Arg and Gln²⁹Glu, which have in vitro effects on receptor desensitization, but clinical studies have shown inconsistent effects on the bronchodilator responses to short- and long-acting β₂ agonists (Hawkins et al., 2008). Some studies have shown that patients with the common homozygous Arg¹⁶Arg variant have more frequent adverse effects and a poorer response to short- and long-acting β₂ agonists than heterozygotes or Gly²⁹Gly homozygotes, but overall these differences are small, and there appears to be no clinical value in measuring *ADRB2* genotype. No differences have been found with responses to LABA between these genotypes (Bleecker et al., 2007).

**Side Effects.** Unwanted effects are dose related and due to stimulation of extrapulmonary β receptors (Table 36–1 and Chapter 12). Side effects are not common with inhaled therapy but quite common with oral or intravenous administration.

- **Muscle tremor** due to stimulation of β₂ receptors in skeletal muscle is the most common side effect. It may be more troublesome with elderly patients and so is a more frequent problem in COPD patients.
- **Tachycardia and palpitations** are due to reflex cardiac stimulation secondary to peripheral vasodilation, from direct stimulation of atrial β₂ receptors (human heart has a relatively high proportion of β₂ receptors; see Chapter 12), and possibly also from stimulation of myocardial β₂ receptors as the doses of β₂ agonist are increased. These side effects tend to disappear with continued use of the drug, reflecting the development of tolerance. There can be a dose-related prolongation of the corrected QT interval (QTc).
- **Hypokalemia** is a potentially serious side effect. This is due to β₂ receptor stimulation of potassium entry into skeletal muscle, which may be secondary to a rise in insulin secretion. Hypokalemia might be serious in the presence of hypoxia, as in acute asthma, when there may be a predisposition to cardiac arrhythmias (Chapter 29). In practice, however, significant arrhythmias after nebulized β₂ agonists are rarely observed in acute asthma or COPD patients.

<tr>
<td>Hypoxemia (increased V/Q mismatch due to reversal of hypoxic pulmonary vasoconstriction)</td>
</tr>
</tbody>
</table>

- **Ventilation-perfusion (V/Q) mismatch** due to pulmonary vasodilation in blood vessels previously constricted by hypoxia, resulting in the shunting of blood to poorly ventilated areas and a fall in arterial oxygen tension. Although in practice the effect of β₂ agonists on PaO₂ is usually very small (<5 mm Hg fall), occasionally in severe COPD it can be large, although it may be prevented by giving additional inspired oxygen (O₂).
- **Metabolic effects** (increase in free fatty acid, insulin, glucose, pyruvate, and lactate) are usually seen only after large systemic doses.

**Tolerance.** Continuous treatment with an agonist often leads to tolerance (desensitization, subsensitivity), which may be due to down-regulation of the receptor (Chapter 12). For this reason there have been many studies of bronchial β receptor function after prolonged therapy with β₂ agonists. Tolerance of non-airway β₂ receptor–mediated responses, such as tremor and cardiovascular and metabolic responses, is readily induced in normal and asthmatic subjects. Tolerance of human airway smooth muscle to β₂ agonists in vitro has been demonstrated, although the concentration of agonist necessary is high and the degree of desensitization is variable. In normal subjects, bronchodilator tolerance is not a consistent finding after high-dose inhaled albuterol. In asthmatic patients tolerance to the bronchodilator effects of β₂ agonists has not usually been found. However, tolerance develops to the bronchoprotective effects of β₂ agonists, and this is more marked with indirect bronchoconstrictors that activate mast cells (e.g., adenosine, allergen, and exercise) than with direct bronchoconstrictors, such as histamine and methacholine. The reason for the relative resistance of airway smooth muscle β₂ responses to desensitization remains uncertain but may reflect the large receptor reserve: >90% of β₂ receptors may be lost without any reduction in the relaxation response. The high level of *ADRB2* expression in airway smooth muscle compared with peripheral lung may also contribute to the resistance to tolerance because a high rate of β receptor synthesis is likely. In addition, the expression of GRK2, which phosphorylates and inactivates occupied β₂ receptors, is very low in airway smooth muscle (McGraw and Liggett, 1997). By contrast there is no receptor reserve in inflammatory cells, GRK2 expression is high, and tolerance to β₂ agonists rapidly develops at these sites.

Experimental studies have shown that corticosteroids prevent the development of tolerance in airway smooth muscle, and prevent and reverse the fall in pulmonary β receptor density (Mak et al., 1995). However, ICS fail to prevent the tolerance to the bronchoprotective effect of inhaled β₂ agonists, possibly because they do not reach airway smooth muscle in a high enough concentration.

**Long-Term Safety.** Because of a possible relationship between adrenergic drug therapy and the rise in asthma deaths in several countries during the early 1960s, doubts were cast on the long-term safety of β agonists. A causal relationship between β agonist use and mortality has never been firmly established, although in retrospective studies this would not be possible. A particular β₂ agonist, fenoterol, was linked to the rise in asthma deaths in New Zealand in the early 1990s because significantly more of the fatal cases were prescribed fenoterol than the case-matched control patients. An epidemiological study examined the links between drugs prescribed for asthma and death or near death from asthma attacks, based on computerized records of prescriptions. There was
a marked increase in the risk of death with high doses of all inhaled 
\( \beta_2 \) agonists (Spitzer et al., 1992). The risk was greater with 
fenoterol, but when the dose is adjusted to the equivalent dose for 
albuterol, there is no significant difference in the risk for these two 
drugs. The link between high \( \beta_2 \) agonist usage and increased 
asthma mortality does not prove a causal association because 
patients with more severe and poorly controlled asthma, who are 
more likely to have an increased risk of fatal attacks, are more 
likely to be using higher doses of \( \beta_2 \) agonist inhalers and less likely 
to be using effective anti-inflammatory treatment. Indeed, in 
the patients who used regular inhaled steroids there was a significant 
reduction in risk of death (Suissa et al., 2000).

Regular use of inhaled \( \beta_2 \) agonists has also been linked to 
increased asthma morbidity. Regular use of fenoterol was associated 
with worse asthma control and a small increase in airway hyperre-
sponsiveness compared with patients using fenoterol “on demand” 
for symptom control over a 6-month period (Sears et al., 1990). 
However, this was not found in a study with regular albuterol (Dennis 
et al., 2000). There is some evidence that regular inhaled 
\( \beta_2 \) agonists may increase allergen-induced asthma and sputum eosinophilia 
(Mcivor et al., 1998). A possible mechanism is that \( \beta_2 \) agonists 
upregulate expression of PLC\(_{\beta_1}\), resulting in augmentation of the 
bronchoconstrictor responses to cholinergic agonists and mediators 
(McGrave et al., 2003). Short-acting inhaled \( \beta_2 \) agonists should only 
be used on demand for symptom control, and if they are required 
frequently (more than three times weekly), an ICS is needed.

The safety of LABA in asthma remains controversial. A large 
study of the safety of salmeterol showed an excess of respiratory 
deaths and near deaths in patients prescribed salmeterol, but these 
deaths occurred mainly in African Americans living in inner cities 
who were not taking ICS (Nelson et al., 2006). Similar data have 
also raised concerns about formoterol. This may be predictable 
because LABA do not treat the underlying chronic inflammation 
of asthma. However, concomitant treatment with ICS appears to obvi-
sate such risk, so it is recommended that LABA should only be used 
when ICS are also prescribed (preferably in the form of a combina-
tion inhaler so that the LABA can never be taken without the inhaled 
corticosteroids) (Jaeschke et al., 2008). All LABA approved in the 
U.S. carry a black box warning cautioning against overuse. Studies 
are underway to examine their long-term safety profile, especially 
in children with asthma. There are less safety concerns with LABA use 
in COPD. No major adverse effects were reported in a large study 
over 3 years in COPD patients and in several other studies (Calverley 
et al., 2007; Rodrigo et al., 2008).

**Future Developments**

\( \beta_2 \) Agonists will continue to be the bronchodilators of choice for asthma 
in the foreseeable future because they are effective in all patients and 
have few or no side effects when used in low doses. It would be diffi-
cult to find a bronchodilator that improves on the efficacy and safety of 
inhaled \( \beta_2 \) agonists. Although some concerns have been 
expressed about the long-term effects of short-acting inhaled \( \beta_2 \) agonists, 
when used as required for symptom control, inhaled \( \beta_2 \) agonists appear safe. 
Use of large doses of inhaled \( \beta_2 \) agonists indicates poor asthma control; 
such patients should be assessed and appropriate controller medication 
used. LABA are a very useful option for long-term control in asthma 
and COPD. In asthma patients LABA should probably only be used if 
the patient is receiving concomitant ICS. There is little advantage to be 
gained by improving \( \beta_2 \) receptor selectivity because most of the side 
effects of these agents are due to \( \beta_2 \) receptor stimulation (muscle 
tremor, tachycardia, hypokalemia). Several once daily inhaled \( \beta_2 \) ago-
nists, such as indacaterol and carmoterol, are now in clinical develop-
ment (Cazzola and Matera, 2008).

**METHYLXANTHINES**

Methylxanthines, such as theophylline, which are related 
to caffeine, have been used in the treatment of asthma 
since 1930, and theophylline is still widely used in develop-
ing countries because it is inexpensive. Theophylline 
became more useful with the availability of rapid plasma 
assays and the introduction of reliable slow-release prepa-
rations. However, the frequency of side effects and the rela-
tive low efficacy of theophylline have led to reduced use 
in many countries because inhaled \( \beta_2 \) agonists are far more 
effective as bronchodilators and ICS have a greater anti-
flammatory effect. In patients with severe asthma and 
COPD it still remains a very useful drug, however.

**Chemistry.** Theophylline is a methylxanthine similar in structure to 
the common dietary xanthines caffeine and theobromine. Several 
substituted derivatives have been synthesized, but only two appear 
to have any advantage over theophylline: the 3-propyl derivative, 
enprofylline, which is more potent as a bronchodilator and may have 
fewer toxic effects because it does not antagonize adenosine recep-
tors; and doxofylline (7-[1,3-dioxalan-2-ylmethyl] theophylline), a 
novel methylxanthine available in some countries (Dini and Cogo, 
2001). Doxofylline, which has a dioxolane group at position 7, has 
an inhibitory effect on phosphodiesterases (PDEs) similar to that of 
theophylline but is less active as an adenosine antagonist and may 
have a more favorable side-effect profile. Many salts of theophylline 
have also been marketed; the most common is aminophylline, which 
is the ethylenediamine salt used to increase its solubility at neutral 
\( pH \). Other salts either do not have any advantage (e.g., oxtriphylline 
[choline theophyllinate] or are virtually inactive (e.g., acepifylline). 
Thus, theophylline remains the major methylxanthine in clinical use.

**Mechanism of Action.** The mechanisms of action of theophylline 
are still uncertain. In addition to its bronchodilator action, theo-
phylline has many nonbronchodilator effects that may be relevant to 
its effects in asthma and COPD (Figure 36–6). Many of these molec-
ular effects are seen only at high concentrations that exceed the ther-
apeutic range, however. Several molecular mechanisms of action 
have been proposed:

- **Inhibition of phosphodiesterases.** Theophylline is a nonselect-
  tive PDE inhibitor, but the degree of inhibition is relatively
minimal at concentrations of theophylline that are within the so-called therapeutic range. PDE inhibition and the concomitant elevation of cellular cAMP and cyclic guanosine monophosphate (cGMP) almost certainly account for the bronchodilator action of theophylline, but PDE inhibition is unlikely to account for the nonbronchodilator effects of theophylline that are seen at lower concentrations. Inhibition of PDE should lead to synergistic interaction with agonists through an increase in cAMP (Figure 36–5), but this has not been convincingly demonstrated in clinical studies. Several isoenzyme families of PDE have now been recognized and those important in smooth muscle relaxation include PDE3, PDE4, and PDE5. Theophylline is a weak inhibitor of all PDE isoenzymes.

- **Adenosine receptor antagonism.** Theophylline antagonizes adenosine receptors at therapeutic concentrations. Adenosine causes bronchoconstriction in airways from asthmatic patients by releasing histamine and leukotrienes. Adenosine antagonism is unlikely to account for the anti-inflammatory effects of theophylline but may be responsible for serious side effects, including cardiac arrhythmias and seizures through the antagonism of A1 receptors. Of interest may be the adenosine A2B receptor on mast cells, which is activated by adenosine in asthmatic patients (Wilson, 2008).

- **Interleukin-10 release.** IL-10 has a broad spectrum of anti-inflammatory effects, and there is evidence that its secretion is reduced in asthma. IL-10 release is increased by theophylline, and this effect may be mediated via inhibition of PDE activities, although this has not been seen at the low doses that are effective in asthma (Oliver et al., 2001).

- **Effects on gene transcription.** Theophylline prevents the translocation of the pro-inflammatory transcription factor NF-κB into the nucleus, potentially reducing the expression of inflammatory genes in asthma and COPD. Inhibition of NF-κB appears to be due to a protective effect against the degradation of the inhibitory protein I-κBα (Ichiyama et al., 2001). However, these effects are seen at high concentrations and may be mediated by inhibition of PDE.

- **Effects on apoptosis.** Prolonged survival of granulocytes due to a reduction in apoptosis may be important in perpetuating chronic inflammation in asthma (eosinophils) and COPD (neutrophils). Theophylline promotes apoptosis in eosinophils and neutrophils in vitro. This is associated with a reduction in the anti-apoptotic protein Bcl-2 (Chung et al., 2000). This effect is not mediated via PDE inhibition, but in neutrophils may be mediated by antagonism of adenosine A2A receptors (Yasui et al., 2000). Theophylline also induces apoptosis in T lymphocytes, reducing their survival; this effect appears to be mediated via PDE inhibition (Ohta and Yamashita, 1999).

- **Histone deacetylase activation.** Recruitment of histone deacetylase-2 (HDAC2) by glucocorticoid receptors switches off inflammatory genes. Therapeutic concentrations of theophylline activate HDAC, thereby enhancing the anti-inflammatory effects of corticosteroids (Cosio et al., 2004; Ito et al., 2002). This mechanism is independent of PDE inhibition or adenosine receptor antagonism and appears to be mediated by inhibition of PI3-kinase-δ, which is activated by oxidative stress (Marwick et al., 2009). The anti-inflammatory effects of theophylline are inhibited by a HDAC inhibitor, trichostatin A. Low doses of theophylline increase HDAC activity in bronchial biopsies of asthmatic patients and correlate with the reduction in eosinophil numbers in the biopsy.

- **Other effects.** Several other effects of theophylline have been described, including an increase in circulating catecholamines, inhibition of calcium influx into inflammatory cells, inhibition of prostaglandin effects, and antagonism of tumor necrosis
of theophylline (Cp ~5 mg/L) reduce the numbers of eosinophils seen in airways after allergen challenge. In patients with mild asthma, low doses result in increased numbers of activated CD4+ cells and eosinophils in bronchial biopsies, bronchoalveolar lavage, and induced sputum (Lim et al., 2001); conversely, in severe asthma, withdrawal of theophylline, resulting in increased metabolic breakdown, so that higher doses may be required. 

Deceased clearance

- CYP inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, fluvoxamine, zileuton, zafirlukast)
- Congestive heart failure
- Liver disease
- Pneumonia
- Viral infection and vaccination
- High-carbohydrate diet
- Old age

Studies suggest that theophylline has anti-asthma effects other than bronchodilation below 10mg/L, so the therapeutic range is now taken as 5-15 mg/L. The dose of theophylline required to give these therapeutic concentrations varies among subjects, largely because of differences in clearance of the drug. In addition, there may be differences in bronchodilator response to theophylline; furthermore, with acute bronchoconstriction, higher concentrations may be required to produce bronchodilation. Theophylline is rapidly and completely absorbed, but there are large interindividual variations in clearance, due to differences in hepatic metabolism (Table 36–3). Theophylline is metabolized in the liver, mainly by CYP1A2, and a large number of factors are known to influence hepatic metabolism of theophylline (Zhang and Kaminsky, 1995):

Increased clearance

- Enzyme induction (mainly CYP1A2) by co-administered drugs (e.g., rifampicin, barbiturates, ethanol)
- Smoking (tobacco, marijuana) via CYP1A2 induction
- High-protein, low-carbohydrate diet
- Barbecued meat
- Childhood

Reduced clearance

- CYP inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, fluvoxamine, zileuton, zafirlukast)
- Congestive heart failure
- Liver disease
- Pneumonia
- Viral infection and vaccination
- High-carbohydrate diet
- Old age

Because of these variations in clearance, individualization of theophylline dosage is required and plasma concentrations should be measured 4 hours after the last dose with slow-release preparations when steady state has been achieved. There is no significant circadian variation in theophylline metabolism, although there may be delayed absorption at night related to supine posture.

### Preparations and Routes of Administration

**Intravenous** aminophylline has been used for many years in the treatment of acute severe asthma. The recommended dose is 6 mg/kg given intravenously over 20-30 minutes, followed by a maintenance dose of 0.5 mg/kg per hour. If the patient is already taking theophylline, or there are any factors that decrease clearance, these doses should be halved and the plasma level checked more frequently. Nebulized β2 agonists are now preferred over intravenous aminophylline for acute exacerbations of asthma and COPD.

**Oral** immediate-release theophylline tablets or elixir, which are rapidly absorbed, give wide fluctuations in plasma levels, and are not recommended. Several sustained-release preparations are now available that are absorbed at a constant rate and provide steady plasma concentrations over a 12- to 24-hour period. Both slow-release aminophylline and theophylline are available and are equally effective (although the ethylene diamine component of aminophylline has been implicated in allergic reactions). For continuous treatment twice daily therapy (~8 mg/kg twice daily) is needed. Recently, once-daily preparations have gained popularity. For nocturnal asthma a single dose of slow-release theophylline at night is often effective. Once optimal doses have been determined,
Routine monitoring of plasma concentrations is usually not necessary, unless a change in clearance is suspected or evidence of toxicity emerges.

**Clinical Use.** In patients with acute asthma, intravenous aminophylline is less effective than nebulized β₂ agonists and should therefore be reserved for those patients who fail to respond to, or are intolerant of, β₂ agonists. Theophylline should not be added routinely to nebulized β₂ agonists because it does not increase the bronchodilator response and may increase their side effects (Parameswaran et al., 2000). Indeed, the role of theophylline in the contemporary management of asthma and COPD has been questioned. However, there is good evidence that theophylline may provide an additional bronchodilator effect even when maximally effective doses of β₂ agonists have been given (Rivington et al., 1995). Thus, if adequate bronchodilation is not achieved by a β₂ agonist alone, theophylline may be added to the maintenance therapy with benefit. Addition of low-dose theophylline to either a high or low dose of ICS in patients who are not adequately controlled provides better symptom control and lung function than doubling the dose of inhaled steroid (Evans et al., 1997; Lim et al., 2000; Ukena et al., 1997), although it is less effective than doubling the dose of ICS in uncontrolled patients, and is a less expensive alternative add-on therapy than a LABA or antileukotriene. Theophylline reverses corticosteroid resistance in COPD cells by restoring HDAC2 to normal levels (Cosio et al., 2004) and accelerates the recovery from acute exacerbations of COPD through this mechanism (Cosio et al., 2009). Theophylline reverses corticosteroid resistance in COPD cells by restoring HDAC2 to normal levels (Cosio et al., 2004) and accelerates the recovery from acute exacerbations of COPD through this mechanism (Cosio et al., 2009). Theophylline has some anti-asthma effect at doses that are lower than those needed for bronchodilation, and plasma levels of 5-15 mg/L are recommended.

**Summary and Future Developments**

Theophylline use has been declining, partly because of the problems with side effects, but mainly because more effective therapy with ICS has been introduced. Oral theophylline remains a useful treatment in some patients with difficult asthma and appears to have effects beyond those provided by steroids. Rapid-release theophylline preparations are the only affordable anti-asthma medication in some developing countries. There is increasing evidence that theophylline has some anti-asthma effect at doses that are lower than those needed for bronchodilation, and plasma levels of 5-15 mg/L are recommended.

Given theophylline’s anti-inflammatory effects, there is a strong scientific rationale for combining low-dose theophylline with ICS, particularly in patients with more severe asthma and in COPD. Adding a low dose of theophylline gives better control of asthma than doubling the dose of ICS in uncontrolled patients, and is a less expensive alternative add-on therapy than a LABA or antileukotriene. Theophylline reverses corticosteroid resistance in COPD cells by restoring HDAC2 to normal levels (Cosio et al., 2004) and accelerates the recovery from acute exacerbations of COPD through this mechanism (Cosio et al., 2009). In COPD, low-dose theophylline

PDE, phosphodiesterase; A, adenosine.
is the first drug to demonstrate clear anti-inflammatory effects; thus, theophylline may have a role in preventing progression of this disease (Culpitt et al., 2002).

**MUSCARINIC CHOLINERGIC ANTAGONISTS**

Chemical antagonism of the effects of acetylcholine at muscarinic receptors in the lung for the relief of asthma is not a new idea. *Datura stramonium* (jimson weed) and related species of the nightshade family contain a mixture of muscarinic antagonists (atropine, hyoscyamine, scopolamine) and were smoked for relief of asthma two centuries ago. Subsequently, the purified plant alkaloid atropine was introduced for treating asthma. Due to the significant side effects of atropine, particularly drying of secretions, less soluble quaternary compounds, such as atropine methyl nitrate and ipratropium bromide, have been developed. These compounds are topically active and are not significantly absorbed from the respiratory or GI tracts. The basic pharmacology of the antimuscarinic agents is presented in Chapter 9.

**Mode of Action**

These agents are competitive antagonists of ACh binding to muscarinic cholinergic receptors; thus these drugs block the effects of endogenous ACh at muscarinic receptors, including the direct constrictor effect on bronchial smooth muscle mediated via the M3-Gq-PLC-IP3-Ca2+ pathway (Chapter 3). Their predicted efficacy stems from the role played by the parasympathetic nervous system in regulating bronchomotor tone. Multiple and diverse stimuli cause reflex increases in parasympathetic activity that contribute to bronchoconstriction. The effects of ACh on the respiratory system include not only bronchoconstriction but also increased tracheobronchial secretion and stimulation of the chemoreceptors of the carotid and aortic bodies. Thus antimuscarinic drugs might be expected to antagonize these effects of acetylcholine. One complicating factor studied in animal models is that myriad inflammatory mediators involved in the pathogenesis of asthma and COPD may also induce components of muscarinic responsiveness, such as Gq and rho, and contribute to hyperresponsiveness of the airway (Chiba et al., 2008). Thus, the contractility of bronchial smooth muscle and antagonism of muscarinic responsiveness could be moving targets in asthma and COPD.

Basic research is demonstrating that the muscarinic agonists are not functionally equivalent, however. Recent research has focused on the differential capacity of muscarinic antagonists to act as antagonists, as inverse agonists inhibiting the constitutive activity of the M3 receptor, and as modulators of upregulation of M3 receptor expression (Casarosa et al., 2009). Such differences may have clinical relevance for long-term use of these compounds, where tolerance and withdrawal/rebound could be major issues. In this regard, a long-term study of tiotropium demonstrates no loss of its capacity for bronchodilation over 4 years (Tashkin et al., 2008).

In animals and man there is a small degree of resting bronchomotor tone that is probably due to tonic vagal nerve impulses that release acetylcholine in the vicinity of airway smooth muscle because it can be blocked by anticholinergic drugs. Acetylcholine may also be released from other airway cells, including epithelial cells (Wessler and Kirkpatrick, 2008). The synthesis of acetylcholine in epithelial cells is increased by inflammatory stimuli (such as TNF-α), which increase the expression of choline acetyltransferase, which could contribute to cholinergic effects in airway diseases. Muscarinic receptors are expressed in airway smooth muscle of small airways that do not appear to be innervated by cholinergic nerves; these receptors may be a mechanism of cholinergic narrowing in peripheral airways that could be relevant in COPD, responding to locally synthesized, non-neuronal ACh.

Myriad mechanical, chemical, and immunological stimuli elicit reflex bronchoconstriction via vagal pathways, and cholinergic pathways may play an important role in regulating acute bronchomotor responses in animals. These observations suggested that cholinergic mechanisms might underlie airway hyperresponsiveness and acute bronchoconstrictor responses in asthma, with the implication that anticholinergic drugs would be effective bronchodilators. These drugs may afford protection against acute challenge by sulfur dioxide, inert dusts, cold air, and emotional factors, but they are less effective against antigen challenge, exercise, and fog. This is not surprising because anticholinergic drugs will only inhibit reflex ACh-mediated bronchoconstriction and have no blocking effect on the direct effects of inflammatory mediators, such as histamine and leukotrienes, on bronchial smooth muscle. Furthermore, cholinergic antagonists probably have little or no effect on mast cells, microvascular leak, or the chronic inflammatory response.

Theoretically, anticholinergics may reduce airway mucus secretion and reduce mucus clearance, but this is generally not observed in clinical studies. Oxitropium bromide (not available in the U.S.) in high doses reduces mucus hypersecretion in patients with COPD with chronic bronchitis.

**Clinical Use.** In asthmatic patients, anticholinergic drugs are less effective as bronchodilators than β2 agonists and offer less efficient protection against bronchial challenges. These drugs may be more effective in older patients with asthma in whom there is an element of fixed airway obstruction. Anticholinergics are currently used as an additional bronchodilator in asthmatic patients not controlled on a LABA. Nebulized anticholinergic drugs are effective in acute severe asthma but less effective than β2 agonists. Nevertheless, in the acute and chronic treatment of asthma, anticholinergic drugs may have an additive effect with β2 agonists and should therefore be considered...
when control of asthma is not adequate with nebulized β₂ agonists. A muscarinic antagonist should be considered when there are problems with theophylline or when inhaled β₂ agonists cause a troublesome tremor in elderly patients.

In COPD, anticholinergic drugs may be as effective as or even superior to β₂ agonists. Their relatively greater effect in COPD than in asthma may be explained by an inhibitory effect on vagal tone, which, although not necessarily increased in COPD, may be the only reversible element of airway obstruction and one that is exaggerated by geometric factors in the narrowed airways of COPD patients (Figure 36–7). Anticholinergic drugs reduce air trapping and improve exercise tolerance in COPD patients.

**Therapeutic Choices.** Ipratropium bromide (ATROVENT, others) is available as a pMDI and nebulized preparation. The onset of bronchodilation is relatively slow and is usually maximal 30-60 minutes after inhalation, but may persist for 6-8 hours. It is usually given by MDI three to four times daily on a regular basis, rather than intermittently for symptom relief, in view of its slow onset of action.

Oxitropium bromide (not available in the U.S.) is a quaternary anticholinergic bronchodilator that is similar to ipratropium bromide in terms of receptor blockade. It is available in higher doses by inhalation and may therefore have a more prolonged effect. Thus, it may be useful in some patients with nocturnal asthma.

**Combination inhalers** of an anticholinergic and β₂ agonist, such as ipratropium/albuterol (COMBIVENT, DUONEB, others), are popular, particularly among patients with COPD. Several studies have demonstrated additive effects of these two drugs, thus providing an advantage over increasing the dose of β₂ agonist in patients who have side effects.

Tiotropium bromide is a long-acting anticholinergic drug that is suitable for once-daily dosing as a DPI (SPIRIVA) or via a soft mist mini-nebulizer device (not available in the U.S.) (Barr et al., 2006). Tiotropium binds to all muscarinic receptor subtypes but dissociates very slowly from M₃ and M₁ receptors, giving it a degree of kinetic receptor selectivity for these receptors compared with M₂ receptors, from which it dissociates more rapidly. Thus, compared with ipratropium, tiotropium is less likely to antagonize M₂-mediated inhibition of ACh release (the resulting increase in ACh could counteract the blockade of M₁ receptor–mediated bronchoconstriction) (Chapter 9). It is an effective bronchodilator in patients with COPD and is more effective than ipratropium four times daily without any loss of efficacy over a 1-year treatment period. Over a 4-year period, tiotropium improves lung function and health status and reduces exacerbations and all-cause mortality, although there is no effect on disease progression (Tashkin et al., 2008). As a result, tiotropium is becoming the bronchodilator of choice for COPD patients.

**Adverse Effects.** Inhaled anticholinergic drugs are generally well tolerated. On stopping inhaled anticholinergics, a small rebound increase in airway responsiveness has been described, but the clinical relevance of this is uncertain. Systemic side effects after ipratropium bromide and tiotropium bromide are uncommon during normal clinical use because there is little systemic absorption. Because cholinergic agonists can stimulate mucus secretion, there has been concern that anticholinergics may reduce secretion and lead to more viscous mucus. However, ipratropium bromide, even in high doses, has no detectable effect on mucociliary clearance in either normal subjects or in patients with airway disease. A significant unwanted effect is the unpleasant bitter taste of inhaled ipratropium, which may contribute to poor compliance. Nebulized ipratropium bromide may precipitate glaucoma in elderly patients due to a direct effect of the nebulized drug on the eye. This may be prevented by nebulization with a mouthpiece rather than a face mask. Reports of paradoxical bronchoconstriction with ipratropium bromide, particularly when given by nebulizer, were largely explained as effects of the hypotonic nebulizer solution and by antibacterial additives, such as benzalkonium chloride and ethylenediaminetetraacetic acid (EDTA). This problem has not been described with tiotropium. Occasionally, bronchoconstriction may occur with ipratropium bromide given by MDI. It is possible that this is due to blockade of prejunctional M₁ receptors on airway cholinergic nerves that normally inhibit acetylcholine release. Tiotropium causes dryness of the mouth in 10-15% of patients, but this usually disappears during continued therapy. Urinary retention is occasionally seen in elderly patients.

**Future Developments.** Anticholinergics are the bronchodilators of choice in COPD and therefore have a growing market. Several long-acting muscarinic antagonists are now in clinical development,
including glycopyrrolate and aclidinium (Cazzola, 2009; Hansel et al., 2005). Dual-action drugs that are both muscarinic antagonists and \( \beta_2 \) agonist (MABA) are also in clinical development (Ray and Alcaraz, 2009).

**NOVEL CLASSES OF BRONCHODILATORS**

Several new classes of bronchodilator are under development, but it is difficult to foresee a more effective bronchodilator than a LABA for asthma and a long-acting anticholinergic for COPD. Inventing new classes of bronchodilators has been difficult; several agents have had problems with vasodilator side effects because they relaxed vascular smooth muscle to a greater extent than airway smooth muscle. Nonetheless, there are several classes of bronchodilators under development, as described next.

**Magnesium Sulfate.** Increasing evidence indicates that magnesium sulfate (MgSO\(_4\)) is useful as an additional bronchodilator in patients with acute severe asthma. Intravenous or nebulized MgSO\(_4\) benefits adults and children with severe exacerbations (forced expiratory volume in 1 second [FEV\(_1\)] <30% of predicted value), giving improvement in lung function when added to nebulized \( \beta_2 \) agonist and a reduction in hospital admissions (Mohammed and Goodacre, 2007). The treatment is cheap and well tolerated, although the clinical benefit appears small. Side effects include flushing and nausea but are usually minor. Magnesium sulfate appears to act as a bronchodilator and may reduce cytosolic Ca\(^{2+}\) concentrations in airway smooth muscle cells. The concentration of magnesium is lower in serum and erythrocytes of asthmatic patients than in normal controls and correlates with airway hyperresponsiveness (Emelyanov et al., 1999), although the improvement in acute severe asthma after magnesium does not correlate with plasma concentrations. More studies are needed before intravenous and inhaled MgSO\(_4\) are routinely recommended for the management of acute severe asthma. There are too few studies in acute exacerbations of COPD to make any firm recommendation (Skorodin et al., 1995).

**K\(^+\) Channel Openers.** K\(^+\) channels are involved in recovery of excitable cells after depolarization and are important in stabilization of cells. K\(^+\) channel openers such as cromakalim or levcromakalim (the levo-isomer of cromakalim) open ATP-dependent K\(^+\) channels in smooth muscle, leading to membrane hyperpolarization and relaxation of airway smooth muscle (Black et al., 1990). This suggests that K\(^+\) channel activators may be useful as bronchodilators (Pelaia et al., 2002). Clinical studies in asthma, however, have been disappointing, with no bronchodilation or protection against bronchoconstrictor challenges. The cardiovascular side effects of these drugs (postural hypotension, flushing) limit the oral dose; furthermore, inhaled formulations are problematic. New developments include K\(^+\) channel openers that open Ca\(^{2+}\)-activated large conductance K\(^+\) channels (maxi-K channels) that are also opened by \( \beta_2 \) agonists; these drugs may be better tolerated. Maxi-K channel openers also inhibit mucus secretion and cough, and they may be of particular value in the treatment of COPD.

**Atrial Natriuretic Peptides.** Atrial natriuretic peptide (ANP) activates membrane-bound guanylyl cyclase and increases cellular cyclic GMP, leading to bronchodilation by mechanisms similar to those of NO on smooth muscle (Chapter 3). ANP and the related peptide urodilatin are bronchodilators in asthma and give effects comparable to those of \( \beta_2 \) agonists (Angus et al., 1993; Fluge et al., 1999). Because ANP and congensers work via a mechanism distinct from that of \( \beta_2 \) agonists, they may give additional bronchodilation that may be useful in acute severe asthma when \( \beta_2 \) receptor function might be impaired.

**Vasoactive Intestinal Polypeptide Analogs.** Vasoactive intestinal polypeptide (VIP) is a 28 amino acid peptide that binds to two GPCRs, VPAC\(_1\) and VPAC\(_2\), both of which couple primarily to \( G_i \) to stimulate the adenylcyclase-cAMP-PKA pathway leading to relaxation of smooth muscle. VIP is a potent dilator of human airway smooth muscle *in vitro* but is not effective in patients because it is rapidly metabolized (plasma \( t_{1/2} \sim 2 \) minutes); in addition, VIP causes vasodilator side effects. More stable analogs of VIP, such as Ro 25-1533, which selectively stimulates VIP receptors in airway smooth muscle (via the VPAC\(_2\) receptor), have been synthesized. Inhaled Ro 25-1533 has a rapid bronchodilator effect in asthmatic patients but is not as prolonged as formoterol (Linden et al., 2003).

**Other Inhibitors of Smooth Muscle Contraction.** Agents that inhibit the contractile machinery of airway smooth muscle, including rho kinase inhibitors, inhibitors of myosin light chain kinase, and myosin inhibitors, are also in development. Because these agents also cause vasodilation, it will be necessary to administer them by inhalation.

**CORTICOSTEROIDS**

Corticosteroids are used in the treatment of several inflammatory lung diseases. Oral corticosteroids were introduced for the treatment of asthma shortly after their discovery in the 1950s and remain the most effective controller therapy available for asthma. However, their considerable side effects have prompted considerable research into discovering new or related agents that retain the beneficial action on airways without the adverse effects. The introduction of ICS (inhaled corticosteroids), initially as a way of reducing the requirement for oral steroids, has revolutionized the treatment of chronic asthma (Barnes et al., 1998b). Because asthma is a chronic inflammatory disease, ICS are considered as first-line therapy in all but the mildest of patients. In marked contrast, ICS are much less effective in COPD and should only be used in patients with severe disease who have frequent exacerbations. Oral corticosteroids remain the mainstay of treatment of several other pulmonary diseases, such as sarcoidosis, interstitial lung diseases, and pulmonary eosinophilic syndromes. The general pharmacology of corticosteroids is presented in Chapter 42.
Chemistry. The adrenal cortex secretes cortisol (hydrocortisone) and, by modification of its structure, it was possible to develop derivatives, such as prednisone, prednisolone, and dexamethasone, with enhanced corticosteroid effects but with reduced mineralocorticoid activity (Chapter 42). These derivatives with potent glucocorticoid actions were effective in asthma when given systemically but had no anti-asthmatic activity when given by inhalation. Further substitution in the 17α ester position resulted in steroids with high topical activity, such as beclomethasone dipropionate, triamcinolone, flunisolide, budesonide, and fluticasone propionate, which are potent in the skin (dermal blanching test) and were later found to have significant anti-asthma effects when given by inhalation (Figure 36–8).

Mechanism of Action. Corticosteroids enter target cells and bind to glucocorticoid receptors (GR) in the cytoplasm (Chapter 42). There is only one type of GR that binds corticosteroids and no evidence for the existence of subtypes that might mediate different aspects of corticosteroid action (Barnes, 2006a). The steroid-GR complex moves into the nucleus, where it binds to specific sequences on the upstream regulatory elements of certain target genes, resulting in increased (or rarely, decreased) transcription of the gene, with subsequent increased (or decreased) synthesis of the gene products. GR may also interact with protein transcription factors and coactivator molecules in the nucleus and thereby influence the synthesis of certain proteins independently of any direct interaction with DNA. The repression of transcription factors, such as activator protein-1 (AP-1) and NF-κB, is likely to account for many of the anti-inflammatory effects of steroids in asthma. In particular, corticosteroids reverse the activating effect of these pro-inflammatory transcription factors on histone acetylation by recruiting HDAC2 to inflammatory genes that have been activated through acetylation of associated histones (Figure 36–9). GRs are acetylated when corticosteroids are bound and bind to DNA in this acetylated state as dimers, whereas the acetylated GR has to be deacetylated by HDAC2 in order to interact with inflammatory genes and NF-κB (Ito et al., 2006).

There may be additional mechanisms that are also important in the anti-inflammatory actions of corticosteroids. Corticosteroids have potent inhibitory effects on MAP kinase signaling pathways through the induction of MKP-1, which may inhibit the expression of multiple inflammatory genes (Clark, 2003).

Anti-Inflammatory Effects in Asthma. The mechanisms of action of corticosteroids in asthma are still poorly understood, but their efficacy is most likely related to their anti-inflammatory properties. Corticosteroids have widespread effects on gene transcription, increasing the transcription of several anti-inflammatory genes and suppressing transcription of many inflammatory genes. Steroids have inhibitory effects on many inflammatory and structural cells that are activated in asthma and prevent the recruitment of inflammatory cells into the airways (Figure 36–10). Studies of bronchial biopsies in asthma have demonstrated a reduction in the number and activation of inflammatory cells in the epithelium and submucosa after regular ICS, together with a healing of the damaged epithelium. Indeed, in patients with mild asthma the inflammation may be completely resolved after inhaled steroids.

Figure 36–8. Chemical structures of commonly used inhaled corticosteroids, showing changes from hydrocortisone nucleus.
Steroids potently inhibit the formation of cytokines (e.g., IL-1, IL-3, IL-4, IL-5, IL-9, IL-13, TNF-α, and granulocyte-macrophage colony-stimulating factor, GM-CSF) that are secreted in asthma by T-lymphocytes, macrophages, and mast cells. Corticosteroids also decrease eosinophil survival by inducing apoptosis. Corticosteroids inhibit the expression of multiple inflammatory genes in airway epithelial cells, probably the most important action of ICS in suppressing asthmatic inflammation. Corticosteroids also prevent and reverse the increase in vascular permeability due to inflammatory mediators in animal studies and may therefore lead to resolution of airway edema. Steroids have a direct inhibitory effect on mucus glycoprotein secretion from airway submucosal glands, as well as indirect inhibitory effects by down-regulation of inflammatory stimuli that stimulate mucus secretion.

Corticosteroids have no direct effect on contractile responses of airway smooth muscle; improvement in lung function after ICS is presumably due to an effect on the chronic airway inflammation and airway hyperresponsiveness. A single dose of ICS has no effect on the early response to allergen (reflecting their lack of effect on mast cell mediator release) but inhibits the late response (which may be due to an effect on macrophages, eosinophils, and airway wall edema) and also inhibits the increase in airway hyperresponsiveness.

ICS have rapid anti-inflammatory effects, reducing airway hyperresponsiveness and inflammatory mediator concentrations in sputum within a few hours (Erin et al., 2008). However, it may take several weeks or months to achieve maximal effects on airway hyperresponsiveness, presumably reflecting the slow healing of the damaged inflamed airway. It is important to recognize that
corticosteroids suppress inflammation in the airways but do not cure the underlying disease. When steroids are withdrawn there is a recurrence of the same degree of airway hyperresponsiveness, although in patients with mild asthma it may take several months to return.

Effect on \( \beta_2 \) Adrenergic Responsiveness. Corticosteroids increase \( \beta \) adrenergic responsiveness, but whether this is relevant to their effect in asthma is uncertain. Steroids potentiate the effects of \( \beta \) agonists on bronchial smooth muscle and prevent and reverse \( \beta \) receptor desensitization in airways in vitro and in vivo (Barnes, 2002; Giembycz et al., 2008). At a molecular level, corticosteroids increase the transcription of the \( \beta_2 \) receptor gene in human lung in vitro and in the respiratory mucosa in vivo and also increase the stability of its messenger RNA. They also prevent or reverse uncoupling of \( \beta_2 \) receptors to \( G_s \). In animal systems, corticosteroids prevent downregulation of \( \beta_2 \) receptors.

\( \beta_2 \) Agonists also enhance the action of GR, resulting in increased nuclear translocation of liganded GR receptors and enhancing the binding of GR to DNA. This effect has been demonstrated in sputum macrophages of asthmatic patients after an ICS and inhaled LABA (Usmani et al., 2005). This suggests that \( \beta_2 \) agonists and corticosteroids enhance each other’s beneficial effects in asthma therapy.

Pharmacokinetics. The pharmacokinetics of oral corticosteroids are described in Chapter 42. The pharmacokinetics of inhaled corticosteroids are important in relation to systemic effects (Barnes et al., 1998b). The fraction of steroid that is inhaled into the lungs acts locally on the airway mucosa but may be absorbed from the airway and alveolar surface. Thus, a portion of an inhaled dose reaches the systemic circulation. Furthermore, the fraction of inhaled steroid that is deposited in the oropharynx is swallowed and absorbed from the gut. The absorbed fraction may be metabolized in the liver (first-pass metabolism) before reaching the systemic circulation (Figure 36–3). The use of a spacer chamber reduces oropharyngeal deposition and therefore reduces systemic absorption of ICS, although this effect is minimal in corticosteroids with a high first-pass metabolism. Mouth rinsing and discarding the rinse have a similar effect, and this procedure should be used with high-dose dry powder steroid inhalers with which spacer chambers cannot be used.

Beclomethasone dipropionate and ciclesonide are prodrugs that release the active corticosteroid after the ester group is cleaved by esterases in the lung. Ciclesonide is available as a MDI (ALVESCO) for asthma and as a nasal spray for allergic rhinitis (OMNARIS). Budesonide and fluticasone propionate have a greater first-pass metabolism than beclomethasone dipropionate and are therefore less likely to produce systemic effects at high inhaled doses.
**Routes of Administration and Dosing**

**Inhaled Corticosteroids in Asthma.** Inhaled corticosteroids are recommended as first-line therapy for all patients with persistent asthma. They should be started in any patient who needs to use a β₂ agonist inhaler for symptom control more than twice weekly. They are effective in mild, moderate, and severe asthma and in children as well as adults (Barnes et al., 1998b). Although it was recommended that ICS be initiated at a relatively high dose and then the dose reduced once control was achieved, there is no evidence that this is more effective than starting with the maintenance dose. Dose-response studies for ICS are relatively flat, with most of the benefit derived from doses <400 μg beclomethasone dipropionate or equivalent (Adams et al., 2008). However, some patients (with relative corticosteroid resistance) may benefit from higher doses (up to 2000 μg/day).

For most patients, ICS should be used twice daily, a regimen that improves compliance once control of asthma has been achieved (which may require four-times daily dosing initially or a course of oral steroids if symptoms are severe). Administration once daily of some steroids (e.g., budesonide, mometasone, and ciclesonide) is effective when doses ≤400 μg are needed. If a dose >800 μg daily via pMDI is used, a spacer device should be employed to reduce the risk of oropharyngeal side effects. ICS may be used in children in the same way as in adults; at doses ≤400 μg/day there is no evidence of significant growth suppression (Pedersen, 2001). The dose of ICS should be the minimal dose that controls asthma; once control is achieved, the dose should be slowly reduced (Hawkins et al., 2003). Nebulized corticosteroids (e.g., budesonide) are useful in the treatment of small children who are not able to use other inhaler devices.

**Inhaled Corticosteroids in Chronic Obstructive Pulmonary Disease.** Patients with COPD occasionally respond to steroids, and these patients are likely to have concomitant asthma. Corticosteroids have no objective short-term benefit on airway function in patients with true COPD, although these agents often produce subjective benefit because of their euphoric effect. Corticosteroids do not appear to have any significant anti-inflammatory effect in COPD; there appears to be an active resistance mechanism, which may be explained by impaired activity of HDAC2 as a result of oxidative stress (Barnes, 2009). ICS have no effect on the progression of COPD, even when given to patients with presymptomatic disease; additionally, ICS have no effect on mortality (Calverley et al., 2007; Yang et al., 2007). ICS reduce the number of exacerbations in patients with severe COPD (FEV₁ <50% predicted) who have frequent exacerbations and are recommended in these patients, although there is debate about whether these effects are due to inappropriate analysis of the data (Suissa et al., 2008). Oral corticosteroids are used to treat acute exacerbations of COPD, but the effect is very small (Niewoehner et al., 1999).

Patients with cystic fibrosis, which involves inflammation of the airways, are also resistant to high doses of ICS.

**Systemic Steroids.** Intravenous steroids are indicated in acute asthma if lung function is <30% predicted and in patients who show no significant improvement with nebulized β₂ agonist. Hydrocortisone is the steroid of choice because it has the most rapid onset (5-6 hours after administration), compared with 8 hours with prednisolone. The required dose is uncertain; it is common to give hydrocortisone 4 mg/kg initially, followed by a maintenance dose of 3 mg/kg every 6 hours. Methylprednisolone is also available for intravenous use, but there is no evidence that the high doses previously used (1 g) are more effective. Intravenous therapy is usually given until a satisfactory response is obtained, and then oral prednisolone may be substituted. Oral prednisolone (40-60 mg) has a similar effect to intravenous hydrocortisone and is easier to administer. A high dose of inhaled fluticasone propionate (2000 μg daily) is as effective as a course of oral prednisolone in controlling acute exacerbations of asthma in a family practice setting and in children in an emergency department setting, although this route of delivery is more expensive (Levy et al., 1996; Manjra et al., 2000).

Prednisolone and prednisone are the most commonly used oral steroids. Clinical improvement with oral steroids may take several days; the maximal beneficial effect is usually achieved with 30-40 mg prednisone daily, although a few patients may need 60-80 mg daily to achieve control of symptoms. The usual maintenance dose is ~10-15 mg/day. Short courses of oral steroids (30-40 mg prednisolone daily for 1-2 weeks) are indicated for exacerbations of asthma; the dose may be tapered over 1 week after the exacerbation is resolved (the taper is not strictly necessary after a short course of therapy, but patients find it reassuring). Oral steroids are usually given as a single dose in the morning because this coincides with the normal diurnal increase in plasma cortisol and produces less adrenal suppression than if given in divided doses or at night. Alternate-day treatment has the advantage of less adrenal suppression, although in many patients control of asthma is not optimal on this regimen.

**Adverse Effects.** Corticosteroids inhibit ACTH and cortisol secretion by a negative feedback effect on the pituitary gland (Chapter 42). Hypothalamic-pituitary-adrenal (HPA) axis suppression depends on dose and usually only occurs with doses of prednisone >7.5-10 mg/day. Significant suppression after short courses of corticosteroid therapy is not usually a problem, but prolonged suppression may occur after several months or years. Steroid doses after prolonged oral therapy must be reduced slowly. Symptoms of “steroid withdrawal syndrome” include lassitude, musculoskeletal pains, and, occasionally, fever. HPA suppression with inhaled steroids is usually seen only when the daily inhaled dose exceeds 2000 μg beclomethasone dipropionate or its equivalent daily.

Side effects of long-term oral corticosteroid therapy include fluid retention, increased appetite, weight gain, osteoporosis, capillary fragility, hypertension, peptic ulceration, diabetes, cataracts, and psychosis. Their frequency tends to increase with age. Very occasionally adverse reactions (such as anaphylaxis) to intravenous hydrocortisone have been described, particularly in aspirin-sensitive asthmatic patients.

The incidence of systemic side effects after ICS is an important consideration, particularly in children (Barnes et al., 1998b) (Table 36–4). Initial studies suggested that adrenal suppression occurred only with inhaled doses >1500-2000 μg/day. More sensitive measurements of systemic effects include indices of bone metabolism, such as serum osteocalcin and urinary pyridinium cross-links, and in children, knemometry, which may be increased with inhaled doses as low as 400 μg/day beclomethasone dipropionate in some patients. The clinical relevance of these measurements is not yet clear, however. Nevertheless, it is important to reduce the likelihood of systemic effects by using the lowest dose of inhaled steroid.
needed to control the asthma, and by use of a large-volume spacer to reduce oropharyngeal deposition.

Several systemic effects of inhaled steroids have been described and include dermal thinning and skin capillary fragility (relatively common in elderly patients after high-dose inhaled steroids). Other side effects, such as cataract formation and osteoporosis, are reported but often in patients who are also receiving courses of oral steroids. There has been particular concern about the use of inhaled steroids in children because of growth suppression (Pedersen, 2001). Most studies have been reassuring that doses ≤400 µg/day have not been associated with impaired growth; on the contrary, there may even be a growth spurt as asthma is better controlled. There is some evidence that use of high-dose ICS is associated with cataract and glaucoma, but it is difficult to dissociate the effects of ICS from the effects of courses of oral steroids that these patients usually require.

ICS may have local side effects due to the deposition of inhaled steroid in the oropharynx. The most common problem is hoarseness and weakness of the voice (dysphonia) due to atrophy of the vocal cords following laryngeal deposition of steroid; it may occur in up to 40% of patients and is noticed particularly by patients who need to use their voices during their work (lecturers, teachers, and singers). Throat irritation and coughing after inhalation are common with MDI and appear to be due to additives because these problems are not usually seen if the patient switches to a DPI. There is no evidence for atrophy of the lining of the airway. Oropharyngeal candidiasis occurs in ~5% of patients. There is no evidence for increased lung infections, including tuberculosis, in patients with asthma. Growing evidence suggests that high doses of ICS increase the risk of pneumonia in patients with COPD (Singh et al., 2009); although this is reported with high doses of fluticasone propionate, a similar increase in pneumonia has not been found with budesonide, which may be explained by its lower systemic effects (Sin et al., 2009).

It may be difficult to extrapolate systemic side effects of corticosteroids using data from normal subjects. In asthmatic patients, systemic absorption form the lung is reduced, presumably because of reduced and more central deposition of the inhaled drug in more severe patients (Brutsche et al., 2000; Harrison et al., 2001); most of the inhaled drug deposits in larger airways, thereby limiting effects in the smaller airways where inflammation is also found, especially in patients with severe asthma. Corticosteroid MDIs with HFA propellants produce smaller aerosol particles and may have a more peripheral deposition, making them useful in treating patients with more severe asthma.

**Therapeutic Choices.** Numerous ICS are now available including beclomethasone dipropionate (QVAR), triamcinolone, flunisolide (AEROBID), budesonide (PULMICORT, others), fluticasone hemihydrate (AEROSPAN), fluticasone propionate (FLOVENT), mometasone furoate (ASMANEX), and ciclesonide (ALVESCO). All are equally effective as anti-asthma drugs, but there are differences in their pharmacokinetics: Budesonide, fluticasone, mometasone, and ciclesonide have a lower oral bioavailability than beclomethasone dipropionate because they are subject to greater first-pass hepatic metabolism; this results in reduced systemic absorption from the fraction of the inhaled drug that is swallowed (Derendorf et al., 2006) and thus reduced adverse effects. At high doses (>1000 µg), budesonide and fluticasone propionate have less systemic effects than beclomethasone dipropionate and triamcinolone, and they are preferred in patients who need high doses of ICS and in children. Ciclesonide is another choice; it is a prodrug that is converted to the active metabolite by esterases in the lung, giving it a low oral bioavailability and a high therapeutic index (Manning et al., 2008).

When doses of inhaled steroid exceed 800 µg beclomethasone dipropionate or equivalent daily, a large volume spacer is recommended to reduce oropharyngeal deposition and systemic absorption in the case of beclomethasone dipropionate. All currently available ICS are absorbed from the lung into the systemic circulation, so that some systemic absorption is inevitable. However, the amount of drug absorbed does not appear to have clinical effects in doses of <800 µg beclomethasone dipropionate equivalent. Although there are potency differences among corticosteroids, there are relatively few comparative studies, partly because dose comparison of corticosteroids is difficult due to their long time course of action and the relative flatness of their dose-response curves. Triamcinolone and flunisolide appear to be the least potent, with beclomethasone dipropionate and budesonide approximately of equal potency; fluticasone propionate is approximately twice as potent as beclomethasone dipropionate.

**Future Developments.** Early treatment with ICS in both adults and children may give a greater improvement in
lung function than if treatment is delayed (O’Byrne et al., 2006), likely reflecting the fact that corticosteroids are able to modify the underlying inflammatory process and prevent structural changes (fibrosis, smooth muscle hyperplasia, etc.) in the airway that occur as a result of chronic inflammation. ICS are currently recommended for patients with persistent asthmatic symptoms. There is evidence for airway inflammation in patients with episodic asthma, but at present ICS are recommended only when there are chronic symptoms (e.g., need for an inhaled β₂ agonist more than twice a week).

New corticosteroids with fewer systemic effects would be desirable. Corticosteroids that are rapidly metabolized in the airways (“soft steroids”), such as butiloxor and tipredane, proved disappointing in clinical trials; they are probably metabolized too rapidly to achieve sufficient concentration and duration to cause an anti-inflammatory effect. There is a search for corticosteroids that are metabolized rapidly in the circulation after absorption from the lungs. The anti-inflammatory actions of corticosteroids may be mediated via different molecular mechanisms from side effects (which are endocrine and metabolic actions of corticosteroids). It has been possible to develop corticosteroids that dissociate the DNA-binding effect of corticosteroids (which mediates most of the adverse effects) from the inhibitory effect on transcription factors such as NF-κB (which mediates much of the anti-inflammatory effect). Such “dissociated steroids” or selective glucocorticoid receptor agonists (SEGRAs) should, theoretically, retain anti-inflammatory activity but have a reduced risk of adverse effects; achieving this separation of desired and adverse effects is difficult in vivo (Schecke et al., 2007). Nonsteroidal SEGRAs are now in development.

Corticosteroid resistance is a major barrier to effective therapy in patients with severe asthma, in asthmatic patients who smoke, and in patients with COPD and cystic fibrosis (Barnes and Adcock, 2009). “Steroid-resistant” asthma is thought to be due to reduced anti-inflammatory actions of corticosteroids. Major strides have been made in understanding the molecular mechanisms for this corticosteroid resistance and in the development of therapies that have the potential to reverse this resistance and restore steroid responsiveness.

**Cromolyn**

Cromolyn sodium (sodium cromoglycate) is a derivative of khellin, an Egyptian herbal remedy and was found to protect against allergen challenge without any bronchodilator effect. A structurally related drug, nedocromil sodium, which has a similar pharmacological profile to cromolyn, was subsequently developed. Although cromolyn was popular in the past because of its good safety profile, its use has sharply declined with the more widespread use of the more effective ICS, particularly in children. Neither cromolyn nor nedocromil is available in the U.S. for respiratory indications. For further information, consult earlier editions of this text.

**MEDIATOR ANTAGONISTS**

Many inflammatory mediators have been implicated in asthma and COPD, suggesting that inhibition of synthesis or receptors of these mediators may be beneficial (Barnes, 2004; Barnes et al., 1998a). However, specific inhibitors have been largely disappointing in both asthma and COPD treatment. Both H₁ antihistamines and anti-leukotrienes have been applied to airway disease, but their added benefit over β₂ agonists and corticosteroids is slight. The variability in patient response to anti-leukotriene agents may focus our attention on the roles of leukotriene synthesis, action, and metabolism to some, but not all, asthmatic disease.

**Antihistamines.** Histamine mimics many of the features of asthma and is released from mast cells in acute asthmatic responses, suggesting that antihistamines may be useful in asthma therapy. There is little evidence that histamine H₁ receptor antagonists provide any useful clinical benefit, as demonstrated by a meta-analysis (van Gansse et al., 1997). Newer antihistamines, including cetirizine and azelastine, have some beneficial effects, but this may be unrelated to H₁ receptor antagonism. Antihistamines are not recommended in the routine management of asthma.

**Anti-leukotrienes.** There is considerable evidence that cysteinyl-leukotrienes (LTs) are produced in asthma and that they have potent effects on airway function, inducing bronchoconstriction, airway hyperresponsiveness, plasma exudation, mucus secretion, and eosinophilic inflammation (Figure 36–11; also see Chapter 33 and Peters-Golden and Henderson, 2007). These data suggested that blocking the leukotriene pathways with leukotriene modifiers could be useful in the treatment of asthma, leading to the development of 5'-lipoxygenase (5-LO) enzyme inhibitors (of which zileuton [ZYFLO] is the only drug marketed) and several antagonists of the cys-LT₁ receptor, including montelukast (SINGULAIR), zafirlukast (ACCOLATE), and pranlukast (not available in the U.S.).

**Clinical Studies.** Anti-leukotrienes have been intensively investigated in clinical studies (Calhoun, 2001). Leukotriene antagonists inhibit the bronchoconstrictor effect of inhaled LTD₄ in normal and asthmatic volunteers, and they also inhibit bronchoconstriction induced by a variety of challenges, including allergen, exercise, and cold air, by approximately 50%. With aspirin challenge, in aspirin-sensitive asthmatic patients, there is almost complete inhibition of the response (Szczeklik and Stevenson, 2003). Similar results have been obtained with the 5-LO inhibitor zileuton. This suggests there may be no advantage in blocking LTB₄ in addition to cysteinyl-LTs, in treating asthma. These drugs are active by oral administration, possibly an important advantage in chronic treatment.

In patients with mild to moderate asthma, anti-leukotrienes cause a significant improvement in lung function and asthma
Figure 36–11. Effects of cysteinyl-leukotrienes on the airways and their inhibition by anti-leukotrienes. AS, aspirin sensitive; 5-LO, 5’-lipoxygenase; LT, leukotriene; PAF, platelet-activating factor.

symptoms, with a reduction in the use of rescue inhaled β₂ agonists. Several studies show evidence for a bronchodilator effect, with an improvement in baseline lung function, suggesting that leukotrienes are contributing to the baseline bronchoconstriction in asthma, although this varies among patients. However, anti-leukotrienes are considerably less effective than inhaled corticosteroids in the treatment of mild asthma and cannot be considered the treatment of first choice (Ducharme, 2003). Anti-leukotrienes are indicated as an add-on therapy in patients who are not well controlled on ICS. The added benefit is small, equivalent to doubling the dose of ICS, and less effective than adding a LABA (Ducharme et al., 2006).

In patients with severe asthma who are not controlled on high doses of ICS and LABA, anti-leukotrienes do not appear to provide any additional benefit (Robinson et al., 2001). Theoretically, anti-leukotrienes should be of particular value in patients with aspirin-sensitive asthma because they block the airway response to aspirin challenge; however, their benefit is no greater here than in other types of asthma (Dahlen et al., 2002). Anti-leukotrienes are effective in preventing exercise-induced asthma, with efficacy similar to that of LABA (Coreno et al., 2000). Anti-leukotrienes also have a weak effect in rhinitis that may be additive with the effects of an antihistamine (Nathan, 2003).

Studies have demonstrated weak anti-inflammatory effects of anti-leukotrienes in reducing eosinophils in sputum and biopsies (Minoguchi et al., 2002), but this is much less marked than with ICS and there is no additional anti-inflammatory effect when added to an ICS (O’Sullivan et al., 2003). Anti-leukotrienes therefore appear to act mainly as anti-bronchoconstrictor drugs, and they are clearly less broadly effective than β₂ agonists because they antagonize only one of several bronchoconstrictor mediators.

In COPD, Cys-LTs are not elevated in exhaled breath condensate, and cys-LT₁ receptor antagonists have no role in the therapy of COPD (Barnes, 2004). By contrast, LT₄, a potent neutrophil chemoattractant, is elevated in COPD, indicating that 5-LO inhibitors that inhibit LT₄ synthesis may have some potential benefit by reducing neutrophil inflammation. However, a pilot study failed to indicate any clear benefit of a 5-LO inhibitor in COPD patients (Gompertz and Stockley, 2002).

Adverse Effects. Zileuton, zafirlukast, and montelukast are all associated with rare cases of hepatic dysfunction; thus liver-associated enzymes should be monitored. Several cases of Churg-Strauss syndrome have been associated with the use of zafirlukast and montelukast. Churg-Strauss syndrome is a very rare vasculitis that may affect the heart, peripheral nerves, and kidney and is associated with increased circulating eosinophils and asthma. It is uncertain whether the reported cases are due to a reduction in oral or inhaled corticosteroid dose or are a direct effect of the drug. Cases of Churg-Strauss syndrome have been described in patients on anti-leukotrienes who
were not on concomitant corticosteroid therapy, suggesting there is a causal link (Nathani et al., 2008).

**Future Developments.** One of the major advantages of anti-leukotrienes is their effectiveness in tablet form. This may increase compliance with chronic therapy and makes treatment of children easier. Montelukast is effective as a once-daily preparation (10 mg in adults, 5 mg in children). In addition, oral administration may treat concomitant allergic rhinitis. However, the currently available clinical studies indicate a relatively modest effect on lung function and symptom control, which is less for every clinical parameter measured than with ICS. This is not surprising: There are many mediators besides cyst-LTs involved in the pathophysiology of asthma, and it is unlikely that antagonism of a single mediator would be as effective as steroids, which inhibit multiple aspects of the inflammatory process in asthma. Similarly, if anti-leukotrienes are functioning in asthma as bronchodilators and anti-constrictors, it is unlikely that they will be as effective as a β2 agonist, which will counteract bronchoconstriction regardless of the spasmogen. It is likely that anti-leukotrienes will be used less in the future because combination inhalers are the mainstay of asthma therapy.

An interesting feature of the clinical studies is that some patients appear to show better responses than others, suggesting that leukotrienes may play a more important role in some patients. The variability in response to anti-leukotrienes may reflect differences in production of or responses to leukotrienes in different patients, and this in turn may be related to polymorphisms of 5-LO, LTC4 synthase, or cyst-LT1 receptors that are involved in the synthesis of leukotrienes (Tantisira and Drazen, 2009).

It is unlikely that further advances can be made in cyst-LT1-receptor antagonists if montelukast, a once-daily drug, is giving maximal receptor blockade. Cys-LT2 receptors may be important in vascular and airway smooth muscle proliferative effects of cyst-LT and are not inhibited by current cyst-LT1-receptor antagonists (Back, 2002). The role of the cyst-LT2 receptor in asthma is unknown, as is the value of its blockade. 5-LO inhibitors have some potential in COPD, cystic fibrosis, and possible severe asthma as LTB4 may contribute to neutrophil chemoattraction in the lungs of these conditions.

---

**IMMUNOMODULATORY THERAPIES**

**Immunosuppressive Therapy**

Immunosuppressive therapy (e.g., methotrexate, cyclosporine A, gold, intravenous immunoglobulin) has been considered in asthma when other treatments have been unsuccessful or to reduce the dose of oral steroids required. However, immunosuppressive treatments are less effective and have a greater propensity to side effects than oral corticosteroids and therefore cannot be routinely recommended. The role of immunosuppressive therapy in COPD and cystic fibrosis has not been evaluated.

**Anti-IgE Receptor Therapy**

Increased specific IgE is a fundamental feature of allergic asthma. Omalizumab is a humanized monoclonal antibody that blocks the binding of IgE to high-affinity IgE receptors (FceR1) on mast cells and thus prevents their activation by allergens (Figure 36–12) (Avila, 2007). It also blocks binding on IgE to low-affinity IgE receptors (FceRII, CD23) on other inflammatory cells, including T and B lymphocytes, macrophages, and possibly eosinophils, to inhibit chronic inflammation. Omalizumab also reduces levels of circulating IgE.

**Clinical Use.** Omalizumab is used for the treatment of patients with severe asthma. The antibody is administered by subcutaneous injection every 2-4 weeks, and the dose is determined by the titer of circulating IgE. Omalizumab reduces the requirement for oral and inhaled corticosteroids and markedly reduces asthma exacerbations. It is also beneficial in treating allergic rhinitis. Because of its very high cost, this treatment is generally used only in patients with very severe asthma who are poorly controlled even on oral corticosteroids and in patients with very severe concomitant allergic rhinitis (Walker et al., 2006). It may not be useful in concomitant atopic dermatitis due to the high levels of circulating IgE that cannot be neutralized. It may also be of value in protecting against anaphylaxis during specific immunotherapy. The major side effect of omalizumab is an anaphylactic response, which is uncommon (<0.1%) (Cox et al., 2007).

**Specific Immunotherapy**

Theoretically, specific immunotherapy with common allergens should be effective in preventing asthma. Although this treatment is effective in allergic rhinitis due to single allergens, there is little evidence that desensitizing injections to common allergens are effective in controlling chronic asthma (Rolland et al., 2009). Overall, the benefits of specific immunotherapy in asthma are small, and there are no well-designed studies comparing this treatment with effective treatments such as ICS. Sublingual immunotherapy is safer, but its role in asthma therapy has not yet been defined. Because there is a risk of anaphylactic and local reactions, and because the course of treatment is time consuming, this form of therapy cannot be routinely recommended for asthma.

The cellular mechanisms of specific immunotherapy are of interest. Specific immunotherapy induces the secretion of the anti-inflammatory cytokine IL-10 from regulatory helper T-lymphocytes (Treg) and this blocks co-stimulatory signal transduction in T cells (via CD28) so that they are unable to react to allergens presented by antigen-presenting cells (Larche et al., 2006). Applying an understanding of the cellular processes involved might lead to safer and more effective approaches in the future. More specific immunotherapies may be developed with cloned allergen epitopes, T-cell peptide fragments of allergens, CpG oligonucleotides, and vaccines of conjugates of allergen and toll-like receptor (TLR)-9 to stimulate Th1 immunity and suppress Th2 immunity (Broide, 2009).
New Drugs in Development for Asthma and Chronic Obstructive Pulmonary Disease

**Novel Mediator Antagonists.** Blocking the receptors or synthesis of inflammatory mediators is a logical approach to the development of new treatments for asthma and COPD. However, in both diseases many different mediators are involved, and therefore blocking a single mediator is unlikely to be very effective, unless it plays a unique and key role in the disease process (Barnes, 2004; Barnes et al., 1998a). Several specific mediator antagonists have been found to be ineffective in asthma, including antagonists/inhibitors of thromboxane, platelet-activating factor, bradykinin, and tachykinins. However, these blockers have often not been tested in COPD, in which different mediators are involved. A number of other approaches are under study, as noted next.

**CRTh2 Antagonists.** Chemotactic factor for T\textsubscript{H}2 cells has been identified as prostaglandin D\textsubscript{2}, which acts on a DP\textsubscript{2} receptor (Chapter 33). Several CRTh2 antagonists are now in development for asthma with promising initial results (Pettipher et al., 2007).

**Endothelin Antagonists.** Endothelin has been implicated in some of the structural changes that occur in asthma and COPD. Endothelin antagonists are approved for the treatment of pulmonary hypertension and might be useful in treating the structural changes that occur in asthma and COPD, but so far they have not been tested.

**Antioxidants.** Oxidative stress is important in severe asthma and COPD and may contribute to corticosteroid resistance. Existing antioxidants include vitamins C and E and N-acetyl-cysteine. These drugs have weak effects, but more potent antioxidants are in development (Kirkham and Rahman, 2006).

**Inducible Nitric Oxide Synthase Inhibitors.** NO production is increased in asthma and COPD as a result of increased inducible NO synthase (iNOS) expression in the airways (Chapter 3). NO and oxidative stress generate peroxynitrite anion (O=NO\textsuperscript{−}), which may nitrate proteins, leading to altered cell function. Several selective iNOS inhibitors are now in development (Hobbs et al., 1999), and one of these, L-N\textsuperscript{6}-(1-iminoethyl)lysine (L-NIL), gives a profound and long-lasting reduction in the concentrations of NO in exhaled breath (Hansel et al., 2003). An iNOS inhibitor was found to be ineffective in asthma, however (Singh et al., 2007).

**Cytokine Modifiers.** Cytokines play a critical role in perpetuating and amplifying the inflammation in asthma and COPD, suggesting that anti-cytokines may be beneficial as therapies (Barnes, 2008a). Although most attention has focused on inhibition of cytokines, some cytokines are anti-inflammatory and may have therapeutic potential.

IL-5 plays a pivotal role in eosinophilic inflammation and is also involved in eosinophil survival and priming. It is an attractive target in asthma because it is essential for eosinophil inflammation, there do not appear to be any other cytokines with a similar role, and lack of IL-5 in gene knockout mice does not have any deleterious effect. Anti-IL-5 antibodies inhibit eosinophil inflammation and airway hyperresponsiveness in animal models of asthma, and they markedly reduce circulating and airway eosinophils in asthma patients but have no effect on airway hyperresponsiveness or clinical features of asthma (Flood-Page et al., 2007; Leckie et al., 2000). In carefully selected patients with severe asthma and persistent eosinophilia despite high doses of corticosteroids, there is a significant reduction in exacerbations (Haldar et al., 2009). Blocking
IL-4 and IL-13, which determine IgE synthesis (Figure 36–12), has so far proved to be ineffective in clinical studies.

TNF-α may play a key role in amplifying airway inflammation, through the activation of NF-κB, AP-1, and other transcription factors. TNF-α production is increased in asthma and COPD, and it may be associated with the cachexia and weight loss that occur in some patients with severe COPD. In COPD patients and in patients with severe asthma, anti-TNF-α blocking antibodies have been ineffective, at the expense of increasing infections and malignancies (Rennard et al., 2007; Wenzel et al., 2009).

Chemokine Receptor Antagonists. Many chemokines are involved in asthma and COPD and play a key role in recruitment of inflammatory cells, such as eosiinosphilh, neutrophils, macrophages, and lymphocytes into the lungs. Chemokine receptors are attractive targets because they are hepta-spanning membrane proteins; small molecule inhibitors are now in development (Donnelly and Barnes, 2006; Viola and Luster, 2008). In asthma, CCR3 antagonists, which should block eosinophil recruitment into the airways, are the most favored target, but several small molecule CCR3 antagonists have failed in development because of toxicity. In COPD, CXCR2 antagonists, which prevent neutrophil and monocyte chemotaxis due to CXC chemokines such as CXCL1 and CXCL8, have been effective in animal models of COPD and in neutrophilic inflammation in normal subjects, and are now in clinical trials in COPD patients.

Protease Inhibitors
Several proteolytic enzymes are involved in the chronic inflammation of airway diseases. Mast cell tryptase has several effects on airways, including increasing responsiveness of airway smooth muscle to constrictors, increasing plasma exudation, potentiating eosinophil recruitment, and stimulating fibroblast proliferation. Some of these effects are mediated by activation of the proteinase-activated receptor PAR2. Tryptase inhibitors have so far proved to be disappointing in clinical studies.

Proteases are involved in the degradation of connective tissue in COPD, particularly enzymes that break down elastin fibers, such as neutrophil elastase and matrix metalloproteinases (MMP), which are involved in emphysema. Neutrophil elastase inhibitors have been difficult to develop, and there are no positive clinical studies in COPD patients. MMP9 appears to be the predominant elastolytic enzyme in emphysema, and several selective inhibitors are now in development.

New Anti-Inflammatory Drugs
Phosphodiesterase Inhibitors. The preservation and elevation of cellular cyclic AMP in inflammatory cells often reduces cell activation and release of inflammatory mediators. PDE4 is the predominant PDE isoform in inflammatory cells, including mast cells, eosiinosphilh, neutrophils, T lymphocytes, macrophages, and structural cells such as sensory nerves and epithelial cells (Houslay et al., 2005), suggesting that PDE4 inhibitors could be useful as an anti-inflammatory treatment in both asthma and COPD. In animal models of asthma, PDE4 inhibitors reduce eosinophil infiltration and responses to allergen, whereas in COPD they are effective against smoke-induced inflammation and emphysema. Several PDE4 inhibitors have been tested clinically, but with disappointing results; their usefulness has been limited by side effects, particularly nausea, vomiting, headaches, and diarrhea. In COPD, an oral PDE4 inhibitor, roflumilast, has some effect in reducing exacerbations and improving lung function, but side effects also limit its efficacy (Fabbri et al., 2009). Of the four subfamilies of PDE4, PDE4D is the major form whose inhibition is associated vomiting; inhibition of PDE4B is important for anti-inflammatory effects. Thus, selective PDE4B inhibitors may have a greater therapeutic index. Inhaled PDE4 inhibitors to reduce systemic absorption and adverse responses have proved to be ineffective. PDE5 inhibitors are vasodilators that are used in the treatment of pulmonary hypertension.

NF-κB Inhibitors. NF-κB plays an important role in the orchestration of chronic inflammation (Figure 36–9); many of the inflammatory genes that are expressed in asthma and COPD are regulated by this transcription factor (Barnes and Karin, 1997). This has prompted a search for specific blockers of these transcription factors. NF-κB is naturally inhibited by the inhibitory protein IkB, which is degraded after activation by specific kinases. Small molecule inhibitors of the IB kinase IKK2 (or IKKβ) are in clinical development (Karin et al., 2004; Kishore et al., 2003). These drugs may be of particular value in COPD, where corticosteroids are largely ineffective. However, there are concerns that inhibition of NF-κB may cause side effects such as increased susceptibility to infections, which has been observed in gene disruption studies when components of NF-κB are inhibited.

Mitogen-Activated Protein Kinase Inhibitors. There are three major MAP kinase pathways, and there is increasing recognition that these pathways are involved in chronic inflammation (Delhase et al., 2000). There has been particular interest in the p38 MAP kinase pathway that is blocked by a novel class of drugs, such as SB203580 and RWJ67657. These drugs inhibit the synthesis of many inflammatory cytokines, chemokines, and inflammatory enzymes (Cuenda and Rousseau, 2007). The p38 MAPK inhibitors are in development for the treatment of asthma (they inhibit Th2 cytokine synthesis) and for COPD (they inhibit neutrophilic inflammation and signaling of inflammatory cytokines and chemokines). However, clinical studies have revealed marked adverse effects and toxicities; inhaled delivery is being explored.

Mucoregulators
Many pharmacological agents may influence the secretion of mucus in the airways, but there are few drugs that have demonstrably useful clinical effects on mucus hypersecretion (Rogers and Barnes, 2006). Mucus hypersecretion occurs in chronic bronchitis, COPD, cystic fibrosis, and asthma. In chronic bronchitis, mucus hypersecretion is related to chronic irritation by cigarette smoke and may involve neural mechanisms and the activation of neutrophils to release enzymes such as neutrophil elastase and proteinase-3 that have powerful stimulatory effects on mucus secretion. Mast cell–derived chymase is also a potent mucus secretagogue. This suggests that several classes of drugs may be developed to control mucus hypersecretion.

A major problem in assessing the effects of drugs on mucus hypersecretion is the difficulty in accurately quantifying airway mucus production, quality, and clearance. Several current drugs for airway disease might affect mucus production. Systemic anticholinergic drugs appear to reduce mucociliary clearance, but this is not observed with either ipratropium bromide or tiotropium bromide, presumably reflecting their poor absorption from the respiratory tract. β2 Agonists increase mucus production and mucociliary clearance and have been shown to increase ciliary beat
frequency in vitro. Because inflammation leads to mucus hypersecretion, anti-inflammatory treatments should reduce mucus hypersecretion; ICS are very effective in reducing increased mucus production in asthma.

Sensory nerves and neuropeptides are important in the secretory activities of the submucosal gland (which predominates in proximal airways) and goblet cell (more notable in peripheral airways). Opioids and K+ channel openers inhibit mucus secretion mediated via sensory neuropeptide release; peripherally acting opioids may be developed to control mucus hypersecretion due to irritants in the future (Rogers, 2002).

Mucolytics
Several agents can reduce the viscosity of sputum in vitro. One group are derivatives of cysteine that reduce the disulfide bridges that bind glycoproteins to other proteins such as albumin and secretory IgA. These drugs also act as antioxidants and may therefore reduce airway inflammation. Only N-acetylcysteine (mucolytics, others) is available in the U.S.; carbocysteine, methylcysteine, erdosteine, and bromhexine are available elsewhere. Orally administered, these agents are relatively well tolerated, but clinical studies in chronic bronchitis, asthma, and bronchiectasis have been disappointing. A systematic review of several small studies showed a small benefit in terms of reducing exacerbations, with most of the benefit from N-acetylcysteine; whether this relates to the mucolytic activity of N-acetylcysteine or to its action as an antioxidant is unclear (Poole and Black, 2001). A large controlled study of oral N-acetylcysteine in COPD patients showed no effect in disease progress or in preventing exacerbations, although there was some benefit in the patients not treated with inhaled corticosteroids (Decramer et al., 2005), as confirmed in a subsequent study of carbocysteine in COPD patients not treated with other medications (Zheng et al., 2008). N-acetylcysteine is not currently recommended for COPD management.

DNAse (dornase alfa, PULMOZYME) reduces mucus viscosity in sputum of patients with cystic fibrosis and is indicated if there is significant symptomatic and lung function improvement after a trial of therapy (Henke and Ratjen, 2007). There is no evidence that dornase alfa is effective in COPD or asthma, however.

The epidermal growth factor receptor (EGFR) plays a critical role in airway mucus secretion from goblet cells and submucosal glands and appears to mediate the mucus secretory response to several secretagogues, including oxidative stress, cigarette smoke, inflammatory cytokines, and activated TLRs (Burgel and Nadel, 2004). Small molecule inhibitors of EGFR kinase, such as gefitinib and erlotinib, have been developed for use as anticancer therapies and are currently being assessed as treatments for mucus hypersecretion in COPD patients.

Expectorants
Expectorants are oral drugs that are supposed to enhance the clearance of mucus. Although expectorants were once commonly prescribed, there is little or no objective evidence for their efficacy. Such drugs are often emetics that are given in sub-emetic doses on the basis that gastric irritation may stimulate an increase in mucus clearance via a reflex mechanism. However, there is no good evidence for this assumption. Lacking evidence for their efficacy, the FDA has removed most expectorants from the market in a review of over-the-counter drugs. With the exception of guaifenesin, no agents are approved as expectorants in the U.S. In patients who find it difficult to clear mucus, adequate hydration and inhalation of steam may be of some benefit.

ANTITUSSIVES
Despite the fact that cough is a common symptom of airway disease, its mechanisms are poorly understood, and current treatment is unsatisfactory (Pavord and Chung, 2008). Viral infections of the upper respiratory tract are the most common cause of cough; postviral cough is usually self-limiting and commonly patient-medicated. Their wide use notwithstanding, over-the-counter cough medications are largely ineffective (Dicpinigaitis, 2009a). Because cough is a defensive reflex, its suppression may be inappropriate in bacterial lung infection. Before treatment with antitussives, it is important to identify underlying causal mechanisms that may require therapy.

Whenever possible, treat the underlying cause, not the cough. Asthma commonly presents as cough, and the cough will usually respond to ICS. A syndrome characterized by cough in association with sputum eosinophilia but no airway hyperresponsiveness and termed eosinophilic bronchitis also responds to ICS (Birring et al., 2003). Nonasthmatic cough does not respond to ICS but sometimes responds to anticholinergic therapy. The cough associated with postnasal drip of sinusitis responds to antibiotics (if warranted), nasal decongestants, and intranasal steroids. The cough associated with ACE inhibitors (in ~15% of patients treated) responds to lowering the dose or withdrawal of the drug and substitution of an AT1 receptor antagonist (Chapter 45). Gastroesophageal reflux is a common cause of cough through a reflex mechanism and occasionally as a result of acid aspiration into the lungs. This cough may respond to suppression of gastric acid with an H2 receptor antagonist or a proton pump inhibitor (Chapter 45), although even large doses may not always be effective (Chang et al., 2006). Some patients have a chronic cough with no obvious cause, and this chronic idiopathic cough may be due to airway sensory neural hyperesthesia (Haque et al., 2005).

Opiates. Opiates have a central mechanism of action on µ opioid receptors in the medullary cough center, but there is some evidence that they may have additional peripheral action on cough receptors in the proximal airways. Codeine and pholcodine (not available in the U.S.) are commonly used, but there is little evidence that they are clinically effective, particularly on postviral cough; in addition, they are associated with sedation and constipation (Dicpinigaitis, 2009a). Morphine and methadone are effective but indicated only for intractable cough associated with bronchial carcinoma. A peripherally acting opioid agonist, 443C81, does not appear to be effective for cough.

Dextromethorphan. Dextromethorphan is a centrally active N-methyl-D-aspartate (NMDA) receptor antagonist. It may also antagonize opioid receptors. Despite the fact that it is in numerous over-the-counter cough suppressants and used commonly to treat cough, it is poorly effective. In children with acute nocturnal cough, it is not significantly different from placebo in reducing cough
It can cause hallucinations at higher doses and has significant abuse potential.

**Benzonatate.** (TESSALON, others), a local anesthetic, acts peripherally by anesthetizing the stretch receptors located in the respiratory passages, lungs, and pleura. By dampening the activity of these receptors, benzonatate may reduce the cough reflex at its source. The recommended dose is 100 mg, three times/day, and up to 600 mg/day, if needed. Although clinical studies shortly after its approval showed some efficacy, benzonatate, 200 mg, was not effective in suppressing experimentally-induced cough in a recent clinical trial (Dicpinigaitis et al., 2009b). Side effects include dizziness and dysphagia. Seizures and cardiac arrest have occurred following an acute ingestion. Severe allergic reactions have been reported in patients allergic to para-aminobenzoic acid, a metabolite of benzonatate.

**Other Drugs.** Several other drugs reportedly have small benefits in protecting against cough challenges or in reducing cough in pulmonary diseases (Dicpinigaitis, 2009a). These drugs include mguistine (not available in the U.S.), which acts peripherally and appears to open ATP-sensitive K+ channels; baclofen, a GABA	extsubscript{B}-selective agonist; and theobromine, a naturally occurring methylxanthine. Although the expectorant guaifenesin is not typically known as a cough suppressant, it is significantly better than placebo in reducing acute viral cough and inhibits cough-reflex sensitivity in patients with upper respiratory tract infections (Dicpinigaitis et al., 2009b).

**Novel Antitussives.** There is clearly a need to develop new more effective therapies for cough, particularly drugs that act peripherally in order to avoid sedation. There are close analogies between chronic cough and sensory hyperesthesia, so new therapies are likely to arise from pain research (Barnes, 2007).

**Transient Receptor Potential V1 Antagonists.** TRPV1 (previously called the vanilloid receptor) is a member of the transient receptor potential (TRP) family of ion channels activated by capsaicin, H+, and bradykinin, all of which are potent tussive agents. TRPV1 antagonist block cough induced by capsaicin and bradykinin and are effective in some models of cough (McLeod et al., 2008). A side effect of these drugs is loss of temperature regulation and hyperthermia, which has prevented clinical development.

**Transient Receptor Potential A1 Antagonists.** TRPA1 is emerging as a more promising novel target for antitussives. This channel is activated by oxidative stress and many irritants and may be sensitized by inflammatory cytokines (Taylor-Clark et al., 2009). Several selective TRPA1 antagonists are now in development.

### DRUGS FOR DYSPNEA AND VENTILATORY CONTROL

**Drugs for Dyspnea**

Bronchodilators should reduce breathlessness in patients with airway obstruction. Chronic oxygen may have a beneficial effect, but in a few patients dyspnea may be extreme. Drugs that reduce breathlessness may also depress ventilation in parallel and may therefore be dangerous in severe asthma and COPD. Some patients show a beneficial response to dihydrocodeine and diazepam; however, these drugs must be used with great caution because of the risk of ventilatory depression. Slow-release morphine tablets may also be helpful in COPD patients with extreme dyspnea (Currow and Abernethy, 2007). Nebulized morphine may also reduce breathlessness in COPD and could act in part on opioid receptors in the lung. Nebulized furosemide has some efficacy in treating dyspnea from a variety of causes, but the evidence is not yet sufficiently convincing to recommend this as routine therapy (Newton et al., 2008).

**Ventilatory Stimulants**

Several classes of drug stimulate ventilation and are indicated when ventilatory drive is inadequate. Nikethamide and ethamivan were originally introduced as respiratory stimulants, but effective doses are close to those causing convulsions so the use of these agents has ceased. More selective respiratory stimulants have been developed and are indicated if ventilation is impaired as a result of overdose with sedatives, in postanesthetic respiratory depression, and in idiopathic hypoventilation. Respiratory stimulants are rarely indicated in COPD because respiratory drive is already maximal and further stimulation of ventilation may be counterproductive because of the increase in energy expenditure caused by the drugs.

**Doxapram** (DOPRAM, others). At low doses (0.5 mg/kg IV), doxapram stimulates carotid chemoreceptors; at higher doses it stimulates medullary respiratory centers. Its effect is transient; thus, intravenous infusion (0.3-3 mg/kg per minute) is needed for sustained effect. Unwanted effects include nausea, sweating, anxiety, and hallucinations. At higher doses, increased pulmonary and systemic pressures may occur. Both the kidney and the liver participate in the clearance of doxapram, which should be used with caution if hepatic or renal function is impaired. In COPD, the infusion of doxapram is restricted to 2 hours. The use of doxapram to treat ventilatory failure in COPD has now largely been replaced by noninvasive ventilation (Greenstone and Lasserson, 2003).

**Almitrine.** Almitrine bismesylate is a piperazine derivative that appears to selectively stimulate peripheral chemoreceptors and is without central actions (Winkelmann et al., 1994). It is ineffective in patients with surgically removed carotid bodies. Almitrine stimulates ventilation only when there is hypoxia. Long-term use of almitrine is associated with peripheral neuropathy, limiting its availability in most countries.

**Acetazolamide.** The carbonic anhydrase inhibitor acetazolamide (Chapter 25) induces metabolic acidosis and thereby stimulates ventilation, but it is not widely used because the metabolic imbalance it produces may be detrimental in the face of respiratory acidosis. It has a very small beneficial effect in respiratory failure in COPD patients (Jones and Greenstone, 2001). The drug has proved useful in prevention of high altitude sickness (Basnyat and Murdoch, 2003).
Naloxone. Naloxone is a competitive opioid antagonist that is indicated only if ventilatory depression is due to overdose of opioids.

Flumazenil. Flumazenil is a benzodiazepine receptor antagonist that can reverse respiratory depression due to overdose of benzodiazepines (Gross et al., 1996).

PHARMACOTHERAPY OF PULMONARY ARTERIAL HYPERTENSION

Pulmonary arterial hypertension (PAH) is characterized by vascular proliferation and remodeling of small pulmonary arteries, resulting in a progressive increase in pulmonary vascular resistance, which may lead to right heart failure and death (Morrell et al., 2009). PAH involves dysfunction of pulmonary vascular endothelial and smooth muscle cells and their interplay and results from an imbalance in vasoconstrictor and vasodilator mediators.

Vasodilators are the mainstay of drug therapy for PAH (Barnes and Liu, 1995). However, the vasodilators used to treat systemic hypertension are problematic: they lower systemic blood pressure, which may result in reduced pulmonary perfusion. Calcium channel blockers, such as nifedipine, are poorly effective, but a few patients may benefit. There have been important advances in the development of more selective pulmonary vasodilators, based on a better understanding of the pathophysiology of PAH (McLaughlin et al., 2009). In PAH, there is an increase in the vasoconstrictor mediators endothelin-1, thromboxane A₂, and serotonin, and a decrease in the vasodilating mediators prostacyclin (PGI₂), NO, and VIP (Figure 36–13) (Humbert et al., 2004). Therapies aim at antagonizing the vasoconstrictive mediators and enhancing vasodilation. Because different classes of vasodilators work through different mechanisms, it may be possible to increase efficacy while reducing adverse effects by using combinations of agents from different classes in therapy of PAH.

Primarily (idiopathic and familial) pulmonary hypertension (PPAH), where there is no identifiable cause, is uncommon. Most cases of pulmonary hypertension are associated with connective tissue disorders, such as systemic sclerosis, or they are secondary to hypoxic lung diseases, such as interstitial lung disease and COPD, where chronic hypoxia leads to hypoxic pulmonary vasoconstriction. Secondary pulmonary hypertension in COPD rarely requires specific therapy. In secondary pulmonary hypertension due to chronic hypoxia, the initial treatment is correction of hypoxia using supplementary O₂ therapy, including ambulatory oxygen, with the aim of increasing O₂ saturation to >90%. Right heart failure is treated initially with diuretics. Anticoagulants are indicated for the treatment of pulmonary hypertension secondary to chronic thromboembolic disease, but they may also be indicated for patients with severe pulmonary hypertension who have an increased risk of venous thrombosis.

Prostacyclin. Prostacyclin (PGI₂; Epoprostenol) is produced by endothelial cells in the pulmonary circulation and directly relaxes pulmonary vascular smooth muscle cells by increasing intracellular cyclic AMP concentrations (see Chapter 33). Reduced prostacyclin production in PAH has led to the therapeutic use of epoprostenol and other stable prostacyclin derivatives (Gomberg-Maitland and Olschewski, 2008). Functionally and physiologically, PGI₂ opposes the effects of TXA₂.

Intravenous epoprostenol (Flolan, others) is effective in lowering pulmonary arterial pressures, improving exercise performance, and prolonging survival in PPAH. Because of its short plasma t½, prostacyclin must be administered by continuous intravenous infusion using an infusion pump. Common side effects are headache, flushing, diarrhea, nausea, and jaw pain. Continuous intravenous infusion is inconvenient and very expensive. This has led to the development of more stable prostacyclin analogs. Treprostinil (Remodulin) is given by continuous subcutaneous infusion or as an inhalation (Tyvaso), consisting of four daily treatment sessions with nine breaths per session. Oral beraprost sodium appears to be somewhat less effective and its effect seems to diminish after 3 months of therapy, so it has not been approved in most countries. Iloprost (Ventavis) is a stable analog that is given by inhalation, but it needs to be given by nebulizer six to nine times daily. It is associated with the vasodilator side effects of prostacyclin, including syncope. It may also cause cough and bronchoconstriction because it sensitizes airway sensory nerves.

Endothelin Receptor Antagonists

Endothelin-1 (ET-1) is a potent pulmonary vasoconstrictor that is produced in increased amounts in PAH. ET-1 contracts vascular smooth muscle cells and causes proliferation mainly via ETA receptors. ET₁ receptors mediate the release of prostacyclin and NO from endothelial cells. Several endothelin antagonists are now on the market for the treatment of PPAH (see Chapter 26).

Bosentan (Tracleer) was the first ET antagonist developed and is a antagonist of both ET₁ and ET₂ receptors. Several long-term clinical trials have now established the efficacy of oral bosentan in reducing symptoms and improving mortality in PPAH. Starting dose is 62.5 mg twice daily for 4 weeks, then increasing to the maintenance dose of 125 mg twice daily. The drug is generally well tolerated. Adverse effects include abnormal liver function tests, anemia, headaches, peripheral edema, and nasal congestion. Given the risk of serious liver injury, liver aminotransferases should be monitored monthly. A class effect is a risk of testicular atrophy and infertility; bosentan is potentially teratogenic.

Ambrisentan (Letairis) is selective ET₂ receptor antagonist. It is given orally once daily at a dose of 5-10 mg. The theoretical advantage of blocking only ET₂ receptors is that ET₂ receptors may continue to stimulate release of PGI₂ and NO, giving a greater therapeutic effect. However, its clinical efficacy is similar to that of bosentan, as are its adverse effects. Use of ambrisentan also requires monthly monitoring of liver aminotransferases. Sitaxsentan (not available in the U.S.) is similar to ambrisentan but may be less likely to cause liver dysfunction.

Phosphodiesterase 5 Inhibitors

Nitric oxide activates soluble guanylate cyclase to increase cyclic GMP, which is hydrolyzed to 5’GMP by PDE5 (Chapter 27). Elevation of cGMP in smooth muscle causes relaxation (Chapter 3),...
**Figure 36–13. Interactions of endothelium and vascular smooth muscle in pulmonary artery hypertension (PAH).**

**A.** In normal pulmonary artery, there is a balance between constrictor and relaxant influences that may be viewed as competition between Ca$^{2+}$ signaling pathways and cyclic nucleotide signaling pathways in vascular smooth muscle (VSM). Endothelin (ET-1) binds to the ET$_A$ receptor on VSM cells and activates the G$_i$-PLC-IP$_3$ pathway to increase cytosolic Ca$^{2+}$; ET-1 may also couple to G$_i$ to inhibit cyclic AMP (cAMP) production. In depolarizing VSM cells, Ca$^{2+}$ may enter via the L-type Ca$^{2+}$ channel (Cav1.2). Endothelial cells also produce relaxant factors, prostacyclin (PGI$_2$) and NO. NO stimulates the soluble guanylyl cyclase (sGC), causing accumulation of cyclic GMP (cGMP) in VSM cells; PGI$_2$ binds to the IP prostanoid receptor and stimulates the Gs-adenylyl cyclase pathway to enhance cAMP accumulation; elevation of these cyclic nucleotides promotes VSM relaxation (see Chapter 3).

**B.** In PAH, ET-1 production is enhanced, production of PGI$_2$ and NO is reduced, and the balance is shifted toward constriction and proliferation of vascular smooth muscle.

**C.** In treating PAH, ET$_A$ receptor antagonists can reduce the constrictor effects of ET-1, and Ca$^{2+}$ channel antagonists can further reduce Ca$^{2+}$-dependent contraction. Exogenous PGI$_2$ and NO can be supplied to promote vasodilation (relaxation of VSM); inhibition of PDE5 can enhance the relaxant effect of NO by inhibiting the degradation of cGMP, thereby promoting intracellular accumulation of cGMP and relaxation of VSM. Thus, these drugs can reduce Ca$^{2+}$ signaling and enhance cyclic nucleotide signaling, restoring the balance between the forces of contraction/proliferation and relaxation/anti-proliferation. Remodeling and deposition of extracellular matrix by adjacent fibroblasts is influenced positively and negatively by the same contractile and relaxant signaling pathways, respectively.
which the inhibition of PDE5 prolongs and accentuates. In the pulmonary bed, inhibition of PDE5 induces vasodilation.

**Sildenafil.** Sildenafil (REVA) is a selective PDE5 inhibitor that is given at a dose (20 mg three time daily orally) that is lower than used for erectile dysfunction (100 mg; Chapter 27). It is effective in lowering pulmonary resistance and improving exercise tolerance in patients with PAH. Side effects include headache, flushing, dyspepsia, and visual disturbances.

**Tadalafil.** Tadalafil (ADСIRCA) has a longer duration of action than sildenafil so may be suitable for once-daily dosing. It is approved for World Health Organization group I PAH to improve exercise ability.

The finite life span of most mature blood cells requires their continuous replacement, a process termed hematopoiesis. New cell production must respond to basal needs and states of increased demand. Red blood cell production can increase >20-fold in response to anemia or hypoxemia, white blood cell production increases dramatically in response to a systemic infection, and platelet production can increase 10- to 20-fold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare bone marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the nine distinct blood-cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma, and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. A number of these hormones and cytokines have been identified and cloned, permitting their production in quantities sufficient for therapeutic use. Clinical applications range from the treatment of primary hematologic diseases to use as adjuncts in the treatment of severe infections and in the management of patients who are undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (e.g., iron, cobalt, and copper) and vitamins (e.g., folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin); deficiencies generally result in characteristic anemias, or, less frequently, a general failure of hematopoiesis (Hoffbrand and Herbert, 1999; Wrighting and Andrews, 2008). Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state, knowledge about the correct dose, the use of these agents in various combinations, and the expected response. This chapter deals with the growth factors, vitamins, minerals, and drugs that affect the blood and blood-forming organs.
Individual growth factors then were isolated based on their activities in clonal \textit{in vitro} assays. Many of these same assays were instrumental in purifying a hierarchy of progenitor cells committed to individual and combinations of mature blood cells (Akashi, 2000; Nakorn, 2003).

The existence of a circulating growth factor that controls red blood cell development was first suggested by the experiments of Paul Caro in 1906. He observed an increase in the red-cell count in rabbits injected with serum obtained from anemic animals and postulated the existence of a factor that he called hemopoietin. However, it was not until the 1950s that Reissmann, Erslev, and Jacobsen and coworkers defined the origin and actions of the hormone, now called erythropoietin. Subsequently, extensive studies of erythropoietin were carried out in patients with anemia and polycythemia, leading to the purification of erythropoietin from urine and the subsequent cloning of the erythropoietin gene. The high-level expression of erythropoietin in cell lines has allowed for its purification and use in humans with anemia.

Similarly, the existence of specific leukocyte growth factors was suggested by the capacity of different conditioned culture media to induce the \textit{in vitro} growth of colonies containing different combinations of granulocytes and monocytes. An activity that stimulated the production of both granulocytes and monocytes was purified from murine lung-conditioned medium, leading to cloning of granulocyte/macrophage colony-stimulating factor (G-CSF), first from mice (Gough et al., 1984) and subsequently from humans (Wong, 1985). Finding an activity that stimulated the exclusive production of neutrophils permitted the cloning of granulocyte colony-stimulating factor (G-CSF) (Welte et al., 1985). Subsequently, a megakaryocyte colony-stimulating factor termed thrombopoietin was purified and cloned (Kaushansky, 1998).

The growth factors that support lymphocyte growth were not identified using \textit{in vitro} colony-forming assays but rather using assays that measured the capacity of the cytokine to promote lymphocyte proliferation \textit{in vitro}. This permitted the identification of the growth-promoting properties of interleukin (II)-7, II-4, or II-15 for all lymphocytes, B cells, or NK cells, respectively (Goodwin et al., 1989; Grabstein et al., 1994). Again, recombinant expression of these cDNAs permitted production of sufficient quantities of biologically active growth factors for clinical investigations, allowing for the demonstration of the potential clinical utility of such factors.

\textbf{Growth Factor Physiology.} Steady-state hematopoiesis encompasses the production of \textgreater 400 billion blood cells each day. This production is tightly regulated and can be increased several fold with increased demand. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Stem cell differentiation can be described as a series of steps that produce so-called burst-forming units (BFU) and colony-forming units (CFU) for each of the major cell lines. These early progenitors (BFU and CFU) are capable of further proliferation and differentiation, increasing their number by some 30-fold. Subsequently, colonies of morphologically distinct cells form under the control of an overlapping set of additional growth factors (G-CSF, M-CSF, erythropoietin, and thrombopoietin). Proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another 30-fold or more, generating \textgreater 1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and also stimulate production of additional growth factors, a process called \textit{networking}. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function. However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia. Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 37–1 and listed in Table 37–1.

\textbf{ERYTHROPOIESIS STIMULATING AGENTS}

\textit{Erythropoiesis stimulating agent} (ESA) is the term given to a pharmacological substance that stimulates red blood cell production. Although erythropoietin is not the sole growth factor responsible for erythropoiesis, it is the most important regulator of the proliferation of committed erythroid progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia is invariably present, commonly seen in patients with renal failure. Erythropoiesis is controlled by a feedback system in which a sensor in the kidney detects changes in oxygen delivery to modulate the erythropoietin secretion. The sensor mechanism is now understood at the molecular level (Maxwell et al., 2001). Hypoxia-inducible factor (HIF-1) is a heterodimeric (HIF-1α and
HIF-1\(\beta\)) transcription factor that enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin. HIF-1\(\alpha\) is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1\(\alpha\) and activating erythropoietin expression, which in turn stimulates a rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively elevated levels of HIF-1\(\alpha\) and erythropoietin, with a resultant polycythemia (Gordeuk et al., 2004). Recently, a potential role for a second isoform of HIF, HIF-2\(\alpha\), was identified in erythropoiesis because genetic gain-of-function mutation of that gene induces erythrocytosis in patients (Percy et al., 2008).

Erythropoietin is encoded by a single copy gene on human chromosome 7 that is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of \(\sim30,000\) Da. After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by 100-fold or more, serum erythropoietin levels rise, and marrow progenitor cell survival,
### Hematopoietic Growth Factors

<table>
<thead>
<tr>
<th><strong>ERYTHROPOIETIN (EPO)</strong></th>
<th>Stimulates proliferation and maturation of committed erythroid progenitors to increase red cell production</th>

**ABBREVIATIONS:** BFU, burst-forming unit; CFU, colony-forming unit; E, erythrocyte; G, granulocyte; M, macrophage; Meg, megakaryocyte; NK cells, natural killer cells; LAK cells, lymphokine-activated killer cells.
proliferation, and maturation are dramatically stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein hepcidin (Nemeth et al., 2004).

Recombinant human erythropoietin (epoetin alfa) is nearly identical to the endogenous hormone except for two subtle differences. First, the carbohydrate modification pattern of epoetin alfa differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. However, modern assays can detect these differences (Skibeli et al., 2001) and identify athletes who use the recombinant product for "blood doping." The second difference probably is related to the manufacturing process because one commercially available form of the drug was recently associated with the development of anti-recombinant erythropoietin antibodies that cross-react with the patient’s own erythropoietin, potentially causing pure red-cell aplasia (Macdougall, 2004). Most of these cases were caused by one preparation of the drug shortly after albumin was removed from the formulation (Casadevall, 2003).

**Preparations.** Available preparations of epoetin alfa include EPOGEN, PROCRIT, and EPREX, supplied in single-use vials containing 2000-40,000 units/mL for intravenous or subcutaneous administration. When injected intravenously, epoetin alfa is cleared from plasma with a \( t_{1/2} \) of 4-8 hours. However, the effect on marrow progenitors lasts much longer, and once-weekly dosing can be sufficient to achieve an adequate response. Although allergic reactions have been reported with the administration of epoetin alfa, no consistent pattern of significant allergic reactions has emerged; except as noted earlier, antibodies have not been detected even after prolonged administration.

More recently, a novel erythropoiesis-stimulating protein, darbepoetin alfa (ARANESP), has been approved for clinical use in patients with indications similar to those for epoetin alfa. It is a genetically modified form of erythropoietin in which four amino acids have been mutated such that additional carbohydrate side chains are added during its synthesis, prolonging the circulatory survival of the drug to 24-26 hours (Jelkmann, 2002).

**Therapeutic Uses, Monitoring, and Adverse Effects.** Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with a poor erythropoietic response. There is a clear dose–response relationship between the epoetin alfa dose and the rise in hematocrit in anephric patients, with eradication of their anemia at higher doses (Eschbach et al., 1987). Epoetin alfa also is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbepoetin alfa also has been approved for use in patients with anemia associated with chronic kidney disease and is under review for several other indications.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Virtually all patients eventually will require supplemental iron to increase or maintain transferrin saturation to levels that will adequately support stimulated erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is <100 \( \mu g/L \) or whose serum transferrin saturation is <20%.

During initial therapy and after any dosage adjustment, the hematocrit is determined once a week (HIV-infected and cancer patients) or twice a week (renal failure patients) until it has stabilized in the target range and the maintenance dose has been established; the hematocrit then is monitored at regular intervals. If the hematocrit increases by >4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte half-life, hematocrit changes lag behind dosage adjustments by 2-6 weeks. The dose of darbepoetin should be decreased if the hemoglobin increase exceeds 1 g/DL in any 2-week period because of the association of excessive rate of rise of hemoglobin with adverse cardiovascular events.

During hemodialysis, patients receiving epoetin alfa or darbepoetin may require increased anticoagulation. Serious thromboembolic events have been reported, including migratory thrombophlebitis, microvascular thrombosis, pulmonary embolism, and thrombosis of the retinal artery and temporal and renal veins. The risk of thrombotic events, including vascular access thromboses, was higher in adults with ischemic heart disease or congestive heart failure receiving epoetin alfa therapy with the goal of reaching a normal hematocrit (42%) than in those with a lower target hematocrit of 30%. A large meta-analysis indicated that there was a relative risk of 1.6 for developing venous thromboembolic events associated with erythropoietic therapies (Bennett et al., 2008). The higher risk of cardiovascular events from erythropoietic therapies may be associated with higher hemoglobin or higher rates of rise of hemoglobin. The hemoglobin level should be managed to avoid exceeding a target level of 12 g/DL. ESA use is associated with increased rates of cancer recurrence and decreased on-study survival in patients in whom the drugs are administered for cancer-induced or for chemotherapy-induced anemia. The magnitude of the effect was
estimated as ~17% based on a meta-analysis of nearly 14,000 cancer patients (Bohlius et al., 2008). The cause(s) of this effect is presently unclear, but some studies suggest that tumor cells bearing the erythropoietin receptor are more likely to be affected by the use of ESAs (Henke et al., 2003). Although epoetin alfa is not associated with direct pressor effects, blood pressure may rise, especially during the early phases of therapy when the hematocrit is increasing. ESAs should not be used in patients with preexisting uncontrolled hypertension. Patients may require initiation of, or increases in, anti-hypertensive therapy. Hypertensive encephalopathy and seizures have occurred in chronic renal failure patients treated with epoetin alfa. The incidence of seizures appears to be higher during the first 90 days of therapy with epoetin alfa in patients on dialysis (occurring in ~2.5% of patients) when compared with subsequent 90-day periods. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, and flu-like symptoms (e.g., arthralgias and myalgias) also have been reported in conjunction with epoetin alfa therapy. Pure red-cell aplasia in association with neutralizing antibodies to native erythropoietin has been observed in patients treated with specific epoetin alfa formulations (see earlier discussion). Resistance to therapy can be caused by multiple factors (see following discussion).

**Anemia of Chronic Renal Failure.** Patients with anemia secondary to chronic kidney disease are ideal candidates for epoetin alfa therapy because the disorder represents a pure erythropoietin deficiency state. The response in predialysis, peritoneal dialysis, and hemodialysis patients depends on the severity of the renal failure, the erythropoietin dose and route of administration, and iron availability (Besarab et al., 1999, Kaufman et al., 1998). The subcutaneous route of administration is preferred over the intravenous route because absorption is slower and the amount of drug required is reduced by 20-40%.

The dose of epoetin alfa should be adjusted to obtain a gradual rise in the hematocrit over a 2- to 4-month period to a final hematocrit of 33-36%. Treatment to hematocrit levels >36% is not recommended because patients treated to a hematocrit >40% showed a higher incidence of myocardial infarction and death (Besarab et al., 1998). The drug should not be used to replace emergency transfusion in patients who need immediate correction of a life-threatening anemia.

Patients are started on doses of 80-120 units/kg of epoetin alfa, given subcutaneously, three times a week. It can be given on a once-weekly schedule, but somewhat more drug is required for an equivalent effect. If the response is poor, the dose should be progressively increased. The final maintenance dose of epoetin alfa can vary from as little as 10 units/kg to >300 units/kg, with an average dose of 75 units/kg, three times a week. Children <5 years of age generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health and iron status is essential. Less common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, and osteitis fibrosa cystica secondary to hyperparathyroidism.

The most common side effect of epoetin alfa therapy is aggravation of hypertension, which occurs in 20-30% of patients and most often is associated with a rapid rise in hematocrit. Blood pressure usually can be controlled either by increasing antihypertensive therapy or ultrafiltration in dialysis patients or by reducing the epoetin alfa dose to slow the hematocrit response.

Darbepoetin alfa also is approved for use in patients who are anemic secondary to chronic kidney disease. The recommended starting dose is 0.45 μg/kg administered intravenously or subcutaneously once weekly, with dose adjustments depending on the response. Like epoetin alfa, side effects tend to occur when patients experience a rapid rise in hemoglobin concentration; a rise of <1 g/dL every 2 weeks generally has been considered safe.

**Anemia in AIDS Patients.** Epoetin alfa therapy has been approved for the treatment of HIV-infected patients, especially those on zidovudine therapy (Fischl et al., 1990). Excellent responses to doses of 100-300 units/kg, given subcutaneously three times a week, generally are seen in patients with zidovudine-induced anemia. In the face of advanced disease, marrow damage, and elevated serum erythropoietin levels (>500 IU/L), therapy is less effective.

**Cancer-Related Anemias.** Epoetin alfa therapy, 150 units/kg three times a week or 450-600 units/kg once a week, can reduce the transfusion requirement in cancer patients undergoing chemotherapy. Evidence-based guidelines for the therapeutic use of recombinant erythropoietin in patients with cancer have been published (Rizzo et al., 2002). Briefly, the guidelines recommend the use of epoetin alfa in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dL, basing the decision to treat less severe anemia (Hb, 10-12 g/dL) on clinical circumstances. For anemia associated with hematologic malignancies, the guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome, although the evidence that the drug is effective in anemic patients with multiple myeloma, non-Hodgkin’s lymphoma, or chronic lymphocytic leukemia not receiving chemotherapy is less robust. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels >500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experienced an improvement in their anemia, sense of well-being, and quality of life (Littlewood et al., 2001). This improved sense of well-being, particularly in cancer patients, may not be solely due to the rise in the hematocrit. Erythropoietin receptors have been demonstrated in cells of the central nervous system (CNS), and erythropoietin has been found to act as a cytoprotectant in several models of CNS ischemia. Thus high levels of the hormone may directly affect cancer patients’ sense of well-being.

Darbepoetin alfa also has been tested in cancer patients undergoing chemotherapy and preliminary studies appear promising. However, recent case reports have suggested a direct effect of both epoetin alfa and darbepoetin alfa in stimulation of tumor cells. For example, patients with cancer of the head and neck randomized to receive recombinant erythropoietin had a statistically significant increase in likelihood of tumor progression during the duration of the study (Henke et al., 2003). A meta-analysis of a large number of patients and clinical trials estimates the risk at ~10% higher than non-treated cancer patients (Bohlius et al., 2008). This finding is being evaluated by the FDA and warrants serious attention.

**Surgery and Autologous Blood Donation.** Epoetin alfa has been used perioperatively to treat anemia and reduce the need for erythrocyte transfusion. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150-300 units/kg of epoetin alfa once
daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days 21, 14, and 7 before surgery, with an additional dose on the day of surgery. This can correct a moderately severe preoperative anemia (i.e., hematocrit 30-36%) and reduce the need for transfusion. Epoetin alfa also has been used to improve autologous blood donation (Goodnough et al., 1989). However, the potential benefit generally is small, and the expense is considerable. Patients treated for 3-4 weeks with epoetin alfa (300-600 units/kg twice a week) are able to donate only 1 or 2 more units than untreated patients, and most of the time this goes unused. Still, the ability to stimulate erythropoiesis for blood storage can be invaluable in the patient with multiple alloantibodies to red blood cells.

Other Uses. Epoetin alfa has received orphan drug status from the FDA for the treatment of the anemia of prematurity, HIV infection, and myelodysplasia. In the latter case, even very high doses >1000 units/kg two to three times a week have had limited success. The utility of very high-dose therapy in other hematologic disorders, such as sickle cell anemia, is still under study. Highly competitive athletes have used epoetin alfa to increase their hemoglobin levels (“blood doping”) and improve performance. Unfortunately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

MYELOID GROWTH FACTORS

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell lines. They also enhance the function of mature granulocytes and monocytes. Recombinant forms of several growth factors have been produced, including granulocyte-macrophage colony-stimulating factor (GM-CSF) (Wong et al., 1985), granulocyte colony-stimulating factor (G-CSF) (Welte et al., 1985), IL-3 (Yang et al., 1986), macrophage colony-stimulating factor (M-CSF) or CSF-1 (Kawasaki et al., 1985), and stem cell factor (SCF) (Huang et al., 1990) (Table 37–1).

The myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 37–2). They are active at extremely low concentrations and act via membrane receptors of the cytokine receptor superfamily to activate the JAK/STAT signal transduction pathway. GM-CSF is capable of stimulating the proliferation, differentiation, and function of a number of the myeloid cell lineages (Figure 37–1). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates the CFU-GEMM, CFU-GM, CFU-M, CFU-E, and CFU-Meg to increase cell production. It also enhances the migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils (Weisbart et al., 1987).

The activity of G-CSF is restricted to neutrophils and their progenitors, stimulating their proliferation, differentiation, and function. It acts primarily on the CFU-G, although it also can play a synergistic role with IL-3 and GM-CSF in stimulating other cell lines. G-CSF enhances phagocytic and cytotoxic activities of neutrophils. Unlike GM-CSF, G-CSF has little effect on monocytes, macrophages, and eosinophils and reduces inflammation by inhibiting IL-1, tumor necrosis factor, and interferon gamma. G-CSF also mobilizes primitive hematopoietic cells, including hematopoietic stem cells, from the marrow into the peripheral blood (Sheridan et al., 1992). This observation has virtually transformed the practice of stem cell transplantation, such that >90% of all such procedures today use G-CSF–mobilized peripheral blood stem cells as the donor product.

Granulocyte-Macrophage Colony-Stimulating Factor. Recombinant human GM-CSF (sargramostim) is a 127–amino acid glycoprotein produced in yeast. Except for the substitution of a leucine in position 23 and variable levels of glycosylation, it is identical to endogenous human GM-CSF. Although sargramostim, like natural GM-CSF, has a wide range of effects on cells in culture, its primary therapeutic effect is to stimulate myelopoiesis. The initial clinical application of sargramostim was in patients undergoing autologous bone marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly
reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process (Brandt et al., 1988). GM-CSF has also been tested as an adjuvant for immunotherapy, based on its stimulation of dendritic cell growth and development. However, its use in that setting is not discussed in this chapter.

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment for graft-versus-host disease (GVHD), and studies have failed to show a significant effect on transplantation mortality, long-term survival, the appearance of GVHD, or disease relapse. However, it may improve survival in transplant patients who exhibit early graft failure (Nemunaitis et al., 1990). It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell collection for transplantation after myeloablative chemotherapy (Haas et al., 1990). Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy (Gerhartz et al., 1993). It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia.

Sargramostim (leukine) is administered by subcutaneous injection or slow intravenous infusion at doses of 125-500 μg/m² per day. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a t₁/₂ of 2-3 hours. When given intravenously, infusions should be maintained over 3-6 hours. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to margination and sequestration in the lungs. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7-10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2-10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, whereas monocytes and eosinophils are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. The dose may be increased if the patient fails to respond after 7-14 days of therapy. However, higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. An acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial oxygen saturation due to granulocyte sequestration in the pulmonary circulation occurs in sensitive patients. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects include transient supraventricular arrhythmia, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.

**Granulocyte Colony-Stimulating Factor.** Recombinant human G-CSF filgrastim (Neupogen) is a 175–amino acid glycoprotein produced in *Escherichia coli*. Unlike natural G-CSF, it is not glycosylated and carries an extra N-terminal methionine. The principal action of filgrastim is the stimulation of CFU-G to increase neutrophil production (Figure 37–1). It also enhances the phagocytic and cytotoxic functions of neutrophils.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy (Lieschke and Burgess, 1992). Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections. When used as a part of an intensive chemotherapy regimen, it can decrease the frequency of hospitalization for febrile neutropenia and interruptions in the chemotherapy protocol; a positive impact on patient survival has not been demonstrated. G-CSF also is effective in the treatment of severe congenital neutropenias. In patients with cyclic neutropenia, G-CSF therapy will increase the level of neutrophils and shorten the length of the cycle sufficiently to prevent recurrent bacterial infections (Hammond et al., 1989). Filgrastim therapy can improve neutrophil counts in some patients with myelodysplasia or marrow damage (moderately severe aplastic anemia or tumor infiltration of the marrow). The neutropenia of AIDS patients receiving zidovudine also can be partially or completely reversed. Filgrastim is routinely used in patients undergoing peripheral blood stem cell (PBSC) collection for stem cell transplantation. It promotes the release of CD34⁺ progenitor cells from the marrow, reducing the number of collections necessary for transplant. Moreover, filgrastim-mobilized PBSCs appear more capable of rapid engraftment. PBSC-transplanted patients require fewer days of platelet and red blood cell transfusions and a shorter duration of hospitalization than do patients receiving autologous bone marrow transplants. Finally, G-CSF–induced mobilization of stem cells into the circulation has been promoted as a way to enhance repair of other damaged organs in which PBSC might play a role. For example, many anecdotal reports have claimed improved cardiac function following the treatment of myocardial infarction patients with G-CSF. However, a meta-analysis of these studies have failed to demonstrate an overall benefit (Abdel-Latif et al., 2008).

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 minutes at doses of 1-20 μg/kg per day. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 μg/kg per day. The distribution and clearance rate from plasma (t₁/₂ of 3.5 hours) are similar for both routes of administration. As with GM-CSF therapy, filgrastim given daily after hematopoietic stem cell transplantation or intensive cancer
chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for ≥14-21 days may be necessary to correct the neutropenia. With less intensive chemotherapy, <7 days of treatment may suffice. In AIDS patients on zidovudine or patients with cyclic neutropenia, chronic G-CSF therapy often is required.

One indication for G-CSF presently under investigation is its use to increase the number of peripheral blood neutrophils in leukocyte donors. For many years it had been hoped that, like platelet transfusions for the bleeding associated with severe thrombocytopenia, neutrophil transfusion could diminish the infectious complications of neutropenia. However, given the short circulatory \( t_{1/2} \) of neutrophils (~6 hours) and the need for large numbers of cells, the practical collection of sufficient cell numbers has eluded hematologists. With few complications of therapy in >15 years of clinical experience, G-CSF now has been used to increase peripheral neutrophil counts in prospective donors and neutrophil transfusions (Hubel et al., 2002). Although initial results were modest, the therapy is likely to be optimized and greater efficacy is anticipated.

Adverse reactions to filgrastim include mild to moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by \( E. \) \( \text{coli} \) should not receive the drug. Marked granulocytosis, with counts >100,000/\( \mu \)L, can occur in patients receiving filgrastim over a prolonged period of time. However, this is not associated with any reported clinical morbidity or mortality and rapidly resolves once therapy is discontinued. Mild to moderate splenomegaly has been observed in patients on long-term therapy.

Pegylated recombinant human G-CSF pegfilgrastim (NEULASTA) is generated through conjugation of a 20,000-Da polyethylene glycol moiety to the N-terminal methionyl residue of the 175–amino acid G-CSF glycoprotein produced in \( E. \) \( \text{coli} \). The clearance of pegfilgrastim by glomerular filtration is minimized, thus making neutrophil-mediated clearance the primary route of elimination. Consequently the circulating \( t_{1/2} \) of pegfilgrastim is longer than that of filgrastim, allowing for more sustained duration of action and less frequent dosing. Clinical studies suggest that neutrophil-mediated clearance of pegfilgrastim may be self-regulating and therefore specific to each patient’s hematopoietic recovery (Crawford, 2002). As such, the recommended dose for pegfilgrastim is fixed at 6 mg administered subcutaneously.

The therapeutic roles of other growth factors still need to be defined, although IL-3 and IL-6 have been removed from testing due to poor efficacy and/or significant toxicity. M-CSF may play a role in stimulating monocyte and macrophage production, although with significant side effects, including splenomegaly and thrombocytopenia. Stem cell factor (SCF) has been shown to augment peripheral blood mobilization of primitive hematopoietic progenitor cells (Moskowitz et al., 1997).

**Thrombopoietic Growth Factors**

**Interleukin-11.** Interleukin-11 was cloned based on its activity to promote proliferation of an IL-6–dependent myeloma cell line (Du and Williams, 1994). The 23,000-Da cytokine contains 178 amino acids and stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclasto-genesis and inhibits adipogenesis. Interleukin-11 enhances megakaryocyte maturation in vitro (Teramura et al., 1992), and its in vivo administration to animals modestly increases peripheral blood platelet counts (Neben et al., 1993). Clinical trials in patients who previously demonstrated significant chemotherapy-induced thrombocytopenia demonstrated that administration of the recombinant cytokine was associated with less severe thrombocytopenia and reduced use of platelet transfusions (Tepler et al., 1996), leading to its approval for clinical use by the FDA.

Recombinant human IL-11 oprelvekin (NEUMEGA) is a bacterially derived 19,000-Da polypeptide of 177 amino acids that differs from the native protein only because it lacks the amino terminal proline residue and is not glycosylated. The recombinant protein has a 7-hour \( t_{1/2} \) after subcutaneous injection. In normal subjects, daily administration of oprelvekin leads to a thrombopoietic response in 5-9 days.

The drug is available in single-use vials containing 5 mg and is administered to patients at 25-50 μg/kg per day subcutaneously. Orelvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies that displayed severe thrombocytopenia (platelet count <20,000/\( \mu \)L) on a prior cycle of the same chemotherapy, and it is administered until the platelet count returns to >100,000/\( \mu \)L. The major complications of therapy are fluid retention and associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Fluid retention reverses upon drug discontinuation, but volume status should be carefully monitored in elderly patients, those with a history of heart failure, or those with preexisting fluid collections in the pleura, pericardium, or peritoneal cavity. Also reported are blurred vision, injection-site rash or erythema, and paresthesias.

**Thrombopoietin.** The cloning and expression of recombinant thrombopoietin, a cytokine that predominantly stimulates megakaryopoiesis, is potentially another milestone in the development of hematopoietic growth factors as therapeutic agents (Lok et al., 1994) (Table 37–1). Thrombopoietin is a 45,000- to 75,000-Da glycoprotein containing 332 amino acids that is produced by the liver, marrow stromal cells,
and many other organs. In both humans and mice, genetic elimination of thrombopoietin or its receptor reduces the platelet counts to 10% of normal values. Moreover, blood levels of the hormone are inversely related to the blood platelet count, together indicating that the hormone is the primary regulator of platelet production.

Administration of recombinant thrombopoietin leads to a log-linear increase in the platelet count in mice, rats, dogs, and nonhuman primates (Harker, 1999) that begins on the third day of administration. In a number of human preclinical trials in several models of chemotherapy- and radiation-induced myelosuppression, thrombopoietin accelerated the recovery of platelet counts and other hematologic parameters (Kaushansky et al., 1998). Of note, however, the agent failed to substantially affect hematopoietic recovery when administered after myeloablative therapy and stem cell transplantation, unless given to the stem cell donor (Fibbe et al., 1995).

Two forms of recombinant thrombopoietin have been developed for clinical use. One is a truncated version of the native polypeptide, termed recombinant human megakaryocyte growth and development factor (rHuMGDF), which is produced in bacteria and then covalently modified with polyethylene glycol to increase the circulatory t1/2. The second is the full-length polypeptide termed recombinant human thrombopoietin (rHuTPO), which is produced in mammalian cells. In vitro, both drugs are equally potent in stimulating megakaryocyte growth.

In clinical trials, both drugs are safe in the patient populations selected for study. However, efficacy results using these agents have been mixed. In a small number of patients with gynecological cancers who were receiving carboplatin (Vadhan-Raj et al., 2000), rHuTPO therapy reduced the duration of severe thrombocytopenia and the need for platelet transfusions. In a similar study of patients treated with carboplatin plus cyclophosphamide, patients receiving a cycle of chemotherapy supplemented with G-CSF plus thrombopoietin had higher platelet counts at nadir and a shorter median duration of severe thrombocytopenia than they did after cycles of therapy supplemented only with G-CSF (Bassir et al., 2000). When used to augment peripheral blood counts in preparation for platelet donation, a single dose of thrombopoietin in the platelet donors tripled their platelet counts, allowed for a threefold increase in the number of platelets that could be collected in a singlepheresis, and led to a fourfold increase in the mean platelet count noted in transfusion recipients (Kuter et al., 2001). However, this particular regimen was associated with several instances of anti-recombinant thrombopoietin antibodies that cross-reacted with the native hormone, resulting in subsequent thrombocytopenia (Li et al., 2001).

In several studies, although the drug was safe, rHuMGDF was not effective. In two studies of patients treated for 7 days with chemotherapy supplemented with G-CSF plus thrombopoietin had higher platelet counts at nadir and a shorter median duration of severe thrombocytopenia than they did after cycles of therapy supplemented only with G-CSF (Bassir et al., 2000). When used to augment peripheral blood counts in preparation for platelet donation, a single dose of thrombopoietin in the platelet donors tripled their platelet counts, allowed for a threefold increase in the number of platelets that could be collected in a singlepheresis, and led to a fourfold increase in the mean platelet count noted in transfusion recipients (Kuter et al., 2001). However, this particular regimen was associated with several instances of anti-recombinant thrombopoietin antibodies that cross-reacted with the native hormone, resulting in subsequent thrombocytopenia (Li et al., 2001).

In several studies, although the drug was safe, rHuMGDF was not effective. In two studies of patients treated for 7 days with standard aggressive therapy for acute leukemia, the addition of recombinant thrombopoietin failed to accelerate platelet recovery (Archimbaud et al., 1999). A similar lack of efficacy was seen when the drug was used following autologous peripheral blood stem cell transplantation (Bolwell et al., 2000). Failure to improve hematopoiesis in some of these trials may have resulted from the dosing regimen employed; the optimal dose and schedule of administration in various clinical settings need to be established. After a single bolus injection, platelet counts showed a detectable increase by day 4, peaked by 12–14 days, and then returned to normal over the next 4 weeks. The peak platelet response follows a log-linear dose response. Platelet activation and aggregation are not affected, and patients are not at increased risk of thromboembolic disease, unless the platelet count is allowed to rise to very high levels. These kinetics need to be taken into account when planning therapy in cancer chemotherapy patients.

Due to concerns over the immunogenicity of these agents, and to other considerations, efforts now are under way to develop small molecular mimics of recombinant thrombopoietin, discovered either through screening of phage display peptide libraries or of small organic molecules that have been developed for clinical use. Two of these agents are FDA approved for use in patients with immune thrombocytopenic purpura (ITP) who have failed to respond to more conventional treatments. Romiplostim (NPLATE) contains four copies of a small peptide that binds with high affinity to the thrombopoietin receptor, grafted onto an immunoglobulin scaffold. Romiplostim was found safe and efficacious in two randomized controlled studies in patients with ITP. Overall, ~84% of patients responded to the drug with substantial increases in platelet levels, of which approximately half were durable (platelets >50,000/μL for 6 of the last 8 weeks of study) (Kuter et al., 2008). The drug is administered weekly by subcutaneous injection, starting with a dose of 1 μg/kg, titrated to a maximum of 10 μg/kg, until platelet count increases above 50,000/μL. Eltrombopag (PROMACTA) is a small organic molecule that binds specifically to the thrombopoietin receptor and is administered orally. The safety and efficacy of eltrombopag were evaluated in two double-blind placebo-controlled clinical studies of >200 adult patients with chronic ITP who had completed at least one prior treatment course and who had severe thrombocytopenia (Bussel et al., 2007). These studies demonstrated that 70–81% of patients with ITP can be expected to respond to a 6-week course of 50–75 mg/day of eltrombopag. The recommended starting dose is 30 g per day, titrated to 75 mg depending on platelet response. Several of these agents are in clinical trials.

### Drugs Effective in Iron Deficiency and Other Hypochromic Anemias

#### Iron and Iron Salts

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron
intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. However, the impact of iron deficiency is not limited to the erythron (Dallman, 1982). Iron also is an essential component of myoglobin; heme enzymes such as the cytochromes, catalase, and peroxidase; and the metalloflavoprotein enzymes, including xanthine oxidase and the mitochondrial enzyme α-glycerophosphate oxidase. Iron deficiency can affect metabolism in muscle independently of the effect of anemia on oxygen delivery. This may reflect a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and possibly, impaired heat production. Awareness of the ubiquitous role of iron has stimulated considerable interest in the early and accurate detection of iron deficiency and in its prevention.

History. The modern understanding of iron metabolism began in 1937 with the work of McCance and Widdowson on iron absorption and excretion and Heilmeyer and Plotner’s measurement of iron in plasma (Beutler, 2002). In 1947, Laurell described a plasma iron transport protein that he called transferrin (Laurell, 1951). Hahn and coworkers first used radioactive isotopes to measure iron absorption and define the role of the intestinal mucosa to regulate this function (Hahn, 1948). In the next decade, Huff and associates initiated isotopic studies of internal iron metabolism. The subsequent development of practical clinical measurements of serum iron, transferrin saturation, plasma ferritin, and red-cell protoporphyrin permitted the definition and detection of the body’s iron store status and iron-deficient erythropoiesis. In 1994, Feder and colleagues identified the HFE gene, which is mutated in type 1 hemochromatosis, on the short arm of chromosome 6 at 6p21.3 (Feder et al., 1996). In 2000, Ganz and colleagues discovered a peptide produced by the liver, which was termed hepcidin (Park et al., 2001). Soon thereafter hepcidin was found to be the master regulator of iron homeostasis and to play a role in anemia of chronic disease (Ganz, 2003; Ganz and Nemeth, 2009).

Iron and the Environment. Iron exists in the environment largely as ferric oxide or hydroxide or as polymers. In this state, its biological availability is limited unless solubilized by acid or chelating agents. For example, bacteria and some plants produce high-affinity chelating agents that extract iron from the surrounding environment. Most mammals have little difficulty in acquiring iron; this is explained by an ample iron intake and perhaps also by a greater efficiency in absorbing iron. Humans, however, appear to be an exception. Although total dietary intake of elemental iron in humans usually exceeds requirements, the bioavailability of the iron in the diet is limited.

Metabolism of Iron. The body store of iron is divided between essential iron-containing compounds and excess iron, which is held in storage. Quantitatively, hemoglobin dominates the essential fraction (Table 37–2). This protein, with a molecular weight of 64,500 Da, contains four atoms of iron per molecule, amounting to 1.1 mg (20 μmol) of iron per milliliter of red blood cells. Other forms of essential iron include myoglobin and a variety of heme and nonheme iron-dependent enzymes. Ferritin is a protein-iron storage complex that exists as individual molecules or as aggregates. Apoferritin has a molecular weight of ~450,000 and is composed of 24 polypeptide subunits that form an outer shell, within which resides a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as hemosiderin and visible by light microscopy, constitute about one-third of normal stores, a fraction that increases as stores enlarge. The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes, although some storage also occurs in muscle.

Internal exchange of iron is accomplished by the plasma protein transferrin (Garrick and Garrick, 2009). This 76-kDa β1-glycoprotein has two binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron-transferrin complex binds to the receptor, and the ternary complex is internalized through clathrin-coated pits by receptor-mediated endocytosis. A proton-pumping ATPase lowers the pH of the intracellular vesicular compartment (the endosomes) to ~5.5. Iron subsequently dissociates and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment.

Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply (De Domenico et al., 2008). The synthesis of apoferritin and transferrin receptors is regulated post-transcriptionally by two iron-regulatory proteins 1 and 2.
Double knockout of the genes encoding these proteins is embryonic lethal, and conditional double knockout of these genes in the intestine results in cellular iron depletion and death of intestinal epithelial cells (Galy et al., 2008). These IRPs are cytosolic RNA-binding proteins that bind to iron regulating elements (IREs) present in the 5′ or 3′ untranslated regions of mRNA encoding apoferritin or the transferrin receptors, respectively. Binding of these IRPs to the 5′ IRE of apoferritin mRNA represses translation, whereas binding to the 3′ IRE of mRNA encoding the transferrin receptors enhances transcript stability, thereby increasing protein production. When iron is abundant, IRP2 undergoes rapid proteolysis and IRP1 is converted from a RNA-binding protein into aconitase, an enzyme that catalyzes the interconversion of citrate and isocitrate. This results in increased production of apoferritin and reduced production of transferrin receptors. Conversely, when iron is in short supply, these IRPs accumulate, thereby repressing translation of apoferritin while enhancing production of transferrin receptors.

The flow of iron through the plasma amounts to a total of 30-40 mg per day in the adult (~0.46 mg/kg of body weight) (Finch and Huebers, 1982). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 37–3). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for ~120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. Isotopic studies indicate some degree of iron wastage in this process, in which defective cells or unused portions of their iron are transferred to the reticuloendothelial cell during maturation, bypassing the circulating blood. With abnormalities in erythrocyte maturation, the predominant portion of iron assimilated by the erythroid marrow may be rapidly localized in the reticuloendothelial cells as defective red-cell precursors are broken down; this is termed ineffective erythropoiesis. The rate of iron turnover in plasma may be reduced by half or more with red-cell aplasia, with all the iron directed to the hepatocytes for storage.

The most remarkable feature of iron metabolism is the degree to which body stores are conserved. Only 10% of the total is lost per year by normal men (i.e., ~1 mg/day). Two-thirds of this iron is excreted from the gastrointestinal (GI) tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in dequamatated skin and in the urine. Physiological losses of iron in men vary over a narrow range, from 0.5 mg in the iron-deficient individual to 1.5-2 mg per day when excessive iron is consumed. Additional losses of iron occur in women due to menstruation. Although the average loss in menstruating women is ~0.5 mg per day, 10% of menstruating women lose >2 mg per day. Pregnancy and lactation impose an even greater requirement for iron (Table 37–3). Other causes of iron loss include blood donation, the use of anti-inflammatory drugs that cause bleeding from the gastric mucosa, and GI disease with associated bleeding. Two much rarer causes are the hemosiderinuria that follows intravascular hemolysis, and pulmonary siderosis, where iron deposited in the lungs becomes unavailable to the rest of the body.

The limited physiological losses of iron point to the primary importance of absorption in determining the body’s iron content (Garrick and Garrick, 2009). After acidification and partial digestion of food in the stomach, iron is presented to the intestinal mucosa as either
inorganic iron or heme iron. A ferrireductase, duodenal cytochrome B (Dcytb), located on luminal surface of absorptive cells of the duodenum and upper small intestine, reduces the iron to the ferrous state, which is the substrate for the divalent metal (ion) transporter 1 (DMT1). DMT1 transports the iron to basolateral membrane, where it is taken up by another transporter, ferroportin (Fpn; SLC40A1), and subsequently reoxidized to Fe$^{3+}$, primarily by hephaestin (Hp; HEPH), a transmembrane copper-dependent ferroxidase. Apo-transferrin (Tf) binds the resultant oxidized iron.

Mucosal cell iron transport and the delivery of iron to transferrin from reticuloendothelial stores are both determined by the human hemochromatosis protein, which is a major histocompatibility complex class 1 molecule encoded by the HFE gene (for High Fe) located on the short arm of chromosome 6 at 6p21.3. Regulation is finely tuned to prevent iron overload in times of iron excess while allowing for increased absorption and mobilization of iron stores with iron deficiency. A predominant negative regulator of iron absorption in the small intestine is hepcidin, a 25–amino acid peptide made by hepatocytes (Ganz, 2003). The synthesis of hepcidin is greatly stimulated by inflammation or by iron overload. A deficient hepcidin response to iron loading can contribute to iron overload and one type of hemochromatosis. In anemia of chronic disease, hepcidin production can be increased up to 100-fold, potentially accounting for characteristic features of this condition, namely poor GI uptake and enhanced sequestration of iron in the reticuloendothelial system.

Normal iron absorption is ~1 mg per day in adult men and 1.4 mg per day in adult women; 3-4 mg of dietary iron is the most that normally can be absorbed. Increased iron absorption is seen whenever iron stores are depleted or when erythropoiesis is increased or ineffective. Patients with hereditary hemochromatosis due to HFE mutations demonstrate increased iron absorption and loss of the normal regulation of iron delivery to transferrin by reticuloendothelial cells (Ajioka and Kushner, 2003). The resulting increased saturation of transferrin permits abnormal iron deposition in non-hematopoietic tissues.

### Iron Requirements and the Availability of Dietary Iron

Iron requirements are determined by obligatory physiological losses and the needs imposed by growth. Thus adult men require only 13 μg/kg per day (~1 mg), whereas menstruating women require ~21 μg/kg per day (~1.4 mg). In the last two trimesters of pregnancy, requirements increase to ~80 μg/kg per day (5-6 mg), and infants have similar requirements due to their rapid growth. These requirements (Table 37–4) must be considered in the context of the amount of dietary iron available for absorption.

In developed countries, the normal adult diet contains ~6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer’s yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. The content of iron in food is affected further by the manner of its preparation because iron may be added from cooking in iron pots.

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2002).

The nonheme fraction nonetheless represents far the largest amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed very poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. Ascorbate forms complexes with and/or reduces ferric to ferrous iron. Meat facilitates the absorption of iron by stimulating production of gastric acid; other effects also may be involved. Either of these substances can increase availability several fold. Thus assessment of available dietary iron should include both the amount of iron ingested and an estimate of its availability (Figure 37–4) (Monsen et al., 1978).

A comparison of iron requirements with available dietary iron is seen in Table 37–4. Obviously, pregnancy and infancy represent periods of negative balance. Menstruating women also are at

risk, whereas iron balance in adult men and nonmenstruating women is reasonably secure. The difference between dietary supply and requirements is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable (Table 37–2). Thus in infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men, indicative of the extent to which the additional average daily loss of ~0.5 mg of iron affects iron balance.

Iron Deficiency. Iron deficiency is the most common nutritional disorder (McLean et al., 2009). The prevalence of iron-deficiency anemia in the U.S. is on the order of 1-4% and depends on the economic status of the population. In developing countries, up to 20-40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron-deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption (Clark, 2009). This can have a genetic basis, as in iron-refractory iron deficiency anemia in which patients have iron deficiency that is unresponsive to oral iron, but partially responsive to parenteral iron (Finberg, 2009). Poor oral absorption also can be acquired, as in conditions associated with impaired oral absorption of vitamin B₁₂ (Fernandez-Banares et al., 2009), or following partial gastrectomy. More severe iron deficiency is usually the result of blood loss, either from the GI tract, or in women, from the uterus. Finally, treatment of patients with erythropoietin can result in a functional iron deficiency.

Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birthweight infants are at greatest risk for developing iron deficiency, especially if they are not breast-fed and/or do not receive iron-fortified formula. After the age of 2-3 years, the requirement for iron declines until adolescence when rapid growth combined with irregular dietary habits again increases the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11-18 is insufficient to meet their requirements.
The recognition of iron deficiency rests on an appreciation of the sequence of events that lead to depletion of iron stores. A negative balance first results in a reduction of iron stores and eventually a parallel decrease in red-cell iron and iron-related enzymes (Figure 37–5). In adults, depletion of iron stores may be recognized by a plasma ferritin <12 μg/L and the absence of reticuloendothelial hemosiderin in the marrow aspirate. Iron-deficient erythropoiesis is identified by a decreased saturation of transferrin to <16% and/or by an increase above normal in red-cell protoporphyrin. Iron-deficiency anemia is associated with a recognizable decrease in the concentration of hemoglobin in blood. However, the physiological variation in hemoglobin levels is so great that only about half the individuals with iron-deficient erythropoiesis are identified from their anemia. Moreover, so-called normal hemoglobin and iron values in infancy and childhood are lower because of the more restricted supply of iron in young children (Dallman et al., 1980).

In mild iron deficiency, identifying the underlying cause is more important than any symptoms related to the deficiency state. Because of the frequency of iron deficiency in infants and in menstruating or pregnant women, the need for exhaustive evaluation of such individuals usually is determined by the severity of the anemia. However, iron deficiency in men or postmenopausal women necessitates a search for a site of bleeding.

Although the presence of microcytic anemia is the most common indicator of iron deficiency, laboratory tests—such as measurement of transferrin saturation, red-cell protoporphyrin, and plasma ferritin—are required to distinguish iron deficiency from other causes of microcytosis. Such measurements are particularly useful when circulating red cells are not yet microcytic because of the recent nature of blood loss, but iron supply nonetheless limits erythropoiesis. More difficult is the differentiation of true iron deficiency from iron-deficient erythropoiesis due to inflammation. In the latter condition, iron stores actually are increased, but the release of iron from reticuloendothelial cells is blocked, the concentration of iron in plasma is decreased, and the supply of iron to the erythroid marrow becomes inadequate. The increased stores of iron in this condition may be demonstrated directly by examination of an aspirate of marrow or may be inferred from determination of an elevated plasma concentration of ferritin.

### Treatment of Iron Deficiency

**General Therapeutic Principles.** The response of iron-deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient’s ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption, and with increasing doses of oral iron,
limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with a moderately severe iron-deficiency anemia, tolerable doses of oral iron will deliver, at most, 40-60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Complicating illness also can interfere with the response of an iron-deficiency anemia to iron therapy. By decreasing the number of red-cell precursors, intrinsic disease of the marrow can blunt the response. Inflammatory illnesses suppress the rate of red-cell production, both by reducing iron absorption and reticuloendothelial release and by direct inhibition of erythropoietin and erythroid precursors. Continued blood loss can mask the response as measured by recovery of the hemoglobin or hematocrit.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4-7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision as to the effectiveness of treatment should not be made for 3-4 weeks after the start of treatment. An increase of ≥20 g/L in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient’s clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient’s ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3-4 weeks if a favorable response has not occurred.

Once a response to oral iron is demonstrated, therapy should be continued until the hemoglobin returns to normal. Treatment may be extended if it is desirable to replenish iron stores. This may require a considerable period of time because the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

**Therapy with Oral Iron.** Orally administered ferrous sulfate is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts, and the discrepancy becomes even greater at high dosages. Variations in the particular ferrous salt have relatively little effect on bioavailability; the sulfate (FEOSOL, others), fumarate (HEMOCYTE, FEOSTAT, others), succinate, gluconate (FERGON, others), aspartate, other ferrous salts, and polysaccharide-ferrihydrite complex (NIFEREX, others), are absorbed to approximately the same extent. The effective dose of all of these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle ferrum reductum and iron phosphate salts have a much lower bioavailability, and their use for the fortification of foods is undoubtedly responsible for some of the confusion concerning effectiveness. Ferric edetate has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food.

The amount of iron, rather than the mass of the total salt in iron tablets, is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Surprisingly, because iron usually is absorbed in the upper small intestine, certain delayed-release preparations have been reported to be effective and have been said to be even more effective than ferrous sulfate when taken with meals. However, reports of absorption from such preparations vary. Because a number of forms of delayed-release preparations are on the market and information on their bioavailability is limited, the effectiveness of most such preparations must be considered questionable.

A variety of substances designed to enhance the absorption of iron has been marketed, including surface-acting agents, carbohydrates, inorganic salts, amino acids, and vitamins. When present in an amount of ≥200 mg, ascorbic acid increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with a significant increase in the incidence of side effects; therefore, the addition of ascorbic acid seems to have little advantage over increasing the amount of iron administered. It is inadvisable to use preparations that contain other compounds with therapeutic actions of their own, such as vitamin B₁₂, folate, or cobalt, because the patient’s response to the combination cannot easily be interpreted.

The average dose for the treatment of iron-deficiency anemia is ~200 mg of iron per day (2-3 mg/kg), given in three equal doses of 65 mg. Children weighing 15-30 kg can take half the average adult dose; small children and infants can tolerate relatively large doses of iron, e.g., 5 mg/kg. The dose used is a compromise between the desired therapeutic action and the toxic effects. Prophylaxis and mild nutritional iron deficiency may be managed with modest doses. When the object is the prevention of iron deficiency in pregnant women, e.g., doses of 15 to 30 mg of iron per day are adequate to meet the 3- to 6-mg daily requirement of the last two trimesters. When the purpose is to treat iron-deficiency anemia, but the circumstances do not demand haste, a total dose of ~100 mg (35 mg three times daily) may be used.

The responses expected for different dosage regimens of oral iron are given in Table 37-5. These effects are modified by the severity of the iron-deficiency anemia and by the time of ingestion of iron relative to meals. Bioavailability of iron ingested with food is
probably one-half or one-third of that seen in the fasting subject (Grebe et al., 1975). Antacids also reduce iron absorption if given concurrently. It is always preferable to administer iron in the fasting state, even if the dose must be reduced because of GI side effects. For patients who require maximal therapy to encourage a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day. Sustained high rates of red-cell production require an uninterrupted supply of iron, and oral doses should be spaced equally to maintain a continuous high concentration of iron in plasma.

The duration of treatment is governed by the rate of recovery of hemoglobin and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red-cell mass usually is reconstituted within 1-2 months. Thus an individual with a hemoglobin of 50 g per liter may achieve a normal complement of 150 g/L in ~50 days, whereas an individual with a hemoglobin of 100 g/L may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3-4 months of treatment, stores may increase at a rate of not much more than 100 mg/month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

**Untoward Effects of Oral Preparations of Iron.** Intolerance to oral preparations of iron primarily is a function of the amount of soluble iron in the upper GI tract and of psychological factors. Side effects include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate therapy at a small dosage, to demonstrate freedom from symptoms at that level, and then gradually to increase the dosage to that desired. With a dose of 200 mg of iron per day divided into three equal portions, symptoms occur in ~25% of treated individuals versus 13% among those receiving placebo; this increases to ~40% when the dosage of iron is doubled. Nausea and upper abdominal pain are increasingly common at high dosage. Constipation and diarrhea, perhaps related to iron-induced changes in the intestinal bacterial flora, are not more prevalent at higher dosage, nor is heartburn. If a liquid is given, one can place the iron solution on the back of the tongue with a dropper to prevent transient staining of teeth.

The normal individual apparently is able to control absorption of iron despite high intake, and it is only individuals with underlying disorders that augment the absorption of iron who run the hazard of developing iron overload (hemochromatosis). However, hemochromatosis is a relatively common genetic disorder, present in 0.5% of the population.

**Iron Poisoning.** Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1-2 g of iron may cause death, but 2-10 g usually is ingested in fatal cases. The frequency of iron poisoning relates to its availability in the household, particularly the supply that remains after a pregnancy. The colored sugar coating of many of the commercially available tablets gives them the appearance of candy. All iron preparations should be kept in childproof bottles.

Signs and symptoms of severe poisoning may occur within 30 minutes after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 hours, there may be a transient period of apparent recovery, followed by death in 12-24 hours. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring. Hemorrhagic gastroenteritis and hepatic damage are prominent findings at autopsy. In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and an emergency determination of the concentration of iron in plasma can be performed. If the latter is <63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an x-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). Iron in the upper GI tract can be precipitated by lavage with sodium bicarbonate or phosphate solution, although the clinical benefit is questionable. When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol; 3.5 mg/L), deferoxamine should be administered (Chapter 67). Shock, dehydration, and acid-base abnormalities should be treated in the conventional manner. Most important is the speed of diagnosis and therapy. With early effective treatment, the mortality from iron poisoning can be reduced from as high as 45% to ~1%.

**Therapy with Parenteral Iron.** When oral iron therapy fails, parenteral iron administration may be an effective alternative (Silverstein and Rodgers, 2004). The rate of response to parenteral therapy is similar to that which

### Table 37–5

**Average Response to Oral Iron**

The normal individual apparently is able to control absorption of iron despite high intake, and it is only individuals with underlying disorders that augment the absorption of iron who run the hazard of developing iron overload (hemochromatosis). However, hemochromatosis is a relatively common genetic disorder, present in 0.5% of the population.

**Iron Poisoning.** Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1-2 g of iron may cause death, but 2-10 g usually is ingested in fatal cases. The frequency of iron poisoning relates to its availability in the household, particularly the supply that remains after a pregnancy. The colored sugar coating of many of the commercially available tablets gives them the appearance of candy. All iron preparations should be kept in childproof bottles.

Signs and symptoms of severe poisoning may occur within 30 minutes after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 hours, there may be a transient period of apparent recovery, followed by death in 12-24 hours. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring. Hemorrhagic gastroenteritis and hepatic damage are prominent findings at autopsy. In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and an emergency determination of the concentration of iron in plasma can be performed. If the latter is <63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an x-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). Iron in the upper GI tract can be precipitated by lavage with sodium bicarbonate or phosphate solution, although the clinical benefit is questionable. When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol; 3.5 mg/L), deferoxamine should be administered (Chapter 67). Shock, dehydration, and acid-base abnormalities should be treated in the conventional manner. Most important is the speed of diagnosis and therapy. With early effective treatment, the mortality from iron poisoning can be reduced from as high as 45% to ~1%.

**Therapy with Parenteral Iron.** When oral iron therapy fails, parenteral iron administration may be an effective alternative (Silverstein and Rodgers, 2004). The rate of response to parenteral therapy is similar to that which
follows usual oral doses. Common indications are iron malabsorption (e.g., sprue, short bowel syndrome), severe oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin (Eschbach et al., 1987). In particular, when hemodialysis patients are started on erythropoietin, oral iron therapy alone generally is insufficient to provide an optimal hemoglobin response. It therefore is recommended that sufficient parenteral iron be given to maintain a plasma ferritin level between 100 and 800 μg/L and a transferrin saturation of 20-50% (Goodnough et al., 2000).

Parenteral iron also has been given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. The belief that the response to parenteral iron, especially iron dextran, is faster than oral iron is open to debate. In otherwise healthy individuals, the rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1-3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Parenteral iron therapy should be used only when clearly indicated because acute hypersensitivity, including anaphylactic and anaphylactoid reactions, can occur in 0.2-3% of patients (Faich and Strobos, 1999). Other reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and in some patients with rheumatoid arthritis, exacerbation of the disease.

Four iron formulations are available in the U.S. These are iron dextran (DEXFERRUM or INFED), sodium ferric gluconate (FERLICIT), ferumoxytol (FERAHEMI), and iron sucrose (VENOFER). Ferumoxytol is a semisynthetic carbohydrate-coated superparamagnetic iron oxide nanoparticle that is approved for treatment of iron deficiency anemia in patients with chronic kidney disease (Balakrishnan et al., 2009). The indications for the iron dextran preparations include treatment of any patient with documented iron deficiency and intolerance or irresponsiveness to oral iron. In contrast, the indications for the ferric gluconate and iron sucrose are limited to patients with chronic kidney disease who have a documented iron deficiency, although broader applications are being advocated (Wish, 2008). Iron dextran is the only preparation that can be given as a total-dose infusion, which is the entire dose of elemental iron required to replace iron stores. However, ferric gluconate and iron sucrose are administered as a fixed dose every week for several weeks until total iron stores are replenished.

Iron Dextran. Iron dextran injection (INFED or DEXFERRUM) is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight, ~180,000 Da) that contains 50 mg/mL of elemental iron. The use of low-molecular-weight iron dextran has reduced the incidence of toxicity relative to that observed with high molecular weight preparations (IMPERON) (Auerbach and Al Talib, 2008). Iron dextran can be administered by either intravenous (preferred) or intramuscular injection. When given by deep intramuscular injection, it is gradually mobilized via the lymphatics and transported to reticuloendothelial cells; the iron then is released from the dextran complex. Intravenous administration gives a more reliable response. Given intravenously in a dose <500 mg, the iron dextran complex is cleared exponentially with a plasma t1/2 of 6 hours. When ≥1 g is administered intravenously as total dose therapy, reticuloendothelial cell clearance is constant at 10-20 mg/hour. This slow rate of clearance results in a brownish discoloration of the plasma for several days and an elevation of the serum iron for 1-2 weeks.

Once the iron is released from the dextran within the reticuloendothelial cells, it is either incorporated into stores or transported via transferrin to the erythroid marrow. Although a portion of the processed iron is rapidly made available to the marrow, a significant fraction is only gradually converted to usable iron stores. All of the iron eventually is released, although many months are required before the process is complete. During this time, the iron dextran stores in reticuloendothelial cells can confuse the clinician who attempts to evaluate the iron status of the patient.

Intramuscular injection of iron dextran should only be initiated after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing <4.5 kg (10 lb), 1 mL (50 mg of iron) for children weighing <9 kg (20 lb), and 2 mL (100 mg of iron) for other patients. Iron dextran should be injected only into the muscle mass of the upper outer quadrant of the buttck using a z-track technique (displacement of the skin laterally before injection). However, local reactions and the concern about malignant change at the site of injection (Weinhren et al., 1978) make intramuscular administration inappropriate except when the intravenous route is inaccessible.

A test injection of 0.5 mL of undiluted iron dextran or an equivalent amount (25 mg of iron) diluted in saline also should precede intravenous administration of a therapeutic dose of iron dextran. The patient should be observed for signs of immediate anaphylaxis and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. When widely spaced total-dose infusion therapy is given, a test dose injection should be given before each infusion because hypersensitivity can appear at any time. Furthermore, the patient should be monitored closely throughout the infusion for signs of cardiovascular instability. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Therefore, iron dextran should be used with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases, and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.
Before initiating iron dextran therapy, the total dose of iron required to repair the patient’s iron-deficient state should be calculated. Relevant factors are the hemoglobin deficit, the need to reconstitute iron stores, and continued excess losses of iron, as seen with hemodialysis and chronic GI bleeding. Iron dextran solution (50 mg/mL of elemental iron) can be administered undiluted in daily doses of 2 mL until the total dose is reached or given off label as a single total-dose infusion. In the latter case, the iron dextran should be diluted in 250-1000 mL of 0.9% saline and infused over an hour or more.

With repeated doses of iron dextran—especially multiple total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss—accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. Although disease-related hemochromatosis has been associated with an increased risk of infections and cardiovascular disease, this has not been shown to be true in hemodialysis patients treated with iron dextran (Owen, 1999). It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 μg/L.

Sodium Ferric Gluconate. Sodium ferric gluconate is an intravenous iron preparation with a molecular size of ~295,000 Da and an osmolality of 990 mOsm/kg. Unlike iron dextran, which requires processing by macrophages that may require several weeks, 80% of sodium ferric gluconate is delivered to transferrin within 24 hours. Sodium ferric gluconate also has a lower risk of inducing serious anaphylactic reactions than iron dextran (Sengolge et al., 2005). No deaths were reported with 25 million infusions of sodium ferric gluconate, whereas there were 31 infusion-related deaths reported from approx-

Iron Sucrose. Iron sucrose is complex of polynuclear iron (III)-hydroxide in sucrose with a molecular weight of 252,000 Da and an osmolality of 1316 mOsm/kg. Following intravenous injection, the complex is taken up by the reticuloendothelial system, where it dissociates into iron and sucrose. Iron sucrose is generally administered in daily amounts of 100-200 mg within a 14-day period to a total cumulative dose of 1000 mg. It can be administered repeatedly to hemodialysis patients as maintenance therapy without inducing hypersensitivity (Aronoff et al., 2004).

Like sodium ferric gluconate, iron sucrose appears to be better tolerated and to cause fewer adverse events than iron dextran (Hayat, 2008). This agent is FDA-approved for the treatment of iron deficiency in patients with chronic kidney disease. However, iron sucrose has been used effectively to treat iron deficiency observed in other clinical settings (al-Momen et al., 1996; Bodemar et al., 2004). However, one study reported that iron sucrose may be most likely of available parenteral iron preparations to induce renal tubular injury because of its high renal uptake (Zager et al., 2004), potentially resulting in tubulointerstitial damage with chronic repeated use (Agarwal, 2006).

Copper deficiency is extremely rare because the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. There is speculation that marginal deficiency of copper can contribute to development or progression of a number of chronic disorders, such as diabetes or cardiovascular disease (Uriu-Adams and Keen, 2005). However, there is no evidence that copper ever needs to be added to a normal diet, either prophylactically or therapeutically. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery (Zidar et al., 1977), in those who are receiving parenteral nutrition (Dunlap et al., 1974), in malnourished infants (Graham and Cordano, 1976), and in patients ingesting excessive amounts of zinc (Hoffman et al., 1988).

Copper has redox properties similar to that of iron, which simultaneously is essential and potentially toxic to the cell (Kim et al., 2008). Cells have virtually no free copper. Instead copper is stored by metallothioneins and distributed by specialized chaperones to sites that make use of its redox properties (Lalioti et al., 2009). Transfer of copper to nascent cuproenzymes is performed by individual or collective activities of P-type ATPases, ATP7A and ATP7B, which are expressed in all tissues (Linz and Lutsenko, 2007). In mammals, the liver is the organ most responsible for the storage, distribution, and excretion of copper. Mutations in ATP7A or ATP7B that interfere with this function have been found responsible for Wilson’s disease or Menkes syndrome (steely hair syndrome) (de Bie et al., 2007), respectively, which can result in life-threatening hepatic failure.

Copper deficiency in experimental animals interferes with the absorption of iron and its release from reticuloendothelial cells (Gambling et al., 2008). The associated microcytic anemia is related to a decrease in the availability of iron to the normoblasts, and perhaps even more importantly, to decreased mitochondrial production of heme. It may be that the specific defect in the latter case is a decrease in the activity of cytochrome oxidase. Other pathological effects involving the skeletal, cardiovascular, and nervous systems have been observed in copper-deficient experimental animals. In humans, the prominent findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a
therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1-2 mg per day may be added to the solution of nutrients for parenteral administration. The daily U.S. Recommended Daily Allowance (RDA) of copper ranges from 1,300 µg for nursing women to 200 µg for infants 0-6 months of age.

**Pyridoxine**

Harris and associates first described pyridoxine-responsive anemia in 1956. Subsequent reports suggested that the vitamin might improve hematopoiesis in up to 50% of patients with either hereditary or acquired sideroblastic anemia. These patients characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ-aminolevulinate synthase. Affected men typically show a dual population of normal red cells and microcytic, hypochromic cells in the circulation. In contrast, idiopathic acquired sideroblastic anemia and the sideroblastic anemias associated with a number of drugs, inflammatory states, neoplastic disorders, and preleukemic syndromes show a variable morphological picture. Moreover, erythrokinetic studies demonstrate a spectrum of abnormalities, from a hypoproliferative defect without interfering with treatment, and routine supplementation of pyridoxine often is recommended (see Chapter 56). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson’s disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead.

Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral pyridoxine, and those individuals who appear to have a pyridoxine-responsive anemia require prolonged therapy with large doses of the vitamin, 50-500 mg per day. Unfortunately, the early enthusiasm for treatment with pyridoxine was not reinforced by results of later studies. Moreover, even when a patient with sideroblastic anemia responds, the improvement is only partial because both the ringed sideroblasts and the red-cell defect persist, and the hematocrit rarely returns to normal. Nonetheless, in view of the low toxicity of oral pyridoxine, a therapeutic trial with pyridoxine is appropriate.

As shown in studies of normal subjects, oral pyridoxine in a dosage of 100 mg three times daily produces a maximal increase in red-cell pyridoxine kinase and the major pyridoxal phosphate–dependent enzyme glutamic-aspartic aminotransferase (Solomon and Hillman, 1978). For an adequate therapeutic trial, the drug is administered for at least 3 months while the response is monitored by measuring the reticuloocyte index and the hemoglobin concentration. The occasional patient who is refractory to oral pyridoxine may respond to parenteral administration of pyridoxal phosphate. However, oral pyridoxine in doses of 200-300 mg per day produces intracellular concentrations of pyridoxal phosphate equal to or greater than those generated by therapy with the phosphorylated vitamin.

**Riboflavin**

Pure red-cell aplasia that responded to the administration of riboflavin was reported in patients with protein depletion and complicating infections. Lane and associates induced riboflavin deficiency in humans and demonstrated that a hypoproliferative anemia resulted within a month. The spontaneous appearance in humans of red-cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. It has been described in combination with infection and protein deficiency, both of which are capable of producing a hypoproliferative anemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

**B<sub>12</sub>, Folic Acid, and the Treatment of Megaloblastic Anemias**

Vitamin B<sub>12</sub> and folic acid are dietary essentials (Varela-Moreiras et al., 2009). A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Because tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins. An early sign of deficiency is megaloblastic anemia. Abnormal macrocytic red blood cells are produced, and the patient becomes severely anemic. Recognized in the 19th century, this pattern of abnormal hematopoiesis, termed **pernicious anemia**, spurred investigations that ultimately led to the discovery of vitamin B<sub>12</sub> and folic acid. Even today, the characteristic abnormality in red blood cell morphology is important for diagnosis and as a therapeutic guide following administration of the vitamins.

**History.** The discovery of vitamin B<sub>12</sub> and folic acid is a dramatic story that started >180 years ago and includes two discoveries that won the Nobel Prize. The first descriptions of what must have been megaloblastic anemias came from the work of Combe and Addison, who published a series of case reports beginning in 1824. It still is
common practice to describe megaloblastic anemia as Addisonian pernicious anemia. Although Combe suggested that the disorder might have some relationship to digestion, it was Austin Flint who in 1860 first described the severe gastric atrophy and called attention to its possible relationship to the anemia.

After the observation by Whipple in 1925 that liver is a source of a potent hematopoietic substance for iron-deficient dogs, Minot and Murphy carried out Nobel Prize–winning experiments that demonstrated the effectiveness of the feeding of liver to reverse pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Rickes and coworkers and Smith and Parker isolated and crystallized vitamin B$_{12}$; Dorothy Hodgkin received the Nobel Prize for determining its x-ray crystal structure.

As attempts were being made to purify extrinsic factor, Wills and her associates described a macrocytic anemia in women in India that responded to a factor present in crude liver extracts but not in the purified fractions known to be effective in pernicious anemia. This factor, first called Wills’ factor and later vitamin M, is now known to be folic acid. The term folic acid was coined by Mitchell and coworkers in 1941, after its isolation from leafy vegetables.

More recent work has shown that neither vitamin B$_{12}$ nor folic acid as purified from foodstuffs is the active coenzyme in humans. During extraction, active labile forms are converted to stable congeners of vitamin B$_{12}$ and folic acid, cyanocobalamin and pteroylglutamic acid, respectively. These congeners must then be modified in vivo to be effective. Although a great deal has been learned about the intracellular metabolic pathways in which these vitamins function as required cofactors, many questions remain, among them: what is the relationship of vitamin B$_{12}$ deficiency to the neurological abnormalities that occur with this disorder?

**Figure 37–6. Interrelationships and metabolic roles of vitamin B$_{12}$ and folic acid.** See text for explanation and Figure 37–7 for structures of the various folate coenzymes. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II; CH$_3$H$_4$PteGlu$_1$, methyltetrahydrofolate.

**Relationships Between Vitamin B$_{12}$ and Folic Acid.**

The major roles of vitamin B$_{12}$ and folic acid in intracellular metabolism are summarized in Figure 37–6. Intracellular vitamin B$_{12}$ is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin. Deoxyadenosylcobalamin (deoxyadenosyl B$_{12}$) is a cofactor for the mitochondrial mutase enzyme that catalyzes the isomerization of l-methylmalonyl CoA to succinyl CoA, an important reaction in carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate. In contrast, methylcobalamin (CH$_3$B$_{12}$) supports the methionine synthetase reaction, which is essential for normal metabolism of folate (Weissbach, 2008). Methyl groups contributed by methyltetrahydrofolate (CH$_3$H$_4$PteGlu$_1$) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate–cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of polyglutamates; and, through the synthesis of methionine and its product, S-adenosylmethionine, the maintenance of a number of methylation reactions.

Because methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the
methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate \( (H_4\text{PteGlu})_n \), the substrate for a number of metabolic steps. Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate \( (5,10\text{-CH}_2\text{H}_4\text{PteGlu}) \). The latter derivative donates the methylene group to deoxyuridylate \( (\text{dUMP}) \) for the synthesis of thymidylate \( (\text{dTMP}) \)—an extremely important reaction in DNA synthesis. In the process, the 5,10-\text{CH}_2\text{H}_4\text{PteGlu} \) is converted to dihydrofolate \( (H_2\text{PteGlu}) \). The cycle then is completed by the reduction of the \( H_2\text{PteGlu} \) to \( H_4\text{PteGlu} \) by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (Chapter 61). As shown in Figure 37–6, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of formiminoglutamic acid \( (\text{FIGLU}) \) and purines and pyrimidines.

In the presence of a deficiency of either vitamin \( \text{B}_{12} \) or folate, the decreased synthesis of methionine and S-adenosylmethionine interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin \( \text{B}_{12} \) deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 37–6). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin \( \text{B}_{12} \) to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin \( \text{B}_{12} \) or folic acid.

The mechanisms responsible for the neurological lesions of vitamin \( \text{B}_{12} \) deficiency are less well understood (Solomon, 2007). Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion that the deoxyadenosyl \( \text{B}_{12} \)–dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to S-adenosylmethionine are more likely to be responsible.

Nitrous oxide \( (N_2O) \), used for anesthesia (Chapter 19), can cause megaloblastic changes in the marrow and a neuropathy that resemble those of vitamin \( \text{B}_{12} \) deficiency. Studies with \( N_2O \) have demonstrated a reduction in methionine synthetase and reduced concentrations of methionine and S-adenosylmethionine. The latter is necessary for methylation reactions, including those required for the synthesis of phospholipids and myelin. Significantly, the neuropathy induced with \( N_2O \) can be prevented partially by feeding methionine. A neuropathy similar to that occurring with vitamin \( \text{B}_{12} \) deficiency has been reported in dentists who are exposed to \( N_2O \) used as an anesthetic.

Vitamin \( \text{B}_{12} \)

Chemistry. The structural formula of vitamin \( \text{B}_{12} \) is shown in Figure 37–7. These are the three major portions of the molecule:

1. A planar group or corrin nucleus—a porphyrin-like ring structure with four reduced pyrrole rings (A-D in Figure 37–7).
linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues.

2. A 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the corrin nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring.

3. A variable R group—the most important of which are found in the stable compounds cyanocobalamin and hydroxocobalamin and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin.

The terms vitamin B₁₂ and cyanocobalamin are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B₁₂ for therapeutic use contain either cyanocobalamin or hydroxocobalamin because only these derivatives remain active after storage.

Metabolic Functions. The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative S-adenosylmethionine. In addition, when concentrations of vitamin B₁₂ are inadequate, folate becomes “trapped” as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid (see Figures 37–6 and 37–7 and preceding discussion). The hematologic abnormalities in vitamin B₁₂-deficient patients result from this process. 5-Deoxyadenosylcobalamin is required for the re-arrangement of methylmalonyl CoA to succinyl CoA (Figure 37–6).

Sources in Nature. Humans depend on exogenous sources of vitamin B₁₂. In nature, the primary sources are certain microorganisms that grow in soil, sewage, water, or the intestinal lumen of animals that synthesize the vitamin. Vegetable products are free of vitamin B₁₂ unless they are contaminated with such microorganisms, so that animals are dependent on synthesis in their own alimentary tract or the ingestion of animal products containing vitamin B₁₂. The daily nutritional requirement of 3-5 μg must be obtained from animal by-products in the diet. Despite this, strict vegetarians rarely develop vitamin B₁₂ deficiency. Some vitamin B₁₂ is available from legumes, which are contaminated with bacteria capable of synthesizing vitamin B₁₂, and vegetarians often fortify their diets with a wide range of vitamins and minerals.

Absorption, Distribution, Elimination, and Daily Requirements. In the presence of gastric acid and pancreatic proteases, dietary vitamin B₁₂ is released from food and salivary binding protein and bound to gastric intrinsic factor. When the vitamin B₁₂–intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Adequate intrinsic factor, bile, and sodium bicarbonate (to provide a suitable pH) all are required for ileal transport of vitamin B₁₂. Vitamin B₁₂ deficiency in adults is rarely the result of a deficient diet per se; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 37–8). Achlorhydria and decreased secretion of intrinsic factor by parietal cells secondary to gastric atrophy or gastric surgery is a common cause of vitamin B₁₂ deficiency in adults. Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. A number of intestinal diseases can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Once absorbed, vitamin B₁₂ binds to transcobalamin II, a plasma β-globulin, for transport to tissues. Two other transcobalamins (I and III) also are present in plasma; their concentrations are related to the rate of turnover of granulocytes. They may represent

![Figure 37–8. The absorption and distribution of vitamin B₁₂.](image-url)
intracellular storage proteins that are released with cell death. Vitamin B₁₂ bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells. The liver is a storage depot for other tissues. In normal adults, as much as 90% of the body’s stores of vitamin B₁₂, from 1-10 mg, is in the liver. Vitamin B₁₂ is stored as the active coenzyme with a turnover rate of 0.5-8 μg per day, depending on the size of the body stores. The recommended daily intake of the vitamin in adults is 2.4 μg.

Approximately 3 μg of cobalamin are secreted into bile each day, 50-60% of which is not destined for reabsorption. This enterohepatic cycle is important because interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the vitamin. This process may help explain why patients can develop vitamin B₁₂ deficiency within 3-4 years of major gastric surgery, even though a daily requirement of 1-2 μg would not be expected to deplete hepatic stores of more than 2 to 3 mg during this time.

The supply of vitamin B₁₂ available for tissues is directly related to the size of the hepatic storage pool and the amount of vitamin B₁₂ bound to transcobalamin II (Figure 37–8). The plasma concentration of vitamin B₁₂ is the best routine measure of B₁₂ deficiency, and normally ranges from 150-660 pmol (~200-900 pg/mL). Deficiency should be suspected whenever the concentration falls below 150 pmol. The correlation is excellent except when the plasma concentrations of transcobalamin I and III are increased, as occurs with hepatic disease or a myeloproliferative disorder. Inasmuch as the vitamin B₁₂ bound to these transport proteins is relatively unavailable to cells, tissues can become deficient when the concentration of vitamin B₁₂ in plasma is normal or even high. In subjects with congenital absence of transcobalamin II, megaloblastic anemia occurs despite relatively normal plasma concentrations of vitamin B₁₂; the anemia will respond to parenteral doses of vitamin B₁₂ that exceed the renal clearance (Hakami et al., 1971).

Defects in intracellular metabolism of vitamin B₁₂ have been reported in children with methylmalonic aciduria and homocystinuria. Potential mechanisms include an incapacity of cells to transport vitamin B₁₂ or accumulate the vitamin because of a failure to synthesize an intracellular acceptor, a defect in the formation of deoxyadenosylcobalamin, or a congenital lack of methylmalonyl CoA isomerase.

**Vitamin B₁₂ Deficiency.** Vitamin B₁₂ deficiency is recognized clinically by its impact on the hematopoietic and nervous systems. The sensitivity of the hematopoietic system relates to its high rate of cell turnover. Other tissues with high rates of cell turnover (e.g., mucosa and cerebral epithelium) also have high requirements for the vitamin.

As a result of an inadequate supply of vitamin B₁₂, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon referred to as ineffective hematopoiesis. These abnormalities are readily identified by examination of the marrow and peripheral blood. Maturation of red-cell precursors is highly abnormal (megaloblastic erythropoiesis). Those cells that do leave the marrow also are abnormal, and many cell fragments, poikilocytes, and macrocytes appear in the peripheral blood. The mean red-cell volume increases to values >110 fL. Severe deficiency affects all cell lines, and a pronounced pancytopenia results.

The diagnosis of a vitamin B₁₂ deficiency usually can be made using measurements of the serum vitamin B₁₂ and/or serum methylmalonic acid. The latter is somewhat more sensitive and has been used to identify metabolic deficiency in patients with normal serum vitamin B₁₂ levels. As part of the clinical management of a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red-cell production. The Schilling test can be used to measure the absorption of the vitamin and delineate the mechanism of the disease. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease.

Vitamin B₁₂ deficiency can irreversibly damage the nervous system. Progressive swelling of myelinated neurons, demyelination, and neuronal cell death are seen in the spinal column and cerebral cortex. This causes a wide range of neurological signs and symptoms, including paresthesias of the hands and feet, decreased vibration and position senses with resultant unsteadiness, decreased deep tendon reflexes, and in the later stages, confusion, moodiness, loss of memory, and even a loss of central vision. The patient may exhibit delusions, hallucinations, or even overt psychosis. Because the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B₁₂ deficiency must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic.

**Vitamin B₁₂ Therapy.** Vitamin B₁₂ is available for injection or oral administration; combinations with other
vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Although oral preparations may be used to supplement deficient diets, they are of limited value in the treatment of patients with deficiency of intrinsic factor or ileal disease. Even though small amounts of vitamin $B_{12}$ may be absorbed by simple diffusion, the oral administration cannot be relied on for effective therapy in the patient with a marked deficiency of vitamin $B_{12}$ and abnormal hematopoiesis or neurological deficits. Therefore, the preparation of choice for treatment of a vitamin $B_{12}$ deficiency state is cyanocobalamin, and it should be administered by intramuscular or subcutaneous injection.

Cyanocobalamin injection is safe when given by the intramuscular or deep subcutaneous route, but it should never be given intravenously. There have been rare reports of transitory exanthema and anaphylaxis after injection. If a patient reports a previous sensitivity to injections of vitamin $B_{12}$, an intradermal skin test should be performed before the full dose is administered.

Cyanocobalamin is administered in doses of 1-1000 μg. Tissue uptake, storage, and utilization depend on the availability of transcobalamin II (discussed earlier). Doses >100 μg are cleared rapidly from plasma into the urine, and administration of larger amounts of vitamin $B_{12}$ will not result in greater retention of the vitamin. Administration of 1000 μg is of value in the performance of the Schilling test. After isotopically labeled vitamin $B_{12}$ is administered orally, the compound that is absorbed can be quantitatively recovered in the urine if 1000 μg of cyanocobalamin is administered intramuscularly. This unlabeled material saturates the transport system and tissue binding sites, so >90% of the labeled and unlabeled vitamin is excreted during the next 24 hours.

A number of multivitamin preparations are marketed either as nutritional supplements or for the treatment of anemia. Many of these contain up to 80 μg of cyanocobalamin without or with intrinsic factor concentrate prepared from the stomachs of hogs or other domestic animals. One oral unit of intrinsic factor is defined as that amount of material that will bind and transport 15 μg of cyanocobalamin. Most multivitamin preparations supplemented with intrinsic factor contain 0.5 oral unit per tablet. Although the combination of oral vitamin $B_{12}$ and intrinsic factor would appear to be ideal for patients with an intrinsic factor deficiency, such preparations are not reliable. With prolonged therapy, some patients become refractory to oral intrinsic factor, perhaps related to production of an intraluminal antibody against the hog protein. Patients taking such preparations must be reevaluated at periodic intervals for recurrence of pernicious anemia.

Hydroxocobalamin given in doses of 100 μg intramuscularly has been reported to have a more sustained effect than cyanocobalamin, with a single dose maintaining plasma vitamin $B_{12}$ concentrations in the normal range for up to 3 months. However, some patients show reductions of the concentration of vitamin $B_{12}$ in plasma within 30 days, similar to that seen after cyanocobalamin. Furthermore, the administration of hydroxocobalamin has resulted in the formation of antibodies to the transcobalamin II–vitamin $B_{12}$ complex.

Vitamin $B_{12}$ has an undeserved reputation as a health tonic and has been used for a number of disease states. Effective use of the vitamin depends on accurate diagnosis and an understanding of the following general principles of therapy:

1. Vitamin $B_{12}$ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist. Dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin $B_{12}$ in patients who have had a gastrectomy, and certain diseases of the small intestine constitute such indications. When GI function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin $B_{12}$, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.

2. The relative ease of treatment with vitamin $B_{12}$ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by a macrocytic anemia or an unexplained neuropsychiatric disorder. Full understanding of the etiology of vitamin $B_{12}$ deficiency involves studies of dietary supply, GI absorption, and transport.

3. Therapy always should be as specific as possible. Although a large number of multivitamin preparations are available, the use of shotgun vitamin therapy in the treatment of vitamin $B_{12}$ deficiency can be dangerous. With such therapy, there is the danger that sufficient folic acid will be given to result in a hematologic recovery that can mask continued vitamin $B_{12}$ deficiency and permit neurological damage to develop or progress.

4. Although a classical therapeutic trial with small amounts of vitamin $B_{12}$ can help confirm the diagnosis, acutely ill elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin $B_{12}$ to guarantee rapid recovery.

5. Long-term therapy with vitamin $B_{12}$ must be evaluated at intervals of 6-12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (e.g., pregnancy), reassessment should be performed more frequently.

**Treatment of the Acutely Ill Patient.** The therapeutic approach depends on the severity of the patient’s illness. In uncomplicated pernicious anemia, in which the abnormality is restricted to a mild or moderate anemia without leukopenia, thrombocytopenia, or
neurological signs or symptoms, the administration of vitamin \( B_{12} \) alone will suffice. Moreover, therapy may be delayed until other causes of megaloblastic anemia have been excluded and sufficient studies of GI function have been performed to reveal the underlying cause of the disease. In this situation, a therapeutic trial with small amounts of parenteral vitamin \( B_{12} \) \((1-10 \, \mu g \text{ per day})\) can confirm the presence of an uncomplicated vitamin \( B_{12} \) deficiency.

In contrast, patients with neurological changes or severe leukopenia or thrombocytopenia associated with infection or bleeding require emergency treatment. The older individual with a severe anemia (hematocrit <20%) is likely to have tissue hypoxia, cerebrovascular insufficiency, and congestive heart failure. Effective therapy must not wait for detailed diagnostic tests. Once the megaloblastic erythrocytosis has been confirmed and sufficient blood collected for later measurements of vitamin \( B_{12} \) and folic acid, the patient should receive intramuscular injections of 100 \( \mu g \) of cyanocobalamin and 1-5 mg of folic acid. For the next 1-2 weeks the patient should receive daily intramuscular injections of 100 \( \mu g \) of cyanocobalamin, together with a daily oral supplement of 1 to 2 mg of folic acid. Because an effective increase in red-cell mass will not occur for 10-20 days, the patient with a markedly depressed hematocrit and tissue hypoxia also should receive a transfusion of 2-3 units of packed red blood cells. If congestive heart failure is present, diuretics can be administered to prevent volume overload.

Patients usually report an increased sense of well-being within the first 24 hours of the initiation of therapy. Objectively, memory and orientation can improve dramatically, although full recovery of mental function may take months, or it may never occur. In addition, even before an obvious hematologic response is apparent, the patient may report an increase in strength, a better appetite, and reduced soreness of the mouth and tongue.

The first objective hematologic change is the disappearance of the megaloblastic morphology of the bone marrow. As the ineffective erythrocytosis is corrected, the concentration of iron in plasma falls dramatically as the metal is used in the formation of hemoglobin. This usually occurs within the first 48 hours. Full correction of precursor maturation in marrow with production of an increased number of reticulocytes begins about the second or third day and peaks 3-5 days later. When the anemia is moderate to severe, the maximal reticulocyte index will be between three and five times the normal value (i.e., a reticulocyte count of 20-40%). The ability of the marrow to sustain a high rate of production determines the rate of recovery of the hematocrit. Patients with complicating iron deficiency, an infection or other inflammatory state, or renal disease may be unable to correct their anemia. Therefore it is important to monitor the reticulocyte index over the first several weeks. If it does not continue at elevated levels while the hematocrit is <35%, plasma concentrations of iron and folic acid should again be determined and the patient reevaluated for an illness that could inhibit the response of the marrow.

The degree and rate of improvement of neurological signs and symptoms depend on the severity and the duration of the abnormalities. Those that have been present for only a few months usually disappear relatively rapidly. When a defect has been present for many months or years, full return to normal function may never occur.

**Long-Term Therapy with Vitamin \( B_{12} \)** Once begun, vitamin \( B_{12} \) therapy must be maintained for life. This fact must be impressed on the patient and family, and a system must be established to guarantee continued monthly injections of cyanocobalamin.

Intramuscular injection of 100 \( \mu g \) of cyanocobalamin every 4 weeks is sufficient to maintain a normal concentration of vitamin \( B_{12} \) in plasma and an adequate supply for tissues. Patients with severe neurological symptoms and signs may be treated with larger doses of vitamin \( B_{12} \) in the period immediately after the diagnosis. Doses of 100 \( \mu g \) per day or several times per week may be given for several months with the hope of encouraging faster and more complete recovery. It is important to monitor vitamin \( B_{12} \) concentrations in plasma and to obtain peripheral blood counts at intervals of 3-6 months to confirm the adequacy of therapy. Because refractoriness to therapy can develop at any time, evaluation must continue throughout the patient’s life. Intranasal preparations are available for maintenance following normalization of vitamin \( B_{12} \)-deficient patients without nervous system involvement (CALOMIST, NASCOBAL) or as a supplement for vitamin \( B_{12} \) deficiencies of various etiologies (NASCOBAL).

**Other Therapeutic Uses of Vitamin \( B_{12} \)** Vitamin \( B_{12} \) has been used in the therapy of a number of conditions, including trigeminal neuralgia, multiple sclerosis and other neuropathies, various psychiatric disorders, poor growth or nutrition, and as a “tonic” for patients complaining of tiredness or easy fatigue. There is no evidence for the validity of such therapy in any of these conditions. Maintenance therapy with vitamin \( B_{12} \) has been used with some apparent success in the treatment of children with methylmalonic aciduria.

**Folic Acid**

**Chemistry and Metabolic Functions.** The structural formula of pterooyglutamic acid (PteGlu) is shown in Figure 37–9. Major portions of the molecule include a pteridine ring linked by a methylene bridge to para-aminobenzoic acid, which is joined by an amide linkage to glutamic acid. Although pterooyglutamic acid is the common pharmaceutical form of folic acid, it is neither the principal folate congener in food nor the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to tetrahydrofolic acid (H\( _{4}\)PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-membered ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 37–9. Each plays a specific role in intracellular metabolism, summarized as follows (see “Relationships Between Vitamin \( B_{12} \) and Folic Acid,” as well as Figure 37–6).

**Conversion of Homocysteine to Methionine.** This reaction requires CH\(_{3}\)H\(_{4}\)PteGlu as a methyl donor and uses vitamin \( B_{12} \) as a cofactor.

**Conversion of Serine to Glycine.** This reaction requires tetrahydrololate as an acceptor of a methyl group from serine and uses pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH\(_{2}\)H\(_{4}\)PteGlu, an essential coenzyme for the synthesis of thymidylate.

**Synthesis of Thymidylate.** 5,10-CH\(_{2}\)H\(_{4}\)PteGlu donates a methylene group and reducing equivalents to deoxyuridylate for the synthesis of thymidylate—a rate-limiting step in DNA synthesis.

**Histidine Metabolism.** H\(_{4}\)PteGlu also acts as an acceptor of a formiminogroup in the conversion of formiminoglutaric acid to glutamic acid.

**Synthesis of Purines.** Two steps in the synthesis of purine nucleotides require the participation of 10-CHOH\(_{4}\)PteGlu as a formyl donor in
reactions catalyzed by ribotide transformylases: the formylation of glycaminamide ribonucleotide and the formylation of 5-aminoimidazole-4-carboxamide ribonucleotide. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.

Utilization or generation of formate. This reversible reaction uses H4PteGlu and 10-CHOH4PteGlu.

Daily Requirements. Many food sources are rich in folates, especially fresh green vegetables, liver, yeast, and some fruits. However, lengthy cooking can destroy up to 90% of the folate content of such food.

Generally, a standard U.S. diet provides 50-500 μg of absorbable folate per day, although individuals with high intakes of fresh vegetables and meats will ingest as much as 2 mg per day. In the normal adult, the recommended daily intake is 400 μg; pregnant or lactating women and patients with high rates of cell turnover (such as patients with a hemolytic anemia) may require 500-600 μg or more per day. For the prevention of neural tube defects, a daily intake of at least 400 μg of folate in food or in supplements beginning a month before pregnancy and continued for at least the first trimester is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine.

Absorption, Distribution, and Elimination. As with vitamin B12, the diagnosis and management of deficiencies of folic acid depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 37–10). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a pteroylglutamyl carboxypeptidase associated with mucosal cell membranes. The mucosae of the duodenum and upper part of the jejunum are rich in dihydrofolate reductase and can methylate most or all of the reduced folate that is absorbed. Because most absorption occurs in the proximal portion of the small intestine, it is not unusual for folate deficiency to occur when the jejunum is diseased. Both nontropical and tropical sprue are common causes of folate deficiency and megaloblastic anemia.

Once absorbed, folate is transported rapidly to tissues as CH3H4PteGlu. Although certain plasma proteins do bind folate derivatives, they have a greater affinity for nonmethylated analogs. The role of such binding proteins in folate homeostasis is not well understood. An increase in binding capacity is detectable in folate deficiency and in certain disease states, such as uremia, cancer, and alcoholism, but how binding affects transport and tissue supply requires further investigation.

A constant supply of CH3H4PteGlu is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H2 or H4PteGlu) and then transports the CH3H4PteGlu into bile for reabsorption by the gut and subsequent delivery to tissues. This pathway may provide ≥200 μg of folate each day for recirculation to tissues. The importance of the enterohepatic cycle is suggested by animal studies that show a rapid reduction of the plasma folate concentration after drainage of bile or ingestion of alcohol, which apparently blocks the release of CH3H4PteGlu from hepatic parenchymal cells.

Folate Deficiency. Folate deficiency is a common complication of diseases of the small intestine that interferes with the absorption of folate from food and the recirculation of folate through the enterohepatic cycle. In acute
or chronic alcoholism, daily intake of folate in food may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis. However, it also is the most amenable to therapy, inasmuch as the reestablishment of a normal diet is sufficient to overcome the effect of alcohol. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. Additionally, drugs that inhibit dihydrofolate reductase (e.g., methotrexate and trimethoprim) or that interfere with the absorption and storage of folate in tissues (e.g., certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia (Scott and Weir, 1980).

Folate deficiency has been implicated in the incidence of neural tube defects, including spina bifida, encephaloceles, and anencephaly. This is true even in the absence of folate-deficient anemia or alcoholism. A less-than-adequate intake of folate also can result in elevations in plasma homocysteine (Green and Miller, 1999). Because even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is getting increased attention. Patients who are heterozygous for one or another enzymatic defect and have high normal to moderate elevations of plasma homocysteine may improve with folic acid therapy.

Folate deficiency is recognized by its impact on the hematopoietic system. As with vitamin B<sub>12</sub>, this fact reflects the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B<sub>12</sub> deficiency. This finding is to be expected because of the final common pathway of the major intracellular metabolic roles of the two vitamins. At the same time, folate deficiency is rarely if ever associated with neurological abnormalities. Thus the observation of characteristic abnormalities in vibratory and position sense and in motor and sensory pathways is incompatible with an isolated deficiency of folic acid.

After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B<sub>12</sub> absorption (e.g., gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1-4 weeks, depending on the individual’s dietary habits and stores of the vitamin.

Folate deficiency is best diagnosed from measurements of folate in plasma and in red cells. However, an empirical trial of folate in cases of suspected deficiency has been proposed as more cost effective (Robinson and Mladenovic, 2001). Indeed, the concentration of folate in plasma is extremely sensitive to changes in dietary intake of the vitamin and the influence of inhibitors of folate metabolism or transport, such as alcohol. Normal folate concentrations in plasma range from 9-45 nmol (4-20 ng/mL); <9 nmol is considered folate deficient. The plasma folate concentration rapidly falls to values indicative of deficiency within 24-48 hours of steady ingestion of alcohol (Eichner and Hillman 1973). The plasma folate concentration will revert quickly to normal once such ingestion is stopped, even while the marrow is still megaloblastic. Such rapid fluctuations detract from the clinical usefulness of the plasma folate concentration. The amount of folate in red cells or the adequacy of stores in lymphocytes (as measured by the deoxyuridine suppression test) may be used to diagnose a longstanding deficiency of folic acid. A positive result on either test shows that the deficiency must have existed for a sufficient time to allow the production of a population of cells with deficient folate stores.

Folic acid is marketed as oral tablets containing pteroylglutamic acid or l-methylfolate, as an aqueous solution for injection (5 mg/mL), and in combination with other vitamins and minerals.

Folinic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose methotrexate therapy and to potentiate fluorouracil in the treatment of colorectal cancer (Chapter 61). It also has been used as an antidote to counteract the toxicity of folate antagonists such as pyrimethamine or trimethoprim. Although it can be used to treat any folate-deficient state, folinic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency.
Leucovorin should never be used for the treatment of pernicious anemia or other megaloblastic anemias secondary to a deficiency of vitamin B₁₂. As just is seen with folic acid, its use can result in an apparent response of the hematopoietic system, but neurological damage may occur or progress if already present. Leucovorin is marketed as oral tablets and as products for intravenous infusion.

**Untoward Effects.** There have been rare reports of reactions to parenteral injections of folic acid and leucovorin. If a patient describes a history of a reaction before the drug is given, caution should be exercised. Oral folic acid usually is not toxic. Even with doses as high as 15 mg/day, there have been no substantiated reports of side effects. Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone, and increase the frequency of seizures in susceptible children (Reynolds, 1968). Although some studies have not supported these contentions, the FDA recommends that oral tablets of folic acid be limited to strengths of ≤1 mg.

**General Principles of Therapy.** The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B₁₂ therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are operative in a specific disease state. The following general principles of therapy should be respected:

1. **Prophylactic administration of folic acid should be undertaken for clear indications.** Dietary supplementation is necessary when there is a requirement that may not be met by a “normal” diet. The daily ingestion of a multivitamin preparation containing 400-500 μg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breast-feeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger dose of 4 mg/day has been recommended (MRC Vitamin Study Research Group, 1991). Patients on total parenteral nutrition should receive folic acid supplements as part of their fluid regimen because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (e.g., hemolytic anemia) generally require larger doses, 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.

2. **As with vitamin B₁₂ deficiency, any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state.** This should include evaluation of the effects of medications, the amount of alcohol intake, the patient’s history of travel, and the function of the GI tract.

3. **Therapy always should be as specific as possible.** Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.

4. **The potential danger of mistreating a patient who has vitamin B₁₂ deficiency with folic acid must be kept in mind.** The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia, inasmuch as PteGlu is converted by dihydrofolate reductase to H₄PteGlu; this circumvents the methylfolate “trap.” However, folate therapy does not prevent or alleviate the neurological defects of vitamin B₁₂ deficiency, and these may progress and become irreversible.

**Treatment of the Acutely Ill Patient.** As described in detail in the section on vitamin B₁₂, treatment of the patient who is acutely ill with megaloblastic anemia should begin with intramuscular injections of vitamin B₁₂ and folic acid. Inasmuch as the patient requires therapy before the exact cause of the disease has been defined, it is important to avoid the potential problem of a combined deficiency of vitamin B₁₂ and folic acid. When the patient is deficient in both, therapy with only one vitamin will not provide an optimal response. Longstanding nontropical sprue is one example of a disease in which combined deficiency of B₁₂ and folate is common. When indicated, vitamin B₁₂ (100 μg) and folic acid (1-5 mg) should be administered intramuscularly, and the patient should then be maintained on daily oral supplements of 1-2 mg of folic acid for the next 1-2 weeks.

Oral administration of folate generally is satisfactory for patients who are not acutely ill, regardless of the cause of the deficiency state. Even the patient with tropical or nontropical sprue and a demonstrable defect in absorption of folic acid will respond adequately to such therapy. Abnormalities in the activity of pteroyl-γ-glutamyl carboxypeptidase and the function of mucosal cells will not prevent passive diffusion of sufficient amounts of PteGlu across the mucosal barrier if the dosage is adequate, and continued ingestion of alcohol or other drugs also will not prevent an adequate therapeutic response. The effects of most inhibitors of folate transport or dihydrofolate reductase are overcome easily by administration of pharmacological doses of the vitamin. Folic acid is the appropriate form of the vitamin for use in chemotherapeutic protocols, including “rescue” from methotrexate (Chapter 61). Perhaps the only situation in which oral administration of folate will be ineffective is when vitamin C is severely deficient. Patients with scurvy may suffer from a megaloblastic anemia despite increased intake of folate and normal or high concentrations of the vitamin in plasma and cells.

The therapeutic response may be monitored by study of the hematopoietic system in a fashion identical to that described for vitamin B₁₂. Within 48 hours of the initiation of appropriate therapy, megaloblastic erythropoiesis disappears, and as efficient erythropoiesis begins, the concentration of iron in plasma falls to normal or below-normal values. The reticulocyte count begins to rise on the second or third day and reaches a peak by the fifth to
seventh days; the reticulocyte index reflects the proliferative state of the marrow. Finally, the hematocrit begins to rise during the second week.

It is possible to use the pattern of recovery as the basis for a therapeutic trial. For this purpose, the patient should receive a daily parental injection of 50-100 μg of folic acid. Administration of doses >100 μg/day entails the risk of inducing a hematopoietic response in patients who are deficient in vitamin B₁₂, and oral administration of the vitamin may be unreliable because of intestinal malabsorption. A number of other complications also may interfere with the therapeutic trial. The patient with sprue and deficiencies of other vitamins or iron may fail to respond because of these inadequacies. In cases of alcoholism, the presence of hepatic disease, inflammation, or iron deficiency can blunt the proliferative response of the marrow and prevent the correction of the anemia. For these reasons, the therapeutic trial for the evaluation of the patient with a potential deficiency of folic acid has not gained great popularity.

**CLINICAL SUMMARY**

Several hematopoietic growth factors are available for clinical use. Recombinant erythropoietin routinely is used for patients with the anemia of renal insufficiency, inflammation, and associated with cancer or the therapy of cancer. Longer-acting growth factors that permit less frequent dosing schedules are coming into increased use. One of the first of these is novel erythropoiesis-stimulating protein (NESP), produced by the insertion of two extra N-linked sialic acid side chains into the erythropoietin molecule. Myeloid growth factors (e.g., GM-CSF and G-CSF) are used to hasten the recovery of granulocytes after myelosuppressive therapy, to help mobilize hematopoietic stem cells into the peripheral blood to allow their harvest for transplantation, and to augment the number of mature leukocytes in the peripheral blood so that they can be used in patients with overwhelming infection. Finally, the development of IL-11 for use in thrombocytopenia and the investigational use of thrombopoietin or mimics of the molecule may provide many of the same therapeutic advances.

ENDOCRINOLOGY AND HORMONES: GENERAL CONCEPTS

Endocrinology analyzes the biosynthesis of hormones, their sites of production, and the sites and mechanisms of their action and interaction. The term hormone is of Greek origin and classically refers to chemical messengers that circulate in body fluids and produce specific effects on cells distant from their point of origin. The major functions of hormones include the regulation of energy storage, production, and utilization; the adaptation to new environments or conditions of stress; the facilitation of growth and development; and the maturation and function of the reproductive system. Although hormones were originally defined as products of ductless glands, we now appreciate that many organs that were not classically considered as “endocrine” (e.g., the heart, kidneys, GI tract, adipocytes, and brain) synthesize and secrete hormones that play key physiological roles; many of these hormones are now employed either diagnostically or therapeutically in clinical medicine. In addition, the field of endocrinology has expanded to include the actions of growth factors acting by means of autocrine and paracrine mechanisms, the influence of neurons—particularly those in the hypothalamus—that regulate endocrine function, and the reciprocal interactions of cytokines and other components of the immune system with the endocrine system.

As discussed in Chapter 3, hormones generally exert their actions on target cells via a plenitude of receptors, including heptaspanning GPCRs, monospanning membrane tyrosine kinases and guanylyl cyclases, cytokine receptors, ligand-activated ion channels, and nuclear transcription factors. Conceptually, it is useful to divide hormones into two classes: those that act predominantly via nuclear receptors to modulate transcription in target cells and those that typically act via membrane receptors to exert rapid effects on signal transduction pathways. Steroid hormones, thyroid hormone, and vitamin D belong to the first class, whereas peptide and amino acid hormones are generally assigned to the second class. The receptors for both classes of hormones provide tractable targets for a diverse group of compounds that are among the most widely used drugs in clinical medicine.

DISORDERS OF ENDOCRINE REGULATION

Because of their potent effects, circulating levels of hormones generally are tightly regulated within a normal range. The physiological strategies used to maintain the appropriate levels of hormones range from relatively simple ones involving direct feedback or feed-forward mechanisms (e.g., the secretion of parathyroid hormone by the parathyroid glands is inversely related to the serum Ca\(^{2+}\) concentration, which is sensed by a GPCR termed the Ca\(^{2+}\)-sensing receptor; Chapter 44) to more complex ones involving reciprocal interactions among the hypothalamus, anterior pituitary, and endocrine glands (see the section “The Hypothalamic-Pituitary-Endocrine Axis”).

Regardless of the mechanism, normal regulation can be perturbed in disease states when a given hormone is either over or underproduced or when its signaling mechanisms are impaired. Understanding the normal regulation and actions of the various hormones is critical to both diagnosis and treatment of these endocrine
disorders. Chapters 38 through 44 describe the different endocrine organs and the drugs that are employed to affect their function or to mimic or block their hormonal products.

**THE HYPOTHALAMIC-PITUITARY-ENDOCRINE AXIS**

Many of the classic endocrine hormones (e.g., cortisol, thyroid hormone, sex steroids, growth hormone) are regulated by complex reciprocal interactions among the hypothalamus, anterior pituitary, and endocrine glands (Table 38–1). These interactions permit precise control over the levels of circulating hormones and also provide a means to alter hormone levels under special physiological or pathological circumstances.

The basic organization of the hypothalamic-pituitary-endocrine axis is summarized in Figure 38–1. Discrete sets of hypothalamic neurons produce different releasing hormones, which are axonally transported to the median eminence. Upon stimulation, these neurons secrete their respective hypothalamic releasing hormones into the hypothalamic-adenohypophyseal plexus, which flows to the anterior pituitary gland. The hypothalamic releasing hormones bind to membrane receptors on specific subsets of pituitary cells and stimulate the secretion of the corresponding pituitary hormones. The pituitary hormones, which can be thought of as the master signals, then circulate to the target endocrine glands, where they again activate specific receptors to stimulate the synthesis and secretion of the target endocrine hormones. These interactions thus represent feed-forward regulation in which the master (signal) hormones stimulate the production of target hormones by the endocrine organs.

Superimposed on this positive feed-forward regulation is negative feedback regulation, which permits precise control of hormone levels. Figures 38–2 and 38–7 show examples of this negative feedback regulation. Typically, the endocrine target hormone circulates to both the hypothalamus and pituitary, where it acts via specific receptors to inhibit the production and secretion of both its hypothalamic releasing hormone and the regulatory pituitary hormone, thereby tightly regulating target hormone levels. In addition, other brain regions have inputs to the hypothalamic releasing neurons, further integrating the regulation of hormone levels in response to diverse stimuli.

An understanding of this regulation facilitates the diagnosis and management of a number of endocrine diseases. Endocrine deficiency states can be divided into those with impaired function at the level of the target endocrine gland (primary disease; as is the case in the autoimmune destruction of the adrenal or thyroid glands) and those with defects at the level of the pituitary gland and/or hypothalamus that impair delivery of the pituitary trophic hormone to its target gland (secondary/tertiary disease). In primary hypofunction, the production of the target endocrine hormone will be impaired; however, the hypothalamus and pituitary will sense the diminished feedback inhibition and the anterior pituitary gland will secrete higher than normal levels of the signal hormone. In secondary hypofunction, both the signal hormone and the target hormone will be below the normal range.

IGF-1, insulin-like growth factor-1; DHEA, dehydroepiandrosterone; f, female; m, male.
Hormone excess similarly can result either from primary disorders at the level of the target endocrine glands (e.g., a hyperfunctioning tumor of the adrenal cortex that oversecretes cortisol) or from secondary disorders at the level of the pituitary gland (e.g., a pituitary corticotrope adenoma that oversecretes corticotropin, the predominant stimulator of adrenal glucocorticoid biosynthesis). Again, knowledge of the levels of the pituitary signal hormone and the target hormone allows the clinician to identify the site of the endocrine disorder.
hormone (GHRH), gonadotropin-releasing hormone (GnRH), and thyrotropin-releasing hormone (TRH). *Somatostatin* (SST), another hypothalamic peptide, negatively regulates secretion of pituitary GH and TSH. The neurotransmitter dopamine inhibits the secretion of prolactin by lactotropes.

The posterior pituitary gland, also known as the neurohypophysis, contains the endings of nerve axons arising from distinct populations of neurons in the supraoptic and paraventricular nuclei of the hypothalamus that synthesize either arginine vasopressin or oxytocin (Figure 38–1). Arginine vasopressin plays an important role in water homeostasis (Chapter 25); oxytocin plays important roles in labor and parturition and in milk letdown, as discussed in the following sections and in Chapter 66.

### SOMATOTROPIC HORMONES: GROWTH HORMONE AND PROLACTIN

GH and prolactin are structurally related members of the somatotropic hormone family and share many biological features, thus providing a rationale for discussing them together. The somatotropes and lactotropes, the pituitary cells that produce GH and prolactin, respectively, derive during pituitary development from a common precursor and are eosinophilic in histological sections. Consistent with their common origin, defects in certain transcription factors affect both cell lineages. In addition to their structural similarities, GH and prolactin act via membrane receptors that belong to the cytokine receptor family and modulate target cell function via very similar signal transduction pathways (Chapter 3). The secretion of both hormones is subject to strong inhibitory input from hypothalamic neurons; for prolactin, this negative dopaminergic input clearly is the predominant regulator of secretion. Finally, several drugs that are used to treat excessive secretion of these hormones are effective to varying degrees for both GH and prolactin.

### Physiology of the Somatotropic Hormones

**Structures of the Somatotropic Hormones.** The gene encoding human GH resides on the long arm of
chromosome 17 (17q22), which also contains three different variants of placental lactogen and a GH variant, chorionic somatotropin, expressed in the syncytiotrophoblast. GH is secreted by somatotropes as a heterogeneous mixture of peptides; the principal form is a single polypeptide chain of 22 kDa that has two disulfide bonds and is not glycosylated. Alternative splicing deletes residues 32 to 46 of the larger form to produce a smaller form (~20 kDa) with equal bioactivity that makes up 5-10% of circulating GH. Recombinant human GH consists entirely of the 22 kDa form, which provides a way to detect GH abuse for sports performance enhancement.

Additional GH species, differing in size or charge, are found in serum, but their physiological significance is unclear. In the circulation, a 55 kDa protein binds approximately 45% of the 22 kDa and 25% of the 20 kDa forms; this binding protein contains the extracellular domain of the GH receptor and apparently arises from proteolytic cleavage. A second protein unrelated to the GH receptor also binds approximately 5-10% of circulating GH with lower affinity. Bound GH is cleared more slowly and has a biological t1/2 ~10 times that of unbound GH, suggesting that the bound hormone may provide a GH reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion. Alternatively, the binding protein may decrease GH bioactivity by preventing it from binding to its receptor in target tissues. Obesity increases circulating levels of GH binding proteins and thus may affect the clinical response to exogenous GH.

Human prolactin is a 23 kDa protein with three intramolecular disulfide bonds. It is synthesized by lactotropes, and a portion of the secreted hormone is glycosylated at a single Asn residue. In circulation, dimeric and polymeric forms of prolactin also are found, as are degradation products of 16 kDa and 18 kDa. As with GH, the biological significance of these different forms is not known.

**Regulation of Secretion of the Somatotropic Hormones.** Daily GH secretion varies throughout life; secretion is high in children, peaks during puberty, and then decreases in an age-related manner in adulthood. GH is secreted in discrete but irregular pulses. Between these pulses, circulating GH falls to levels that are undetectable with most assays. The amplitude of secretory pulses is greatest at night, and the most consistent period of GH secretion is shortly after the onset of deep sleep.

GH secretion, as illustrated in Figure 38–2, incorporates many of the classic features of endocrine regulation. GHRH, produced by hypothalamic neurons found predominantly in the arcuate nucleus, stimulates GH secretion by binding to a specific GPCR on somatotropes that resembles most closely the receptors for secretin, vasoactive intestinal polypeptide (VIP), pituitary adenyl cyclase-activating peptide (PACAP), glucagon, glucagon-like peptide-1 (GLP-1), calcitonin, and parathyroid hormone (PTH). Upon binding GHRH, the GHRH receptor couples to \( G_s \) to raise intracellular levels of cyclic AMP and \( Ca^{2+} \), thereby stimulating GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of short stature in humans, thereby demonstrating its essential role in normal GH secretion (Wajnrajch et al., 1996).

Typical of endocrine systems, GH and its major peripheral effector, insulin-like growth factor I (IGF-1), act in negative feedback loops to suppress GH secretion. The negative effect of IGF-1 is predominantly through direct effects on the anterior pituitary gland. In contrast, the negative feedback action of GH is mediated in part by SST, which is synthesized in more widely distributed neurons.
Somatostatin is synthesized as a 92–amino acid precursor and processed by proteolytic cleavage to generate two peptides: SST-28 and SST-14. SST-14 consists of the carboxy-terminal 14 amino acids of SST-28, which form an intrapeptide disulfide bond (Figure 38–3). SST exerts its effects by binding to and activating a family of five related GPCRs that signal through Gi to inhibit cyclic AMP accumulation and to activate K+ channels and protein phosphotyrosine phosphatases.

Each of the SST receptor subtypes (abbreviated SSTRs) binds SST with nanomolar affinity; whereas receptor types 1-4 (SSTR1-4) bind the two SSTs with approximately equal affinity, type 5 (SSTR5) has a 10- to 15-fold greater affinity for SST-28. SSTR2 and SSTR5 are the most important for regulation of GH secretion, and recent studies suggest that these two SSTRs form functional heterodimers with distinctive signaling behavior (Grant et al., 2008). SST exerts direct effects on somatotropes in the pituitary and indirect effects mediated via GHRH neurons in the arcuate nucleus. As discussed later, SST analogs play a key role in the pharmacotherapy of syndromes of GH excess and certain cancers.

Ghrelin, a 28-amino acid peptide that is octanoylated at Ser3, also stimulates GH secretion. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach but also is produced at lower levels at a number of other sites. Both fasting and hypoglycemia stimulate circulating ghrelin levels.

Ghrelin acts primarily through a GPCR called the GH secretagogue receptor. Although the interaction of ghrelin with this receptor directly stimulates GH release by isolated somatotropes, the major action on GH secretion apparently is through actions on the GHRH neurons in the arcuate nucleus. Apart from its effects on GH secretion, ghrelin also stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. Thus, ghrelin and its receptor act in a complex manner to integrate the functions of the GI tract, the hypothalamus, and the anterior pituitary (Ghigo et al., 2005). Peptide and nonpeptide agonists (termed GH secretagogues) and antagonists of the GH secretagogue receptor are undergoing evaluation as possible modulators of neuroendocrine function.

Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH and/or SST and thereby affect GH secretion. DA, 5-HT, and α2 adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, IGF-1, and GH itself inhibit release, as does the administration of glucose to normal subjects in an oral glucose-tolerance test.

Many of the physiological factors that influence prolactin secretion also affect GH secretion. Thus sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of prolactin secretion is DA, which is released by tuberoinfundibular neurons and interacts with the D2 receptor, a GPCR on lactotropes, to inhibit prolactin secretion (Figure 38–4). Recent reports have suggested that the D2 receptor and the SST2 receptor can form heterodimers (Baragli et al., 2007), which may have implications for therapy (see following discussion).

A number of putative prolactin-releasing factors have been described, including TRH, VIP, prolactin-releasing peptide, and PACAP, but their physiological roles are unclear. Under certain
prolactin receptors are widely distributed cell surface
tors on target tissues (Figure 38–5). Both the GH and
from their interactions with specific membrane recep-
Action.

Molecular and Cellular Bases of Somatotropic Hormone
Action. All of the effects of GH and prolactin result from
their interactions with specific membrane receptors on target tissues (Figure 38–5). Both the GH and
prolactin receptors are widely distributed cell surface
pathological conditions, such as severe primary hypothyroidism, persistently elevated levels of TRH can induce hyperprolactinemia.

Unlike GH, which plays important roles throughout life in both sexes, prolactin acts predominantly in women, both during pregnancy and in the postpartum period in women who breast-feed. Serum prolactin levels remain low in men but are elevated somewhat in normal cycling females. During pregnancy, the maternal serum prolactin level starts to increase at 8 weeks of gestation, increases to peak levels of 250 ng/mL at term, and declines thereafter to prepregnancy levels unless the mother breast-feeds the infant. Suckling or breast manipulation in nursing mothers transmits signals from the breast to the hypothalamus via the spinal cord and the median forebrain bundle, which, in turn, stimulate circulating prolactin levels. Prolactin levels can rise 10- to 100-fold within 30 minutes of stimulation. This response is distinct from milk letdown, which is mediated by oxytocin release from the posterior pituitary gland. The suckling-induced prolactin secretion involves both decreased secretion of dopamine by tuberoinfundibular neurons and possibly increased release of factors that stimulate prolactin secretion. The suckling response becomes less pronounced after several months of breast-feeding, and prolactin concentrations eventually decline to prepregnancy levels.

Prolactin also is synthesized in lactotropes near the end of the luteal phase of the menstrual cycle and by decidual cells early in pregnancy; the latter source is responsible for the very high levels of prolactin in amniotic fluid during the first trimester of human pregnancy. The function of this prolactin and what regulates its expres-
sion are not known.

The mature human GH receptor contains 620 amino acids, approximately 250 of which are extracellular, 24 of which are trans-
membrane, and ~350 of which are cytoplasmic. It exists as a pre-
formed homodimer that forms a ternary complex with one molecule of GH. The formation of the GH-GH receptor ternary complex is initiated by high-affinity interaction of GH with one monomer of the GH receptor dimer (mediated by GH site 1), followed by a second, lower affinity interaction of GH with the GH receptor mediated by GH site 2; these interactions induce a conformational change that activates downstream signaling. As discussed later, pegvisomant is a GH analog with amino acid substitutions that disrupt site 2; it binds the receptor and causes its internalization but cannot trigger the conformational change that stimulates downstream events in the signal transduction pathway. Amino acid–substituted versions of human prolactin that act as antagonists at the prolactin receptor are also under development (Goffin et al., 2006).

The ligand-occupied GH receptor dimer lacks inherent tyro-
sine kinase activity. Rather, it provides docking sites for two mole-
cules of JAK2, a cytoplasmic tyrosine kinase of the Janus kinase family. The juxtaposition of two JAK2 molecules leads to trans-
phosphorylation and autoactivation of JAK2, with consequent tyro-
sine phosphorylation of cytoplasmic proteins that mediate downstream signaling events (Lanning and Carter-Su, 2006). These include STAT proteins (Signal Transducers and Activators of Transcription), Shc (an adapter protein that regulates the Ras/MAPK signaling pathway), and IRS-1 and IRS-2 (insulin-receptor substrate proteins that activate the PI3K pathway). One critical target of STAT5 is the gene encoding IGF-1 (Figure 38–5). The fine control of GH action also involves feedback regulatory events that subse-
quently turn off the GH signal. As part of its action, GH induces the expression of a family of SOCS (suppressor of cytokine signaling) proteins and a group of protein tyrosine phosphatases that, by differ-
ent mechanisms, disrupt the communication of the activated GH receptor with JAK2 (Flores-Morales et al., 2006).

Some studies have shown that the GH receptor can translo-
cate to the nucleus and act as a coregulator to activate transcription and cell proliferation (Swanson and Kopchick, 2007). The precise role of this signal transduction pathway in GH physiology and patho-
physiology remains to be defined.

The effects of prolactin on target cells also result from inter-
actions with a cytokine receptor that is widely distributed and signals through many of the same pathways as the GH receptor. Alternative splicing of the prolactin receptor gene on chromosome 5 gives rise to multiple forms of the receptor that are identical in the extracellu-
lar domain but differ in their cytoplasmic domains. In addition, soluble forms that correspond to the extracellular domain of the receptor are found in circulation. Unlike human GH and placental

Figure 38–4. Prolactin secretion and actions. Prolactin is the only anterior pituitary hormone for which a unique stimulatory releasing factor has not been identified. Thyrotropin-releasing hormone (TRH), however, can stimulate prolactin release and dopamine can inhibit it. Suckling induces prolactin secretion, and prolactin affects lactation and reproductive functions but also has varied effects on many other tissues. Prolactin is not under feedback control by peripheral hormones.

Figure 38–5. Prolactin receptor activation. Prolactin, or a prolactin variant, binds to a GH receptor homodimer, which activates a downstream signaling pathway. This pathway includes STAT proteins (S), tyrosine kinases (T), and transcription factors (A) that induce a conformational change that stimulates downstream events in the signal transduction pathway. The GH receptor forms a dimer with a prolactin receptor variant, which leads to activation of downstream signaling pathways. The activated receptor then translocates to the nucleus, where it activates transcription.
lactogen, which also bind to the prolactin receptor and thus are lactogenic, prolactin binds specifically to the prolactin receptor and has no somatotropic (GH-like) activity.

**Physiological Effects of the Somatotropic Hormones.** The most striking physiological effect of GH—and the basis for its name—is the stimulation of the longitudinal growth of bones (Giustina et al., 2008). GH also increases bone mineral density after the epiphyses have closed and longitudinal growth ceases. These effects of GH involve the differentiation of prechondrocytes to chondrocytes and stimulation of osteoclast and osteoblast proliferation. Other effects of GH include the stimulation of myoblast differentiation (in experimental animals) and increased muscle mass (in human subjects with GH deficiency), increased glomerular filtration rate, and stimulation of preadipocyte differentiation into adipocytes. GH has potent anti-insulin actions in both the liver and peripheral sites (e.g., adipocytes and muscle) that decrease glucose utilization and increase lipolysis.

Finally, GH has been implicated in the development and function of the immune system.

Growth hormone acts directly on adipocytes to increase lipolysis and on hepatocytes to stimulate gluconeogenesis, but its anabolic and growth-promoting effects are mediated indirectly through the induction of IGF-1. Although most circulating IGF-1 is made in the liver, IGF-1 produced locally in many tissues is critical for growth, as revealed by normal growth in mice that have a hepatocyte-specific inactivation of IGF-1. Circulating IGF-1 is associated with a family of binding proteins, designated the IGF-binding proteins (IGFBPs), that serve as transport proteins and also may mediate certain aspects of IGF-1 signaling. Most IGF-1 in circulation is bound to IGFBP-3 and another protein called the acid-labile subunit.

The essential role of IGF-1 in growth is evidenced by patients with loss-of-function mutations in both alleles of the IGF1 gene, whose severe intrauterine and

---

**Figure 38–5. Mechanisms of growth hormone and prolactin action and of GH receptor antagonism.** **Left (A):** The binding of GH to a homodimer of the growth hormone receptor (GHR) induces autophosphorylation of JAK2. JAK2 then phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including STAT5 and mediators upstream of MAPK, which ultimately modulate gene expression. The structurally related prolactin receptor also is a ligand activated homodimer that recruits the JAK-STAT signaling pathway (see text for further details). The GHR also activates IRS-1, which may mediate the increased expression of glucose transporters on the plasma membrane. The diagram does not reflect the localization of the intracellular molecules, which presumably exist in multicomponent signaling complexes. JAK2, janus kinase 2; IRS-1, insulin receptor substrate-1; PI3K, phosphatidylinositol-3 kinase; STAT, signal transducer and activator of transcription; MAPK, mitogen-activated protein kinase; SHC, Src homology containing. **Right (B):** Pegvisomant, a recombinant pegylated variant of human GH, contains amino acid substitutions that increase the affinity for one site of the GHR but do not activate its downstream signaling cascade. It thus interferes with GH signaling in target tissues.
postnatal growth retardation is unresponsive to GH but responsive to recombinant human IGF-1, and by the association of mutations in the IGF-1 receptor with intrauterine growth retardation (Walenkamp and Wit, 2008).

After its synthesis and release, IGF-1 interacts with receptors on the cell surface that mediate its biological activities. The type 1 IGF receptor is closely related to the insulin receptor and consists of a heterotetramer with intrinsic tyrosine kinase activity. This receptor is present in essentially all tissues and binds IGF-1 and the related growth factor, IGF-2, with high affinity; insulin also can activate the type 1 IGF receptor but with an affinity approximately two orders of magnitude less than that of the IGFs. The signal transduction pathway for the insulin receptor is described in detail in Chapter 43.

Unlike GH, prolactin does not induce the synthesis of a second hormone that then mediates many of its effects in an indirect manner. Rather, prolactin effects are limited to tissues that express the prolactin receptor, particularly the mammary gland. A number of hormones—including estrogens, progesterone, placental lactogen, and GH—stimulate development of the breast and prepare it for lactation. Prolactin, acting via prolactin receptors, plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelia and is essential for lactation. Target genes, by which prolactin induces mammary development, include those encoding milk proteins (e.g., caseins), genes important for intracellular structure (e.g., keratins), genes important for cell-cell communication (e.g., amphiregulin and Wnt4), and components of the extracellular matrix (e.g., laminin and collagen).

Prolactin receptors are present in many other sites, including the hypothalamus, liver, adrenal, testes, ovaries, prostate, and immune system, suggesting that prolactin may play multiple roles outside of the breast. The physiological effects of prolactin at these sites remain poorly characterized, and specific defects in their function that result from prolactin deficiency have not been defined.

Pathophysiology of the Somatotropic Hormones

Distinct endocrine disorders result from either excessive or deficient GH production. In contrast, prolactin predominantly impacts endocrine function when produced in excess.

Excess Production of Somatotropic Hormones

Syndromes of excess secretion of GH and prolactin typically are caused by somatotrope or lactotrope adenomas that oversecrete the respective hormones. These adenomas often retain some features of the normal regulation described earlier, thus permitting pharmacological modulation of secretion—an important modality in therapy.

Clinical Manifestations.

GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in gigantism. In adults, GH excess causes acromegaly. The symptoms and signs of acromegaly (e.g., arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroGLOSSIA, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and diagnosis often is delayed. Mortality is increased at least 2-fold relative to age-matched controls, predominantly due to increased death from cardiovascular disease.

Hyperprolactinemia is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothyroidism associated with increased TRH levels, or from treatment with dopamine receptor antagonists. Most often, hyperprolactinemia is caused by prolactin-secreting pituitary adenomas—either microadenomas (≤1 cm in diameter) or macroadenomas (>1 cm in diameter). Manifestations of prolactin excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, erectile dysfunction, and infertility.

Diagnosis of Somatotropin Hormone Excess.

Although acromegaly should be suspected in patients with the appropriate symptoms and signs, diagnostic confirmation requires the demonstration of increased circulating GH or IGF-1. The “gold standard” diagnostic test for acromegaly is the oral glucose tolerance test. Whereas normal subjects suppress their GH level to <1 ng/mL in response to an oral glucose challenge (the absolute value may vary depending on the sensitivity of the assay), patients with acromegaly either fail to suppress or show a paradoxical increase in GH level.

In patients with hyperprolactinemia, the major question is whether conditions other than a prolactin-producing adenoma are responsible for the elevated prolactin level. A number of medications that inhibit DA signaling can cause moderate elevations in prolactin (e.g., antipsychotics, metoclopramide), as can primary hypothyroidism, pituitary mass lesions that interfere with dopamine delivery to the lactotropes, and pregnancy. Thus thyroid function and pregnancy tests are indicated, as is magnetic resonance imaging (MRI) to look for a pituitary adenoma or other defect that might elevate serum prolactin.

Impaired Production of the Somatotropic Hormones

Prolactin deficiency may result from conditions that damage the pituitary gland, but prolactin is not given as part of endocrine replacement therapy.
Clinical Manifestations of Growth Hormone Deficiency. Clinically, children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. Specific etiologies associated with GH deficiency in children include genetic disorders that affect pituitary development and can cause deficiencies of multiple pituitary hormones, pituitary or hypothalamic tumors, previous CNS irradiation, and infiltrative processes such as histiocytosis. In most patients, however, the deficiency is idiopathic, with normal production of other pituitary hormones and no obvious structural abnormalities.

GH deficiency in adults does not impair linear growth, which ceases with closure of the epiphyses. Rather, GH deficiency in adults is associated with decreased muscle mass and exercise capacity, decreased bone density, impaired psychosocial function, and increased mortality from cardiovascular causes, probably secondary to deleterious changes in fat distribution, increases in circulating lipids, and increased inflammation (Molitch et al., 2006). Decreased bone density is associated with decreased muscle mass and exercise capacity, which ceases with closure of the epiphyses. Rather, GH deficiency in adults is associated with decreased muscle mass and exercise capacity, decreased bone density, impaired psychosocial function, and increased mortality from cardiovascular causes, probably secondary to deleterious changes in fat distribution, increases in circulating lipids, and increased inflammation (Molitch et al., 2006).

Diagnosis of Growth Hormone Deficiency. Because GH secretion is highly pulsatile, random sampling of serum GH is insufficient to diagnose GH deficiency. Whereas tests for substances that provide an estimate of integrated GH levels over time (e.g., IGF-1 and IGFBP-3) are more useful, provocative tests usually are required. After excluding other causes of poor growth, the diagnosis of GH deficiency should be entertained in children with height >2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height. In this setting, a serum GH level <10 ng/mL following provocative testing (e.g., insulin-induced hypoglycemia, arginine, levodopa, clonidine, or glucagon) indicates GH deficiency; a stimulated value <5 ng/mL reflects severe deficiency.

In adults, overt GH deficiency usually results from pituitary lesions caused by a functioning or nonfunctioning pituitary adenoma, secondary to trauma, or related to surgery or radiotherapy for a pituitary or suprasellar mass (Molitch et al., 2006). Almost all patients with multiple deficits in other pituitary hormones also have deficient GH secretion, and some experts incorporate the number of other pituitary deficiencies into a diagnostic algorithm for diagnosing GH deficiency. Others accept a serum IGF-1 level below the age- and sex-adjusted normal range as indicative of GH deficiency in a patient with known pituitary disease. The converse is not true because an IGF-1 level within the normal range does not exclude adult GH deficiency. Some experts require an inadequate GH response to provocative testing (i.e., a value <5 ng/mL), with either insulin-induced hypoglycemia or a combination of Arg and GHRH as the preferred stimulus for GH secretion. Finally, in patients with known hypothalamic/pituitary disease of recent onset, Arg alone can be used as the stimulus, with the hGH cutoff set at 1.4 ng/mL. The risk of false-positive provocative tests (i.e., a subnormal GH response) is increased in obese subjects.

Pharmacotherapy of Disorders of the Somatotropin Hormones

Pharmacotherapy of Growth Hormone Excess. Treatment options in gigantism/acromegaly include transphenoidal surgery, radiation, and drugs that inhibit GH secretion or action. Pituitary surgery traditionally has been the treatment of choice. In patients with microadenomas, skilled neurosurgeons can achieve cure rates of 65-85%; however, the long-term success rate for patients with macroadenomas typically is <50%. In addition, there is increasing appreciation that acromegalic patients previously considered cured by pituitary surgery actually have persistent GH excess, with its attendant complications. Pituitary irradiation may be associated with significant long-term complications, including visual deterioration and pituitary dysfunction. Thus, increased attention has been given to the pharmacological management of acromegaly, either as primary treatment or for the treatment of persistent GH excess after transphenoidal surgery or irradiation. Another area receiving increased investigation is the potential role of medical therapy before surgery to improve outcome (Carlsen et al., 2008).

The favored therapy has been with SST analogs, although the GH receptor antagonist pegvisomant increasingly is used. In patients who refuse these injected treatments, DA agonists may be used, although they are much less effective.

Somatostatin Analogs. The development of synthetic analogs of SST (Figure 38–3) revolutionized the medical treatment of acromegaly. The goal of treatment is to decrease GH levels to <2.5 ng/mL after an oral glucotolerance test and to bring IGF-1 levels to within the normal range for age and sex. Some have argued that a basal GH level of <1 ng/mL indicates cure, whereas a basal level of >2 ng/mL is highly suggestive of persistent disease.

Chemistry. Structure-function studies of SST and its derivatives established that the amino acid residues in positions 7-10 of the SST-14 peptide (Phe-Trp-Lys-Thr) are the major determinants of biological activity. Residues Trp³ and Lys⁴ appear to be essential, whereas conservative substitutions at Phe⁷ and Thr¹⁰ are permissible. Active SST analogs retain this core segment constrained in a cyclic structure, formed either by a disulfide bond (octreotide, lanreotide, vapreotide) or an amide linkage (seglitide, pasireotide) that stabilizes the optimal conformation (Pawlowski and Melen-Mucha, 2004). The endogenous peptides, SST-14 and SST-28, do not show specificity for SST receptor subtypes except for SST₂, which preferentially binds SST-28. Some SST analogs exhibit greater selectivity. For example, the octapeptides octreotide and lanreotide bind to the SST subtypes with the following order of selectivity: SST₂ > SST₃ > SST₁ > SST₄ and SST₅. The cyclohexapeptide, pasireotide (SOM230), binds with high affinity to all but the SST₃ receptor. Small nonpeptide agonists that exhibit high selectivity for SST receptor subtypes have been isolated from combinatorial chemical libraries; these compounds may lead to a new class of highly selective, orally active SST mimetics (Weckbecker et al., 2003).

A chimeric compound that activates SST receptors and the D₂ receptor (BIM-23A387) is now in clinical trials for therapy of
mixed GH- and prolactin-secreting adenomas and for nonfunctioning pituitary adenomas (Pawlikowski and Melen-Mucha, 2004). Based on the apparent formation of heterodimers between the SST₂ and D₂ receptors, such chimeric compounds may have efficacy for certain tumors that do not respond to either classic SST analogs or DA agonists (Florio et al., 2008).

**Therapeutic Uses**

Currently, the two somatostatin analogs used widely are octreotide and lanreotide, synthetic derivatives that have longer half-lives and bind preferentially to SST₂ and SST₅ receptors. Octreotide (100 µg) administered subcutaneously three times daily is virtually 100% bioactive, peak effects are seen within 30 min, serum T₁/₂ is ~90 min, and duration of action is ~12 hour. This formulation successfully controls the biochemical parameters of acromegaly in 50-60% of patients.

The need to inject octreotide three times daily poses a significant obstacle to patient compliance. A long-acting, slow-release form (SANDOSTATIN-LAR DEPOT) in which the active species is incor-

controls the biochemical parameters of acromegaly in 50-60% of patients. A long-acting, slow-release formulation of octreotide has been used to treat symptoms associated with metasta-

tic carcinoid tumors (e.g., flushing and diarrhea) and adenomas secreting vasoactive intestinal peptide (e.g., watery diarrhea). Octreotide also is used for treatment of acute variceal bleeding and for perioperative prophylaxis in pancreatic surgery (see Chapter 46 for discussion of the use of SST analogs in GI disease). Octreotide also has significant inhibitory effects on TSH secretion, and it is the treatment of choice for patients who have thyrotrope adenomas that oversecrete TSH who are not good candidates for surgery. Finally, modified forms of octreotide labeled with indium or technetium have been used for diagnostic imaging of neuroendocrine tumors such as pituitary adenomas and carcinoids (OCTREOSCAN); modified forms labeled with β emitters such as ⁹⁰Y have been used in selective destruction of SST₅ receptor-positive tumors.

Novel uses under evaluation include the treatment of eye dis-

cases associated with excessive proliferation and inflammation (e.g., Graves’ orbitopathy and diabetic retinopathy), diabetic nephropathy, and various diseases associated with inflammation (e.g., rheumatoid arthritis, inflammatory bowel disease, pulmonary fibrosis, and psoriasis).

**Growth Hormone Antagonists.** Pegvisomant (SOMAVERT) is a GH receptor antagonist that is FDA-approved for the treatment of acromegaly. Pegvisomant binds to the GH receptor but does not activate JAK-STAT signaling or stim-

ulate IGF-1 secretion (Figure 38–5).

Pegvisomant is administered subcutaneously as a 40-mg loading dose under physician supervision, followed by self-admin-

istration of 10 mg per day. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 40 mg per day. Pegvisomant should not be used in patients with an unexplained elevation of hepatic transaminases, and liver function tests should be monitored in all patients. In addition, lipohypertrophy has occurred at injection sites, sometimes requiring cessation of therapy; this is believed to reflect the inhibition of direct actions of GH on adipocytes. Because of concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is strongly recommended, although this may change as more data become available (Jimenez et al., 2008). Pegvisomant differs structurally from native GH and induces the formation of specific antibodies in ~15% of patients despite the covalent coupling of Lys residues to 4-5 molecules of a polyethylene glycol polymer per modified GH molecule. Nevertheless, the development of tachyphylaxis due to these anti-

bodies has not been reported.

In clinical trials, pegvisomant at higher doses decreased serum IGF-1 to normal age- and sex-adjusted levels in >90% of patients and significantly improved clinical parameters such as ring size, soft-
tissue swelling, excessive perspiration, and fatigue. Thus pegvisomant
provides a highly effective alternative for use in patients who have not responded to SST analogs, either as sole therapy or as a temporizing measure while waiting for radiation therapy to achieve its full effect; it also is receiving increased scrutiny as first-line therapy.

Therapy of Prolactin Excess. The therapeutic options for patients with prolactinomas include transphenoidal surgery, radiation, and treatment with DA receptor agonists that suppress prolactin production via activation of D_2 receptors. The surgical success rates are 75% for microadenomas and 33% for macroadenomas. Given these results, D_2 receptor agonists are widely recognized as the treatment of choice for most patients (Gillam et al., 2006).

Dopamine Receptor Agonists

These agents generally decrease both prolactin secretion and the size of the adenoma, thereby improving both the endocrine abnormalities and neurological symptoms caused directly by the adenoma (including visual field deficits). Over time, especially with cabergoline, the prolactinoma may decrease in size to the extent that the drug can be discontinued without recurrence of the hyperprolactinemia. Some experts therefore recommend treatment with a dopamine receptor agonist for a minimum of 2 years, followed by a trial of dopamine agonist withdrawal in patients who have responded to dopamine agonist therapy with normalization of prolactin and disappearance of the tumor on MRI scanning (Gillam et al., 2006).

Patients with prolactinomas who wish to become pregnant comprise a special subset of hyperprolactinemic patients because drug safety during pregnancy becomes an important consideration. The dopamine agonists described here relieve the inhibitory effect of prolactin on ovulation and permit most patients with prolactinomas to become pregnant. Clinical experience also indicates that many patients can discontinue the dopaminergic agonist during pregnancy without clinically significant tumor growth. Although drug therapy ideally is discontinued before pregnancy to avoid any fetal exposure, most experts discontinue therapy after pregnancy is confirmed and carefully follow for symptoms or signs of pituitary mass effect throughout gestation. Because of its greater track record, bromocriptine is recommended for fertility induction in patients with hyperprolactinemia and has become the preferred drug in most settings for this disorder. Its greater efficacy in decreasing serum prolactin in patients with hyperprolactinemia may reflect

Bromocriptine. Bromocriptine (PARLODEL) is the dopamine receptor agonist against which newer agents are compared.

Chemistry. Bromocriptine is a semisynthetic ergot alkaloid (Figure 38–6) that interacts with D_2 receptors to inhibit spontaneous and TRH-induced release of prolactin; to a lesser extent, it also activates D_1 receptors.

Absorption, Distribution, and Elimination. Although a large fraction of the oral dose of bromocriptine is absorbed, only 7% of the dose reaches the systemic circulation because of a high extraction rate and extensive first-pass metabolism in the liver. Bromocriptine has a relatively short elimination t_{1/2} (between 2 and 8 hours) and thus is usually administered in divided doses (see Adverse Effects). To avoid the need for frequent dosing, a slow release oral form is available outside of the U.S. Bromocriptine may be administered vaginally (2.5 mg once daily), reportedly with fewer gastrointestinal side effects.

Therapeutic Uses. Bromocriptine normalizes serum prolactin levels in 70-80% of patients with prolactinomas and decreases tumor size in >50% of patients, including those with macroadenomas. Typically, bromocriptine does not cure the underlying adenoma, and hyperprolactinemia and tumor growth recur upon cessation of therapy.

Adverse Effects. Frequent side effects of bromocriptine include nausea and vomiting, headache, and postural hypotension, particularly on initial use. Less frequently, nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia are observed. These adverse effects can be diminished by starting at a low dose (1.25 mg) administered at bedtime with a snack. After 1 week, a morning dose of 1.25 mg can be added. If clinical symptoms persist or serum prolactin levels remain elevated, the dose can be increased gradually, every 3-7 days, to 5 mg two or three times a day as tolerated. Patients often develop tolerance to the adverse effects of bromocriptine. Those who do not respond to bromocriptine or who develop intractable side effects often respond better to cabergoline. At higher concentrations, bromocriptine is used in the management of acromegaly, as noted earlier, and at still higher concentrations is used in the management of Parkinson’s disease (Chapter 22).

Cabergoline. Cabergoline (DOSTINEX) is an ergot derivative with a longer t_{1/2} (~65 hours), higher affinity, and greater selectivity for the D_2 receptor (approximately four times more potent) than bromocriptine. It undergoes significant first-pass metabolism in the liver, and the precise oral availability is not known.

Therapeutic Uses. Cabergoline is FDA-approved for the treatment of hyperprolactinemia and has become the preferred drug in most settings for this disorder. Its greater efficacy in decreasing serum prolactin in patients with hyperprolactinemia may reflect
improved adherence to therapy due to decreased side effects. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. If the serum prolactin remains elevated, the dose can be increased to a maximum of 1.5-2 mg two or three times a week as tolerated; the dose should not be increased more often than once every 4 weeks.

Cabergoline induces remission in a significant number of patients with prolactinomas, and a trial of drug discontinuation is advocated for the subset of patients with normalization of prolactin and disappearance of a detectable pituitary lesion on MRI scanning.

At higher doses, cabergoline is used in some patients with acromegaly and is now under investigation for patients with Cushing’s disease due to corticotrope adenomas (Chapter 42).

**Adverse Effects.** Compared to bromocriptine, cabergoline has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. Cabergoline has been linked to valvular heart disease, an effect proposed to reflect agonist activity at the serotonin 5-HT$_{2B}$ receptor. A similar effect has been seen with pergolide (see later). Thus echocardiographic assessment seems appropriate for patients receiving chronic therapy with cabergoline, particularly those on higher doses (Colao et al., 2008b).

**Quinagolide.** Quinagolide (NORPROLAC) is a non-ergot D$_2$ agonist (Figure 38–6) with a $t_{1/2}$ (22 hours) between those of bromocriptine and cabergoline. Quinagolide is administered once daily at doses of 0.1-0.5 mg/day. It is not approved by the FDA but has been used extensively in Europe and Canada.

**Pergolide.** Pergolide (PERMAX), an ergot derivative FDA-approved for treatment of Parkinson disease, also was used off label to treat hyperprolactinemia. In part due to concerns of valvular heart disease, pergolide has been withdrawn from the market.

**Therapy of Growth Hormone Deficiency**

The pharmacology of somatotropic hormone deficiency is focused on GH because prolactin is not used clinically. Replacement therapy is well established in GH-deficient children and is gaining wider acceptance for GH-deficient adults. Several other indications are also approved, as described later. More recently, recombinant human IGF-1 has been approved for use in patients with mutations in the GH receptor that impair its action, as well as in GH-deficient children who develop antibodies against the recombinant hGH preparation. Although once marketed, a synthetic GHRH analog is no longer available.

**Recombinant Human Growth Hormone.** Humans do not respond to GH from nonprimate species. In earlier times, GH for therapeutic use was purified from human cadaver pituitaries; it thus was available in very limited quantities and in the mid-1980s was linked to the transmission of Creutzfeld-Jakob disease. Currently, human GH is produced by recombinant DNA technology, thereby providing virtually unlimited amounts of the hormone while eliminating the risk of disease transmission associated with the pituitary-derived preparations.

Somatropin refers to the many GH preparations whose sequences match that of native GH (ACCRETROPIN, GENOTROPIN, HUMATROPE, NORDITROPIN, NUTROPIN, OMNITROPE, SAIZEN, SEROSTIM, TEV-TROPIN, VALTROPIN, and
ZORBTIVE); somatrem refers to a derivative of GH with an additional methionine at the amino terminus that is no longer available in the U.S.

Chemistry. Although the bacterial or yeast systems used to express the recombinant GH subtly affect the structures of these preparations, they all have similar biological actions and potencies (3 IU/mg). An FDA-approved, encapsulated form of somatropin (NUTROPIN DEPOT) injected intramuscularly, either monthly (1.5 mg/kg body weight) or every 2 weeks (0.75 mg/kg body weight), has been discontinued by the manufacturer.

Pharmacokinetics. As a peptide hormone, GH is administered subcutaneously, with a bioavailability of 70%. Although the circulating t1/2 of GH is only 20 minutes, its biological t1/2 is considerably longer, and once-daily administration is sufficient. To match the usual pattern of secretion, GH typically is administered at bedtime, although this is not essential.

Indications for Growth Hormone Treatment. GH deficiency in children is a well-accepted cause of short stature, and replacement therapy has been used for half a century to treat children with severe GH deficiency. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner’s syndrome, Noonan’s syndrome, Prader-Willi syndrome, chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (i.e., >2.25 standard deviations below mean height for age and sex but with normal laboratory indices of growth hormone levels).

Attention also has shifted to the proper role of GH therapy in GH-deficient adults. The consensus of experts is that at least the most severely affected GH-deficient adults may benefit from GH replacement therapy (Molitch et al., 2006). The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short bowel syndrome. The latter indication is based on the finding that GH stimulates the adaptation of gastrointestinal epithelial cells.

Contraindications. Based on controlled clinical trials showing increased mortality, GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of neoplasia, and antitumor therapy should be completed before GH therapy is initiated. Other contraindications include proliferative retinopathy or severe nonproliferative diabetic retinopathy. In Prader-Willi syndrome, sudden death has been observed when GH was given to children who were severely obese or who had severe respiratory impairment.

Therapeutic Uses. In GH-deficient children, somatropin typically is administered in a dose of 25-50 μg/kg per day subcutaneously in the evening; higher daily doses (e.g., 50-67 μg/kg) are employed for patients with Noonan’s syndrome or Turner’s syndrome, who have partial GH resistance. In children with overt GH deficiency, measurement of serum IGF-1 levels sometimes is used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels (Cohen et al., 2007). Although the most pronounced increase in growth velocity occurs during the first 2 years of therapy, GH is continued until the epiphyses are fused and also may be extended into the transition period from childhood to adulthood.

In view of the effects of GH on bone density and visceral adiposity and the manifestations of GH deficiency in adults, many experts now continue therapy into adulthood for children with GH deficiency (Radovick and DiVall, 2007). However, many patients who were GH deficient in childhood based on provocative testing, especially those with idiopathic, isolated GH deficiency, respond normally to provocative tests as adults. Thus, it is essential to confirm GH deficiency after full growth has been achieved, ideally after discontinuation of GH replacement for at least 1 month, to identify patients who will benefit from continuing GH treatment.

For adults, weight-based dosing largely has been supplanted by initiation with relatively low doses irrespective of weight, followed by dose titration as tolerated to raise IGF-1 levels to the mid-normal range adjusted for age and sex. A typical starting dose is 150-300 μg per day, with higher doses used in younger patients transitioning from pediatric therapy; lower doses are used in older patients (e.g., >60 years of age). Either an elevated serum IGF-1 level or persistent side effects mandates a decrease in dose; conversely, the dose can be increased (typically by 100-200 μg per day) if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen inhibits GH action, women taking oral—but not transdermal—estrogen may require larger GH doses to achieve the target IGF-1 level. In the setting of AIDS-related wasting, considerably higher doses (e.g., 100 μg/kg) have been used. Studies are also underway to assess the effect of GH therapy on reducing visceral adiposity and increasing lean body mass in HIV-infected patients with the adipose redistribution syndrome (Grunfeld et al., 2007; Lo et al., 2008).

Based on the known age-related decline in GH levels, the use of GH therapy to ameliorate or even reverse the consequences of aging has been widely promoted. Many of the studies supporting this use were not placebo controlled and involved small numbers of subjects. Moreover, one review concluded that there was no significant improvement in strength or aerobic performance with GH therapy in elderly subjects (Liu et al., 2007). Thus, this remains an area of considerable debate. In violation of regulations and standard medical practice, some athletes also use injected GH preparations as anabolic agents to enhance performance (Gibney et al., 2007). In addition to the parenteral GH preparations, oral preparations containing “stacked” amino acids that reputedly stimulate GH release have been marketed as nutritional supplements. Despite the absence of validation in controlled trials, these formulations are part of multibillion dollar anti-aging and performance-enhancing programs (Olishansky and Perls, 2008).

Adverse Effects of Growth Hormone Therapy. In children, GH therapy is associated with remarkably few side effects. Rarely, generally within the first 8 weeks of therapy, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, and/or vomiting. Because of this, funduscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. Leukemia has been reported in some children receiving GH therapy; a causal relationship has not been established, and conditions associated with GH deficiency (e.g., Down’s syndrome, cranial irradiation for CNS tumors) probably explain the apparent increased
incidence of leukemia. Despite this, the consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. Because an increased incidence of type 2 diabetes mellitus has been reported, fasting glucose levels should be followed periodically during therapy. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis, although a causal link with GH has not been proven.

Side effects associated with the initiation of GH therapy in adults include peripheral edema, carpal tunnel syndrome, arthralgias, and myalgias, which occur most frequently in patients who are older or obese and generally respond to a decrease in dose. These volume-related adverse effects occur less frequently with standard-dose rather than weight-based regimens. Although there are potential concerns about impaired glucose tolerance secondary to anti-insulin actions of GH, this generally has not been a major problem at the recommended doses. In fact, changes in visceral fat composition associated with GH replacement may improve insulin sensitivity in some patients.

**Drug Interactions.** The effects of estrogen on GH therapy were noted earlier. This effect is much less marked with transdermal estrogen preparations. Recent studies suggest that GH therapy can increase the metabolic inactivation of glucocorticoids in the liver. Thus, GH may precipitate adrenal insufficiency in patients with occult secondary adrenal insufficiency or in patients receiving replacement doses of glucocorticoids. This has been attributed to the inhibition of the type 1 isozyme of steroid 11β-hydroxysteroid dehydrogenase, which normally converts inactive cortisol into the active 11-hydroxy derivative cortisol (Chapter 42).

**Insulin-like Growth Factor 1 (IGF-1)**

Based on the hypothesis that GH predominantly acts via increases in IGF-1, there has been a longstanding interest in developing IGF-1 preparations for therapeutic use. To this end, recombinant human IGF-1 (mecasermin, INCRELEX) and a combination of recombinant human IGF-1 with its binding protein, IGFBP-3 (mecasermin rinfabate; IPLEX), are FDA-approved. The latter formulation was subsequently discontinued for use in short stature due to patent issues, although it remains available for other conditions such as severe insulin resistance, muscular dystrophy, and HIV-related adipose redistribution syndrome.

**Absorption, Distribution, and Elimination.** Mecasermin is administered by subcutaneous injection and absorption is virtually complete. As discussed earlier, IGF-1 in circulation is bound by six proteins; a ternary complex that includes IGFBP-3 and the acid labile subunit accounts for >80% of the circulating IGF-1. This protein binding prolongs the t½ of IGF-1 to ~6 hours. Both the liver and kidney have been shown to metabolize IGF-1.

**Therapeutic Uses.** Mecasermin is FDA-approved for patients with impaired growth secondary to mutations in the GH receptor or postreceptor signaling pathway, patients with GH deficiency who develop antibodies against GH that interfere with its action, and the very rare patients with IGF-1 gene defects that lead to primary IGF-1 deficiency (Collet-Solberg and Misra, 2008). Typically the starting dose is 40-80 μg/kg per dose twice daily by subcutaneous injection, with a maximum of 120 μg/kg per dose twice daily.

Clinical trials also have examined the efficacy of mecasermin in the much larger cohort of patients with impaired growth secondary to GH deficiency or with idiopathic short stature. In these settings, mecasermin stimulates linear growth but is less effective than conventional therapy using recombinant GH, suggesting direct effects of GH on linear growth independent of IGF-1. Although further study is needed, mecasermin should be reserved for therapy in patients with FDA-approved indications and is unlikely to replace GH as preferred therapy for most patients with GH deficiency or short stature.

**Adverse Effects.** Side effects of mecasermin include hypoglycemia and lipohypertrophy, both presumably secondary to activation of the insulin receptor. To diminish the frequency of hypoglycemia, mecasermin should be administered shortly before or after a meal or snack. Lymphoid tissue hypertrophy, including enlarged tonsils, also is seen and may require surgical intervention. Other adverse effects are similar to those associated with GH therapy and include intracranial hypertension, slipped epiphyses, and scoliosis.

**Contraindications.** Mecasermin should not be used for growth promotion in patients with closed epiphyses. It should not be given to patients with active or suspected neoplasia and should be stopped if evidence of neoplasia develops.

**Sermorelin.** Sermorelin (GEREF) is a synthetic form of human GHRH that corresponds in sequence to the first 29 amino acids of human GHRH (a 44–amino acid peptide) and has full biological activity. Although sermorelin is FDA-approved for treatment of GH deficiency and as a diagnostic agent to differentiate between hypothalamic and pituitary disease, the drug was withdrawn from the U.S. market in late 2008.

**THE GYCO PROTEIN HORMONES: TSH AND THE GONADOTROPINS**

The gonadotropins include LH, FSH, and hCg. They are referred to as the gonadotropins because of their actions on the gonads (Table 38–2). Together with TSH, they constitute the glycoprotein family of pituitary hormones. Each hormone is a glycosylated heterodimer containing a common α-subunit and a distinct β-subunit that confers specificity of action.

LH and FSH were named initially based on their actions on the ovary; appreciation of their roles in male reproductive function came later. LH and FSH are synthesized and secreted by gonadotropes, which make up ~10% of the hormone-secreting cells in the anterior pituitary. hCg, which is produced only in primates and horses, is synthesized by the syncytiotrophoblast of the placenta. Pituitary gonadotropin production is stimulated by GnRH and further...
Regulation of Gonadotropin Synthesis and Secretion. The predominant regulator of gonadotropin synthesis and secretion is the hypothalamic peptide GnRH. It is a decapeptide with blocked amino and carboxyl termini (Table 38–3) derived by proteolytic cleavage of a 92–amino acid precursor peptide. A separate gene encodes a related GnRH peptide, termed GnRH-II (Millar et al., 2004); its potential functions in reproduction remain to be defined. GnRH release is pulsatile and is governed by a neural pulse generator in the hypothalamus, primarily in the arcuate nucleus, that controls the frequency and amplitude of GnRH release. The GnRH pulse generator is active late in fetal life and for ~1 year after birth but decreases considerably thereafter, presumably secondarily to CNS inhibition. Shortly before puberty, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotropes and forms the basis for the clinical use of long-acting GnRH agonists to suppress gonadotropin secretion, as discussed later.

Molecular and Cellular Bases of GnRH Action. GnRH signals through a specific GPCR on gonadotropes that activates $G_{q/11}$ and stimulates the PLC-IP$_3$-Ca$^{2+}$ pathway (Chapter 3), resulting in increased synthesis and secretion of LH and FSH. Although cyclic AMP is not the major mediator of GnRH action, binding of GnRH to its receptor also increases adenylyl cyclase activity. GnRH receptors also are present in the ovary, testis, and other sites, where their physiological significance remains to be determined. The presence of these receptors on certain tumors has led to investigation of the role of GnRH analogs in cancer therapy (Engel and Schally, 2007).

Other Regulators of Gonadotropin Production. Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate. The feedback effects of gonadal steroids are dependent on sex, concentration, and time. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator. Higher and more sustained levels of estradiol have positive feedback effects that ultimately result in the gonadotropin surge that triggers ovulation. In men, testosterone inhibits gonadotropin production, in part through direct actions and in part via its conversion by aromatase to estradiol.

Physiology of the Gonadotropins

Structure-Function Aspects of the Gonadotropins. The carbohydrate residues on the gonadotropins influence their rates of clearance from the circulation, and thus their serum half-lives, and also play a role in activating the gonadotropin receptors. Among the gonadotropin β-subunits, that of hCG is most divergent because it contains a carboxy-terminal extension of 30 amino acids and extra carbohydrate residues that prolong its $t_{1/2}$. The longer $t_{1/2}$ of hCG has some clinical relevance for its use in assisted reproduction technologies (Chapter 66).

regulated by feedback effects of the gonadal hormones (Figures 38–7 and 40–2). Chapters 40 and 41 provide more detailed descriptions of gonadotropin regulation.

TSH is measured in the diagnosis of thyroid disorders, and recombinant TSH is used in the evaluation and treatment of well-differentiated thyroid cancer, as discussed in Chapter 39.

HORMONES AND HORMONE ANTAGONISTS

SECTION V

Figure 38–7. The hypothalamic-pituitary-gonadal axis. A single hypothalamic releasing factor, gonadotropin-releasing hormone (GnRH), controls the synthesis and release of both gonadotropins (LH and FSH) in males and females. Gonadal steroid hormones (androgens, estrogens, and progesterone) exert feedback inhibition at the level of the pituitary and the hypothalamus. The pre-ovulatory surge of estrogen also can exert a stimulatory effect at the level of the pituitary and the hypothalamus. Inhibins, a family of polypeptide hormones produced by the gonads, specifically inhibit FSH secretion by the pituitary.

Ac, acetyl; Bzl, benzyl; EtNH₂, N-ethylamide; tBu, t butyl; D-Nal, 3-(2-naphthyl)-D-alanyl; Cpa, chlorophenylalanyl; Lys(iPr), isopropyl-lysyl; Pal, 3-pyridylalanyl; AzGly, azaglycyl; hArg(Et)₂, ethyl homoarginine; IV, intravenous; SC, subcutaneous; IN, intranasal; IM, intramuscular. A dash (–) denotes amino acid identity with GnRH.
Gonadotropin production also is regulated by the inhibins, which are members of the bone morphogenetic protein family of secreted signaling proteins. Inhibin A and B are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors (Bilezikjian et al., 2006). They act directly in the pituitary to inhibit FSH secretion without affecting that of LH. Inhibin A exhibits variation during the menstrual cycle, suggesting that it acts as a dynamic regulator of FSH secretion.

**Molecular and Cellular Bases of Gonadotropin Action.**

The actions of LH and hCG on target tissues are mediated by the LH receptor; those of FSH are mediated by the FSH receptor. Both of these GPCRs have large glycosylated extracellular domains that contribute to their affinity and specificity for their ligands. The FSH and LH receptors couple to Gs to activate the adenyllyl cyclase/cyclic AMP pathway. At higher ligand concentrations, the agonist-occupied gonadotropin receptors also activate PKC and Ca^{2+} signaling pathways via Gq-mediated effects on PLCβ. Because most, if not all, actions of the gonadotropins can be mimicked by cyclic AMP analogs, the precise physiological role of Ca^{2+} and PKC in gonadotropin action remains to be determined.

**Physiological Effects of Gonadotropins.**

In men, LH acts on testicular Leydig cells to stimulate the de novo synthesis of androgens, primarily testosterone, from cholesterol. Testosterone is required for gametogenesis within the seminiferous tubules and for maintenance of libido and secondary sexual characteristics (Chapter 41). FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation.

In women, the actions of FSH and LH are more complicated. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the expression of aromatase in granulosa cells, thereby stimulating the production of estradiol. LH acts on the theca cells to stimulate the de novo synthesis of androstenedione, the major precursor of ovarian estrogens in premenopausal women (Figure 40-1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

**CLINICAL DISORDERS OF THE HYPOTHALAMIC-PITUITARY-GONADAL AXIS**

Clinical disorders of the hypothalamic-pituitary-gonadal axis can manifest either as alterations in levels and effects of sex steroids (hyper- or hypogonadism) or as impaired reproduction. This section focuses on those conditions that specifically affect the hypothalamic-pituitary components of the axis and those for which gonadotropins are used diagnostically or therapeutically.

Deficient sex steroid production resulting from hypothalamic or pituitary defects is termed hypogonadotropic hypogonadism because circulating levels of gonadotropins are either low or undetectable (Layman, 2007). Hypogonadotropic hypogonadism in some patients results from GnRH receptor mutations; some of these mutations impair targeting of the GnRH receptor to the plasma membrane of gonadotropes, prompting efforts to develop pharmacological strategies to correct receptor trafficking and restore function (Conn et al., 2007). Many other disorders can impair gonadotropin secretion, including pituitary tumors, other genetic disorders such as Kallmann’s syndrome, infiltrative processes such as sarcoidosis, and functional disorders such as exercise-induced amenorrhea.

In contrast, reproductive disorders caused by processes that directly impair gonadal function are termed hypergonadotropic because the impaired production of sex steroids leads to a loss of negative feedback inhibition, thereby increasing the synthesis and secretion of gonadotropins.

**Precocious Puberty.** Puberty normally is a sequential process requiring several years over which the GnRH neurons escape CNS inhibition and initiate pulsatile secretion of GnRH. This stimulates the secretion of gonadotropins and gonadal steroids, thus directing the development of secondary sexual characteristics appropriate for sex. Normally, the initial signs of puberty (breast development in girls and testes enlargement in boys) do not occur before age 8 in girls or age 9 in boys; the initiation of sexual maturation before this time is termed “precocious.”

Precocious puberty can be divided into processes that lead to the premature activation of the normal hypothalamic-pituitary-gonadal axis, termed central or GnRH-dependent precocious puberty, and processes that lead to peripheral production of sex steroids in a GnRH-independent manner (Carel and Léger, 2008). Specific etiologies of GnRH-dependent precocious puberty include CNS tumors (including hypothalamic hamartomas), developmental abnormalities of the CNS, and encephalitis or other infectious processes; in most patients and especially in girls, a specific etiology is never defined, and patients are deemed to have an idiopathic process. GnRH-independent precocious puberty
results from peripheral production of sex steroids in a manner not driven by pituitary gonadotropins; etiologies include adrenal or gonadal tumors, activating mutations of the LH receptor in boys, and congenital adrenal hyperplasia. As discussed later, synthetic GnRH analogs play important roles in the diagnosis and treatment of GnRH-dependent precocious puberty. In contrast, drugs that interfere with the production of sex steroids, including ketoconazole and aromatase inhibitors, are used in patients with GnRH-independent precocious puberty (Shulman et al., 2008), with varying success.

Sexual Infantilism. The converse of precocious puberty is a failure to initiate the processes of pubertal development at the normal time. This can reflect defects in the GnRH neurons or gonadotropes (secondary hypogonadism) or primary dysfunction in the gonads. In either case, induction of sexual maturation using sex steroids (estrogen followed by estrogen/progesterone in females, testosterone in males) is standard therapy. This suffices to direct sex differentiation in the normal manner. If fertility is the goal, then therapy with either GnRH or gonadotropins is needed to stimulate appropriate germ cell maturation.

Infertility. Infertility, or a failure to conceive after 12 months of unprotected intercourse, is seen in up to 10-15% of couples and is increasing in frequency as women choose to delay childbearing. The rising incidences of obesity, sexually transmitted diseases that disrupt the reproductive tract, and reduced sperm count due to environmental pollution also are contributing factors. When the infertility is due to impaired synthesis or secretion of gonadotropins (hypogonadotropic hypogonadism), various pharmacological approaches are employed. In contrast, when infertility results from intrinsic processes affecting the gonads, pharmacotherapy generally is less effective. Therapeutic approaches to male infertility are described later in this chapter; strategies for female infertility are described in Chapter 66.

Clinical Uses of GnRH and Its Synthetic Analogs

A synthetic peptide comprising the native sequence of GnRH has been used both diagnostically and therapeutically in human reproductive disorders. In addition, as illustrated in Table 38–3, a number of GnRH analogs with structural modifications have been synthesized and brought to market.

Synthetic GnRH. Synthetic GnRH (gonadorelin; Fac-Trel, Lutrepulse) is FDA-approved, but ongoing problems with availability have limited its clinical use in the U.S. to a few specialized centers; synthetic analogs have largely supplanted gonadorelin.

Chemistry. The structure of gonadorelin (Table 38–3) corresponds to that of native GnRH; it is a decapeptide with blocked amino and carboxyl termini.

Absorption, Distribution, and Elimination. As a peptide, gonadorelin is administered either subcutaneously or intravenously. It is well-absorbed following subcutaneous injection and has a circulating t1/2 of ~2-4 minutes. For therapeutic uses, it must be administered in a pulsatile manner to avoid down-regulation of the GnRH receptor.

Diagnostic and Therapeutic Uses. Because of the limited availability of GnRH, many of its diagnostic and therapeutic uses have been discontinued. For diagnostic purposes, gonadorelin was used in the GnRH stimulation test in patients with hypogonadotropic hypogonadism in an effort to differentiate between hypothalamic and pituitary defects. A blood sample was obtained for a baseline LH value, a single 100-μg dose of GnRH was administered subcutaneously or intravenously, and serum LH levels were measured at various times after injection. A normal LH response to >10 mIU/mL indicated the presence of functional pituitary gonadotropes and prior exposure to GnRH. Inasmuch as the long-term absence of GnRH can impair the responsiveness of otherwise normal gonadotropes, the absence of a response did not always indicate intrinsic pituitary disease. Thus some experts had advocated use of multiple doses of GnRH in an effort to restore gonadotrope responsiveness.

GnRH-stimulation testing also was used to determine whether a child with precocious puberty had a GnRH-dependent (central) or GnRH-independent (peripheral) disorder. A GnRH-induced increase in plasma LH to >10 mIU/mL in boys or >7 mIU/mL in girls indicated true precocious puberty rather than a GnRH-independent process. Currently, some experts in the U.S. and elsewhere have used long-lasting GnRH agonists off label as the stimulating agent for diagnostic assessment (see section on Gonadotropin-Releasing Hormone Agonists).

To treat female infertility secondary to impaired GnRH secretion, gonadorelin was administered by infusion in pulses that promoted a physiological cycle. Advantages over gonadotropin therapy included a lower risk of multifetal pregnancies and a decreased need to monitor plasma estradiol levels or follicle size by ovarian ultrasonography. Side effects usually were minimal; the most common was local irritation due to the infusion device. In women, normal cycling levels of ovarian steroids could be achieved, leading to ovulation and menstruation. The manufacturer has discontinued production for this indication, and gonadorelin is no longer generally available in the U.S.

GnRHA. Synthetic agonists have longer half-lives than native GnRH. After a transient stimulation of gonadotropin secretion, they down-regulate the GnRH receptor and inhibit gonadotropin secretion; this is used
to therapeutic advantage in a number of conditions, as outlined in the following discussion and in Chapter 66.

**Chemistry.** The sequences of the available GnRH agonists are listed in Table 38–3. They contain substitutions of the native sequence at position 6 that protect against proteolysis and substitutions at the carboxyl terminus that improve receptor-binding affinity. Compared to GnRH, these analogs exhibit enhanced potency and prolonged duration of action.

**Pharmacokinetics.** The GnRH agonists are available in a variety of formulations for diverse applications, including relatively short-term effects (e.g., assisted reproduction technology) and more prolonged action (e.g., depot forms that inhibit gonadotropin secretion in GnRH-dependent precocious puberty). The rates and extents of absorption thus vary considerably. The intranasal formulations are noteworthy because their bioavailability (~4%) is considerably lower than those of the parenteral formulations.

**Clinical Uses.** Based on the intermittent supply of gonadorelin, the depot form of the GnRH agonist leuprolide (LUPRON) has been used diagnostically to differentiate between GnRH-dependent and GnRH-independent precocious puberty (Brito et al., 2004). Leuprolide depot (3.75 mg) is injected subcutaneously, and serum LH is measured 2 hours later. A plasma LH level of >6.6 mIU/mL is diagnostic of GnRH-dependent (central) disease.

Clinically, the various GnRH agonists are used to achieve pharmacological castration in disorders that respond to reduction in gonadal steroids. A clear indication is in children with GnRH-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a depot form of a GnRH agonist. Long-acting GnRH agonists are used for palliative therapy of hormone responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (Chapters 40-42). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine fibroids, acute intermittent porphyria, and priapism. They also have been evaluated off label for their potential to preserve follicles in women undergoing therapy with cytotoxic drugs for cancer treatment, although efficacy in this setting has not been established. Depot preparations can be administered subcutaneously or intramuscularly monthly or every 3 months in these settings and may be particularly useful for pharmacological castration in disorders such as paraphilia (an off-label use), where strict patient compliance is problematic.

Finally, the long-lasting GnRH agonists have been used to avoid a premature LH surge, and thus ovulation, in various ovarian stimulation protocols for in vitro fertilization. The specifics of this use are outlined in Chapter 66.

**Adverse Effects.** The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes and decreased bone density in both sexes, vaginal dryness and atrophy in women, and erectile dysfunction in men). Because of these effects, therapy in non-life-threatening diseases such as endometriosis or uterine fibroids generally is limited to 6 months unless add-back therapy with sex steroids is incorporated into the regimen. Postmarketing surveillance noted an apparent increase in the incidence of pituitary apoplexy, a syndrome of headache, neurological manifestations, and impaired pituitary function that usually results from infarction of a pituitary adenoma (Davis et al., 2006); the product labeling for the GnRH agonists has been updated to include this risk. Although definitive evidence of an increased risk of congenital abnormalities is lacking (Elizur and Tulundi, 2008), the GnRH agonists interfered with pregnancy in animal models and thus are considered as contraindicated in pregnant women (FDA Category X). Thus caution should be exercised to avoid the exposure of pregnant women to GnRH agonists.

**Specific Drug Formulations and Approved Indications**

**Leuprolide** (LUPRON, ELIGARD) is formulated in multiple doses for injection: subcutaneous (500 mg/day), subcutaneous depot (7.5 mg/month; 22.5 mg/3 months; 30 mg/4 months; 45 mg/6 months), and intramuscular depot (3.75 mg/month; 11.25 mg/3 months). It is approved for endometriosis, uterine fibroids, advanced prostate cancer, and central precocious puberty.

**Goserelin** (ZOLADEX) is formulated as a subcutaneous implant (3.6 mg/month; 10.8 mg/12 weeks). It is approved for endometriosis and advanced prostate and breast cancer.

**Histrelin** (VANTAS, SUPPRELINA LA) is formulated as a subcutaneous implant (50 mg/12 months). It is approved for central precocious puberty and advanced prostate cancer.

**Nafarelin** (SYNAREL) is formulated as a nasal spray (200 μg/spray). It is approved for endometriosis (400 μg/day) and central precocious puberty (1600 μg/day).

**Triptorelin** (TRELSTAR DEPOT, TRELSTAR LA) is formulated for depot intramuscular injection (3.75 mg/month; 11.25 mg/12 weeks) and approved for advanced prostate cancer.

**Buserelin and Deslorelin** are not available in the U.S.

**GnRH Antagonist Analogs.** Two GnRH antagonists, ganirelix (ANTAGON) and cetrorelix (CETROTIDE; Table 38–3), are FDA approved to suppress the LH surge and thus prevent premature ovulation in ovarian-stimulation protocols as part of assisted reproduction technology. Specifics of use in that setting are given in Chapter 66. Cetrorelix is also used off label for endometriosis and uterine fibroids, both of which are estrogen dependent. As antagonists rather than agonists, these drugs do not transiently increase gonadotropin secretion and sex steroid biosynthesis. A depot form of a third GnRH antagonist, abarelix (PLENAXIS) was FDA approved for androgen suppression in men with advanced prostate cancer but has since been withdrawn from market for economic reasons.

**Chemistry.** The GnRH antagonists are synthetic peptides with modifications of certain residues found in the native GnRH sequence. In addition to a D-amino acid at position 6 and a D-Ala amide at position 10, the antagonists each contain D-chlorophenylalanyl and 3-pyridy-lalanyl substitutions at positions 2 and 3, respectively, which affect receptor activation and increase inhibitory potency and solubility. The additional substitution at position 8, along with that at position 10, reduces the induction of histamine release and the tendency to trigger immediate hypersensitivity reactions (Reissmann et al., 1995).
Absorption, Distribution, and Elimination. Both available GnRH antagonists are formulated for subcutaneous administration. Bioavailability exceeds 90% within 1-2 hours, and the $t_{1/2}$ varies depending on the dose. Once-daily administration suffices for therapeutic effect.

Adverse Effects. In contrast to older antagonists, the FDA-approved drugs did not manifest potent histamine release in preclinical or clinical trials. However, hypersensitivity reactions, including anaphylaxis, have been noted in postmarketing surveillance, some with the initial dose. When used in conjunction with gonadotropin injections for assisted reproduction, the effects of estrogen withdrawal (e.g., hot flashes) are not seen. The product labeling indicates that the GnRH antagonists are contraindicated in pregnant women (FDA Category X), although definitive data linking them to an increased risk of congenital abnormalities is lacking (Elizur and Tulandi, 2008).

NATURAL AND RECOMBINANT GONADOTROPINS

The gonadotropins are used for both diagnosis and therapy in reproductive endocrinology. The therapeutic uses of the gonadotropins are briefly presented here; further discussion of the uses of gonadotropins in female reproduction is provided in Chapter 66.

The original gonadotropin preparations for clinical therapy were prepared from human urine and included chorionic gonadotropin, obtained from the urine of pregnant women, and menotropins, obtained from the urine of postmenopausal women. Because of their relatively low purity, these gonadotropins were administered intramuscularly to decrease the incidence of hypersensitivity reactions. Subsequently, urine-derived preparations of sufficient purity to be administered subcutaneously were developed. Highly purified preparations of human gonadotropins now are prepared using recombinant DNA technology that exhibit less batch-to-batch variation; this same technology is likely to lead to improved forms of gonadotropins with increased half-lives or higher clinical efficacy. One such “designer” gonadotropin, FSH-CTP, contains the β—subunit of FSH fused to the carboxy-terminal extension of hCG, thereby increasing considerably the $t_{1/2}$ of the recombinant protein. In clinical trials, FSH-CTP has been shown to stimulate follicle maturation in vivo when injected weekly (reviewed by Macklin et al., 2006).

Preparations

Follicle-Stimulating Hormone. Follicle-stimulating hormone has long been a mainstay of regimens for either ovarian stimulation or in vitro fertilization. The original menotropin formulations (REPRONEX) contained roughly equal amounts of FSH and LH, as well as a number of other urinary proteins, and were administered intramuscularly to diminish local reactions. Urofollitropin (uFSH; BRAVELLE, MENOPUR), prepared by immunoconcentration of FSH with monoclonal antibodies, is pure enough to be administered subcutaneously. The amount of LH contained in such preparations is diminished considerably, prompting (unproven) speculation that the lack of LH activity might impair follicle maturation to some degree.

Recombinant FSH (rFSH) is prepared by expressing cDNAs encoding the α and β subunits of human FSH in mammalian cell lines, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The two available rFSH preparations (follicitropin α [GONAL-F] and follicitropin β [FOLLISTIM, PUREGON]) differ slightly in their carbohydrate structures; both exhibit less interbatch variability than do preparations purified from urine and can be administered subcutaneously because they are considerably purer. The relative advantages (i.e., efficacy, lower frequency of side effects such as ovarian hyperstimulation) of recombinant FSH versus urine-derived gonadotropins have not been definitively established despite much debate in the published literature (see Chapter 66 for further discussion).

Human Chorionic Gonadotropin. The hCG used clinically originally came from the urine of pregnant women. Several urine-derived preparations are available (NOVAREL, PREGNYL, PROFASI), all of them are administered intramuscularly due to local reactions. Recombinant hCG (choriogonadotropin alfa; OVIDREL) also has reached clinical use. Again, it is likely that recombinant hCG preparations will have an increasing role in the future, possibly replacing the urinary preparations entirely.

Recombinant Human LH. Menotropins contain considerable LH activity, thereby providing any LH that is needed to promote follicle maturation. Traditionally, LH was not used for ovulation induction because hCG produced identical effects via the LH receptor and had a longer $t_{1/2}$. Human LH produced using recombinant DNA technology and designated lutropin alfa (LUVERIS, LHADI) now is available. Again, advantages or disadvantages relative to hCG remain to be established, although LH appears to be less likely to induce ovarian hyperstimulation when used to induce ovulation in IVF protocols (Chapter 66).

Diagnostic Uses of Gonadotropins

Pregnancy Testing. During pregnancy, the placenta produces significant amounts of hCG, which can be detected in maternal urine. Over-the-counter pregnancy kits containing antibodies specific for the unique β-subunit of hCG qualitatively assay for the presence of hCG and can detect pregnancy within a few days after a woman’s first missed menstrual period.

Quantitative measurements of plasma hCG concentration by radioimmunoassay can indicate whether pregnancy is proceeding normally and can help to
detect the presence of an ectopic pregnancy, hydatidiform mole, or choriocarcinoma. Such assays also are used to follow the therapeutic response of malignancies that secrete hCG, such as germ cell tumors.

**Timing of Ovulation.** Ovulation occurs ~36 hours after the onset of the LH surge. Therefore urinary concentrations of LH, as measured with an over-the-counter radioimmunoassay kit, can be used to predict the time of ovulation. Urine LH levels are measured every 12-24 hours, beginning on day 10-12 of the menstrual cycle (assuming a 28-day cycle), to detect the rise in LH and estimate the time of ovulation. This estimate facilitates the timing of sexual intercourse to optimize the chance of achieving pregnancy.

**Localization of Endocrine Disease.** Measurements of plasma LH and FSH levels with β subunit–specific radioimmunoassays are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotropic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. A plasma FSH level of ≥10-12 mIU/mL on day 3 of the menstrual cycle, indicative of decreased ovarian reserve, is associated with reduced fertility, even if a woman is menstruating normally, and predicts a lower likelihood of success in assisted reproduction techniques such as in vitro fertilization.

The administration of hCG can be used to stimulate testosterone production and thus to assess Leydig cell function in males suspected of having primary hypogonadism (e.g., in delayed puberty). Serum testosterone levels are assayed after multiple injections of hCG. A diminished testosterone response to hCG indicates Leydig cell failure; a normal testosterone response suggests a hypothalamic-pituitary disorder and normal Leydig cells.

**Therapeutic Uses of the Gonadotropins**

**Male Infertility.** In men with impaired fertility secondary to gonadotropin deficiency (hypogonadotropic hypogonadism), gonadotropins can establish or restore fertility. Due to expense and to the occasional development of antibody-mediated resistance to gonadotropins with prolonged use, standard treatment has been to induce sexual development with androgens, reserving gonadotropins until fertility is desired.

Treatment typically is initiated with hCG (1500-2000 IU/m² body surface area) intramuscularly every other day for six doses. If this does not induce testicular descent, orchiopexy should be performed. Some experts prefer surgery as the initial approach based on the association of hCG treatment with germ cell apoptosis in certain experimental settings (Ritzen, 2008).

**POSTERIOR PITUITARY HORMONES: OXYTOCIN AND VASOPRESSIN**

The structures of the neurohypophyseal hormones oxytocin and arginine vasopressin (also called antidiuretic hormone, or ADH) and the physiology and pharmacology of vasopressin are presented in Chapter 25. The following discussion emphasizes the physiology of oxytocin. Therapeutic uses of synthetic oxytocin as a uterine-stimulating agent to induce or augment labor in selected pregnant women and to decrease postpartum hemorrhage are described in Chapter 66.

**Physiology of Oxytocin**

**Biosynthesis of Oxytocin.** Oxytocin is a cyclic nonapeptide that differs from vasopressin by only two amino
Oxytocin also increases local prostaglandin production, which further increases progressively until the sharp rise that constitutes the initiation of labor. Oxytocin stimulates the frequency and force of uterine contractions. Uterine responsiveness to oxytocin roughly parallels this increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the oxytocin receptors. Progesterone antagonizes the stimulatory effect of oxytocin in vitro, and refractoriness to progesterone in late pregnancy may contribute to the normal initiation of human parturition.

Because of difficulties associated with the measurement of oxytocin levels and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy has been highly debated. Exogenous oxytocin can initiate or enhance rhythmic contractions at any time, but a considerably higher dose is required in early pregnancy. An eight-fold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy, mostly in the last 9 weeks, and is accompanied by a 30-fold increase in oxytocin receptor numbers between week 32 and term. The finding that the oxytocin antagonist atosiban is effective in suppressing preterm labor further supports the physiological importance of oxytocin in this setting.

**Breast.** Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the sucking infant.

**Brain.** As noted earlier, oxytocin is synthesized by hypothalamic neurons, predominantly located in the paraventricular and supraoptic nuclei. Studies in rodents and humans have implicated oxytocin as an important CNS regulator of trust and of autonomic systems linked to anxiety and fear (Leng et al., 2008).

Brain regions proposed to be critical in the response to fearful stimuli, including the amygdala, midbrain, and striatum, showed decreased activation in response to stressful stimuli following oxytocin treatment (Baumgartner et al., 2008; Huber et al., 2005). The role of perturbations of oxytocin signaling in mental conditions such as social phobia and autism and the possible therapeutic benefit of drugs that manipulate CNS oxytocin effects are exciting areas of ongoing investigation.

**Clinical Therapeutics of Oxytocin**

Deficiencies of oxytocin associated with disorders of the posterior pituitary impair milk letdown after delivery and may be one of the earliest signs of pituitary insufficiency secondary to postpartum hemorrhage (Sheehan’s syndrome); oxytocin is not used clinically in this setting. Rather, oxytocin is used therapeutically to induce or augment labor and to treat or prevent postpartum hemorrhage, as described in Chapter 66.
Progress continues to be made in the pharmacotherapy of endocrine and reproductive disorders related to the anterior pituitary gland. In children, the indications for therapy with recombinant human GH have been expanded beyond patients with classic, unequivocal GH deficiency, and the drug increasingly is used in conditions such as Turner’s syndrome, Noonan’s syndrome, chronic renal failure, cystic fibrosis, and other conditions associated with short stature, including idiopathic short stature. Recombinant human GH also is used increasingly to treat adults with GH deficiency, with proposed benefits that include increased muscle mass, decreased adiposity, increased bone mineral density, and improved subjective well-being. Adverse effects occur more commonly in adults, and the dose should be adjusted so that the serum IGF-1 level is in the mid-normal range.

Pharmacotherapy also plays an important role in the treatment of functional tumors that produce GH (gigantism/acromegaly) or prolactin (prolactinomas). For acromegaly, sustained-release preparations of somatostatin analogs (e.g., octreotide and lanreotide) normalize GH and IGF-1 levels in ~65% of patients. Pegvisomant, a GH receptor antagonist, is even more effective, normalizing these parameters in up to 90% of patients. For prolactinomas, dopamine receptor agonists remain the mainstay of treatment. Cabergoline generally is used because of its lower incidence of side effects; when pregnancy is desired, bromocriptine is preferred.

Pituitary hormones also have a role in reproductive medicine. Both GnRH receptor agonists and antagonists are used to down-regulate gonadotropin levels and block endogenous production of sex steroids. Indications include interruption of central precocious puberty, therapy of cancers whose growth is stimulated by sex steroids (e.g., breast and prostate), and suppression of endogenous gonadotropins in assisted reproduction technologies. Gonadotropins are frequently used in assisted reproduction technologies to stimulate follicular maturation and to induce ovulation. Recombinant gonadotropins largely are replacing gonadotropins purified from human urine in clinical use.

**BIBLIOGRAPHY**

This page intentionally left blank
Thyroid hormone is essential for normal development, especially of the central nervous system (CNS). In the adult, thyroid hormone maintains metabolic homeostasis and influences the function of virtually all organ systems. Thyroid hormone contains iodine that must be supplied by nutritional intake. The thyroid gland contains large stores of thyroid hormone in the form of thyroglobulin. These stores maintain systemic concentrations of thyroid hormone despite variations in iodine availability and nutritional intake. The thyroidal secretion is predominantly the prohormone thyroxine, which is converted in the liver and other tissues to the active form, triiodothyronine. Local activation of thyroxine also occurs in target tissues (e.g., brain and pituitary) and is increasingly recognized as an important regulatory step in thyroid hormone action. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone, thyrotropin (TSH), in a classic negative-feedback system. The predominant actions of thyroid hormone are mediated through binding to nuclear thyroid hormone receptors (TRs) and modulating transcription of specific genes. Thyroid hormones share a common mechanism of action with steroid and steroid-like hormones, such as vitamin D and the retinoids, whose receptors are members of a superfamily of nuclear receptors (Chapter 3). Although the predominant actions of thyroid hormone are nuclear, actions of thyroid hormone outside the nucleus have been reported.

Disorders of the thyroid are common. Thyroid nodules and goiter, thyroid enlargement, are the most common abnormalities and can be either benign or malignant processes. In most of these patients, circulating thyroid hormone levels are normal. Overt hyperthyroidism and hypothyroidism, thyroid hormone excess or deficiency, are usually associated with dramatic clinical manifestations. Milder disease often has a more subtle clinical presentation and is identified based on abnormal biochemical tests of thyroid function. Screening of the newborn population for congenital hypothyroidism occurs in all developed countries, and when followed by the prompt institution of appropriate thyroid hormone replacement therapy, has dramatically decreased the incidence of mental retardation and cretinism. Maternal and neonatal hypothyroidism, due to iodine deficiency, remains the major preventable cause of mental retardation worldwide, although much progress has been made in eradicating iodine deficiency.

Effective treatment of most thyroid disorders is readily available. Treatment of the hypothyroid patient consists of thyroid hormone replacement. Treatment options for the hyperthyroid patient include anti-thyroid drugs to decrease hormone synthesis and secretion, destruction of the gland by the administration of radioactive iodine, or surgical removal. In most patients, disorders of thyroid function can be either cured or have their diseases controlled. Likewise, thyroid malignancies are most often localized and resectable. Metastatic disease often responds to radioiodide treatment but may become highly aggressive and unresponsive to conventional treatment. Newer therapies that target specific genetic mutations in malignancies have shown significant activity in both medullary and papillary thyroid cancers.

**THYROID**

The thyroid gland is the source of two fundamentally different types of hormones. The thyroid follicle produces the iodothyronine hormones *thyroxine* (T₄) and *3,5,3’-triiodothyronine* (T₃). These hormones are essential for normal growth and development and play an
important role in energy metabolism. The thyroid also contains parafollicular cells (C-cells) that produce calcitonin (Chapter 44).

History. The thyroid is named for the Greek word for “shield shaped,” from the shape of the nearby tracheal cartilage. It was first recognized as an organ of importance when thyroid enlargement was observed to be associated with changes in the eyes and the heart in the condition we now call hyperthyroidism. Parry saw his first patient in 1786 but did not publish his findings until 1825. Graves reported the disorder in 1835 and Basedow in 1840. Hypothyroidism was described later, in 1874, when Gull associated atrophy of the gland with the symptoms characteristic of hypothyroidism. The term myxedema was applied to the clinical syndrome in 1878 by Ord in the belief that the characteristic thickening of the subcutaneous tissues was due to excessive formation of mucus. In 1891, Murray first treated a case of hypothyroidism by injecting an extract of sheep thyroid gland, later shown to be fully effective when given by mouth. The successful treatment of thyroid deficiency by administering thyroid extract was an important step toward modern endocrinology.

Exirpation experiments to elucidate the function of the thyroid were at first misinterpreted because of the simultaneous removal of the parathyroids. However, Gley’s research on the parathyroid glands in the late 19th century allowed the functional differentiation of these two endocrine glands. The structure of parathyroid hormone, however, was not reported until the early 1970s. Calcitonin was discovered in 1961, demonstrating that the thyroid gland produced a hormone in addition to thyroxine.

Chemistry of Thyroid Hormones. The principal hormones of the thyroid gland are the iodine-containing amino acid derivatives of thyronine (T₄ and T₃; Figure 39–1). Following the isolation and the chemical identification of thyroxine, it was generally thought that all the hormonal activity of thyroid tissue could be accounted for by its content of thyroxine. However, careful studies revealed that crude thyroid preparations possessed greater calorigenic activity than could be accounted for by their thyroxine content. The presence of a “second” thyroid hormone was debated, but triiodothyronine was finally detected, isolated, and synthesized by Gross and Pitt-Rivers (1952). Triiodothyronine has a much higher affinity for the nuclear thyroid hormone receptor compared with thyroxine and is much more potent biologically on a molar basis. The subsequent demonstration of T₃ production from T₄ in athyreotic humans led to the practice of effective replacement in hypothyroidism with levothyroxine only (Braverman et al., 1970).

Structure–Activity Relationships. The structural requirements for a significant degree of thyroid hormone activity have been defined (Baxter and Webb, 2009; Yoshihara et al., 2003). The 3′-monosubstituted compounds are more active than the 3′,5′-disubstituted molecules. Thus, triiodothyronine is five times more potent than thyroxine, and 3′-isopropyl-3,5-diiodothyronine has seven times the activity. Substitutions at the 3,5,3′, and 5′ sites influence the conformation of the molecule. In thyronine, the two rings are angulated at ~120° at the ether oxygen and are free to rotate on their axes. As depicted schematically in Figure 39–2, the 3,5 iodines restrict rotation of the two rings, which tend to take up positions perpendicular to one another. In general, the affinity of iodothyronines for the thyroid hormone receptors (TRs) parallels their biological potency (Yen, 2001), but additional factors can affect therapeutic potency, including affinity for plasma proteins, rate of metabolism, and rate of entry into cell nuclei. Specific thyroid hormone transporters, such as MCT8, are likely to be important in specific tissues.

The stereochemical nature of the thyroid hormones plays an important role in defining hormone activity. Many structural analogs of thyroxine have been synthesized to define the structure–activity relationship, to detect antagonists of thyroid hormones, and to find compounds exhibiting a desirable activity while not showing unwanted effects. Introduction of specific arylmethyl groups at the 3′ position of triiodothyronine results in analogs that are liver-selective, cardiac-sparing thyromimetics (Brenta et al., 2007). Solving the x-ray crystallographic structure of the ligand binding domains of the nuclear thyroid hormone receptors α and β has resulted in the rapid development of a range of TR isoform-selective compounds. The difference in the ligand binding domain pocket between TRα and TRβ is only a single amino acid (Ser 277 in TRα.
and Asn 331 in TRβ). GC-1, a TRβ-specific agonist, stabilizes the ligand binding domain by promoting hydrogen bonding between Asn331 and Arg282. GC-1 has a 10-fold greater affinity for TRβ, the predominant TR isoform in the liver, than TRα, the predominant TR isoform in the heart, and lowers cholesterol without stimulating the heart. Cholesterol lowering with cardiac sparing by GC-1 and other TRβ-selective agonists, however, is also the result of much higher distribution in the liver and less in the heart compared with T3. Similar compounds, such as KB-141, lower cholesterol in clinical studies (Baxter and Webb, 2009). Interestingly, none of these newer thyroid hormone analogs contains iodine or any halogen.

Biosynthesis of Thyroid Hormones. The synthesis of the thyroid hormones is unique, complex, and seemingly inefficient. The thyroid hormones are synthesized and stored as amino acid residues of thyroglobulin, a protein constituting the vast majority of the thyroid follicular colloid (Rubio and Medeiros-Neto, 2009). The thyroid gland is unique in storing great quantities of potential hormone in this way, and extracellular thyroglobulin can represent a large portion of the thyroid mass. Thyroglobulin is a complex glycoprotein made up of two apparently identical subunits, each of 330,000 Da. Interestingly, molecular cloning has revealed that thyroglobulin belongs to a superfamily of serine hydrolases, including acetylcholinesterase (Chapter 10).

The major steps in the synthesis, storage, release, and interconversion of thyroid hormones are as follows:

1. uptake of iodide ion (I−) by the gland
2. oxidation of iodide and the iodination of tyrosyl groups of thyroglobulin
3. coupling of iodothyrosine residues by ether linkage to generate the iodothyronines
4. resorption of the thyroglobulin colloid from the lumen into the cell
5. proteolysis of thyroglobulin and the release of thyroxine and triiodothyronine into the blood
6. recycling of the iodine within the thyroid cell via de-iodination of mono- and diiodotyrosines and reuse of the I−
7. conversion of thyroxine (T4) to triiodothyronine (T3) in peripheral tissues as well as in the thyroid

These processes are summarized in Figure 39–3 and described in the correspondingly labeled sections that follow.

1. Uptake of Iodide. Iodine ingested in the diet reaches the circulation in the form of iodide ion (I−). Under normal circumstances, the I− concentration in the blood is very low (0.2-0.4 μg/dL; ~15-30 nM), but the thyroid efficiently and actively transports the ion via a specific membrane-bound protein, termed the sodium-iodide symporter (NIS) (Dohan et al., 2003). As a result, the ratio of thyroid to plasma iodide concentration is usually between 20 and 50 and can exceed 100 when the gland is stimulated. The iodide transport mechanism is inhibited by a number of ions such as thiocyanate and perchlorate (Figure 39–3). Thyrotropin (thyroid-stimulating hormone [TSH]) stimulates NIS gene expression and promotes insertion of NIS protein into the membrane in a functional configuration. Thus decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing NIS protein expression (Eng et al., 1999).

NIS has been identified in many other tissues, including the salivary glands, gastric mucosa, midportion of the small intestine, choroid plexus, skin, mammary gland, and perhaps the placenta, all of which maintain a concentration of iodide greater than that of the blood. Iodide accumulation by the placenta and mammary gland may provide adequate supplies for the fetus and infant. Iodine accumulation throughout the body is mediated by a single NIS gene. Individuals with congenital NIS gene mutations have absent or defective iodine concentration in all tissues known to concentrate iodine.

2. Oxidation and Iodination. Consistent with the conditions generally necessary for halogenation of aromatic rings, the iodination of tyrosine residues requires the iodinating species to be in a higher state of oxidation than is the anion. The iodinating species is hypoiiodite, either as hypoiiodous acid or as an enzyme-linked species (Magnusson et al., 1984).

The oxidation of iodide to its active form is accomplished by thyroid peroxidase, a heme-containing enzyme that uses hydrogen peroxide (H2O2) as the oxidant (Dunn and Dunn, 2001). The peroxidase is membrane bound and appears to be concentrated at or near the apical surface of the thyroid cell. The reaction results in the formation of monoiodotyrosyl and diiodotyrosyl residues in
thyroglobulin just prior to its extracellular storage in the lumen of the thyroid follicle. The formation of the H2O2 that serves as a substrate for the peroxidase probably occurs near its site of utilization and is stimulated by a rise in cytosolic Ca2+ (Takasu et al., 1987). The TSH receptor is notably promiscuous in its coupling, stimulating members of four G protein families including Gq, which couples to the PLC-IP3-Ca2+ pathway (Laugwitz et al., 1996); thus, a Ca2+-dependent effect on H2O2 production may be a means by which TSH stimulates the organification of iodide in thyroid cells (Figure 39–3).

3. Formation of Thyroxine and Triiodothyronine from Iodotyrosines. The remaining synthetic step is the coupling of two diiodotyrosyl residues to form thyroxine or of monoiodotyrosyl and diiodotyrosyl residues to form triiodothyronine. These oxidative reactions apparently are catalyzed by the same thyroid peroxidase. The mechanism involves the enzymatic transfer of groups, perhaps as iodotyrosyl free radicals or positively charged ions, within thyroglobulin.

Although many other proteins can serve as substrates for the peroxidase, none is as efficient as thyroglobulin in yielding thyroxine. Presumably, conformation of thyroglobulin facilitates this coupling reaction. Thyroxine formation primarily occurs near the amino terminus of the protein, whereas most of the triiodothyronine is synthesized near the carboxy terminus (Dunn and Dunn, 2001). The relative rates of synthetic activity at the various sites depend on the concentration of TSH and the availability of iodide. Iodine deficiency is associated with an increase in thyroidal T3 relative to T4 content (Zimmerman, 2009). Because triiodothyronine is the transcriptionally active iodothyronine and contains only three-fourths as much iodine, a decrease in the quantity of available iodine need have little impact on the effective amount of thyroid hormone elaborated by the gland. Although a decrease in the availability of iodide and the associated increase in the proportion of monoiodotyrosine favor the formation of triiodothyronine over thyroxine, a deficiency in diiodotyrosine ultimately can impair the formation of both compounds. Intrathyroidal and secreted T3 are also generated by the 5′-deiodination of thyroxine.

4. Resorption; 5. Proteolysis of Colloid; and, 6. Secretion of Thyroid Hormones. Because T4 and T3 are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a thyroglobulin receptor, megalin. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. It is generally believed that thyroglobulin must be completely broken down into its constituent amino acids for the hormones to be released. The molecular mass of thyroglobulin is 660,000 Da, and the protein is made up of ~300 carbohydrate residues and 5500 amino acid residues.

**Figure 39–3. Major pathways of thyroid hormone biosynthesis and release.** Abbreviations: Tg, thyroglobulin; DIT, diiodotyrosine; MIT, monoiodotyrosine; TPO, thyroid peroxidase; HOI, hypooiodous acid; EOI, enzyme-linked species; D1 and D2, deiodinases (see Table 39–1); PTU, propylthiouracil; MMI, methimazole.
residues, only two to five of which are thyroxine; thus this is an extravagant process.

TSH enhances the degradation of thyroglobulin by increasing the activity of several thiol endopeptidases of the lysosomes. Endopeptidases selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases (Dunn and Dunn, 2001). The liberated hormones then exit the cell, presumably at its basal membrane. When thyroglobulin is hydrolyzed, monoiodotyrosine and diiodotyrosine also are liberated but usually do not leave the thyroid; rather, they are selectively metabolized and the iodine, liberated as $I^-$, is reincorporated into protein. The iodotyrosine deiodinase enzyme, DHAL1, is essential for conserving iodine and mutations of this gene identified in several kindreds are associated with goitrous hypothyroidism and cognitive deficit (Moreno et al., 2008). Normally, all this iodide is reused; however, when proteolysis is activated intensely by TSH, some of the iodide reaches the circulation, at times accompanied by trace amounts of the iodotyrosines.

7. Thyroid Hormone Metabolism and the Conversion of Thyroxine to Triiodothyronine in Peripheral Tissues. The normal daily production of thyroxine is estimated to range between 80 and 100 $\mu$g; that of triiodothyronine is between 30 and 40 $\mu$g. Although triiodothyronine is secreted by the thyroid, metabolism of thyroxine by $5'$, or outer ring, deiodination in the peripheral tissues accounts for ~80% of circulating triiodothyronine (Figure 39–4). In contrast, removal of the iodine on position 5 of the inner ring produces the metabolically inactive $3',5'$-triiodothyronine (reverse $T_3$, $rT_3$; Figure 39–1). Under normal conditions, ~40% of $T_4$ is converted to each of $T_3$ and $rT_3$, and ~20% is metabolized via other pathways, such as glucuronidation in the liver and excretion in the bile. Normal circulating concentrations of $T_4$ in plasma range from 4.5-11 $\mu$g/dL; those of $T_3$ are ~1/100 of that (60-180 ng/dL).

Key properties of the three iodothyronine deiodinases are summarized in Table 39–1. The types 1 and 2 deiodinases (D1, D2) convert thyroxine to triiodothyronine (St. Germain et al., 2009). These enzymes contribute approximately equally to the plasma $T_3$ in rats, but it has not been possible to determine their relative contributions in humans. D1 is expressed primarily in the liver and kidney, and also in the thyroid and pituitary (Figure 39–5). It is upregulated in hyperthyroidism and downregulated in hypothyroidism. A clinically important feature of D1 is its inhibition by the anti-thyroid drug propylthiouracil. D1 is localized to the plasma membrane, and the $T_3$ it produces equilibrates rapidly with the plasma. D2 is expressed primarily in the CNS (including the pituitary and hypothalamus) and brown adipose tissue, also in the thyroid, and at very low levels in other organs such as skeletal muscle. The activity of D2 is unaffected.

Figure 39–4. Pathways of iodothyronine deiodination.
by propylthiouracil. D2 localizes to the endoplasmic reticulum, which facilitates access of D2-generated T₃ to the nucleus. Hence organs that express D2 tend to use the locally generated T₃ to increase the occupancy of nuclear T₃ receptors, and D2-generated T₃ equilibrates slowly with the plasma. D2 is dynamically regulated by its substrate, thyroxine, such that elevated levels of the enzyme are found in hypothyroidism and suppressed levels are found in hyperthyroidism. Thus, D2 autoregulates the intracellular supply of triiodothyronine in organs in which it is expressed.

Inner ring- or 5-deiodination, the main inactivating pathway of T₃ metabolism, is catalyzed mainly by the type 3 deiodinase (D3), and to some extent also by D1. D3 is found at highest levels in the CNS and placenta, and it also is expressed in skin and uterus (St. Germain et al., 2009). It is highly expressed in hemangiomas. D3 can be induced at sites of inflammation, and at least in an animal model this can result in local hypothyroidism (Peeters et al., 2003; Simonides et al., 2008).

D2 and D3 also play important roles in regulating local T3 levels during development, during which thyroid hormone tends to promote differentiation and decrease proliferation. Examples include chondrocyte development and bone differentiation, and auditory (cochlea) development. In the brain, D2 is expressed in glial cells and D3 in neurons. Because T₃ receptors are enriched in neurons, the current model is that glial cells convert T₄ to T₃, which is then exported and taken up by neurons where it activates T₃ receptors, with subsequent degradation by D3 and termination of the T₃ effect. There is a growing recognition of circumstances where D2 and D3 regulate local thyroid hormone levels independent of the plasma T₄ and T₃ concentrations.

The three deiodinases contain the rare amino acid selenocysteine in their active sites. Incorporation of selenocysteine into the growing peptide chain is a complex process involving multiple proteins. Mutations in one such protein, SECIS binding protein 2, are associated with abnormal circulating thyroid hormone levels (Dumitrescu et al., 2005).

**Transport of Thyroid Hormones in the Blood.** Iodine in the circulation is normally present in several forms, with 95% as organic iodine and ~5% as iodide. Most organic iodine is thyroxine (90-95%); triiodothyronine represents a relatively minor fraction (~5%). The thyroid hormones are transported in the blood in strong but noncovalent association with certain plasma proteins (Schussler, 2000).

Thyroxine-binding globulin (TBG) is the major carrier of thyroid hormones. It is an acidic glycoprotein with a molecular mass of ~63,000 Da that binds one molecule of T₄ per molecule of protein.

with a very high affinity (the equilibration dissociation constant, $K_d$, is $\sim 10^{-10}$ M). $T_3$ is bound less avidly. Thyroxine, but not triiodothyronine, also is bound by transthyretin (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and primarily binds thyroxine with an equilibrium dissociation constant $\sim 10^{-7}$ M. Transthyretin has four apparently identical subunits but only a single high-affinity binding site. Albumin also can bind thyroxine when the more avid carriers are saturated, but it is difficult to estimate its quantitative or physiological importance except in familial dysalbuminemic hyperthyroxinemia. This syndrome is an autosomal dominant disorder characterized by the increased affinity of albumin for thyroxine due to a point mutation in the albumin gene. There are a number of genetic defects of thyroid-binding globulin (Refetoff, 1989), but these individuals generally have normal circulating free thyroid hormones and serum TSH, and they are euthyroid.

Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage ($\sim 0.03\%$ of thyroxine and $\sim 0.3\%$ of triiodothyronine) of the total hormone in plasma. The differential binding affinities for serum proteins also contribute to establishing the 10- to 100-fold differences in circulating hormone concentrations and half-lives of $T_4$ and $T_3$.

Essential to understanding the regulation of thyroid function is the “free hormone” concept: Only the unbound hormone has metabolic activity. Thus, because of the high degree of binding of thyroid hormones to plasma proteins, changes in either the concentrations of these proteins or the binding affinity of the hormones for the proteins has major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions, such as the changes in circulating concentrations of estrogens during pregnancy or during the administration of oral estrogens, can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (Table 39–2). However, because the pituitary responds to and regulates circulating free hormone levels, minimal changes in free hormone concentrations are seen. Therefore, laboratory tests that measure only total hormone levels can be misleading. Appropriate tests of thyroid function are discussed later in this chapter.

Degradation and Excretion (Figure 39–6). Thyroxine is eliminated slowly from the body, with a $t_{1/2}$ of 6–8 days. In hyperthyroidism, the $t_{1/2}$ is shortened to 3–4 days, whereas in hypothyroidism it may be 9–10 days. These changes presumably reflect altered rates of metabolism of the hormone. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The increase in TBG is due to the estrogen-induced increase in the sialic acid content of the synthesized TBG, resulting in decreased TBG clearance. The opposite effect is observed when there is reduced protein binding of thyroid hormones or when binding to protein is inhibited by certain drugs (Table 39–2). $T_3$, which is less avidly bound to protein, has a $t_{1/2}$ of $\sim 1$ day.

The liver is the major site of non-deiodinative degradation of thyroid hormones; T₄ and T₃ are conjugated with glucuronic and sulfuric acids through the phenolic hydroxyl group and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in feces as the free compounds.

As discussed earlier, the major route of metabolism of T₄ is deiodination to either T₃ or reverse T₃. Triiodothyronine and reverse T₃ are deiodinated to three different diiodothyronines, which are further deiodinated to two monoiodothyronines (Figure 39–4), inactive metabolites that are normal constituents of human plasma. Additional metabolites (monoiodotyrosine and diiodotyrosine) in which the diphenyl ether linkage is cleaved have been detected both in vitro and in vivo.

**Regulation of Thyroid Function.** Thyrotropin or TSH is a glycoprotein hormone with α and β subunits analogous to those of the gonadotropins. Its structure is discussed with those of the other glycoprotein hormones in Chapter 38. TSH is secreted in a pulsatile manner and circadian pattern; its levels in the circulation are highest during sleep at night. TSH secretion is precisely controlled by the hypothalamic peptide thyrotropin-releasing hormone (TRH) and by the concentration of free thyroid hormones in the circulation. Extra thyroid hormone inhibits transcription of both the TRH gene and the genes encoding the α and β subunit of thyrotropin, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress (Chiamolera and Wondisford, 2009). Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH in the absence of exogenous hormone in an attempt to stimulate the thyroid to secrete more hormone. Additional mechanisms mediating the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells. Figure 39–7 summarizes the regulation of thyroid hormone secretion.

**Thyrotropin-Releasing Hormone.** TRH stimulates the release of preformed TSH from secretory granules and also stimulates the subsequent synthesis of both α and β subunits of TSH. Somatostatin, dopamine, and pharmacological doses of glucocorticoids inhibit TRH-stimulated TSH secretion.

TRH is a tripeptide with both terminal amino and carboxyl groups blocked (L-pyroglutamyl-L-histidyl-L-proline amide). The mature hormone is derived from a precursor protein that contains six copies of the tripeptide flanked by dibasic residues. TRH is synthesized by the hypothalamus and released into the hypophyseal-portal circulation, where it interacts with TRH receptors on thyrotropes. The binding of TRH to its receptor, a GPCR, stimulates the Gq-PLC-IP₃-Ca²⁺ pathway and activates PKC, ultimately stimulating the synthesis and release of TSH by the thyrotropes (Monga et al., 2008).

TRH also has been localized in the CNS in the cerebral cortex, circumventricular structures, neurohypophysis, pineal gland, and

spinal cord. These findings, as well as its localization in nerve endings, suggest that TRH may act as a neurotransmitter or neuromodulator outside of the hypothalamus. Administration of TRH to animals produces CNS-mediated effects on behavior, thermoregulation, autonomic tone, and cardiovascular function, including increases in blood pressure and heart rate. TRH also has been identified in pancreatic islets, heart, testis, and parts of the gastrointestinal tract. Its physiological role in these sites is not known. Two TRH receptors have now been identified, TRH-R1 and TRH-R2, as well as selective analogs for these receptors (Monga et al., 2008). TRH analogs with CNS activity, but without other hormonal actions, are being developed for therapeutic applications. TRH is no longer available in the U.S.

**Actions of Thyroid-Stimulating Hormone on the Thyroid.**

When TSH is given to experimental animals, the first measurable effect on thyroid hormone metabolism is increased secretion, which is detectable within minutes. All phases of hormone synthesis and release are eventually stimulated: iodide uptake and organification, hormone synthesis, endocytosis, and proteolysis of colloid. There is increased vascularity of the gland and hypertrophy and hyperplasia of thyroid cells.

These effects follow the binding of TSH to its receptor on the plasma membrane of thyroid cells. The TSH receptor is a GPCR that is structurally similar to the receptors for luteinizing hormone and follicle-stimulating hormone (Chapter 38) (Kleinau and Krause, 2009). These receptors share significant amino acid homology and have large extracellular domains that are involved in hormone binding. Binding of TSH to its receptor stimulates the $G_\alpha$-adenyl cyclase–cyclic AMP pathway. Higher concentrations of TSH activate the $G_\beta\gamma$-PLC pathway. Both the adenylyl cyclase and the phospholipase C signaling pathways appear to mediate effects of TSH on thyroid function in humans (Kogai et al., 2006).

Multiple mutations of the TSH receptor result in clinical thyroid dysfunction (Latif et al., 2009). Germline mutations can present as congenital, nonautoimmune hypothyroidism or as autosomal dominant toxic thyroid hyperplasia. Germline mutations of the TSH receptor can cause gestational hyperthyroidism due to a hypersensitivity of the receptor to HCG (Rodien et al., 1998). Somatic mutations that result in constitutive activation of the receptor are associated with hyperfunctioning thyroid adenomas (Krohn and Paschke, 2001). Finally, resistance to TSH has been described, both in families with mutant TSH receptors (Sunthornthepvarakul et al., 1995) and in those with no apparent mutations in either the TSH receptor or in TSH itself (Xie et al., 1997).

**Relation of Iodine to Thyroid Function.** Normal thyroid function obviously requires an adequate intake of iodine; without it, normal amounts of hormone cannot be made, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophic. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be 10 times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting $T_3$. In more severe iodine deficiency, adult hypothyroidism and cretinism may occur.

In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine (Zimmerman, 2009). Regions of iodine deficiency exist in Central and South America, Africa, Europe, Southeast Asia, and China. In the U.S., recommended daily allowances for iodine range from 90-120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 290 μg for lactation (Becker et al., 2006). Vegetables, meat, and poultry contain minimal amounts of iodine,
Iodine has been used empirically for the treatment of iodine-deficiency goiter for 150 years; however, its modern use evolved from extensive studies using iodine to prevent goiter in school children in Akron, Ohio, where endemic iodine-deficiency goiter was prevalent. The success of these experiments led to the adoption of iodine prophylaxis and therapy in many regions throughout the world where iodine-deficiency goiter was endemic.

The most practical method for providing small supplements of iodine for large segments of the population is the addition of iodide or iodate to table salt; iodate is now preferred. The use of iodized salt is required by law in some countries, but in others such as the U.S., the use is optional. In the U.S., iodized salt provides 100 μg of iodine per gram. Although the U.S. population remains iodine sufficient, iodine intake has steadily decreased over the last 20 years (Hollowell et al., 1998). The most recent data indicate that iodine intake has stabilized, although pregnant women remain a susceptible population for iodine insufficiency (Haddow et al., 2007; Hollowell and Haddow, 2007). Other vehicles for supplying iodine to large populations who are iodine deficient include oral or intramuscular injection of iodized oil (Elnagar et al., 1995), iodized drinking water supplies, iodized irrigation systems, and iodized animal feed.

**Thyroid Hormone Transport Into and Out of Cells.** Thyroid hormone crosses the cell membrane primarily via specific transporter proteins (Visser et al., 2008). Multiple such transporters likely exist, each expressed in overlapping but different subsets of tissues. To date, the only transporter of proven importance in humans is monocarboxylic acid transporter 8 (MCT8, SLC16A2). Ectopic expression in cultured cells demonstrates that MCT8 transports T₄ and T₃ bidirectionally across the cell membrane. MCT8 is widely expressed, including in liver, heart, and brain. MCT8 mutations cause Allan-Herndon-Dudley syndrome, characterized by a severe neurological phenotype and abnormal circulating thyroid hormone levels. The serum T₃ typically is about 2-fold elevated, associated with a slight increase in TSH and slight decrease in T₄.

MCT10 also transports T₄ and T₃ and is widely expressed, but there are no mutation studies to demonstrate its importance for thyroid hormone transport in vivo. The organic anion transporter OATP1C1 preferentially transports T₄ rather than T₃, is highly expressed in brain capillaries, and has been hypothesized to be responsible for the transport of T₄ across the blood-brain barrier (Chapter 5).

**Actions of Thyroid Hormones**

**Classical Nuclear-Mediated Effects.** Thyroid hormone action is mediated largely by the binding of T₃ to thyroid hormone receptors (TRs), which are members of the nuclear receptor superfamily of transcription factors (Bassett et al., 2003; Yen et al., 2006). This superfamily includes the receptors for steroid hormones, vitamin D, retinoic acid, and a variety of small molecule metabolites such as certain fatty acids and bile acids. The nuclear receptor superfamily also includes a number of “orphan receptors” that have no known ligands and may be regulated by posttranslational modifications or other events. The TRs have the classic nuclear receptor structure consisting of an amino terminal domain, a centrally located zinc finger DNA binding domain, and a ligand binding domain that occupies the carboxyl terminal half of the protein (Figure 39–8).

T₃ binds to TRs with ~10-fold greater affinity than does T₄, and T₄ is not thought to be biologically active in normal physiology. TRs bind to specific DNA sequences (thyroid hormone response elements, TREs) in the promoter/regulatory regions of target genes. The transcription of most target genes is repressed by unliganded TRs and induced following the binding of T₃. The mechanisms of these effects have been well studied (Yen, 2001; Yen et al., 2006). In the unliganded state, the TR ligand binding domain interacts with a co-repressor complex that includes

![Figure 39–8. Thyroid hormone receptor isoforms.](image-url)
histone deacetylases and other proteins. The binding of $T_3$ causes replacement of the co-repressor complex by a co-activator complex that includes histone acetyltransferases, methyltransferases, and other proteins. The actual situation is very complex and probably involves cyclical recruitment of multiple protein complexes to the target gene, leading to cyclical transcription despite the constant presence of $T_3$ (Liu et al., 2002). Other thyroid hormone target genes, such as those encoding TRH and the TSH subunits, are negatively regulated by $T_3$. The mechanism is not well defined, but these genes tend to be induced by the unliganded TR in addition to being repressed by $T_3$.

The TRs are the cellular homologs of the avian retroviral oncoprotein c-erbB. There are two genes that encode TRs, $THRA$ and $THRB$. $THRA$ encodes the receptor $TR\alpha1$. The biological function of $TR\alpha1$ is inferred largely through studies of genetically modified mice and cell culture experiments because human mutations in $THRA$ have not been described. Although $TR\alpha1$ is expressed in most cell types, studies in knockout mouse demonstrate that the major specific roles for this isoform are in the regulation of heart rate, body temperature, skeletal muscle function, and the development of bone and small intestine (O’Shea and Williams, 2002). Alternative splicing of the $TR\alpha$ primary transcript results in the production of $TR\alpha2$, which does not bind $T_3$ because it lacks part of the ligand-binding domain (LBD). $TR\alpha2$ is expressed ubiquitously and its function is unknown, although there is some evidence that it may inhibit $T_3$ action. A cryptic promoter within intron 7 of $THRA$ drives the production of small proteins that contain only a portion of the $TR\alpha$LBD. These non-hormone-binding proteins appear to play a role, along with $TR\alpha1$, in GI development.

The $THRB$ gene has two promoters that lead to the production of $TR\beta1$ and $TR\beta2$. These receptors have unique amino terminal domains but otherwise are identical. $TR\beta1$ is ubiquitous, whereas $TR\beta2$ has a highly restricted pattern of expression. Mutations in $THRB$ cause the syndrome of resistance to thyroid hormone (Refetoff and Dumitrescu, 2007). Studies in these patients, as well as in genetically modified mice and in cell culture, demonstrate a specific role for $TR\beta1$ in liver metabolism (including the hypocholesterolemic effect of $T_3$), and for $TR\beta2$ in the negative feedback by $T_3$ on hypothalamic TRH and pituitary TSH (O’Shea and Williams, 2002). $TR\beta2$ also is important in the development of cones in the retina and in inner ear development.

Non-genomic Effects of Thyroid Hormone. Although nuclear receptors were classically described as being DNA-binding transcription factors, it is now clear that these proteins also can be found outside the nucleus where they can exert biological effects via rapid nongenomic mechanisms (Davis et al., 2008). TRs associate in a $T_3$-dependent manner with the p85$\alpha$ subunit of phosphatidylinositol 3-kinase (PI3K), which results in the phosphorylation and activation of PKB/Akt (Hiroi et al., 2006). The PI3K/Akt pathway has broad effects on cellular metabolism. For example, it stimulates NO production by endothelial cells, which leads to vasodilation. Hence, $T_3$ administration causes rapid vasodilation.

There also is evidence for non-genomic actions of thyroid hormone via a plasma membrane receptor within integrin $\alpha V\beta 3$ (Davis et al., 2008). This putative receptor binds extracellular $T_4$ in preference to $T_3$, resulting in activation of MAP kinase. However, the importance of non-genomic actions in thyroid hormone physiology and pathophysiology remains uncertain.

Effects of Thyroid Hormone Metabolites. 3-Iodothyronamine and thyronamine, naturally occurring metabolites of $T_4$, are ligands for the GPCR trace amine-associated receptor 1 (TAAR1) (Scanlan et al., 2004). Administration of 3-iodothyronamine or thyronamine to mice causes hypothermia and bradycardia, presumably through activation of TAAR1 and G$\alpha$. 3-Iodothyronamine activation of TAAR1 also induces insulin secretion in the MIN6 cell line (Regard et al., 2007). Interestingly, 3-iodothyronamine also binds to the $\alpha_{1A}$ adrenergic receptor, leading to decreased insulin secretion from mouse islets via a $G\beta\gamma$ protein-coupled mechanism (Regard et al., 2007). The importance of these effects in human physiology and disease remains to be determined.

MAJOR CLINICAL EFFECTS OF THYROID HORMONES

Growth and Development. Perhaps the most dramatic example of thyroid hormone action is amphibian metamorphosis, in which the tadpole is almost magically transformed into a frog by triiodothyronine. Not only does the animal grow limbs, lungs, and other terrestrial accoutrements, but $T_3$ also causes the tail to regress.

Thyroid hormone plays a critical role in brain development (Anderson et al., 2003, Bernal, 2007). The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation during the first 2 weeks of postnatal life prevents the development of these disturbed morphological changes.

The mechanisms by which thyroid hormone promotes brain development are incompletely understood. Surprisingly, mice with genetic deletions of $TR\alpha$, $TR\beta$, or both have essentially normal brain development (Gothe et al., 1999). Equally surprisingly, genetic deletion of $TR\alpha1$ protects mice from the toxic effects of hypothyroidism on brain development (Morte et al., 2002). Perhaps
it is the effects of unliganded TRs that result in impaired brain development, such that either T3 or the absence of TRs is protective. T3 induces the expression of a number of genes that could plausibly be important in normal brain development, but the exact roles of these specific gene inductions are not known (Anderson et al., 2003). The T3-dependent expression of many proteins appears to be merely delayed in the hypothyroid animal; normal levels are eventually achieved. Myelin basic protein, a major component of myelin, is induced by T3 during development. Decreased expression of myelin basic protein in the hypothyroid brain impairs myelination. RC3/neurogranin, a protein involved in synaptic plasticity, also is induced by T3. Through its induction of the transcription factor BTEB (basic transcription element binding protein), T3 expands a network of secondary genes in brain development.

The actions of thyroid hormones on protein synthesis and enzymatic activity are not limited to the brain, and in fact most tissues are affected by the administration of thyroid hormone or by its deficiency. The extensive defects in growth and development in cretins vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Cretinism is usually classified as endemic or sporadic. Endemic cretinism occurs in regions of endemic goiter and usually is caused by extreme iodine deficiency. Goiter may or may not be present. Sporadic cretinism is a consequence of failure of the thyroid to develop normally or the result of a defect in the synthesis of thyroid hormone. Goiter is present if a synthetic defect is at fault. While detectable at birth, cretinism often is not recognized until 3-5 months of age. When untreated, the condition eventually leads to such gross changes as to be unmistakable: The child is dwarfed, with short extremities, mentally retarded, inactive, uncomplaining, and listless. The face is puffy and expressionless, and the enlarged tongue may protrude through the thickened lips of the half-opened mouth. The skin may have a yellowish hue and feel doughy, dry, and cool to the touch. The heart rate is slow, the body temperature may be low, closure of the fontanel is delayed, and the teeth erupt late. Appetite is poor, feeding is slow and interrupted by choking, constipation is frequent, and there may be an umbilical hernia.

For treatment to be fully effective, the diagnosis must be made long before these changes are obvious. In regions of endemic cretinism due to iodine deficiency, iodine replacement is best instituted before pregnancy. However, iodine replacement given to pregnant women up to the end of the second trimester has been shown to enhance the neurological and psychological development of the children (Cao et al., 1994). Screening of newborn infants for deficient thyroid function is carried out in the U.S. and in most industrialized countries. Concentrations of TSH and thyroxine are measured in blood from the umbilical cord or from a heel stick. The incidence of congenital dysfunction of the thyroid is ~1 per 4000 births.

**Thermogenic Effects.** Thyroid hormone is necessary for both obligatory thermogenesis (the heat resulting from vital processes) as well as for facultative or adaptive thermogenesis (Silva, 2006). Only a few organs, including the brain, gonads, and spleen, are unresponsive to the thermogenic effects of T3. Obligatory thermogenesis is the result of T3 making most biological processes thermodynamically less efficient for the sake of producing heat. Multiple mechanisms underlie the stimulation of obligatory thermogenesis, but the pathways involved and their quantitative contributions have yet to be fully defined. The ability of T3 to induce the skeletal muscle Ca++-dependent ATPase (SERCA1) contributes to thermogenesis by stimulating the cycling of calcium between cytosol and sarcoplasmic reticulum. Metabolic “futile cycling” (e.g., lipogenesis-lipolysis) has been considered a mechanism to produce heat, but best estimates indicate the contribution is minor. Other than in brown adipose tissue, there is no evidence that a major thermogenic mechanism is uncoupling of phosphorylation, although some groups still believe that T3 can increase the proton leak through the inner mitochondrial membrane. Regardless of the mechanism, thermogenesis is highly sensitive to thyroid hormone around the physiological range because small changes in L-thyroxine replacement doses may significantly alter resting energy expenditure in the hypothyroid patient. The discovery of type 2 deiodinase in brown fat and its activation by the sympathetic nervous system showed that thyroid hormone also is important for facultative thermogenesis. The ability of T3 to stimulate thermogenesis has evolved along with ancillary effects to support this thermogenic action, such as the stimulation of appetite and lipogenesis.

**Cardiovascular Effects.** Changes in the cardiovascular system are prominent in both hyper- and hypothyroidism (Kahaly and Dillmann, 2005). Hyperthyroid patients have tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure. Hyperthyroidism is a relatively common cause of atrial fibrillation. Hypothyroid patients have bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure.

Triiodothyronine directly regulates myocardial gene expression primarily through TRβ1, which is expressed at a higher level in cardiomyocytes than TRβ. T3 shortens diastolic relaxation (lusitropic effect) by inducing expression of the sarcoplasmic reticulum ATPase SERCa2 and decreasing phospholamban, a SERCa2 inhibitor. T3 increases the force of myocardial contraction (inotropic effect) in part by inducing expression of the ryanodine channel, the calcium channel of the sarcoplasmic reticulum. T3 induces the gene encoding the myosin heavy chain (MHC) α isoform and decreases expression of the MHC β gene. Because MHCα endows the myosin holoenzyme with greater ATPase activity, this is one mechanism by
which T₃ enhances the velocity of contraction. The chronotropic effect of T₃ is mediated by increases in the pacemaker ion current If in the sinoatrial node. Several proteins that comprise the If channel are induced by T₃, including HCN2 and HCN4. Interestingly, T₃ also appears to have a direct non-genomic vasodilating effect on vascular smooth muscle (Hiroi et al., 2006), which may contribute to the decreased systemic vascular resistance and increased cardiac output of hyperthyroidism.

**Metabolic Effects.** Thyroid hormone stimulates the expression of hepatic low-density lipoprotein (LDL) receptors and the metabolism of cholesterol to bile acids, such that hypercholesterolemia is a characteristic feature of hypothyroidism.

Thyroid hormone has complex effects on carbohydrate metabolism (Crunkhorn and Patti, 2008). Thyrotoxicosis is an insulin-resistant state. Post-receptor defects in the liver and peripheral tissues are manifested by depleted glycogen stores and enhanced gluconeogenesis. In addition, the rate of glucose absorption from the gut is increased. Compensatory increases in insulin secretion result in hyperinsulinemia. There may be impaired glucose tolerance or even clinical diabetes, but most hyperthyroid patients are euglycemic. However, diabetic patients already on insulin may have increased insulin requirements in the setting of hyperthyroidism. Conversely, hypothyroidism results in decreased absorption of glucose from the gut, decreased insulin secretion, and a reduced rate of peripheral glucose uptake. Glucose metabolism generally is not affected in a clinically significant manner in nondiabetic patients, although insulin requirements decrease in the hypothyroid patient with diabetes.

**Thyroid Hypofunction.** Hypothyroidism, known as myxedema when severe, is the most common disorder of thyroid function. Worldwide, hypothyroidism resulting from iodine deficiency remains an all-too-common problem. In non-endemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto’s thyroiditis) accounts for most cases. This disorder is characterized by high levels of circulating antibodies directed against thyroid peroxidase and, less commonly, against thyroglobulin. In addition, blocking antibodies directed at the TSH receptor may be present, exacerbating the hypothyroidism. The conditions just described are examples of primary hypothyroidism, failure of the thyroid gland itself. Central hypothyroidism occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (secondary hypothyroidism) or hypothalamic failure (tertiary hypothyroidism). Hypothyroidism present at birth (congenital hypothyroidism) is the most common preventable cause of mental retardation in the world. Diagnosis and early intervention with thyroid hormone replacement prevent the development of cretinism, as discussed earlier.

Common symptoms of hypothyroidism include fatigue, lethargy, cold intolerance, mental slowness, depression, dry skin, constipation, mild weight gain, fluid retention, muscle aches and stiffness, irregular menses, and infertility. Common signs include goiter (primary hypothyroidism only), bradycardia, delayed relaxation phase of the deep tendon reflexes, cool and dry skin, hypertension, nonpitting edema, and facial puffiness. Deficiency of thyroid hormone during the first few months of life causes feeding problems, failure to thrive, constipation, and sleepiness. Retardation of mental development is irreversible if not treated promptly. Childhood hypothyroidism impairs linear growth and bone maturation. Because the signs and symptoms of hypothyroidism are nonspecific, diagnosis requires the finding of an elevated serum TSH or, in cases of central hypothyroidism, a decreased serum free T₄. Because physicians maintain a high index of suspicion, the diagnosis usually is made at a relatively early stage. Thus, severe hypothyroidism and myxedema coma are uncommon, except in hypothyroid patients who are noncompliant with their thyroid hormone replacement therapy or individuals without access to medical care.

**Thyroid Hyperfunction.** Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Increased thyroid hormone production is the most common cause, with the common link of TSH receptor stimulation and increased iodine uptake by the thyroid gland as shown by the measurement of the percentage uptake of ¹²³I or ¹³¹I in a 24-hour radioactive iodine uptake (RAIU) test. TSH receptor stimulation is either the result of TSH receptor stimulating antibody in Graves’ disease or somatic activating TSH receptor mutations in autonomously functioning nodules or a toxic goiter. In contrast, thyroid inflammation or destruction resulting in excess “leak” of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-hour RAIU. The term subclinical hyperthyroidism is defined as those with a subnormal serum TSH and normal concentrations of T₄ and T₃. Atrial arrhythmias, excess cardiac mortality, and excessive bone loss have been associated with this profile of thyroid function tests (Biondi and Cooper, 2008).

Graves’ disease is the most common cause of high RAIU thyrotoxicosis (Brent, 2008). It accounts for 60-90% of cases, depending on age and geographic region. Graves’ disease is an autoimmune disorder characterized by increased thyroid hormone production, diffuse goiter, and immunoglobulin (Ig)G antibodies that bind to and activate the TSH receptor. This is a relatively common disorder, with an incidence of 0.02-0.4% in the U.S. Endemic areas of iodine deficiency have a lower incidence of autoimmune thyroid disease. As with most
types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1-7:1. Graves’ disease is more common between the ages of 20 and 50, but it may occur at any age. Major histocompatibility alleles (HLA) B8 and DR3 are associated with Graves’ disease in whites. Graves’ disease is commonly associated with other autoimmune diseases.

The characteristic exophthalmos associated with Graves’ disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extracocular muscles. This disorder is clinically evident with various degrees of severity in ~50% of patients with Graves’ disease, but it is present on radiological studies, such as ultrasound or CT scan, in almost all patients. The pathogenesis of Graves’ ophthalmopathy, including the role of the TSH receptor present in retro-orbital tissues, and the management of this disorder, remain controversial (Khoo and Bahn, 2007).

Toxic uninodular/multinodular goiter accounts for 10-40% of cases of hyperthyroidism and is more common in older patients. Infiltrative ophthalmopathy is absent.

A low RAIU is seen in the destructive thyroiditides and in thyrotoxicosis resulting from exogenous thyroid hormone ingestion. Low RAIU thyrotoxicosis caused by subacute (painful) and silent (painless or lymphocytic) thyroiditis represents ~5-20% of all cases. Silent thyroiditis occurs in 7-10% of postpartum women in the U.S. (Abalovich et al., 2007). Other causes of thyrotoxicosis are much less common.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat, increased motor activity, and increased sensitivity to catecholamines produced by the sympathetic nervous system. The skin is flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite and, if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Older patients may experience less manifestations of sympathetic nervous system stimulation, so called apathetic hyperthyroidism. Some individuals may show extensive muscular wasting as a result of thyroid myopathy. Patients with long-standing undiagnosed or undertreated thyrotoxicosis may develop osteoporosis due to increased bone turnover (Murphy and Williams, 2004).

The most severe form of hyperthyroidism is thyroid storm, which is discussed later in the discussion of therapeutic uses of anti-thyroid drugs.

**Thyroid Function Tests.** The development of radioimmunoassays and, more recently, chemiluminescent and enzyme-linked immunoassays for T4, T3, and TSH have greatly improved the laboratory diagnosis of thyroid disorders (Demers and Spencer, 2003). However, measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland. The total hormone concentration changes with alterations in either the amount of TBG in plasma or the binding affinity of TBG for hormones. Although equilibrium dialysis of undiluted serum and radioimmunoassay for free thyroxine (FT4) in the dialysate represent the gold standard for determining FT4 concentrations, this assay is typically not available in routine clinical laboratories. The FT4 index is an estimation of the FT4 concentration and is calculated by multiplying the total thyroxine concentration by the thyroid hormone binding ratio, which estimates the degree of saturation of TBG. The most common assays used for estimating the free T4 and free T3 concentrations employ labeled analogs of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays correlate well with free T4 concentrations measured by the more cumbersome equilibrium dialysis method and are easily adaptable to routine clinical laboratory use. However, the analog assays are affected by extremes of serum binding proteins as well as a wide variety of non-thyroidal disease states, including acute illness, and by certain drugs to a greater degree than are the free T4 index and free T4 determined by equilibrium dialysis.

In individuals with normal pituitary function, serum measurement of TSH is the thyroid function test of choice because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones.

A major use of the TSH assay is to differentiate between normal and thyrotoxic patients, who should exhibit suppressed TSH values. Indeed, the sensitive TSH assay has replaced evaluation of the response of TSH to injection of synthetic TRH (TRH stimulation test) in the thyrotoxic patient. Although the serum TSH assay is extremely useful in determining the euthyroid state and titrating the replacement dose of thyroid hormone in patients with primary hypothyroidism, abnormal serum TSH concentrations may not always indicate thyroid dysfunction. In such patients, assessment of the circulating thyroid hormone levels will further determine whether or not thyroid dysfunction is truly present. Synthetic preparations of TRH (protirelin) are no longer available in the U.S. for the evaluation of pituitary or hypothalamic failure as a cause of secondary hypothyroidism.

Recombinant human TSH (thyrotropin alfa, THYROGEN) is available as an injectable preparation to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and release thyroglobulin (Duntas and Cooper, 2008; Haugen et al., 1999; Pacini and Castangna, 2008).

**Therapeutic Uses of Thyroid Hormone**

The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism and for TSH suppression therapy in patients with thyroid cancer. Other less common uses also are discussed.

**Thyroid Hormone Preparations.** Synthetic preparations of the sodium salts of the natural isomers of the thyroid hormones are available and widely used for thyroid hormone therapy.

**Levothyroxine.** Levothyroxine sodium (L-T4, LEVOTHROID, LEVOXYL, SYNTHROID, UNITHROID, others) is available in
tables and as a lyophilized powder for injection. Concerns have been raised regarding variations in therapeutic effectiveness among the branded and generic levothyroxine products and the standards used to establish bioequivalence (Hennessey, 2006). More recently, the focus has been on improving uniformity among preparations in tablet content of levothyroxine and stability (Burman et al., 2008). Table 39–3 lists drugs and other factors that may influence levothyroxine dosage requirements.

The potency standards of levothyroxine have been narrowed from the previous standard of 90-110% to 95-105%, and the content must be stable at this level for the designated shelf life. Absorption of thyroxine occurs in the stomach and small intestine and is incomplete (~80% of the dose is absorbed). Absorption is slightly increased when the hormone is taken on an empty stomach, and it is associated with less variability in the TSH when taken this way regularly (Bach-Huynh et al., 2009). The serum T₄ peaks 2-4 hours after oral ingestion, but changes are barely discernable with once-daily dosing due to the 7-day plasma t½ of the T₄. Given this long t½, omission of one day’s dose does not materially affect the serum TSH or FT₄, but to maintain consistent dosing the patient should be instructed to take a double dose the next day. For any given serum TSH, the serum T₄/T₃ ratio is higher in patients taking levothyroxine than in patients with endogenous thyroid function, due to the fact that ~20% of circulating T₃ normally is supplied by direct thyroidal secretion (Jonklaas et al., 2008). Occasionally this may result in a levothyroxine-treated patient having a marginally elevated free T₄ and a normal TSH, which is acceptable. Follow-up blood tests typically are done ~6 weeks after any dosage change due to the 1-week plasma t½ of T₄. Dosages are discussed subsequently under specific indications.

In situations where patients cannot take oral medications or where intestinal absorption is in question, levothyroxine may be given intravenously once a day at a dose ~80% of the patient’s daily oral requirement.

**Liothyronine.** Liothyronine sodium (L-T₃) is the salt of triiodothyronine and is available in tablets (CYTOMEL) and in an injectable form (TRIOSTAT, others).

Liothyronine absorption is nearly 100% with peak serum levels 2-4 hours following oral ingestion. Liothyronine may be used occasionally when a more rapid onset of action is desired such as in the rare presentation of myxedema coma or if rapid termination of action is desired such as when preparing a thyroid cancer patient for ¹³¹I therapy. Liothyronine is less desirable for chronic replacement therapy due to the requirement for more frequent dosing (plasma t½ ≈ 0.75 days), higher cost, and transient elevations of serum T₃ concentrations above the normal range. In addition, organs that express the type 2 deiodinase use the locally generated T₃ in addition to plasma T₃, and hence there is theoretical concern that these organs will not maintain physiological intracellular T₃ levels in the absence of plasma T₄. Ten to 15 μg of liothyronine sodium three times per day typically yields a normal serum free T₃ in an athyreotic individual. However, normalization of circulating TSH may require higher levels of free T₃, perhaps because negative feedback normally relies in part on the local generation of T₃ from circulating T₄ (Koutras et al., 1981, Saberi and Utiger, 1974).

**Other Preparations.** A mixture of thyroxine and triiodothyronine 4:1 by weight is marketed as liotrix (THYROLAR). Desiccated thyroid preparations such as (ARMOUR THYROID, others), with a similar T₄:T₃ ratio, also are available. A 60-mg (1 grain) desiccated thyroid tablet is approximately equivalent in activity to 80 μg of thyroxine. This conversion can be used when changing a patient from replacement therapy with desiccated thyroid to levothyroxine, but typically such patients can be dosed with levothyroxine using dosing guidelines based on age and weight.

**Thyroid Hormone Replacement Therapy in Hypothyroidism.** Thyroxine (levothyroxine sodium) is the hormone of choice for thyroid hormone replacement therapy due to its consistent potency and prolonged duration of action. With this therapy, one relies on the types 1 and 2 deiodinases to convert T₄ to T₃ to maintain a steady serum level of free T₃.

The average daily adult replacement dose of levothyroxine sodium is 1.7 μg/kg body weight (0.8 μg/lb), although the variation about this average is substantial. Dosing should generally be based on lean body mass (Santini et al., 2005). Although not ideal, once-a-week dosing can be used in situations where compliance is otherwise not possible (Grebe et al., 1997). The goal of therapy is to normalize the serum TSH (in primary hypothyroidism) or free T₄ (in secondary or tertiary hypothyroidism) and to relieve symptoms of hypothyroidism. In primary hypothyroidism, generally it is sufficient to follow TSH without free T₄. A patient with mild primary hypothyroidism will achieve a normal TSH with substantially less than a full replacement dose, but as the endogenous thyroid function declines, the dose will need to be increased. Thus, especially in young healthy patients, it can be simpler to begin with nearly a full replacement dose. In individuals >60 years of age and those with known or suspected cardiac disease or with areas of autonomous thyroid function, institution of therapy at a lower daily dose of levothyroxine sodium (12.5-50 μg per day) is appropriate. The dose can be increased at a rate of 25 μg per day every 6-8 weeks until the TSH is normalized.

Combination therapy with levothyroxine plus liothyronine seems attractive superficially because the thyroid gland secretes T₄ and T₃. However, the T₄:T₃ ratio in human thyroid secretion is ~11:1, compared with 4:1 in the currently available combination pills. Furthermore, the short plasma t½ of T₃ would necessitate multiple daily dosing to achieve steady circulating T₃ levels. Importantly, randomized blinded controlled trials have failed to uncover evidence of a better therapeutic response to combination therapy with T₄ plus T₃, versus T₄ alone (Grozinsky-Glasberg et al., 2006). Although occasional patients find that they feel better on combination therapy, this is usually short lived. The data indicate that monotherapy with levothyroxine most closely mimics normal physiology and generally is preferred.
**Subclinical Hypothyroidism.** Subclinical hypothyroidism is the presence of a mildly elevated serum TSH concentration and a normal free T\(_4\) without obvious symptoms. Population screening has shown that subclinical hypothyroidism is very common, with a prevalence of up to 15% in some populations and up to 25% in the elderly. The prevalence is strongly influenced by the definition of the upper limit of normal of serum TSH, which itself is controversial (Surks and Hollowell, 2007). The decision to use levothyroxine therapy in these patients to normalize the serum TSH must be made on an individual basis because treatment may not be appropriate for all patients.

An elevated TSH, especially common among elderly patients and among centenarians, may even be associated with longevity (Atzmon et al., 2009). Patients with subclinical hypothyroidism who may benefit from levothyroxine therapy include those with goiter, autoimmune thyroid disease, hypercholesterolemia, cognitive dysfunction, or pregnancy, and those patients who have nonspecific symptoms that could be due to hypothyroidism (Biondi and Cooper, 2008).

**Hypothyroidism During Pregnancy.** The dose of levothyroxine in the hypothyroid patient who becomes pregnant usually needs to be increased (Abalovich et al., 2007), perhaps due to the increased serum concentration of TBG induced by estrogen, the expression of type 3 deiodinase by the placenta, and the small amount of transplacental passage of levothyroxine from mother to fetus. In addition, pregnancy may “unmask” hypothyroidism in patients with preexisting autoimmune thyroid disease or in those who reside in a region of iodine deficiency. Overt hypothyroidism during pregnancy is associated with fetal distress and impaired psychoneural development in the progeny. In addition, studies have suggested that subclinical hypothyroidism during pregnancy is associated with mildly impaired psychomotor development in the children and preterm delivery. An increase in miscarriage rate is strongly associated with the presence of anti-thyroid peroxidase antibodies, and early treatment with thyroxine may reduce miscarriages and preterm delivery. These findings strongly suggest that any degree of hypothyroidism, as judged by an elevated serum TSH or perhaps a relatively low T\(_4\), should be treated during pregnancy.

The increased levothyroxine requirement averages 30-50% and can become apparent as early as the fifth week of gestation. The magnitude of thyroxine dose adjustment is greatest for women who are athyreotic from surgical thyroidectomy or radioiodine ablation (Loh et al., 2009). The optimal way to anticipate this increased dosage need and hence to avoid an elevated TSH is not known. Some experts recommend that women increase their levothyroxine dosage by ~30% as soon as pregnancy is confirmed, which can be accomplished by taking two extra pills per week. Most measure a serum TSH in the first trimester and then adjust the thyroxine dose based on this result. Subsequent dosage adjustments would be based on serum TSH, measured 4-6 weeks after each adjustment. For non-pregnant women of reproductive age not using contraception, maintaining the TSH in the lower portion of the reference range (~0.3-2.0 mIU/L) will allow room to move within the reference range during the early part of pregnancy. For similar reasons, dosage adjustments during pregnancy should be made to bring the TSH into the lower portion of the reference range. The increased dosage requirement plateaus at about gestation week 16-20, and dosage needs fall back to prepregnancy levels immediately after delivery.

**Myxedema Coma.** Myxedema coma is a rare syndrome that represents the extreme expression of severe, longstanding hypothyroidism (Kwaku and Burman, 2007). It is a medical emergency, and even with early diagnosis and treatment, the mortality rate can be as high as 60% (Yamamoto et al., 1999). Myxedema coma occurs most often in elderly patients during the winter months. Common precipitating factors include pulmonary infection, cerebrovascular accidents, and congestive heart failure. The clinical course of lethargy proceeding to stupor and then coma is often hastened by drugs, especially sedatives, narcotics, antidepressants, and tranquilizers. Indeed, many cases of myxedema coma have occurred in hypothyroid patients who have been hospitalized for other medical problems.

Cardinal features of myxedema coma are:

- hypothermia, which may be profound
- respiratory depression
- decreased consciousness

Other clinical features include bradycardia, macroglossia, delayed reflexes, and dry, rough skin. Dilutional hyponatremia is common and may be severe. Elevated plasma creatine kinase (CK) and lactate dehydrogenase (LDH) concentrations, acidosis, and anemia are common findings. Lumbar puncture reveals increased opening pressure and high protein content. Hypothyroidism is confirmed by measuring the serum FT\(_4\) and TSH. Ultimately, myxedema coma is a clinical diagnosis.

The mainstay of therapy is supportive care, with ventilatory support, rewarmin with blankets, correction of hyponatremia, and treatment of the precipitating cause. Due to a 5-10% incidence of coexisting decreased adrenal reserve in patients with myxedema coma, intravenous steroids are indicated before initiating thyroxine therapy and should be continued until adrenal function has been proven normal (Chapter 42).

There are no randomized controlled clinical trials to evaluate the optimal form of thyroid hormone therapy in myxedema coma. Intravenous administration of thyroid hormone is advised due to uncertain absorption through the gut. Therapy with levothyroxine is
commonly begun with a loading dose of 250-500 μg followed by a
daily full replacement dose, although some clinicians omit the load-
ing dose. Some clinicians recommend adding liothyronine (10 μg
intravenously every 8 hours) with the initial dose of levothyroxine,
until the patient is stable and conscious. The limited studies that are
available suggest that excessive treatment with either levothyroxine
(>500 μg per day) or liothyronine (>75 μg) may be associated with
an increased mortality rate.

**Congenital Hypothyroidism.** Success in the treatment of
congenital hypothyroidism depends on the age at which
therapy is started. Because of this, newborn screening
for congenital hypothyroidism is routine in the U.S.,
Canada, and many other countries. In cases that do not
come to the attention of physicians until retardation of
development is clinically obvious, the detrimental
effects of thyroid hormone deficiency on mental deve-
lopment will be irreversible. If, however, therapy is insti-
tuted within the first 2 weeks of life, normal physical
and mental development can be achieved (Rose et al.,
2006). Prognosis also depends on the severity of the
hypothyroidism at birth and may be worse for infants
with thyroid agenesis.

To rapidly normalize the serum thyroxine concentration in
the congenitally hypothyroid infant, an initial daily dose of levoth-
ryoxine of 10-15 μg/kg is recommended. This dose will increase the
serum FT4 concentration to the upper half of the normal range in
most infants within 1-2 weeks. A dose of up to 17 μg/kg has been
suggested for the most severely hypothyroid infants, which can nor-
malize the serum T4 in 3 days (LaFranchi and Austin, 2007).
Laboratory evaluations of TSH and FT4 are performed 2 and 4 weeks
after treatment is initiated, every 1-2 months in the first 6 months,
every 3-4 months between 6 months and 3 years of age, and every
6-12 months from age 3 years until the end of growth. The goal is to
maintain serum FT4 in the upper half of the reference range and the
TSH in the lower normal range during the first 3 years of life.
Assessments that are important guides for appropriate hormone
replacement include physical growth, motor development, bone mat-
uration, and developmental progress.

Management of premature infants with hypothyroxinemia
(~50% of those born at <30 weeks of gestation) remains a therapeu-
tic dilemma. Despite impaired psychomotor development in these
patients (Reuss et al., 1996), it is not clear whether levothyroxine
therapy may be beneficial, and in some settings it may be detrimen-
tal (van Wassenaer et al., 2005).

**Thyroid Nodules.** Nodular thyroid disease is the most
common endocrinopathy. The prevalence of clinically
apparent nodules is 4-7% in the U.S., with the fre-
cuency increasing throughout adult life. When ultra-
sond and autopsy data are included, the prevalence of
thyroid nodules approaches 50% by age 60. As with
other forms of thyroid disease, nodules are more fre-
cuently seen in women. Exposure to ionizing radiation, espe-
cially in childhood, increases the rate of nodule
development. Approximately 5% of thyroid nodules
that come to medical attention are malignant.

The evaluation of the patient with nodular thyroid disease
includes a careful physical examination, biochemical analysis of thy-
roid function, and assessment of the malignant potential of the nod-
ule (Cooper et al., 2006). Thyroid nodules usually are asymptomatic,
although they can cause neck discomfort, dysphagia, and a choking
sensation. Most patients with thyroid nodules are euthyroid, which
should be confirmed by TSH measurement. The most useful diag-
nostic procedures generally are ultrasound imaging and a fine-nee-
dle aspiration biopsy.

TSH suppressive therapy with levothyroxine sometimes is
prescribed for the patient with a benign thyroid nodule and a nor-
mal serum TSH. The rationale is that a benign nodule will either stop
growing or decrease in size after TSH stimulation of the thyroid
gland has been suppressed. However, a meta-analysis of randomized
trials reveals the shortcomings of this approach (Sdano et al., 2005).
Only 22% of nodules decrease in volume by >50% with levothyrox-
ine versus 10% with placebo. Eight patients need to be treated to
have one response, and limited data suggest that the nodule will
regrow if the levothyroxine is stopped. Furthermore, a 50% decrease
in volume represents only about a 20% decrease in linear dimension,
a very modest change. The minimum level of TSH suppression
needed to achieve this modest response is not known, and long-term
exposure to excess thyroid hormone carries risks such as osteopor-
osis and atrial fibrillation. Thus the use of levothyroxine to suppress
TSH in euthyroid individuals with thyroid nodules cannot be recom-
pended as a general practice. However, if the TSH is elevated, it is
appropriate to administer levothyroxine to bring the TSH into the
lower portion of the reference range.

**Thyroid Cancer.** The mainstays of therapy for well-
differentiated thyroid cancer (papillary, follicular) are
surgical thyroidectomy, radioiodine, and levothyroxine
to suppress TSH (Cooper et al., 2006; Tuttle et al.,
2007). The rationale for TSH suppression is that TSH is
a growth factor for these cancers. These interventions
mainly benefit those patients with stage 2 or higher thy-
roid cancer (Jonklaas et al., 2006).

Given the generally excellent prognosis of well-differentiated
thyroid cancer, a prospective randomized controlled trial to assess
which patients benefit from suppressive therapy, how low the TSH
should be, or how long the suppression should be maintained has
not been done. For most low-risk patients with stage 1 or 2 disease,
maintaining the TSH just below the reference range for not more
than 5 years is one reasonable approach. A greater degree of TSH
suppression for a longer duration is recommended for higher risk
patients and those with metastatic disease (Cooper et al., 2006).

Non-thyroidal Illness (Sick Euthyroid) Syndrome. Although the circu-
lating free T3 is low in the non-thyroidal illness syndrome, the cur-
rent standard of care is not to treat with thyroid hormone because
there is no convincing evidence that the low T3 state contributes to
the patient’s prognosis or that thyroid hormone therapy would alter
the course of the illness. However, there have been very few ran-
domized controlled trials, and these generally involve small numbers
of patients and hence have little statistical power. Two trials suggest possible benefit of T₃ therapy in cardiac surgery patients (Klemperer et al., 1995, 1996; Mullis-Jansson et al., 1999).

**Depression.** Data from several small double-blind placebo-controlled studies suggest potential efficacy of thyroid hormone therapy in euthyroid individuals with major depression, when added to tricyclic antidepressants (Carvalho et al., 2007). It is unclear whether T₃ supplementation of specific serotonin reuptake inhibitor (SSRI) therapy is beneficial (Papakostas et al., 2009). One study suggests that a beneficial effect of T₃ added to the SSRI sertraline is seen primarily in subjects with a C785T polymorphism in the type 1 deiodinase gene (Cooper-Kazaz et al., 2009). The mechanism of the T₃ effect (if any) is not known.

**Adverse Effects of Thyroid Hormone.** Adverse effects of thyroid hormone would generally occur only upon overtreatment and would be similar to the consequences of hyperthyroidism. An excess of thyroid hormone can increase the risk of atrial fibrillation, especially in the elderly, and can increase the risk of osteoporosis, especially in postmenopausal women.

**Novel Thyroid Hormone Analogs and Their Potential Therapeutic Applications**

The discovery of multiple thyroid hormone receptor isoforms, combined with tissue specific differences in their levels of expression, has led to the development of isoform-specific thyroid hormone analogs with interesting properties (Baxter and Webb, 2009; Brenta et al., 2007). Additional research will be required to determine the therapeutic value of these novel compounds, but their potential merits brief discussion.

**TRβ Agonists.** Thyroid hormone has long been known to reduce serum cholesterol via effects on hepatic metabolism, but T₄ and T₃ are not useful hypcholesterolemic drugs due to the adverse effects of thyrotoxicosis on the heart and other organs. However, the liver primarily expresses TRβ, whereas the heart primarily expresses TRα. T₃ analogs that have a higher affinity for TRβ than TRα and that accumulate preferentially in the liver have been shown to lower serum cholesterol without causing tachycardia in humans and animals (Erion et al., 2007). These analogs also can induce weight loss in mice with diet-induced obesity. Thyromimetics with preferential action on TRβ also might be useful in the management of thyroid hormone resistance, which in most cases is caused by mutations in TRβ that lower the binding affinity for T₃ (Refetoff and Dumitrescu, 2007).

**Thyroid Hormone Receptor α Agonists.** Because TRα1 is expressed preferentially in the heart, specific agonists might find use in the management of heart failure or bradycardia. The design of specific agonists for TRα, however, has proven much more difficult than for TRβ (Ocasio and Scanlan, 2008).

**Thyromimetics with Altered Entry into Cells.** Monocarboxylate transporter 8 (MCT8) transports T₃ into cells and is highly expressed in the brain. Patients with MCT8 mutations have the Allan-Herndon-Dudley syndrome with severe neurological impairment, presumably due to intracellular thyroid hormone deficiency. A thyromimetic that can enter the brain in an MCT8-independent manner could be valuable in treating these patients. The thyroid hormone analog 3,5-diiodothyropropionic acid (DITPA) has this property in mice (Di Cosmo et al., 2009).

**Thyronamines.** 3-Iodothyronamine and thyronamine are endogenous thyroid hormone metabolites that functions as agonists for the GPRC R Trace Amine Associated Receptor 1 (TAAR1) and the α₂A adrenergic receptor. These compounds appear to have broad metabolic effects in experimental animals, such as inducing hypothermia and bradycardia (Scanlan et al., 2004), and conferring protection against brain ischemia (Doyle et al., 2007). The therapeutic potential of these agents or their analogs requires further investigation.

**ANTI-THYROID DRUGS AND OTHER THYROID INHIBITORS**

A number of compounds are capable of interfering, directly or indirectly, with the synthesis, release, or action of thyroid hormones (Table 39–4). Several are of great clinical value for the temporary or extended control of hyperthyroid states. The major inhibitors may be classified into four categories:

- Anti-thyroid drugs, which interfere directly with the synthesis of thyroid hormones;
- Ionic inhibitors, which block the iodide transport mechanism;
- High concentrations of iodine, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis;
- Radioactive iodine, which damages the thyroid gland with ionizing radiation.

Adjuvant therapy with drugs that have no specific effects on thyroid hormone synthesis is useful in controlling the peripheral manifestations of thyrotoxicosis. These drugs include inhibitors of the peripheral deiodination of thyroxine to the active hormone, triiodothyronine, β adrenergic receptor antagonists, and Ca²⁺ channel blockers. The anti-thyroid drugs have been reviewed by Cooper (2005). Adrenergic receptor antagonists are discussed more fully in Chapter 12 and Ca²⁺ channel blockers in Chapter 27.
Anti-Thyroid Drugs

The anti-thyroid drugs that have clinical utility are the thioureylenes, which belong to the family of thionamides. Propylthiouracil may be considered as the prototype.

**History.** Studies on the mechanism of the development of goiter began with the observation that rabbits fed a diet composed largely of cabbage often developed goiters. This result was probably due to the presence of precursors of the thiocyanate ion in cabbage leaves. Later, two pure compounds were shown to produce goiter: sulfaguanidine, a sulfanilamide antimicrobial used to treat enteric infections, and phenylthiourea.

Investigation of the effects of thiourea derivatives revealed that rats became hypothyroid despite hyperplastic changes in their thyroid glands that were characteristic of intense thyrotropic stimulation. After treatment was begun, no new hormone was made, and the goitrogen had no visible effect on the thyroid gland following hypophysectomy or the administration of thyroid hormone. This suggested that the goitrogen was a compensatory change resulting from the induced state of hypothyroidism and that the primary action of the compounds was to inhibit the formation of thyroid hormone. The therapeutic possibilities of such agents in hyperthyroidism were evident, and the substances so used became known as anti-thyroid drugs (Astwood, 1945).

**Structure–Activity Relationship.** The two goitrogens found in the early 1940s proved to be prototypes of two different classes of anti-thyroid drugs. These two, with one later addition, made up three general categories into which most of the agents can be assigned:

- **Thioureylenes** include all the compounds currently used clinically (Figure 39–9);
- **Aniline derivatives**, of which the sulfonamides make up the largest number, embrace a few substances that have been found to inhibit thyroid hormone synthesis;
- **Polyhydric phenols**, such as resorcinol, which have caused goiter in humans when applied to abraded skin.

A few other compounds, mentioned briefly later, do not fit into any of these categories.

Thiourea and its simpler aliphatic derivatives and heterocyclic compounds containing a thioureylene group make up most of the known anti-thyroid agents that are effective in humans. Although most of them incorporate the entire thioureylene group, in some a nitrogen atom is replaced by oxygen or sulfur so that only the thioamide group is common to all. Among the heterocyclic compounds, active representatives are the sulfur derivatives of imidazole, oxazole, hydantoin, thiazole, thiadiazole, uracil, and barbituric acid.

L-5-Vinyl-2-thiooxazolidone (goitrin) is responsible for the goiter that results from consuming turnips or the seeds or green parts of cruciferous plants. These plants are eaten by cows, and the compound is found in cow’s milk in areas of endemic goiter in Finland; it is about as active as propylthiouracil in humans.

As the result of industrial exposure, toxicological studies, or clinical trials for various purposes, several other compounds have been noted to possess anti-thyroid activity (Miller et al., 2009). Thiopental and oral hypoglycemic drugs of the sulfonylurea class

**Figure 39–9.** Anti-thyroid drugs of the thiamide type.
have weak anti-thyroid action in experimental animals. This is not significant at usual doses in humans. However, anti-thyroid effects in humans have been observed from dimercaprol and lithium salts. Polychlorinated biphenyls bear a striking structural resemblance to the thyroid hormones and may function as either agonists or antagonists of thyroid hormone action (Zoeller et al., 2000). Amiodarone, the iodine-rich drug used in the management of cardiac arrhythmias, has complex effects on thyroid function (Basaria and Cooper, 2005). In areas of iodine sufficiency, amiodarone-induced hypothyroidism due to the excess iodine is not uncommon, whereas in iodine-deficient regions, amiodarone-induced thyrotoxicosis predominates, whether because of the excess iodine or the thyroiditis induced by the drug. Amiodarone and its major metabolite, desethylamiodarone, are potent inhibitors of iodothyronine deiodination, resulting in decreased conversion of thyroxine to triiodothyronine. In addition, desethylamiodarone decreases binding of triiodothyronine to its nuclear receptors. Recommendations have been made as to screening methods to identify chemicals that may alter thyroid hormone action or homeostasis (Diamanti-Kandarakis et al., 2009).

Mechanism of Action. The mechanism of action of the thioureylene drugs has been thoroughly reviewed (Cooper, 2005). Anti-thyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodothyrosyl residues to form iodothyronines. This implies that they interfere with the oxidation of iodide ion and iodothyrosyl groups. The drugs are thought to inhibit the peroxidase enzyme, thereby preventing oxidation of iodide or iodothyrosyl groups to the required active state (Taurog et al., 1996). The anti-thyroid drugs bind to and inactivate the peroxidase only when the heme of the enzyme is in the oxidized state. Over a period of time, the inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. Only when the preformed hormone is depleted and the concentrations of circulating thyroid hormones begin to decline do clinical effects become noticeable.

There is some evidence that the coupling reaction may be more sensitive to an anti-thyroid drug, such as propylthiouracil, than is the iodination reaction. This may explain why patients with hyperthyroidism respond well to doses of the drug that only partially suppress organification.

When Graves’ disease is treated with anti-thyroid drugs, the concentration of thyroid-stimulating immunoglobulins in the circulation often decreases, prompting some to propose that these agents act as immunosuppressants. Perchlorate, which acts by an entirely different mechanism, also decreases thyroid-stimulating immunoglobulins, suggesting that improvement in hyperthyroidism may reduce thyroid antibodies.

In addition to blocking hormone synthesis, propylthiouracil partially inhibits the peripheral deiodination of $T_4$ to $T_3$. Methimazole does not have this effect; although the quantitative significance of this inhibition has not been established, it provides a rationale for the choice of propylthiouracil over other anti-thyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm, where a decreased rate of $T_4 \rightarrow T_3$ conversion would be beneficial.

Absorption, Metabolism, and Excretion. The anti-thyroid compounds currently used in the U.S. are propylthiouracil (6-n-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole; TAPAZOLE, others). In Great Britain and Europe, carbimazole (NEOMERCAZOLE), a carbethoxy derivative of methimazole, is available, and its anti-thyroid action is due to its conversion to methimazole after absorption. Pharmacological properties of propylthiouracil and methimazole are shown in Table 39–5.

Measurements of the course of organification of radioactive iodine by the thyroid show that absorption of effective amounts of propylthiouracil follows within 20-30 minutes of an oral dose and that the duration of action of the compounds used clinically is brief. The effect of a dose of 100 mg of propylthiouracil begins to wane in 2-3 hours, and even a 500-mg dose is completely inhibitory for only 6-8 hours. As little as 0.5 mg of methimazole similarly decreases the organification of radioactive iodine in the thyroid gland, but a single dose of 10-25 mg is needed to extend the inhibition to 24 hours.

The \( t_{1/2} \) of propylthiouracil in plasma is \(~75\) minutes, whereas that of methimazole is \(4-6\) hours. The drugs are concentrated in the thyroid, and methimazole, derived from the metabolism of carbimazole, accumulates after carbimazole is administered. Drugs and metabolites appear largely in the urine.

Propylthiouracil and methimazole cross the placenta equally (Mortimer et al., 1997) and also can be found in milk. The use of these drugs during pregnancy is discussed later.

**Untoward Reactions.** The incidence of side effects from propylthiouracil and methimazole as currently used is relatively low. The overall incidence as compiled from published cases by early investigators was \(3\)% for relatively low. The overall incidence as compiled from propylthiouracil and methimazole as currently used is discussed later.

Antinuclear cytoplasmic antibodies (ANCAs) have been reported to occur in \(~50\)% of patients receiving propylthiouracil and rarely with methimazole (Sato et al., 2000; Sera et al., 2000).

Propylthiouracil-associated hepatic failure has been increasingly recognized, especially in children and pregnant women (Cooper and Rivkees, 2009). There are 47 published reports of propylthiouracil-associated liver failure in adults and children, and 23 liver transplants between 1990 and 2007 due to propylthiouracil-associated liver failure. Methimazole may cause cholestatic dysfunction, but it is not associated with hepatocellular necrosis, and there are no reports of liver transplants due to methimazole-associated liver toxicity. There is increasing concern about using propylthiouracil as a first-line treatment, except in severe thyrotoxicosis when the inhibition of \(T_4\) to \(T_3\) is desired, and possibly in the first trimester of pregnancy. The FDA has added a “black box” warning to propylthiouracil because of liver failure, recommending close monitoring of liver function during its use. Propylthiouracil should not be used in children except in the case of methimazole allergy.

**Therapeutic Uses.** The anti-thyroid drugs are used in the treatment of hyperthyroidism in the following three ways:

- as definitive treatment, to control the disorder in anticipation of a spontaneous remission in Graves’ disease
- in conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation
- to control the disorder in preparation for surgical treatment (Cooper, 2003)

Methimazole is the drug of choice for Graves’ disease; it is effective when given as a single daily dose, has improved adherence, and is less toxic than propylthiouracil. Methimazole has a relatively long plasma and intrathyroidal \( t_{1/2} \), as well as a long duration of action. The usual starting dose for methimazole is 15–40 mg per day. The usual starting dose of propylthiouracil is 100 mg every 8 hours. When doses >300 mg daily are needed, further subdivision of the time of administration to every 4-6 hours is occasionally helpful. Failures of response to daily treatment with 300-400 mg of propylthiouracil or 30-40 mg of methimazole are most commonly due to nonadherence but can be seen with very severe disease. Delayed responses also are noted in patients with very large goiters or those in whom iodine in any form has been given beforehand. Once euthyroidism is achieved, usually within 12 weeks, the dose of anti-thyroid drug can be reduced, but not stopped, lest an exacerbation of Graves’ disease occur (see later section on remissions).

**Response to Treatment.** The thyrotoxic state usually improves within 3-6 weeks after the initiation of anti-thyroid drugs. The clinical response is related to the dose of anti-thyroid drug, the size of the goiter, and pretreatment serum \(T_3\) concentrations. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the \( t_{1/2} \) of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. When large doses are continued, and sometimes with the usual dose, hypothyroidism may develop as a result of overtreatment. The earliest signs of hypothyroidism call for a reduction in dose; if they have advanced to the point of discomfort, thyroid hormone in full replacement doses can be given to hasten recovery;
then the lower maintenance dose of anti-thyroid drug as discussed earlier is instituted for continued therapy. Despite initial suggestions to the contrary, there is no demonstrated benefit of combination levothyroxine and methimazole therapy on either remission rates (Rittmaster et al., 1998) or on changes in serum concentrations of thyroid-stimulating immunoglobulins.

After treatment is initiated, patients should be examined and thyroid function tests (serum FT4 and total or free triiodothyronine concentrations) measured every 2-4 months. Serum TSH will often remain suppressed for several months after a patient has been hyperthyroid, so the circulating thyroxine and triiodothyronine concentrations are the most reliable assessment of thyroid status (Uy et al., 1995). Once euthyroidism is established, follow-up every 4-6 months is reasonable.

Control of the hyperthyroidism usually is associated with a decrease in goiter size. When this occurs, the dose of the anti-thyroid drug should be significantly decreased and/or levothyroxine can be added once hypothyroidism is confirmed by laboratory testing.

Remissions. There is no highly reliable way of predicting before treatment which patients will eventually achieve a lasting remission and which will relapse. A favorable outcome is unlikely when the disorder is of long standing, the thyroid is quite large, serum T3 concentration is high relative to serum T4 concentration, or various forms of treatment have failed. To complicate the issue further, remission and eventual hypothyroidism may represent the natural history of Graves’ disease.

During treatment, a positive sign that a remission may have taken place is reduced size of the goiter. The persistence of goiter often indicates failure, unless the patient becomes hypothyroid. Another favorable indication is continued freedom from all signs of hyperthyroidism when the maintenance dose is small. Finally, a decrease in thyroid-stimulating immunoglobulins is associated with remission, although the clinical features and improvement in thyroid function tests are usually sufficient to make this assessment.

The Therapeutic Choice. Because anti-thyroid drug therapy, radioactive iodine, and subtotal thyroidectomy all are effective treatments for Graves’ disease, there is no worldwide consensus among endocrinologists about the best therapeutic approach. Prolonged drug therapy of Graves’ disease in anticipation of a remission is most successful in patients with small goiters or mild hyperthyroidism. Those with large goiters or severe disease usually require definitive therapy with either surgery or radioactive iodine (131I). Radioactive iodine remains the treatment of choice of many endocrinologists in the U.S. because worsening of ophthalmopathy has been reported after radioactive iodine (Bartalena et al., 1998a), although this remains controversial. Others suggest that development of hypothyroidism, regardless of the treatment, is the strongest risk factor for progression of ophthalmopathy. Smoking is a risk factor for worsening ophthalmopathy (Bartalena et al., 1998b). In older patients, depleting the thyroid gland of preformed hormone by treatment with anti-thyroid drugs is advisable before therapy with radioactive iodine, thus preventing a severe exacerbation of the hyperthyroid state during the subsequent development of radiation thyroiditis. Subtotal thyroidectomy is advocated for Graves’ disease in young patients with large goiters, children who are allergic to anti-thyroid drugs, pregnant women (usually in the second trimester) who are allergic to anti-thyroid drugs, and patients who prefer surgery over anti-thyroid drugs or radioactive iodine. Radioactive iodine or surgery is indicated for definitive therapy in toxic nodular goiter.

Thyrotoxicosis in Pregnancy. Thyrotoxicosis occurs in ~0.2% of pregnancies and is caused most frequently by Graves’ disease (Chan and Mandel, 2007). Anti-thyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Historically, propylthiouracil has been preferred over methimazole because transplacental passage was thought to be lower; however, as noted earlier, both propylthiouracil and methimazole cross the placenta equally (Mortimer et al., 1997). Methimazole is also very rarely associated with aplasia cutis and an embryopathy that can include choanal atresia and other anomalies (Diav-Citrin and Ornoy, 2002). Current data suggest that either may be used safely in the pregnant patient (Momotani et al., 1997; Mortimer et al., 1997), although the concern for propylthiouracil-associated liver failure in pregnancy may favor the use of methimazole, especially after organogenesis in the first trimester (Cooper and Rivkees, 2009). Carbimazole is used in the EU during pregnancy and is rarely associated with congenital gut abnormalities (Barwell et al., 2002).

The anti-thyroid drug dosage should be minimized to keep the serum FT4 index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves’ disease often improves, and it is not uncommon for patients either to be on very low doses or off anti-thyroid drugs completely by the end of pregnancy. Therefore the anti-thyroid drug dose should be reduced, and maternal thyroid function should be frequently monitored to decrease chances of fetal hypothyroidism. Relapse or worsening of Graves’ disease is common after delivery, and patients should be monitored closely. Methimazole up to 20 mg daily in nursing mothers reportedly has no effect on thyroid function in the infant (Azizi et al., 2003), and propylthiouracil is thought to cross into breast milk even less than methimazole.

Adjuvant Therapy. Several drugs that have no intrinsic anti-thyroid activity are useful in the symptomatic treatment of thyrotoxicosis.
Natural Language: 

**Adrenergic receptor antagonists** (Chapter 12) are effective in antagonizing the sympathetic/adrenergic effects of thyrotoxicosis, thereby reducing the tachycardia, tremor, and stare, and relieving palpitations, anxiety, and tension. Either propranolol, 20-40 mg four times daily, or atenolol, 50-100 mg daily, is usually given initially. Propranolol or esmolol can be given intravenously if needed.

Four times daily, or atenolol, 50-100 mg daily, is usually given ining palpitations, anxiety, and tension. Either propranolol, 20-40 mg 

is the only treatment for hyperthyroidism. Usually only short-term treatment with β adrenergic receptor antagonists or Ca²⁺ channel blockers is required, 2-6 weeks, and it should be discontinued once the patient is euthyroid.

Other drugs that are useful in the rapid treatment of the severely thyrotoxic patient are agents that inhibit the peripheral conversion of thyroxine to triiodothyronine. Dexamethasone (0.5-1 mg, two to four times daily) and the iodinated radiological contrast agents iopanoic acid (500-1000 mg once daily) and sodium ipodate (ORAGRAFIN) (500-1000 mg once daily) are effective in preoperative preparation; neither iopanoic acid nor sodium ipodate is available in the U.S. Cholestyramine has been used in severely toxic patients to bind thyroid hormones in the gut and thus block the enterohepatic circulation of the iodothyronines (Mercado et al., 1996).

Immunotherapy has been used for Graves' hyperthyroidism and ophthalmopathy. The B-lymphocyte depleting agent rituximab, when administered in the U.S. (neither of these preparations is available for parenteral administration in the U.S.) or as the only treatment for hyperthyroidism. Usually only short-term treatment with β adrenergic receptor antagonists or Ca²⁺ channel blockers is required, 2-6 weeks, and it should be discontinued once the patient is euthyroid.

**Preoperative Preparation.** To reduce operative morbidity and mortality, patients should be rendered euthyroid before subtotal thyroidectomy as definitive treatment for hyperthyroidism. It is possible to bring almost all patients to a euthyroid state with a normal range serum T₄ and T₃ concentration. The serum TSH concentration will be suppressed below normal for several months after serum T₄ and T₃ is normalized, so it is not required that the serum TSH concentration be normal before surgery. The operative mortality in these patients in the hands of an experienced thyroid surgeon is extremely low. Prior treatment with anti-thyroid drugs usually is successful in rendering the patient euthyroid for surgery. Iodide is added to the regimen for 7-10 days before surgery to decrease the vascularity of the gland, making it less friable and decreasing the difficulties for the surgeon. In the patient who is either allergic to anti-thyroid drugs or is noncompliant, a euthyroid state usually can be achieved by treatment with iopanoic acid (not available in the U.S.), dexamethasone, and propranolol for 5-7 days before surgery. All of these drugs should be discontinued after surgery.

**Thyroid Storm.** Thyroid storm is an uncommon but life-threatening complication of thyrotoxicosis in which a severe form of the disease is usually precipitated by an intercurrent medical problem (Nayak and Burman, 2006). It occurs in untreated or partially treated thyrotoxic patients. Precipitating factors associated with thyrotoxic crisis include infections, stress, trauma, thyroidal or non-thyroidal surgery, diabetic ketoacidosis, labor, heart disease, and, rarely, radioactive iodine treatment.

Clinical features are similar to those of thyrotoxicosis but more exaggerated. Cardinal features include fever (temperature usually >38.5°C) and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. Coma and death may ensue in up to 20% of patients. Thyroid function abnormalities are similar to those found in uncomplicated hyperthyroidism. Therefore thyroid storm is primarily a clinical diagnosis.

Treatment includes supportive measures such as intravenous fluids, antipyretics, cooling blankets, and sedation. Anti-thyroid drugs are given in large doses. Propylthiouracil is preferred over methimazole because it also impairs peripheral conversion of T₄ to T₃. The recommended initial dose of propylthiouracil is 200-400 mg every 6-8 hours (Nayak and Burman, 2006). Propylthiouracil and methimazole can be administered by nasogastric tube or rectally if necessary. Neither of these preparations is available for parenteral administration in the U.S.

Oral iodides are used after the first dose of an anti-thyroid drug has been administered. The agents mentioned earlier as adjuvant therapies of thyrotoxicosis may be usefully applied. Hydrocortisone (100 mg intravenously every 8 hours) can be used in the setting of hypotension both as an inhibitor of conversion of thyroxine to triiodothyronine and as supportive therapy of possible relative adrenal insufficiency (Nayak and Burman, 2006). Finally, treatment of the underlying precipitating illness is essential.

**Ionic Inhibitors**

The term ionic inhibitors designates substances that interfere with the concentration of iodide by the thyroid gland (Diamanti-Kandarakis et al., 2009). The effective agents are anions that resemble iodide: thiocyanate, perchlorate, and fluoroborate, all monovalent hydrated anions of a size similar to that of iodide.

The most studied example, thiocyanate, differs from the others qualitatively; it is not concentrated by the thyroid gland but in large amounts may inhibit the organification of iodine. Thiocyanate is produced following the enzymatic hydrolysis of certain plant glucosides. Thus, certain foods (e.g., cabbage) and cigarette smoking result in an increased concentration of thiocyanate in the blood and urine, as does the administration of sodium nitroprusside. Indeed,
cigarette smoking has been reported to worsen both subclinical hypothyroidism (Müller et al., 1995) and Graves’ ophthalmopathy (Bartalena et al., 1998b). Dietary precursors of thiocyanate may be a contributing factor in endemic goiter in certain parts of the world, especially in Central Africa, where the intake of iodine is very low.

Among other anions, perchlorate (ClO₄⁻) is 10 times as active as thiocyanate (Wolff, 1998). The various NIS inhibitors, perchlorate, thiocyanate, and nitrate, are additive in inhibiting iodine uptake (Tonacchera et al., 2004). Perchlorate blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS. Perchlorate is transported by NIS using a different stoichiometry, electroneutral, compared with that seen with transport of iodine (Dohan et al., 2007). Although perchlorate can be used to control hyperthyroidism, it has caused fatal aplastic anemia when given in excessive amounts (2-3 g daily). Perchlorate in doses of 750 mg daily has been used in the treatment of Graves’ disease and amiodarone-iodine–induced thyrotoxicosis (National Academy of Sciences/National Research Council [NAS/NRC], 2005). Perchlorate can be used to “discharge” inorganic iodide from the thyroid gland in a diagnostic test of iodide organization. Other ions, selected on the basis of their size, also have been found to be active; fluoroborate (BF₄⁻) is as effective as perchlorate.

Ammonium perchlorate is an essential oxidizer in the production of rocket fuel, and water supplies have been contaminated with perchlorate derived from the sites of production. A National Academy of Sciences Committee recommended a reference dose of perchlorate exposure of 0.0007 mg/kg per day that would produce no adverse effect. This level of no effect is much higher than that found in most water supplies, indicating a low risk of perchlorate exposure influencing thyroid function (NAS/NRC, 2005). The reference dose was primarily derived from a 2-week study in normal volunteers that determined the daily dose of perchlorate that produced no effect on thyroid function or ¹²³I uptake (Greer et al., 2002). There remain concerns that accumulated perchlorate exposure from multiple sources and combined exposure to other iodine uptake inhibitors may impair thyroid function, especially as it might affect pregnant women and young children (Miller et al., 2009). A study in the U.S. showed a correlation between perchlorate exposure and an increase in serum TSH (still within the normal range), only among women with low iodine intake (Blount et al., 2006). Men and women with adequate iodine intake did not show any influence of perchlorate on thyroid function. Others have argued that the risk of thyroid dysfunction from perchlorate exposure is extremely low and there is little evidence to support this view (Charnley, 2008). A study among pregnant women living in areas of very high natural perchlorate contamination showed no effect on maternal thyroid function or pregnancy outcome for mother or infant (Tellez et al., 2006). Although reassuring, the high iodine content in this region may limit the effects of perchlorate. Because the primary mode of toxicity of perchlorate is inhibition of iodine uptake, the best approach to reduce susceptibility is to maintain adequate iodine intake, especially during pregnancy (Becker et al., 2006).

Lithium has a multitude of effects on thyroid function; its principal effect is decreased secretion of thyroxine and triiodothyronine (Takami, 1994), which can cause overt hypothyroidism in some patients taking Li⁺ for the treatment of mania (Chapter 16).

### Iodide

Iodide is the oldest remedy for disorders of the thyroid gland. Before the anti-thyroid drugs were used, it was the only substance available for control of the signs and symptoms of hyperthyroidism. Its use in this way is indeed paradoxical, and the explanation for this paradox is still incomplete.

**Mechanism of Action.** High concentrations of iodide appear to influence almost all important aspects of iodine metabolism by the thyroid gland. The capacity of iodide to limit its own transport was mentioned earlier. Acute inhibition of the synthesis of iodotyrosines and iodothyronines by iodide also is well known (the Wolff–Chaikoff effect). This transient 2-day inhibition is observed only above critical concentrations of intracellular rather than extracellular concentrations of iodide. With time, “escape” from this inhibition is associated with an adaptive decrease in iodide transport and a lowered intracellular iodide concentration, associated with a decrease in NIS mRNA and protein (Eng et al., 1999).

An important clinical effect of high [I⁻]plasma is inhibition of the release of thyroid hormone. This action is rapid and efficacious in severe thyrotoxicosis. The effect is exerted directly on the thyroid gland and can be demonstrated in the euthyroid subject as well as in the hyperthyroid patient. Studies in a cultured thyroid cell line suggest that some of the inhibitory effects of iodide on thyrocyte proliferation may be mediated by actions of iodide on crucial regulatory points in the cell cycle (Smerdely et al., 1993).

In euthyroid individuals, the administration of doses of iodide from 1.5-150 mg daily results in small decreases in plasma thyroxine and triiodothyronine concentrations and small compensatory increases in serum TSH values, with all values remaining in the normal range. However, euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 39–6), and these patients do not escape from the acute Wolff-Chaikoff effect (Roti et al., 1997). Among the disorders that predispose patients to iodine-induced hypothyroidism are treated Graves’ disease, Hashimoto’s thyroiditis, postpartum lymphocytic thyroiditis, subacute painful thyroiditis, and lobectomy for benign nodules. The most commonly prescribed iodine-containing drugs are certain expectorants (e.g., potassium iodide), topical antiseptics (e.g., povidone iodine), and iodinated radiological contrast agents.

**Response to Iodide in Hyperthyroidism.** The response to iodides in patients with hyperthyroidism is often striking and rapid. The effect usually is discernible within 24 hours, and the basal metabolic rate may fall at a rate comparable to that following thyroidectomy.
This provides evidence that the release of hormone into the circulation is rapidly blocked. Furthermore, thyroid hormone synthesis also is mildly decreased. In the thyroid gland, vascularity is reduced, the gland becomes much firmer, the cells become smaller, colloid reaccumulates in the follicles, and the quantity of bound iodine increases, as though an excessive stimulus to the gland has been removed or antagonized. The maximal effect is attained after 10-15 days of continuous therapy when the signs and symptoms of hyperthyroidism may have greatly improved.

Unfortunately, iodide therapy usually does not completely control the manifestations of hyperthyroidism, and after a variable period of time, the beneficial effect disappears. With continued treatment, the hyperthyroidism may return in its initial intensity or may become even more severe than it was at first.

**Therapeutic Uses.** The uses of iodide in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidectomy, and in conjunction with anti-thyroid drugs and propranolol, in the treatment of thyrotoxic crisis.

Before surgery, iodide is sometimes employed alone, but more frequently it is used after the hyperthyroidism has been controlled by an anti-thyroid drug. It is then given for 7-10 days immediately preceding the operation. Optimal control of hyperthyroidism is achieved if anti-thyroid drugs are first given alone. If iodine also is given from the beginning, variable responses are observed; sometimes the effect of iodide predominates, storage of hormone is promoted, and prolonged anti-thyroid treatment is required before the hyperthyroidism is controlled. These clinical observations may be explained by the capacity of iodide to prevent the inactivation of thyroid peroxidase by anti-thyroid drugs (Taurog et al., 1996).

Another use of iodide is to protect the thyroid from radioactive iodine fallout following a nuclear accident, military exposure, or large scale radioiodination procedures in laboratories. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30-100 mg of iodide daily will markedly decrease the thyroid uptake of radioisotopes of iodine. Following the Chernobyl nuclear reactor accident in 1986, ~10 million children and adults in Poland were given stable iodide to block the thyroid exposure to radioactive iodine from the atmosphere and from dairy products from cows that ate contaminated grass (Nauman and Wolff, 1993).

The dosage or form in which iodide is administered bears little relationship to the response achieved in hyperthyroidism, provided that not less than the minimal effective amount is given; this dosage is 6 mg of iodide per day in most, but not all, patients.

Strong iodine solution (Lugol’s solution) is widely used and consists of 5% iodine and 10% potassium iodide, which yields a dose of 8 mg of iodine per drop. The iodine is reduced to iodide in the intestine before absorption. Saturated solution of potassium iodide (SSKI) also is available, containing 50 mg per drop. Typical doses include 16-36 mg (2-6 drops) of Lugol’s solution or 50-100 mg (1-2 drops) of SSKI three times a day. A potassium iodide product (THYROSHIELD) is available over the counter in the U.S. to take in the event of a radiation emergency and block the uptake of radioiodide into the thyroid gland. The adult dose is 2 mL (130 mg) every 24 hours, as directed by public health officials, with specific dose recommendations in children and infants based on age and weight.

Untoward Reactions. Occasional individuals show marked sensitivity to iodide or to organic preparations that contain iodine when they are administered intravenously as a supplement (e.g., sodium iodine [IOPROD]) during total parental nutrition therapy. The onset of an acute reaction may occur immediately or several hours after administration. Angioedema is the outstanding symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present. Also, manifestations of the serum-sickness type of hypersensitivity—such as fever, arthralgia, lymph node enlargement, and eosinophilia—may appear. Thrombotic thrombocytopenic purpura and fatal perierteritis nodosa attributed to hypersensitivity to iodide also have been described.

The severity of symptoms of chronic intoxication with iodide (iodism) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased salivation is noted. Coryza, sneezing, and irritation of the eyes with swelling of the eyelids are commonly observed. Mild iodism simulates a “cold.” The patient often complains of a severe headache that originates in the frontal sinuses. Irritation of the mucous glands of the respiratory tract causes a productive cough. Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. There also may be inflammation of the pharynx, larynx, and tonsils. Skin lesions are common and vary in type and intensity. They usually are mildly acneiform and distributed in the seborrhic areas. Rarely, severe and sometimes fatal eruptions (iodema) may occur after the prolonged use of iodides. The lesions are bizarre; they resemble those caused by bromism, a rare problem, and as a rule involute quickly when iodide is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever is occasionally observed, and anorexia and depression may be present.

Fortunately, the symptoms of iodism disappear spontaneously within a few days after stopping the administration of iodide. The renal excretion of $\Gamma$ can be increased by procedures that promote Cl- excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

Radioactive Iodine

Chemical and Physical Properties. Iodine has several radioactive isotopes, although the primary ones used for the diagnosis and treatment of thyroid disease are $^{123}$I and $^{131}$I. The short-lived radionuclide of iodine, $^{123}$I, is primarily a $\gamma$-emitter with a $t_{1/2}$ of only 13 hours and is used in diagnostic studies to measure 24-hour iodine uptake and for thyroid imaging. In contrast, $^{131}$I has a $t_{1/2}$ of 8 days and emits both $\gamma$ rays and $\beta$ particles. More than 99% of its radiation is expended within 56 days. It is used therapeutically for thyroid destruction of an overactive or enlarged thyroid and in thyroid cancer for thyroid ablation and treatment of metastatic disease.

Effects on the Thyroid Gland. The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, $^{127}$I. $^{131}$I is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus the destructive $\beta$ particles originate within the follicle and act almost exclusively on the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The $\gamma$ radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. When small tracer doses of $^{123}$I are administered, thyroid function is not disturbed. However, when large amounts of radioactive iodine gain access to the gland, the characteristic cytotoxic actions of ionizing radiation are observed. Pyknosis and necrosis of the follicular cells are followed by disappearance of colloid and fibrosis of the gland. With properly selected doses of $^{131}$I, it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues. After smaller doses, some of the follicles, usually in the periphery of the gland, retain their function.

Therapeutic Uses. Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. Sodium iodide $^{131}$I (HICON, others) is available as a solution or in capsules containing essentially carrier-free $^{131}$I suitable for oral administration. Sodium iodide $^{123}$I is available for scanning procedures. Discussion here is focused on the therapeutic uses of $^{131}$I.

Hyperthyroidism. Radioactive iodine is a valuable alternative or adjunctive treatment of hyperthyroidism (Brent, 2008). Stable iodide (non-radioactive) used as treatment for hyperthyroidism, however, may preclude treatment and imaging with radioactive iodine for weeks after the stable iodide has been discontinued. A urinary iodine measurement can be performed to monitor the iodine load. In those patients exposed to stable iodide, a 24-hour radiiodine measurement of a tracer dose of $^{123}$I should be performed before $^{131}$I administration to ensure there is sufficient uptake to accomplish the desired ablation.

Dosage and Technique. $^{131}$I, 7000-10,000 rads per gram of thyroid tissue, is administered orally. The effective dose for a given patient depends primarily on the size of the thyroid, the iodine uptake of the gland, and the rate of release of radioactive iodine from the gland subsequent to the nuclide’s deposition in the colloid. Comparison studies have shown little advantage of a standard individualized dose, based on gland weight and radioactive iodine uptake, over a fixed dose (Jarløv et al., 1995). For these reasons, the optimal dose of $^{131}$I, expressed in terms of microcuries taken up per gram of thyroid tissue, varies in different laboratories from 80-150 $\mu$Ci. The usual total dose is 4-15 mCi.

The lower doses produce a lower incidence of hypothyroidism in the early years after treatment; however, many patients with late hypothyroidism may go undetected, and the ultimate incidence of hypothyroidism is probably no less than with the larger doses. In addition, relapse of the hyperthyroid state, or initial failure to alleviate the hyperthyroid state, is increased in patients receiving lower doses of $^{131}$I. Thus, many endocrinologists recommend initial treatment with thyroid ablative doses of $^{131}$I, with subsequent treatment for hypothyroidism. There also is evidence that pretreatment with an antithyroid drug reduces the therapeutic efficacy of $^{131}$I. The medication, therefore, should be discontinued ~1 week before the therapeutic dose.
of $^{131}$I therapy and only resumed 3 days after $^{131}$I (Walter et al., 2007). If the anti-thyroid drug cannot be discontinued, the effect can be overcome by adjusting to a higher radiiodine dose.

**Course of Disease.** The course of hyperthyroidism in a patient who has received an optimal dose of $^{131}$I is characterized by progressive recovery. Beginning a few weeks after treatment, the symptoms of hyperthyroidism gradually abate over a period of 2-3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6-12 months. It is not uncommon, however, for the serum TSH to remain low for several months after $^{131}$I therapy, especially if the patient was not rendered euthyroid before receiving the radioactive iodine. Occasionally, this delayed recovery of the hypothalamic-pituitary-thyroid axis results in a picture of central hypothyroidism, with low circulating thyroid hormones. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free $T_4$ and usually serum $T_3$ concentrations. Furthermore, transient hypothyroidism, lasting up to 6 months, may occur in up to 50% of patients receiving a dose of $^{131}$I calculated to result in euthyroidism (Aizawa et al., 1997). This is less of a problem if the patient receives a higher, ablative dose of $^{131}$I because hypothyroidism occurs far more frequently and persists.

Depending to some extent on the dosage schedule adopted, 80% of patients are cured by a single dose, ~20% require two doses, and a very small fraction require three or more doses before the disorder is controlled. Patients treated with larger doses of $^{131}$I almost always develop hypothyroidism within a few months.

β-Adrenergic antagonists, anti-thyroid drugs, or both, or stable iodide, can be used to hasten the control of hyperthyroidism while awaiting the full effects of the radioactive iodine.

**Advantages.** The advantages of radioactive iodine in the treatment of Graves’ disease are many. No death as a direct result of the use of the isotope has been reported. There have been reports of increased mortality from cardiovascular and cerebrovascular disease in the first year after radioactive iodine therapy (Franklyn et al., 1998); however, there is no evidence that the increased mortality was related to the radioactive iodine itself, and long-term follow-up of radioactive iodine therapy for Graves’ disease has demonstrated no increase in overall cancer mortality in patients treated with $^{131}$I (Ron et al., 1998). In the non-pregnant patient, no tissue other than the thyroid is exposed to sufficient ionizing radiation to be detectably altered. Nevertheless, continuing concern about potential effects of radiation on germ cells prompts some endocrinologists to advocate anti-thyroid drugs or surgery in younger patients who are acceptable operative risks. Hypoparathyroidism is a small risk of surgery. With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the U.S., and patients can participate in their customary activities during the entire procedure, although there are recommendations to limit exposure to young children.

**Disadvantages.** The chief consequence of the use of radioactive iodine is the high incidence of delayed hypothyroidism. Even when elaborate procedures are used to estimate iodine uptake and gland size, most patients become hypothyroid.

Several analyses of groups of patients treated ≥10 years previously suggest that the eventual rate may exceed 80%. However, it now appears that the incidence of hypothyroidism also increases progressively after subtotal thyroidectomy or after anti-thyroid drug therapy, and such failure of glandular function is probably part of the natural progression of Graves’ disease, no matter what the therapy. Although cancer death rate is not increased after radioiodine therapy, there is a small but significant increase shown in specific types of cancer, including stomach, kidney, and breast (Metso et al., 2007). This finding is especially significant because these tissues all express the iodine transporter NIS and may be especially susceptible to radiation effects.

It is essential that patients treated with radioiodine understand that the resulting hypothyroidism will require lifelong treatment and monitoring. Because there are variations in the interval of time from treatment to the development of hypothyroidism, patients must have regular thyroid function testing after radioiodine. Also, once diagnosed, it is difficult to ensure that patients who need the hormone actually take it. Because the health risks of untreated subclinical hypothyroidism are becoming increasingly evident (Biondi and Cooper, 2008), hypothyroidism, either subclinical or overt, requires long-term follow-up to ensure adequate thyroid hormone status and optimal replacement therapy.

Another disadvantage of radioactive iodine therapy is the long period of time that is sometimes required before the hyperthyroidism is controlled. When a single dose is effective, the response is most satisfactory; however, when multiple doses are needed, it may be many months or a year or more before the patient is well. This disadvantage can be largely overcome if the initial dose is sufficiently large. Other disadvantages include possible worsening of ophthalmopathy after treatment (Bartalena et al., 1998a). Radioactive iodine treatment can induce a radiation thyroiditis, with release of preformed thyroxine and triiodothyronine into the circulation. In most patients, this is asymptomatic, but in some there can be worsening of symptoms of hyperthyroidism and rarely cardiac manifestations, such as atrial fibrillation or ischemic heart disease and very rarely thyroid storm. Pretreatment with anti-thyroid drugs should reduce or eliminate this complication and is indicated especially in those with underlying cardiac disease or the elderly. Finally, salivary gland dysfunction may be seen, especially after the higher doses used for the treatment of thyroid cancer (Mandel and Mandel, 2003). Sialogogic agents to hasten the transit of radioiodine through the salivary glands are used by many clinicians but have unproven efficacy. Salivary gland damage is most strongly linked to the cumulative dose of radioiodine.

**Indications.** The clearest indication for this form of treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is the best form of treatment when Graves’ disease has persisted or recurred after subtotal thyroidectomy and
when prolonged treatment with anti-thyroid drugs has not led to remission. Finally, radioactive iodine is indicated in patients with toxic nodular goiter because the disease does not go into spontaneous remission.

The risk of inducing hypothyroidism is less in nodular goiter than in Graves’ disease, perhaps because of the normal progression of the latter and the preservation of nonautonomous thyroid tissue in the former. Usually, larger doses of radioactive iodine are required in the treatment of toxic nodular goiter than in the treatment of Graves’ disease. Radioactive iodine has been used to decrease the size of large nontoxic multinodular goiters that are causing compressive symptoms in patients who are otherwise poor operative risks. Although surgery remains the treatment of choice for patients with compressive multinodular goiters, radioactive iodine therapy may benefit elderly patients, especially those with cardiopulmonary disease. The uptake in multinodular goiters may be low, so some have increased radiiodine uptake by administration of exogenous recombinant human TSH (thyrotropin alfa [THYROGEN]) (Duntas and Cooper, 2008), but caution should be exercised because this treatment may induce transient elevations in serum thyroxine and triiodothyronine that could result in excessive stimulation of the heart.

**Contraindications.** The main contraindication for the use of $^{131}$I therapy is pregnancy. After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. The risk of causing neoplastic changes in the thyroid gland has been an ongoing concern since radioactive iodine was first introduced, and only small numbers of children have been treated in this way. Indeed, many clinics have declined to treat younger patients for fear of causing cancer and have reserved radioactive iodine for patients older than some arbitrary age, such as 25 or 30 years. Because experience with $^{131}$I is now vast, these age limits are lower than they were in the past. The most recent report by the Cooperative Thyrotoxicosis Therapy Follow-up Study Group shows no increase in total cancer mortality following $^{131}$I treatment for Graves’ disease (Ron et al., 1998). Furthermore, there was no increase in the occurrence of leukemia following large-dose $^{131}$I therapy for thyroid cancer, although there was an increase in colorectal cancers in this population (de Vathaire et al., 1997). These data strongly suggest that laxatives be given to all patients receiving $^{131}$I therapy for treatment of thyroid cancer to decrease the risk of future digestive tract malignancies. Transient abnormalities in testicular function have been reported following $^{131}$I therapy for treatment of thyroid cancer, but no long-term effects on fertility in either men or women have been demonstrated (Dottorini et al., 1995; Pacini et al., 1994). Patients with allergies to iodine contrast agents or to topi- cial iodide-containing products should not have any adverse reaction to $^{131}$I. The amount of elemental iodine contained in the treatment is not greater than that contained in iodized salt or flour that is part of regular dietary intake.

**Diagnostic Uses.** Measurement of the thyroidal accumulation of a tracer dose is helpful in the differential diagnosis of hyperthyroidism and nodular goiter. The response of the thyroid to TSH-suppressive doses of thyroid hormone can be evaluated in this way. Following the administration of a tracer dose, the pattern of localization in the thyroid gland can be depicted by a special scanning apparatus, and this technique is sometimes useful in defining thyroid nodules as functional ("hot") or non-functional ("cold") and in finding ectopic thyroid tissue and occasionally metastatic thyroid tumors.

**Thyroid Carcinoma.** Because most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH is required to treat metastases effectively. Currently, endogenous TSH stimulation is evoked by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total thyroidectomy with or without radioactive ablation of residual thyroid tissue. Total-body $^{131}$I scanning and measurement of serum thyroglobulin when the patient is hypothyroid (TSH >35 mU/L) help to identify metastatic disease or residual thyroid bed tissue. Depending on the residual uptake or the presence of metastatic disease, an ablative dose of $^{131}$I ranging from 30 mCi to >150 mCi is administered, and a repeat total body scan is obtained 1 week later. The precise amount of $^{131}$I needed to treat residual tissue and metastases is controversial. Thyrotropin alfa (recombinant human TSH) is now available to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin (Haugen et al., 1999). Thyrogen allows assessment of the presence of metastatic disease, without the necessity for patients to stop their suppressive levothyroxine therapy and become clinically hypothyroid. Thyrotropin alfa is approved for diagnostic scanning and for thyroid remnant ablation after thyroidectomy in thyroid cancer patients, but not for treatment of metastatic disease. (Duntas and Cooper, 2008; Pacini and Castagna, 2008).

TSH-suppressive therapy with levothyroxine is indicated in all patients after treatment for thyroid cancer. The goal of therapy usually is to keep serum TSH levels in the subnormal range, although relaxing the degree and duration of suppression, especially for stage 1 and 2 cancers, is now recommended (Burmeister et al., 1992; Cooper et al., 2006). Follow-up evaluation every 6 months is reasonable, along with determination of serum thyroglobulin concentrations (Spencer and LoPresti, 2008). Patients with a rise in thyroglobulin but no detectable disease on whole-body scan require additional imaging and consideration of alternative treatments including surgery and external radiation (Kloos, 2008). A rise in serum thyroglobulin concentration is often the first indication of recurrent disease. The prognosis in patients with thyroid cancer depends on the pathology and size of the tumor and is generally worse in older individuals. Overall, the vast majority of patients with thyroid cancer will not die of their disease. Papillary cancer is usually not aggressive; the 10-year survival rate exceeds 80%. Follicular cancer is more aggressive and can metastasize via the bloodstream. Still, prognosis is fair and long-term survival is common. Even in patients with metastatic, differentiated thyroid cancer, $^{131}$I therapy is very effective and may be even curative (Cooper et al., 2006). Anaplastic cancer is the exception: It is highly malignant with survival usually <1 year. Medullary thyroid carcinomas do not accumulate I$^{-}$ and cannot be treated with $^{131}$I.
Chemotherapy in Thyroid Cancer

Advanced and metastatic poorly differentiated papillary and follicular thyroid cancer often does not concentrate iodine sufficient for therapy with $^{131}$I (Kloos, 2008). There have been significant advances in targeted chemotherapy for thyroid cancer (Sherman, 2009). Recent advances in the molecular genetics of thyroid cancer have resulted in the identification of oncogenic mutations in the $BRAF$ and $RAS$ genes, known to activate the MAPK signaling pathway. Medullary thyroid carcinoma is associated with mutations in the $RET$ gene, which also enhance MAPK signaling. These findings have led to a number of successful clinical trials in poorly differentiated papillary and follicular thyroid cancer and medullary thyroid cancer. Treatment with inhibitors of receptor tyrosine kinases, vascular endothelial growth factor (VEGF), and the VEGF receptor have produced partial response rates in the range of 30%. Agents studied include axitinib, gefitinib, imatinib, motesanib, sorafenib, sunitinib, and vandetanib (Sipos and Shah, 2010). Single agents in poorly differentiated thyroid cancer have most commonly produced disease stabilization, although combining agents to target multiple growth-promoting pathways may improve the disease response.

CLINICAL SUMMARY

Replacement therapy for hypothyroidism typically uses oral L-thyroxine given once daily. The goals of therapy are to restore the serum TSH concentration to the mid-normal or low-normal range, and to relieve the signs and symptoms of hypothyroidism. In patients with central hypothyroidism, the biochemical goal is to restore the serum-free $T_4$ to the upper half of the normal range. Based on the long $t_{1/2}$ of thyroxine, at least 6–8 weeks are required before a new steady-state level is reached following initiation of therapy or adjustment of dose. Special cases of hypothyroidism include patients following surgical resection of differentiated thyroid carcinoma and pregnancy. In the former setting, the goal is to suppress the TSH level to below normal, thereby removing the potential effect of TSH to stimulate proliferation of the cancer cells. In pregnant patients, the standard replacement dose is usually increased. Realizing the effects of even relatively mild hypothyroidism on neurological development of the fetus and miscarriage, it is especially important to monitor thyroid function tests carefully during pregnancy.

Options available for treating hyperthyroid patients include anti-thyroid drugs (e.g., propylthiouracil and methimazole), radioactive iodine ablation, and surgery. The preferred therapy differs among endocrinologists and geographic regions as well as patient characteristics. Special circumstances, such as the presence of coexisting ophthalmopathy in patients with Graves’ disease, also may influence the choice of therapy; radioactive iodine may aggravate the ophthalmopathy. Although younger patients with hyperthyroidism often can be treated effectively with radioactive iodine, medical therapy with anti-thyroid drugs to reduce the levels of thyroid hormone has been the preferred approach. The potential for increased toxicity of anti-thyroid drugs in children and pregnant women may influence this choice. In older patients or those with cardiac disease, radioactive iodine usually is recommended after the patient has been rendered euthyroid with anti-thyroid medication. Surgery remains an option for those who cannot tolerate anti-thyroid drugs or decline radioactive iodine. Surgery is also the most rapid way to treat hyperthyroidism permanently. The initial treatment for thyroid cancer is surgical, usually a total or near-total thyroidectomy. Radioiodine treatment to ablate remnant thyroid tissue or to identify metastatic spread can be done after withdrawal of thyroxine replacement and elevation of endogenous TSH or treatment with recombinant human TSH in patients who are having a total body scan and serum thyroglobulin measurement to determine the presence of residual tissue. Treatment of metastatic disease with radioiodine is performed after thyroxine withdrawal and elevation of endogenous TSH.

Estrogens and progestins are endogenous hormones that produce numerous physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior. The biosynthesis, biotransformation, and disposition of estrogens and progestins are well established. Two well-characterized receptors are present for each hormone, and there is evidence that the receptors mediate biological actions in both the unliganded and steroid hormone-liganded states.

The therapeutic use of estrogens and progestins largely reflects extensions of their physiological activities. The most common uses of these agents are menopausal hormone therapy and contraception in women, but the specific compounds and dosages used in these two settings differ substantially. Estrogen- and progesterone-receptor antagonists also are available. The main uses of anti-estrogens are treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are useful to prevent breast cancer and osteoporosis. The main use of anti-progestins has been for medical abortion, but other uses are theoretically possible.

A number of naturally occurring and synthetic environmental chemicals mimic, antagonize, or otherwise affect the actions of estrogens in experimental test systems. The precise effect of these agents on humans is unknown, but this is an area of active investigation. Cancer chemotherapeutic strategies based on blockade of estrogen- and/or progesterone-receptor functions are considered in further detail in Chapter 63.

Complementary therapeutic strategies based on suppression of gonadotropin secretion by long-acting gonadotropin-releasing hormone agonists are also discussed in Chapter 63.

History. The hormonal nature of the ovarian control of the female reproductive system was firmly established in 1900 by Knauer when he found that ovarian transplants prevented the symptoms of gonadectomy, and by Halban, who showed that normal sexual development and function occurred when glands were transplanted. In 1923, Allen and Doisy devised a bioassay for ovarian extracts based on the vaginal smear of the rat. Frank and associates in 1925 detected an active sex principle in the blood of sows in estrus, and Loewe and Lange discovered in 1926 that a female sex hormone varied in the urine of women throughout the menstrual cycle. The excretion of estrogen in the urine during pregnancy also was reported by Zondek in 1928 and enabled Butenandt and Doisy in 1929 to crystallize an active substance.

Early investigations indicated that the ovary secretes two substances. Beard had postulated in 1897 that the corpus luteum serves a necessary function during pregnancy, and Fraenkel showed in 1903 that destruction of the corpora lutea in pregnant rabbits caused abortion. Several groups then isolated progesterone from mammalian corpora lutea in the 1930s.

In the early 1960s, pioneering studies by Jensen and colleagues suggested the presence of intracellular receptors for estrogens in target tissues. This was the first demonstration of receptors of the steroid/thyroid superfamily and provided techniques to identify receptors for the other steroid hormones. A second estrogen receptor was identified in 1996 and termed estrogen receptor β (ERβ) to distinguish it from the receptor identified by Jensen and others, termed estrogen receptor α (ERα). Two protein isoforms, A and B, of the progesterone receptor arise from a single gene by transcription initiation from different promoters. For the primary literature references about the history of this subject, consult the ninth and tenth editions of this text.

**ESTROGENS**

Chemistry. Many steroidal and nonsteroidal compounds, some of which are shown in Table 40–1 and Figure 40–1, possess estrogenic activity. The most potent naturally occurring estrogen in
humans, for both ERα- and ERβ-mediated actions, is 17β-estradiol, followed by estrone and estriol. Each contains a phenolic A ring with a hydroxyl group at carbon 3, and a β-OH or ketone in position 17 of ring D.

The phenolic A ring is the principal structural feature responsible for selective high-affinity binding to both receptors. Most alkyl substitutions on the A ring impair binding, but substitutions on ring C or D may be tolerated. Ethinyl substitutions at the C17 position greatly increase oral potency by inhibiting first-pass hepatic metabolism. Models for the ligand-binding sites of both estrogen receptors have been determined from structure–activity relationships (Harrington et al., 2003) and structural analysis (Pike et al., 2000).

Diethylstilbestrol (DES), which is structurally similar to estradiol when viewed in the trans conformation, binds with high affinity to both estrogen receptors and it is as potent as estradiol in most assays but has a much longer t1/2. DES no longer has widespread use, but it was important historically as an inexpensive orally active estrogen.

Selective ligands for ERα and ERβ are available for experimental studies but are not yet used therapeutically (Harrington et al., 2003).

Nonsteroidal compounds with estrogenic or anti-estrogenic activity—including flavones, isoflavones (e.g., genistein), and coumestan derivatives—occur in plants and fungi. Synthetic agents—including pesticides (e.g., p,p′-DDT), plasticizers (e.g., bisphenol A), and a variety of other industrial chemicals (e.g., polychlorinated biphenyls)—also have hormonal or antihormonal activity. Although their affinity is relatively weak, their large number, bioaccumulation, and persistence in the environment have raised concerns about their potential toxicity in humans and wildlife. Over-the-counter and prescription preparations containing naturally occurring estrogen-like compounds from plants (i.e., phytoestrogens) now are available (Fitzpatrick, 2003).

**Biosynthesis.** Steroidal estrogens arise from androstenedione or testosterone (Figure 40–1) by aromatization of the A ring. The reaction is catalyzed by aromatase (CYP19) that uses nicotinamide adenine dinucleotide phosphate (NADPH) and molecular oxygen as co-substrates. A ubiquitous flavoprotein, NADPH–cytochrome P450 reductase, also is essential. Both proteins are localized in the endoplasmic reticulum of ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblasts, preimplantation blastocysts, bone, various brain regions, and many other tissues (Simpson et al., 2002).

The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol the main secretory product.

ᵃDesignates C17 Ketone.
ᵇAlso contains 7, 8 double bond.
Gonadotropins, acting via receptors that couple to the Gs-adenyl cyclase–cyclic AMP pathway, increase the activities of aromatase and the cholesterol side-chain cleavage enzyme and facilitate the transport of cholesterol (the precursor of all steroids) into the mitochondria of cells that synthesize steroids. The ovary contains a form of 17β-hydroxysteroid dehydrogenase (type I) that favors the production of testosterone and estradiol from androstenedione and estrone, respectively. However, in the liver, another form of this enzyme (type II) favors oxidation of circulating estradiol to estrone (Peltoketo et al., 1999), and both of these steroids are then converted to estriol (Figure 40–1). All three of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (e.g., androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens. Thus, the level of estrogens is regulated in part by the availability of androgenic precursors (Simpson, 2003).

Estrogenic effects most often have been attributed to circulating hormones, but locally produced estrogens also may have important actions (Simpson et al., 2002). For example, estrogens may be produced from androgens by the actions of aromatase or from estrogen conjugates by hydrolysis. Such local production of estrogens could play a causal or promotional role in the development of certain diseases such as breast cancer because mammary tumors contain both aromatase and hydrolytic enzymes. Estrogens also may be produced from androgens via aromatase in the central nervous system (CNS) and other tissues and exert local effects near their production site (e.g., in bone they affect bone mineral density).

The placenta uses fetal dehydroepiandrosterone and its 16α-hydroxyl derivative to produce large amounts of estrone and estriol. Human urine during pregnancy is thus an abundant source of natural estrogens, and pregnant mare’s urine is the source of conjugated equine estrogens, which have been widely used therapeutically for many years.

**Physiological and Pharmacological Actions**

**Developmental Actions.** Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics. They cause growth and development of the vagina, uterus, and fallopian tubes, and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (Chapter 41).
Estrogens appear to play important developmental roles in males. In boys, estrogen deficiency diminishes the pubertal growth spurt and delays skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility in some individuals (Grumbach and Auchus, 1999).

**Neuroendocrine Control of the Menstrual Cycle.** A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 40–2). A neuronal oscillator, or “clock,” in the hypothalamus fires at intervals that coincide with bursts of gonadotropin-releasing hormone (GnRH) release into the hypothalamic-pituitary portal vasculature (Chapter 38). GnRH interacts with its cognate receptor on pituitary gonadotropes to cause release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle, controls the relative synthesis of the unique β subunits of FSH and LH.

![Figure 40–2. Neuroendocrine control of gonadotropin secretion in females.](image-url)

The hypothalamic pulse generator located in the arcuate nucleus of the hypothalamus functions as a neuronal “clock” that fires at regular hourly intervals (A). This results in the periodic release of gonadotropin-releasing hormone (GnRH) from GnRH-containing neurons into the hypothalamic-pituitary portal vasculature (B). GnRH neurons (B) receive inhibitory input from opioid, dopamine, and GABA neurons and stimulatory input from noradrenergic neurons (NE, norepinephrine). The pulses of GnRH trigger the intermittent release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes (C), resulting in the pulsatile plasma profile (D). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (E). (See text and Figure 40–3 for additional details.)
The gonadotropins (LH and FSH) regulate the growth and maturation of the graafian follicle in the ovary and the ovarian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus.

Because the release of GnRH is intermittent, LH and FSH secretion is pulsatile. The pulse frequency is determined by the neural “clock” (Figure 40–2), termed the hypothalamic GnRH pulse generator (Knobil, 1981), but the amount of gonadotropin released in each pulse (i.e., the pulse amplitude) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, pulsatile nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles because constant infusion of GnRH results in a cessation of gonadotropin release and ovarian steroid production (Chapter 38). The neuropeptide kisspeptin-1, which is released from the hypothalamic anteroventral periventricular nucleus and the arcuate nucleus, may regulate GnRH pulsatility through its G protein-coupled receptor, GPR54, expressed in GnRH neurons. Inactivating mutations in GPR54 have been associated with hypogonadotropic hypogonadism (Seminara, 2006).

Although the precise mechanism that regulates the timing of GnRH release (i.e., pulse frequency) is unclear, hypothalamic cells appear to have an intrinsic ability to release GnRH episodically. The overall pattern of GnRH release likely is regulated by the interplay of intrinsic mechanism(s) and extrinsic synaptic inputs from opioid, catecholamine, and GABAergic neurons (Figure 40–2). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release, but the cellular and molecular mechanisms of this regulation are not well established. Some GnRH cells have immunoreactive steroid receptors. Some nerve cells that synapse with GnRH neurons also contain steroid receptors, and neighboring glial cells may contain estrogen and progesterone receptors. Steroids may thus directly and indirectly modulate GnRH neuronal function.

At puberty the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. Although the mechanism of activation is not entirely established, it may involve increases in circulating insulin-like growth factor (IGF)-1 and leptin levels, the latter acting to inhibit neuropeptide Y (NPY) in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 40–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. The “average” plasma levels of LH throughout the cycle are shown in panel A of Figure 40–3; inserts illustrate the pulsatile patterns of LH during the proliferative and secretory phases in more detail. The average LH levels are similar throughout the early (follicular) and late (luteal) phases of the cycle, but the frequency and amplitude of the LH pulses are quite different in the two phases. This characteristic pattern of hormone secretions results from complex positive and negative feedback mechanisms (Hotchkiss and Knobil, 1994).

In the early follicular phase of the cycle, (1) the pulse generator produces bursts of neuronal activity with a frequency of about one per hour that correspond with pulses of GnRH secretion, (2) these cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes, and (3) FSH in particular causes the graafian follicle to mature and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to decline (i.e., the amplitude of the LH pulse decreases), so gonadotropin levels gradually fall, as seen in Figure 40–3. Inhibin, produced by the ovary, also exerts a negative feedback to selectively decrease serum FSH at this time (Chapter 38). Activin and follistatin, two other peptides released from the ovary, may also regulate FSH production and secretion to a lesser extent, although their levels do not vary appreciably during the menstrual cycle.

At mid-cycle, serum estradiol rises above a threshold level of 150-200 pg/mL for ~36 hours. This sustained elevation of estrogen no longer inhibits gonadotropin release but exerts a brief positive feedback effect on the pituitary to trigger the preovulatory surge of LH and FSH. This effect primarily involves a change in pituitary responsiveness to GnRH. In some species, estrogens may also exert a positive effect on hypothalamic neurons that contributes to a mid-cycle “surge” of GnRH release; this is not yet established in humans. Progesterone may contribute to the mid-cycle LH surge.

The mid-cycle surge in gonadotropins stimulates follicular rupture and ovulation within 1-2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern characteristic of the follicular phase, the entire system then resets, and a new ovarian cycle occurs.

Regulation of the frequency and amplitude of gonadotropin secretions by steroids may be summarized as follows: Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses, and they may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus.

In the follicular phase of the cycle, estrogens inhibit gonadotropin release but then have a brief mid-cycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely via inhibitory opioid neurons (containing progesterone receptors) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (i.e., to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator, lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle, and less frequent pulses of larger amplitude in the luteal phase. Studies in knockout mice indicate that
Figure 40–3. **Hormonal relationships of the human menstrual cycle.**

**A.** Average daily values of LH, FSH, estradiol (E₂), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian follicle (**top**) and endometrium (**bottom**) also are illustrated schematically. Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Redrawn with permission from Thorneycroft et al., 1971. Copyright © Elsevier).

**B.** Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) released (i.e., gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at mid-cycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (i.e., the pulse amplitude) during the luteal phase of the cycle.
ERα (Hewitt and Korach, 2003) and the progesterone receptor PR-A (Conneely et al., 2002) mediate the major actions of estrogens and progestins, respectively, on the hypothalamic-pituitary axis.

In males, testosterone regulates the hypothalamic-pituitary-gonadal axis at both the hypothalamic and pituitary levels, and its negative feedback effect is mediated to a substantial degree by estrogen formed via aromatization. Thus, exogenous estrogen administration decreases LH and testosterone levels in men, and anti-estrogens such as clomiphene cause an elevation of serum LH, which can be used to evaluate the male reproductive axis.

When the ovaries are removed or cease to function, there is overproduction of FSH and LH, which are excreted in the urine. Measurement of urinary or plasma LH is valuable to assess pituitary function and the effectiveness of therapeutic doses of estrogen. Although FSH levels will also decline upon estrogen administration, they do not return to normal, secondary to production of inhibin by the ovary (Chapter 38). Consequently, the measurement of FSH levels as a means to monitor the effectiveness of hormone therapy is not clinically useful. Additional features of the regulation of gonadotropin secretion and actions are discussed in Chapters 38 and 66.

**Effects of Cyclic Gonadal Steroids on the Reproductive Tract.**
The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge.

The uterus is composed of an endometrium and a myometrium. The endometrium contains an epithelium lining the uterine cavity and an underlying stroma; the myometrium is the smooth muscle component responsible for uterine contractions. These cell layers, the fallopian tubes, cervix, and vagina display a characteristic set of responses to both estrogens and progestins. The changes typically associated with menstruation occur largely in the endometrium (Figure 40–3).

The luminal surface of the endometrium is a layer of simple columnar epithelial secretary and ciliated cells that is continuous with the openings of numerous glands that extend through the underlying stroma to the myometrial border. Fertilization normally occurs in the fallopian tubes, so ovulation, transport of the fertilized ovum through the fallopian tube, and preparation of the endometrial surface must be temporally coordinated for successful implantation.

The endometrial stroma is a highly cellular connective-tissue layer containing a variety of blood vessels that undergo cyclic changes associated with menstruation. The predominant cells are fibroblasts, but macrophages, lymphocytes, and other resident and migratory cell types also are present.

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding of the endometrium by stimulating proliferation and differentiation. Numerous mitoses become visible, the thickness of the layer increases, and characteristic changes occur in the glands and blood vessels. In rodent models, ERα mediates the uterotrophic effects of estrogens (Hewitt and Korach, 2003). The overall endometrial response involves estrogen- and progesterone-mediated expression of peptide growth factors and receptors, cell cycle genes, and other regulatory signals. An important response to estrogen in the endometrium and other tissues is induction of the progesterone receptor (PR), which enables cells to respond to this hormone during the second half of the cycle.

In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models (Conneely et al., 2002). Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (i.e., the decidual response). There is a narrow “window of implantation,” spanning days 19-24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. Because endometrial status is regulated by estrogens and progestins, the efficacy of some contraceptives may be due in part to production of an endometrial surface that is not receptive to implantation. If pregnancy does not occur, the corpus luteum regresses due to lack of continued LH secretion, estrogen and progesterone levels fall, and the endometrium is shed (Figure 40–3).

If implantation occurs, human chorionic gonadotropin (hCG) (Chapter 38), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. In later stages the placenta itself becomes the major site of estrogen and progesterone synthesis.

Estrogens and progesterone have important effects on the fallopian tube, myometrium, and cervix. In the fallopian tube, estrogens stimulate proliferation and differentiation, whereas progesterone inhibits these processes. Also, estrogens increase and progesterone decreases tubal muscular contractility, which affects transit time of the ovum to the uterus. Estrogens increase the amount of cervical mucus and its water content to facilitate sperm penetration of the cervix, whereas progesterone generally has opposite effects. Estrogens favor rhythmic contractions of the uterine myometrium, and progesterone diminishes contractions. These effects are physiologically important and may also play a role in the action of some contraceptives.

**Metabolic Effects.** Estrogens affect many tissues and have many metabolic actions in humans and animals. It is not clear in all cases if effects result directly from hormone actions on the tissue in question or secondarily from actions at other sites. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, gastrointestinal (GI) tract, and heart, express low levels of both estrogen receptors, and the ratio of ERα to ERβ varies in a cell-specific manner. Many metabolic effects of estrogens result directly from receptor-mediated events in affected organs. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.
Estrogens have positive effects on bone mass (reviewed by Riggs et al., 2002). Bone is continuously remodeled at sites called bone-remodeling units by the resorptive action of osteoclasts and the bone-forming action of osteoblasts (Chapter 61). Maintenance of total bone mass requires equal rates of formation and resorption as occurs in early adulthood (ages 18-40 years); thereafter resorption predominates. Osteoclasts and osteoblasts express both ERα and ERβ, with the former apparently playing a greater role. Bone also expresses both androgen and progesterone receptors. Based on animal models, the actions of ERα predominate in bone. Estrogens directly regulate osteoblasts and increase the synthesis of type I collagen, osteocalcin, osteopontin, osteonectin, alkaline phosphatase, and other markers of differentiated osteoblasts. Estrogens also increase osteocyte survival by inhibiting apoptosis. However, the major effect of estrogens is to decrease the number and activity of osteoclasts. Much of the action of estrogens on osteoclasts appears to be mediated by altering cytokine (both paracrine and autocrine) signals from osteoblasts. Estrogens decrease osteoblast and stromal cell production of the osteoclast-stimulating cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α and increase the production of IGF-1, bone morphogenic protein (BMP)-6, and transforming growth factor (TGF)-β, which are anti-resorptive (reviewed by Spelsberg et al., 1999). Estrogens also increase osteoblast production of the cytokine osteoprotegerin (OPG), a soluble non–membrane-bound member of the TNF superfamily (Chapter 44). OPG acts as a “decoy” receptor that antagonizes the binding of OPG-ligand (OPG-L) to its receptor (termed RANK, or receptor activator of NF-κB) and prevents the differentiation of osteoclast precursors to mature osteoclasts. Estrogens increase osteoclast apoptosis, either directly or by increasing OPG. Estrogens have anti-apoptotic effects on both osteoblasts and osteocytes in animal models, and this action may be mediated by rapid signal transduction mechanisms (Kousteni et al., 2002; Levin, 2008). Estrogens affect bone growth and epiphyseal closure in both sexes. The importance of estrogen in the male skeleton is illustrated by a man with a completely defective ER who had osteoporosis, unfused epiphyses, increased bone turnover, and delayed bone age (Smith et al., 1994), and by the observation that male idiopathic osteoporosis is associated with reduced ERα expression in both osteocytes and osteoblasts (Braidman et al., 2000).

Estrogens have many effects on lipid metabolism; of major interest are their effects on serum lipoprotein and triglyceride levels (Walsh et al., 1994). In general, estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. More important, they increase high-density lipoprotein (HDL) levels and decrease the levels of low-density lipoprotein (LDL) and lipoprotein A (LPA) (Chapter 31). This beneficial alteration of the ratio of HDL to LDL is an attractive effect of estrogen therapy in postmenopausal women. The initial conclusions from two large clinical trials—the Heart and Estrogen/Progestin Replacement Study, or HERS (Hulley et al., 1998), and the Women’s Health Initiative, or WHI (Anderson et al., 2004; Rossouw et al., 2002)—were that estrogen-progestin or estrogen-only regimens do not provide any protection from cardiovascular disease. However, re-examination of the data in women who took hormone replacement within 10 years of the menopause showed a 32% reduction in myocardial infarction (heart attack).

At relatively high concentrations, estrogens have antioxidant activity and may inhibit the oxidation of LDL by affecting superoxide dismutase. Long-term administration of estrogen is associated with decreased plasma renin, angiotensin-converting enzyme, and endothelin-1; expression of the AT1 receptor for angiotensin II is also decreased. Estrogen actions on the vascular wall include increased production of nitric oxide (NO), which occurs within minutes via a mechanism involving activation of Akt (protein kinase B) (Simoncini et al., 2000), induction of NO synthase, and increased production of prostacyclin. All of these changes promote vasodilation and retard atherogenesis. Estrogens also promote endothelial cell growth while inhibiting the proliferation of vascular smooth muscle cells.

The presence of estrogen receptors in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism are due partly to direct hepatic actions, but other sites of action cannot be excluded. Estrogens also alter bile composition by increasing cholesterol secretion and decreasing bile acid secretion. This leads to increased saturation of bile with cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. The decline in bile acid biosynthesis may contribute to the decreased incidence of colon cancer in women receiving combined estrogen-progestin treatment. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroxine-binding globulin, and sex hormone-binding globulin (SHBG), which binds both androgens and estrogens. ERα deficiency or aromatase enzyme deficiency in mice is associated with impaired glucose tolerance and other elements of the metabolic syndrome due to increased insulin resistance (Simpson, 2003).

Estrogens alter a number of metabolic pathways that affect the clotting cascade (Mendelsohn and Karas, 1999). Systemic effects include changes in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and they decrease the anticoagulation factors protein C, protein S, and antithrombin III (Chapter 30). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of plasminogen-activator inhibitor 1 (PAI-1) protein with a concomitant increase in fibrinolysis (Koh et al., 1997). Thus, estrogens increase...
both coagulation and fibrinolytic pathways, and imbalance in these
two opposing activities may cause adverse effects.

**Estrogen Receptors**

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The two estrogen receptor genes are located on separate chromosomes: ESR1 encodes ERα, and ESR2 encodes ERβ. Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes (reviewed by Hanstein et al., 2004). Ligands that discriminate between ERα and ERβ have been developed (Harrington et al., 2003) but are not yet in clinical use. Both ERα and ERβ exist as multiple mRNA isoforms due to differential promoter use and alternative splicing (reviewed by Kos et al., 2001; Lewandowski et al., 2002). The two human ERs are 44% identical in overall amino acid sequence and share the domain structure common to members of this family. The estrogen receptor is divided into six functional domains: The NH2-terminal A/B domain contains the activation function-1 (AF-1) segment, which can activate transcription independently of ligand; the highly conserved C domain comprises the DNA-binding domain, which contains four cysteines arranged in two zinc fingers; the D domain, frequently called the “hinge region,” contains the nuclear localization signal; and the E/F domain has multiple functions, including ligand binding, dimerization, and ligand-dependent transactivation, mediated by the AF-2 domain. There are significant differences between the two receptor isoforms in the ligand-binding domains and in both transactivation domains. Human ERβ does not appear to contain a functional AF-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds (Kuiper et al., 1997). However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

ERα, the first discovered, is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. ERβ is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Many cells express both ERα and ERβ, which can form either homo- or heterodimers. Both forms of ER are expressed on breast cancers, although ERα is believed to be the predominant form responsible for growth regulation (Chapter 63). When co-expressed with ERα, ERβ can inhibit ERα-mediated transcriptional activation in many cases (Hall and McDonnell, 1999). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer (Han et al., 2003), bone mass (Kurabayashi et al., 2004), endometrial cancer (Weiderpass et al., 2000), or cardiovascular disease (Herrington and Howard, 2003) have led to contradictory results.

A cloned G protein-coupled receptor, GPR30, also appears to interact with estrogens in some cell systems, and its participation in the rapid effects of estrogen is an attractive idea. However, four GPR30 knockout (KO) mice strains show inconsistent data with few stress or developmental phenotypes, and there is no consistent overlap of these models with ERα and ERβ KO phenotypes. There may be interaction/cross-talk between membrane-associated ERα and membrane-localized GPR30 in some cancer cells, but in vivo confirmation is lacking (Levin, 2008; Olde et al. 2009).

**Mechanism of Action**

Both estrogen receptors (ERs) are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 40–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to heat-shock protein 90 (HSP90), and upon binding estrogen, a change in ER conformation dissociates the heat-shock proteins and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA (Cheskiis et al., 1997). Homodimers of ERα or ERβ and ER α/ERβ heterodimers can be produced depending on the receptor complement in a given cell. The concept of ligand-mediated changes in ER conformation is central to understanding the mechanism of action of estrogen agonists and antagonists. The ER dimer binds to estrogen response elements (EREs), typically located in the promoter region of target genes with the consensus sequence GGTCANNNTGACC, but several similar sequences can act as estrogen response elements in a promoter-specific context. The type of ERE with which ERs interact also regulates the three-dimensional structure of the activated receptor (Hall et al., 2002).

The ER/DNA complex recruits a cascade of co-activator and other proteins to the promoter region of target genes (Figure 40–4B). Three families of proteins interact with ERs. The first of these has the ability to modify nucleosome structure either in an ATP-dependent manner, like SWI/Snf, or by histone methyltransferase (HMT) activity, as in proteins such as PRMT1. The second family comprises the p160/SRC proteins and includes SRC-1 (steroid-receptor co-activator 1), SRC-2, and SRC-3. The third family includes p300/CBP (cyclic AMP response-element binding protein), co-activators...
that are targets of several signal transduction cascades and may integrate function among diverse pathways and the basal transcriptional apparatus. Agonist-bound ERs appear initially to recruit SWI/Snf and HMT members that modify nucleosome structure and facilitate the subsequent recruitment of p160 members and p300 proteins (Metivier et al., 2003). The co-activators and p300 proteins have histone acetyltransferase (HAT) activity. Acetylation of histones further alters chromatin structure in the promoter region of target genes and allows the proteins that make up the general transcription apparatus to assemble and initiate transcription.

Interaction of ERs with antagonists also promotes dimerization and DNA binding. However, an antagonist produces a conformation of ER that is different from the agonist-occupied receptor (Smith and O’Malley, 2004; Wijayaratne et al., 1999). The antagonist-induced conformation facilitates binding of co-repressors such as nuclear-hormone receptor co-repressor (NcoR), are recruited to the complex. NcoR further recruits proteins such as histone deacetylase I (HDAC1) that act on histone proteins to stabilize nucleosome structure and prevent interaction with the GTA.

Figure 40–4. Molecular mechanism of action of nuclear estrogen receptor. A. Unliganded estrogen receptor (ER) exists as a monomer within the nucleus. B. Agonists such as 17β-estradiol (E) bind to the ER and cause a ligand-directed change in conformation that facilitates dimerization and interaction with specific estrogen response element (ERE) sequences in DNA. The ER-DNA complex recruits co-activators such as SWI/Snf that modify chromatin structure, and co-activators such as steroid-receptor co-activator-1 (SRC-1) that has histone acetyltransferase (HAT) activity that further alters chromatin structure. This remodeling facilitates the exchange of the recruited proteins such that other co-activators (e.g., p300 and the TRAP complex) associate on the target gene promoter and proteins that comprise the general transcription apparatus (GTA) are recruited, with subsequent synthesis of mRNA. C. Antagonists such as tamoxifen (T) also bind to the ER but produce a different receptor conformation. The antagonist-induced conformation also facilitates dimerization and interaction with DNA, but a different set of proteins called co-repressors, such as nuclear-hormone receptor co-repressor (NcoR), are recruited to the complex. NcoR further recruits proteins such as histone deacetylase I (HDAC1) that act on histone proteins to stabilize nucleosome structure and prevent interaction with the GTA.
Besides co-activators and co-repressors, both ERα and ERβ can interact physically with other transcription factors such as Sp1 (Saville et al., 2000) or AP-1 (Paech et al., 1997), and these protein-protein interactions provide an alternate mechanism of action. In these circumstances, ER-ligand complexes interact with Sp1 or AP-1 that is already bound to its specific regulatory element, such that the ER complex does not interact directly with an ERE. This may explain how estrogens are able to regulate genes that lack a consensus ERE. Responses to agonists and antagonists mediated by these protein-protein interactions also are ER isoform- and promoter-specific. For example, 17β-estradiol induces transcription of a target gene controlled by an AP-1 site in the presence of an ER α/AP-1 complex but inhibits transcription in the presence of an ER β/AP-1 complex. Conversely, anti-estrogens are potent activators of ERβ/AP-1 but not of ERα/AP-1 complexes.

Other signaling systems may activate nuclear ER by ligand-independent mechanisms. Phosphorylation of ERα at serine 118 by MAP kinase activates the receptor (Kato et al., 1995). Similarly, PI-3-kinase–activated Akt directly phosphorylates ERα, causing ligand-independent activation of estrogen-target genes (Simoncini et al., 2000). This provides a means of cross-talk between membrane-bound receptor pathways (i.e., EGF/IGF-1) that activate MAPK and the nuclear ER. In a reciprocal fashion ER may interact directly with members of the Src-Shc/Erk signaling pathway. Activation of Erk by an estrogen and androgen receptor (AR) agonist is thought to be responsible for the anti-apoptotic action of this drug in bone (reviewed in Manolagas et al., 2002).

Numerous studies indicate that some estrogen receptors are located on the plasma membrane of cells. This cellular pool form of the ER is encoded by the same genes that encode ERα and ERβ (Pedram, 2006) but are transported to the plasma membrane and reside mainly in caveolae. Translocation to the membrane by all sex steroid receptors is mediated by palmitoylation of a nine–amino acid motif in the respective E domains of the receptors (reviewed in Levin, 2008). These membrane-localized ERs mediate the rapid activation of some proteins such as MAPK (phosphorylated in several cell types) and the rapid increase in cyclic AMP caused by the hormone (Aronica and Katzenellenbogen, 1993). The finding that MAPK is activated by estradiol provides an additional level of cross-talk with growth factor receptors for IGF-1 and EGF, which can activate multiple kinase pathways.

**Absorption, Fate, and Elimination**

Various estrogens are available for oral, parenteral, transdermal, or topical administration. Given the lipophilic nature of estrogens, absorption generally is good with the appropriate preparation. Aqueous or oil-based esters of estradiol are available for intramuscular injection, ranging in frequency from every week to once per month. Conjugated estrogens are available for IV or IM administration. Transdermal patches that are changed once or twice weekly deliver estradiol continuously through the skin. Preparations are available for topical use in the vagina or for application to the skin. For many therapeutic uses, estrogen preparations are available in combination with a progestin. All estrogens are labeled with precautionary statements urging the prescribing of the lowest effective dose and for the shortest duration consistent with the treatment goals and risks for each individual patient.

Oral administration is common and may use estradiol, conjugated estrogens, esters of estrone and other estrogens, and ethinyl estradiol (in combination with a progestin). Estradiol is available in nonmicronized (FEMTRACE) and micronized preparations (ESTRACE, others). The micronized formulations yield a large surface for rapid absorption to partially overcome low absolute oral bioavailability due to first-pass metabolism (Fotherby, 1996). Addition of the ethinyl substituent at C17 (ethinyl estradiol) inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens (PREMARIN), which are primarily the sulfate esters of estrone, equilenin, and other naturally occurring compounds; esterified esters (MEGEST); or mixtures of synthetic conjugated estrogens prepared from plant-derived sources (CENESTIN; ENIUVA). These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, estroprogesterone (ORTHO-EST, OGEN, others), estrone is solubilized as the sulfate and stabilized with piperazine. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; ethinyl estradiol, e.g., is much more potent than conjugated estrogens.

A number of foodstuffs and plant-derived products, largely from soy, are available as nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein (Table 40–1), which display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol. In theory, these preparations could produce appreciable estrogenic effects, but their efficacy at relevant doses has not been established in human trials (Fitzpatrick, 2003).

Administration of estradiol via transdermal patches (ALORA, CLIMARA, ESTRADERM, VIVELLE, others) provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical emulsion (ESTRASORB), applied to the upper thigh and calf, or as a gel (ESTROGEL), applied once daily to the arm. The transdermal route does not lead to the high level of the drug that occur in the portal circulation after oral administration, and it is thus expected to minimize hepatic effects of estrogens (e.g., effects on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels).

Other preparations are available for intramuscular injection. When dissolved in oil and injected, esters of estradiol are well absorbed. The aryl and alkyl esters of estradiol become less polar as the size of the substituents increases; correspondingly, the rate of absorption of oily preparations is progressively slowed, and the duration of action can be prolonged. A single therapeutic dose of compounds such as estradiol valerate (DELESTROGEN, others) or estradiol cypionate (DEPO-ESTRADIOL, others) may be absorbed over several weeks following a single intramuscular injection.

Preparations of estradiol (ESTRACE) and conjugated estrogen (PREMARIN) creams are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring (ESTRING,
Femring) may be used for slow release of estradiol, and tablets are also available for vaginal use (Vagifem).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to SHBG and to a lesser degree to serum albumin. In contrast, ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Variations in estradiol metabolism occur and depend on the stage of the menstrual cycle, menopausal status, and several genetic polymorphisms (Herrington and Klein, 2001). In general, the hormone undergoes rapid hepatic biotransformation, with a plasma $t_{1/2}$ measured in minutes. Estradiol is converted primarily by 17β-hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16α-hydroxylation and 17-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Lesser amounts of estrone or estradiol are oxidized to the 2-hydroxycatechols by CYP3A4 in the liver and by CYP1A1 in extrahepatic tissues or to 4-hydroxycatechols by CYP1B1 in extrahepatic sites, with the 2-hydroxycatechol being formed to a greater extent. The 2- and 4-hydroxycatechols are largely inactivated by catechol-O-methyl transferases (COMTs). However, smaller amounts may be converted by CYP- or peroxidase-catalyzed reactions to yield semiquinones or quinones that are capable of forming DNA adducts or of generating (via redox cycling) reactive oxygen species that could oxidize DNA bases (Yue et al., 2003).

Estrogens also undergo enterohepatic recirculation via (1) sulfate and glucuronide conjugation in the liver, (2) biliary secretion of the conjugates into the intestine, and (3) hydrolysis in the gut (largely by bacterial enzymes) followed by reabsorption.

Many other drugs and environmental agents (e.g., cigarette smoke) act as inducers or inhibitors of the various enzymes that metabolize estrogens, and thus have the potential to alter their clearance. Consideration of the impact of these factors on efficacy and untoward effects is increasingly important with the decreased doses of estrogens currently employed for both menopausal hormone therapy and contraception.

Ethinyl estradiol is cleared much more slowly than estradiol due to decreased hepatic metabolism, and the elimination-phase $t_{1/2}$ in various studies ranges from 13 to 27 hours. Unlike estradiol, the primary route of biotransformation of ethinyl estradiol is via 2-hydroxylation and subsequent formation of the corresponding 2- and 3-methyl ethers. Mestranol, another semisynthetic estrogen and a component of some combination oral contraceptives, is the 3-methyl ether of ethinyl estradiol. In the body it undergoes rapid hepatic demethylation to ethinyl estradiol, which is its active form (Fotherby, 1996).

**Untoward Responses**

Estrogens are highly efficacious, but they do carry a number of risks. Many concerns arose initially from studies of early oral contraceptives, which contained high doses of estrogens. Oral contraceptives now contain much lower amounts of both estrogen and progestins, and this has significantly diminished the risks associated with their use. Nevertheless, major concerns about the use of estrogens remain today, especially regarding cancer, thromboembolic disease, and gallbladder disease.

**Concern About Carcinogenic Actions.** The risk of developing breast, endometrial, cervical, and vaginal cancer is probably the major concern for the use of estrogens and oral contraceptives. Landmark studies (Greenwald et al., 1971; Herbst et al., 1971) reported an increased incidence of vaginal and cervical adenocarcinoma in female offspring of mothers who had taken diethylstilbestrol (DES) during the first trimester of pregnancy. The incidence of clear cell vaginal and cervical adenocarcinoma in women who were exposed to DES in utero was 0.01-0.1% (Food and Drug Administration, 1985); these findings established for the first time that developmental exposure to estrogens was associated with an increase in a human cancer. Estrogen use during pregnancy also can increase the incidence of nonmalignant genital abnormalities in both male and female offspring. Thus, pregnant patients should not be given estrogens because of the possibility of such reproductive tract toxicities.

The use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by 5- to 15-fold (Shapiro et al., 1985). This increased risk can be prevented if a progestin is co-administered with the estrogen (Pike et al., 1997), and this is now standard practice.

The association between estrogen and/or estrogen-progestin use and breast cancer is of great concern. The results of two large randomized clinical trials of estrogen/progestin and estrogen-only (i.e., the two arms of WHI) in postmenopausal women clearly established a small but significant increase in the risk of breast cancer, apparently due to the medroxyprogesterone (Anderson et al., 2004; Rossouw et al., 2002). In the WHI study, an estrogen-progestin combination increased the total risk of breast cancer by 25%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received estrogen alone, the relative risk of breast cancer was actually decreased by 23%, and the decrease only narrowly missed reaching statistical significance. Interestingly, the incidence of colon cancer was reduced by 26% in the WHI trial.

The Million Women Study (MWS) in the U.K. was a cohort study rather than a clinical trial (Beral et al., 2003). It surveyed >1 million women; about half had received some type of hormone treatment and half had never used them. Those receiving an estrogen-progestin combination had an increased relative risk of invasive breast cancer of 2, and those receiving estrogen alone had an increased relative risk of 1.3, but the increase in actual attributable cases of the disease was again small.

Both the WHI and MWS data are thus consistent with earlier studies indicating that the progestin component (e.g., medroxyprogesterone) in combined hormone-replacement therapy plays a major role in this increased risk of breast cancer (Ross et al., 2000; Schairer et al., 2000). Importantly, although long-term data have not accumulated for the WHI trials, the available data suggest that the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy. Thus, hormone replacement therapy for ≤5 years is often prescribed to mitigate hot flashes and likely has a minimal effect on the risk of breast cancer.

Historically, the carcinogenic actions of estrogens were thought to be related to their trophic effects. An increase in cell proliferation would be expected to cause an increase in spontaneous errors associated with DNA replication, and estrogens would then enhance the growth of clones with mutations introduced by this or other mechanisms (e.g., chemical carcinogens). More recently, another mechanism has been proposed. If catechol estrogens, especially the...
4-hydroxycatechols, are converted to semiquinones or quinones prior to “inactivation” by COMT, these products, or reactive oxygen species generated during subsequent biotransformations, may cause direct chemical damage to DNA bases (Yue et al., 2003). In this regard, CYP1B1, which has specific estrogen-4-hydroxylase activity, is present in tissues such as uterus, breast, ovary, and prostate, which often give rise to hormone-responsive cancers (Yue et al., 2003).

**Metabolic and Cardiovascular Effects.** Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, as noted in a later section dealing with hormone-replacement regimens, progestins may reduce the favorable actions of estrogens. In contrast, estrogens do increase cholesterol levels in bile and cause a relative 2- to 3-fold increase in gallbladder disease. Currently prescribed doses of estrogens generally do not increase the risk of hypertension, and estrogen engaging the ERβ receptor typically reduces blood pressure.

A number of observational studies, clinical trials using intermediate markers of cardiovascular disease, and numerous animal studies suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease by 35-50% (Manson and Martin, 2001). However, two recent randomized clinical trials have not found such protection. HERS (Hulley et al., 1998) followed women with established coronary heart disease (CHD) and found that estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, and found no overall change in 5 years. The HERS II follow-up (Grady et al., 2002) found no overall change in the incidence of CHD after 6.8 years of the treatment. These results indicate no role for hormone replacement in the secondary prevention of atherosclerotic heart disease. In the WHI trials, women without existing CHD were treated with an estrogen plus progestin (Rossouw et al., 2002); protective effects were seen but only when hormone replacement was initiated within 10 years of menopause.

It is clear, however, that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with pre-existing cardiovascular disease (Grady et al., 2000). The increase in absolute risk is small but significant. In the WHI, e.g., an estrogen-progestin combination led to an increase in eight attributable cases of stroke per 10,000 older women and a similar increase in pulmonary embolism (Rossouw et al., 2002). The latter was seen mainly in women who concomitantly smoked cigarettes.

**Effects on Cognition.** Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the onset of Alzheimer’s disease (Green and Simpkins, 2000). However, the Women’s Health Initiative Memory Study (WHIMS) of a group of women ≥65 years of age (Shumaker et al., 2003) found that estrogen-progestin therapy was associated with a doubling in the number of women diagnosed with probable dementia, and no benefit of hormone treatment on global cognitive function was observed (Rapp et al., 2003). Women in the estrogen-only arm also showed a comparable decrease in cognitive function (Espeland et al., 2004), implicating estrogens in these cognitive changes.

**Other Potential Untoward Effects.** Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just before sleep. Fullness and tenderness of the breasts and edema may occur but sometimes can be diminished by lowering the dose. A more serious concern is that estrogens may cause severe migraine in some women. Estrogens also may reactivate or exacerbate endometriosis.

**Therapeutic Uses.** The two major uses of estrogens are for menopausal hormone therapy (MHT) and as components of combination oral contraceptives (see final section of chapter), and the pharmacological considerations for their use and the specific drugs and doses used differ in these settings. Historically, conjugated estrogens have been the most common agents for postmenopausal use (0.625 mg/day most often used). In contrast, most combination oral contraceptives in current use employ 20-35 μg/day of ethinyl estradiol. These preparations differ widely in their oral potencies (e.g., a dose of 0.625 mg of conjugated estrogens generally is considered equivalent to 5-10 μg of ethinyl estradiol). Thus, the “effective” dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. Furthermore, in the last two decades the doses of estrogens employed in both settings have decreased substantially. The untoward effects of the 20- to 35-μg doses now commonly used thus have a lower incidence and severity than those reported in older studies (e.g., with oral contraceptives that contained 50-150 μg of ethinyl estradiol or mestranol).

**Menopausal Hormone Therapy.** The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

**Vasomotor Symptoms.** The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy for these symptoms (Belchetz, 1994). If estrogen is contraindicated or otherwise undesirable, other options may be considered. Medroxyprogesterone acetate (discussed in the later section on progestins) may provide some relief of vasomotor symptoms for certain patients, and the α2 adrenergic agonist clonidine diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; when prescribed for this purpose the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

**Osteoporosis.** Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (Chapter 44). The result is thinning and weakening of the bones and an increased incidence of fractures, particularly compression fractures of the vertebrae and minimal-trauma fractures of the hip and wrist. The frequency and severity of these fractures and their associated complications (e.g., death and permanent disability) are a major public health problem, especially as the
population continues to age. Osteoporosis is an indication for estrogen therapy, which clearly is efficacious in decreasing the incidence of fractures. However, because of the risks associated with estrogen use, first-line use of other drugs, such as bisphosphonates, should be considered (Chapter 44). Nevertheless, it is important to note that most fractures in the postmenopausal period occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women (Anderson et al., 2004; Rossouw et al., 2002).

The primary mechanism by which estrogens act is to decrease bone resorption; consequently, estrogens are more effective at preventing rather than restoring bone loss (Belchetz, 1994; Prince et al., 1991). Estrogens are most effective if treatment is initiated before significant bone loss occurs, and their maximal beneficial effects require continuous use; bone loss resumes when treatment is discontinued. Other options for treatment of osteoporosis are presented in Chapter 44. An appropriate diet with adequate intake of Ca\(^{2+}\) and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment. Public health efforts to improve diet and exercise patterns in girls and young women also are rational approaches to increase bone mass.

**Vaginal Dryness and Urogenital Atrophy.** Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women (Robinson and Cardozo, 2003). These include dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

**Cardiovascular Disease.** The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause, and epidemiological studies consistently showed an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Furthermore, estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. Studies such as those led to the widespread use of estrogen for prevention of cardiovascular disease in postmenopausal women (Mendelsohn and Karas, 1999). As discussed earlier, estrogens promote coagulation and thromboembolic events. Randomized prospective studies (Grady et al., 2002; Rossouw et al., 2002) unexpectedly have indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time. However, as mentioned, combined estrogen-progestin therapy is associated with a decrease in heart attacks in younger women.

**Other Therapeutic Effects.** Many other changes occur in postmenopausal women, including a general thinning of the skin; changes in the urethra, vulva, and external genitalia; and a variety of changes including headache, fatigue, and difficulty concentrating. Chronic lack of sleep created by hot flashes and other vasomotor symptoms may be contributing factors. Estrogen replacement may help alleviate or lessen some of these via direct actions (e.g., improvement of vasomotor symptoms) or secondary effects resulting in an improved feeling of well-being (Belchetz, 1994). The WHI demonstrated that a conjugated estrogen in combination with a progestin reduces the risk of colon cancer by roughly one-half in postmenopausal women (Rossouw et al., 2002).

**Menopausal Hormone Regimens.** In the 1960s and 1970s, there was an increase in estrogen-replacement therapy, or ERT (i.e., estrogens alone), in postmenopausal women, primarily to reduce vasomotor symptoms, vaginitis, and osteoporosis. About 1980, epidemiological studies indicated that this treatment increased the incidence of endometrial carcinoma. This led to the use of hormone-replacement therapy, or HRT, that includes a progestin to limit estrogen-related endometrial hyperplasia. Although the actions of progesterone on the endometrium are complex, its effects on estrogen-induced hyperplasia may involve a decrease in estrogen-receptor content, increased local conversion of estradiol to the less potent estrone via the induction of 17\(\beta\) hydroxysteroid dehydrogenase in the tissue and/or the conversion of the endometrium from a proliferative to a secretory state. Postmenopausal HRT, when indicated, should include both an estrogen and progestin for women with a uterus (Belchetz, 1994). For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins.

Conjugated estrogens and medroxyprogesterone acetate (MPA) historically have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estriol have been used as estrogens, and norethindrone, norgestimate, levonorgestrel, norethisterone, and progesterone also have been widely used (especially in Europe). Various “continuous” or “cyclic” regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12-14 days of estrogen treatment; and (3) 5-6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. PREMPRO (conjugated estrogens plus MPA given as a fixed dose daily) and PREMPHASE (conjugated estrogens given for 28 days plus MPA given for 14 of 28 days) are widely used combination formulations. Other combination products available in the U.S. are FEMHRT (ethinyl estradiol plus norethindrone acetate), ACTIVELLA (estradiol plus norethindrone), PREFEST (estradiol and norgestimate), and ANGELIQ (estradiol plus drospirenone). Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, and/or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than does transdermal administration. Either route effectively relieves vasomotor symptoms and protects against bone loss. Oral but not transdermal estrogen may increase SHBG, other binding globulins, and angiotensinogen; the oral route might be expected to cause greater increases in the cholesterol
content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (~50% of those seen with the oral route) (Walsh et al., 1994) but may be preferred in women with hypertriglyceridemia.

Tibolone (LIVIAL) is widely used in the E.U. for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the U.S. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to three metabolites that have predominantly estrogenic, progestagenic, and androgenic activities. The drug appears to increase bone mineral density and decrease vasomotor symptoms without stimulating the endometrium, but its effects on fractures, breast cancer, and long-term outcomes remain to be established (Modelska and Cummings, 2002).

Regardless of the specific agent or regimen, menopausal hormone therapy with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

**Selective Estrogen Receptor Modulators and Anti-Estrogens**

In the past, estrogen pharmacology was based on a simple model of an agonist binding to a single ER that subsequently affected transcription by the same molecular mechanism in all target tissues and of antagonists that acted by simple competition with agonists for binding. This simple concept is no longer valid. By altering the conformation of the two different ERs and thereby changing interactions with co-activators and co-repressors in a cell-specific and promoter-specific contexts, ligands may have a broad spectrum of activities from purely anti-estrogenic in all tissues, to partially estrogenic in some tissues with anti-estrogenic or no activities in others, to purely estrogenic activities in all tissues. The elucidation of these concepts has been a major breakthrough in estrogen pharmacology and should permit the rational design of drugs with very selective patterns of estrogenic activity (Smith and O’Malley, 2004).

**Selective Estrogen Receptor Modulators: Tamoxifen, Raloxifene, and Toremifene.** Selective estrogen receptor modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) during postmenopausal hormone therapy but antagonist activity in tissues such as breast and endometrium, where estrogenic actions (e.g., carcinogenesis) might be deleterious. Currently approved drugs in the U.S. in this class are tamoxifen citrate, raloxifene hydrochloride (EVISTA), and toremifene (FARESTON), which is chemically related and has similar actions to tamoxifen. Tamoxifen and toremifene are used for the treatment of breast cancer, and raloxifene is used primarily for the prevention and treatment of osteoporosis and to reduce the risk of invasive breast cancer in high-risk postmenopausal women. They are considered in detail in Chapter 63.

**Anti-Estrogens: Clomiphene and Fulvestrant.** These compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. Clomiphene (CLOMID, SEROPHENE, others) is approved for the treatment of infertility in anovulatory women, and fulvestrant (FASLODEX) is used for the treatment of breast cancer in women with disease progression after tamoxifen.

**Chemistry.** The structures of the trans-isomer of tamoxifen, and of raloxifene, trans-clomiphene (enclomiphene), and fulvestrant are:
Tamoxifen is a triphenylethylene with the same stilbene nucleus as DES; compounds of this class display a variety of estrogenic and anti-estrogenic activities. In general, the trans conformations have anti-estrogenic activity, whereas the cis conformations display estrogenic activity. However, the pharmacological activity of the trans compound depends on the species, target tissue, and gene. Hepatic metabolism produces primarily N-desmethy1tamoxifen, which has affinity for ER comparable to that of tamoxifen, and lesser amounts of the highly active 4-hydroxy metabolite, which has a 25-50 times higher affinity for both ERα and ERβ than does tamoxifen (Kuiper et al., 1997). Tamoxifen is marketed as the pure trans isomer. Toremifene is a triphenylethylene with a chlorine substitution at the R2 position.

Raloxifene is a polyhydroxylated nonsteroidal compound with a benzothiophene core. Raloxifene binds with high affinity for both ERα and ERβ (Kuiper et al., 1997).

Clomiphene citrate is a triphenylethylene; its two isomers, zuclo|miphene (cis-clomiphene) and enclomiphene (trans-clomiphene), are a weak estrogen agonist and a potent antagonist, respectively. Clomiphene binds to both ERα and ERβ, but the individual isomers have not been examined (Kuiper et al., 1997).

Fulvestrant is a 7α-alkylamide derivative of estradiol that interacts with both ERα and ERβ (Van Den Bemd et al., 1999).

Pharmacological Effects

Tamoxifen exhibits anti-estrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug’s activity depends on the tissue and end point measured. For example, tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women (reviewed in Jaiyesimi et al., 1995), and yet it stimulates proliferation of endometrial cells and causes endometrial thickening (Lahti et al., 1993). The drug has an antiresorptive effect on bone, and in humans it decreases total cholesterol, LDL, and LPA but does not increase HDL and triglycerides (Love et al., 1994). Tamoxifen treatment causes a 2- to 3-fold increase in the relative risk of deep vein thrombosis and pulmonary embolism and a roughly 2-fold increase in endometrial carcinoma (Smith, 2003). Tamoxifen produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting.

Raloxifene is an estrogen agonist in bone, where it exerts an antiresorptive effect. It reduces the number of vertebral fractures by up to 50% in a dose-dependent manner (Delmas et al., 1997; Ettinger et al., 1999). The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL or normalize plasminogen-activator inhibitor 1 in postmenopausal women (Walsh et al., 1998). Raloxifene does not cause proliferation or thickening of the endometrium. Preclinical studies indicate that raloxifene has an antiproliferative effect on ER-positive breast tumors and on proliferation of ER-positive breast cancer cell lines (Hol et al., 1997) and significantly reduces the risk of ER-positive but not ER-negative breast cancer (Cummings et al., 1999). Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a 3-fold increase in deep vein thrombosis and pulmonary embolism (Cummings et al., 1999).

Initial animal studies with clomiphene showed slight estrogenic activity and moderate anti-estrogenic activity, but the most striking effect was the inhibition of pituitary gonadotropes. In contrast, the most prominent effect in women was enlargement of the ovaries and the drug-induced ovulation in many patients with amenorrhea, polycystic ovarian syndrome, and dysfunctional bleeding with anovulatory cycles. This is the basis for clomiphene’s major pharmacological use: to induce ovulation in women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production. In some cases, clomiphene is used in conjunction with human gonadotropins (Chapter 38) to induce ovulation.

Fulvestrant and its less potent forerunner ICI 164,384 have been purely anti-estrogenic in studies to date. In vitro, fulvestrant was more potent than 4-hydroxytamoxifen (DeFriend et al., 1994) in inhibiting proliferation of breast cancer cells, and in clinical trials it is efficacious in treating tamoxifen-resistant breast cancers (Robertson et al., 2003).

All of these agents bind to the ligand-binding pocket of both ERα and ERβ and competitively block estradiol binding. However, the conformation of the ligand-bound ERs is different with different ligands (Smith and O’Malley, 2004), and this has two important mechanistic consequences. The distinct ER-ligand conformations recruit different co-activators and co-repressors onto the promoter of a target gene by differential protein-protein interactions at the receptor surface. The tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different co-activator and co-repressor levels in different cell types that together affect the nature of ER complexes formed in a tissue-selective fashion.

The conformation of ERs, especially in the AF-2 domain, determines whether a co-activator or a co-repressor will be recruited to the ER-DNA complex (Smith and O’Malley, 2004). Whereas 17β-estradiol induces a conformation that recruits co-activators to the receptor, tamoxifen induces a conformation that permits the recruitment of the co-repressor to both ERα and ERβ. The agonist activity of tamoxifen seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ERα, because ERβ does not contain a functional AF-1 domain, tamoxifen does not activate ERβ (McNerney et al., 1998).

Raloxifene acts as a partial agonist in bone but does not stimulate endometrial proliferation in postmenopausal women. Presumably this is due to some combination of differential expression...
of transcription factors in the two tissues and the effects of this SERM on ER conformation. Raloxifene induces a configuration in ERα that is distinct from that of tamoxifen-ERβ (Tamrazi et al., 2003), suggesting that a different set of co-activators/co-repressors may interact with ER-raloxifene compared with ER-tamoxifen.

Clomiphene increases gonadotropin secretion and stimulates ovulation. It increases the amplitude of LH and FSH pulses without changing pulse frequency (Kettel et al., 1993). This suggests that the drug is acting largely at the pituitary level to block inhibitory actions of estrogen on gonadotropin release from the gland and/or is somehow causing the hypothalamus to release larger amounts of GnRH per pulse.

Fulvestrant binds to ERα and ERβ with a high affinity comparable to estradiol but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ERα while apparently protecting ERβ from degradation (Van Den Bemd et al., 1999). This effect on ERα protein levels may explain fulvestrant’s efficacy in tamoxifen-resistant breast cancer.

Absorption, Fate, and Excretion
Tamoxifen is given orally, and peak plasma levels are reached within 4-7 hours after treatment. This drug displays two elimination phases with half-lives of 7-14 hours and 4-11 days. Due to the prolonged 1/2, 3-4 weeks of treatment are required to reach steady-state plasma levels. The parent drug is converted largely to metabolites within 4-6 hours after oral administration. Tamoxifen is metabolized in humans by multiple hepatic CYPs, some of which it also induces (Sridar et al., 2002). In humans and other species, 4-hydroxytamoxifen is produced via hepatic metabolism, and this compound is considerably more potent than the parent drug as an anti-estrogen. The major route of elimination from the body involves N-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite. Polymorphisms affect the rate of tamoxifen metabolism to its more potent 4-hydroxy metabolite and may impact its therapeutic activity in breast cancer (Chapter 63).

Raloxifene is adsorbed rapidly after oral administration and has an absolute bioavailability of ~2%. The drug has a 1/2 of ~28 hours and is eliminated primarily in the feces after hepatic glucuronidation; it does not appear to undergo significant biotransformation by CYPs.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces and to a lesser extent in the urine. The long plasma 1/2 (5-7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues. Other active metabolites with long half-lives also may be produced.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. Numerous metabolites are formed in vivo, possibly by pathways similar to endogenous estrogen metabolism, but the drug is eliminated primarily (90%) via the feces in humans.

Therapeutic Uses
Breast Cancer. Tamoxifen is highly efficacious in the treatment of breast cancer. It is used alone for palliation of advanced breast cancer in women with ER-positive tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages (Jaiyesimi et al., 1995). Response rates are ~50% in women with ER-positive tumors. Tamoxifen increases disease-free survival and overall survival; treatment for 5 years reduces cancer recurrence by 50% and death by 27% and is more efficacious than shorter 1- to 2-year treatment periods. Tamoxifen reduces the risk of developing contralateral breast cancer and is approved for primary prevention of breast cancer in women at high risk, in whom it causes a 50% decrease in the development of new tumors. Prophylactic treatment should be limited to 5 years because effectiveness decreases thereafter. The most frequent side effect is hot flashes. Tamoxifen has estrogenic activity in the uterus, increases the risk of endometrial cancer by 2- to 3-fold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anticoagulant therapy (Smith, 2003) and women with a history of deep vein thrombosis or stroke.

Toremifene has therapeutic actions similar to tamoxifen, and fulvestrant may be efficacious in women who become resistant to tamoxifen. Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

Osteoporosis. Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. In a large clinical trial, raloxifene increased spinal bone mineral density by >2% and reduced the rate of vertebral fractures by 30-50% but did not significantly reduce nonvertebral fractures (Delmas et al., 2002; Ettinger et al., 1999). Raloxifene does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; however, HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

Infertility. Clomiphene is used primarily for treatment of female infertility due to anovulation. By increasing gonadotropin levels, primarily FSH, it enhances follicular recruitment. It is relatively inexpensive, orally active, and requires less extensive monitoring than other treatment protocols. However, the drug may exhibit untoward effects, including ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. In addition, clomiphene-induced cycles have a relatively high incidence of luteal phase dysfunction due to inadequate progesterone production, and prolonged use (e.g., ≥12 cycles) may
increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when the drug has been used to induce ovulation. Clomiphene also may be used to evaluate the male reproductive system because testosterone feedback on the hypothalamus and pituitary is mediated to a large degree by estrogens formed from aromatization of the androgen.

**Experimental SERM-Estrogen Combinations.** There is considerable interest in menopausal hormone therapy using combinations of a pure estrogen agonist (e.g., estradiol) with a SERM that has predominantly antagonist activity in the breast and endometrium but does not distribute to the CNS. The strategy is to obtain the beneficial actions of the agonist (e.g., prevention of hot flashes and bone loss) while the SERM blocks unwanted agonist action at peripheral sites (e.g., proliferative effects in breast and endometrium) but does not enter the brain to cause hot flashes. Animal studies have been encouraging (Labrie et al., 2003), but clinical efficacy and safety of this approach remain to be established.

**Estrogen-Synthesis Inhibitors**

Several agents can be used to block estrogen biosynthesis. Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (Chapter 38). Aminoglutethimide inhibits aromatase activity, but its use is limited by its lack of selectivity and its side effects (sedation). It was discontinued in the U.S. in 2008.

The recognition that locally produced as well as circulating estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (Chapter 63). Both steroidal (e.g., formestane and exemestane [AROMASIN]) and nonsteroidal agents (e.g., anastrozole [ARIMIDEX], letrozole [FEMARA], and vorozole) are available. Steroidal, or type I, agents are substrate analogs that act as suicide inhibitors to irreversibly inactivate aromatase, whereas the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs (Haynes et al., 2003). Exemestane, letrozole, and anastrozole are currently approved in the U.S. for the treatment of breast cancer.

As discussed in Chapter 62, these agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen. They are highly efficacious and actually superior to tamoxifen in adjuvant use for postmenopausal women (Coombes et al., 2004), and are indicated either following tamoxifen for 2-5 years or as initial agents. They have the added advantage of not increasing the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. They lack the beneficial effect of tamoxifen to maintain bone density and thus are usually administered with bisphosphonates. Their effects on plasma lipids remain to be established.

**PROGESTINS**

Compounds with biological activities similar to those of progesterone have been variously referred to in the literature as progestins, progestational agents, progestagens, progestogens, gestagens, or gestogens. The progestins (Figure 40–5) include the naturally occurring hormone progesterone, 17α-acetoxyprogesterone derivatives in the pregnane series, 19-nortestosterone derivatives in the estrane series, and norgestrel and related compounds in the gonane series. Medroxyprogesterone acetate (MPA) and megestrol acetate are C21 steroids in the pregnane family with selective activity very similar to that of progesterone itself. MPA and oral micronized progesterone are widely used with estrogens for MHT and other situations in which a selective progestational effect is desired. Furthermore, depot MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives (estranes) were developed for use as progestins in oral contraceptives, and although their predominant activity is progestational, they exhibit androgenic and other activities. The gonanes are another family of “19-nor” compounds, containing an ethyl rather than a methyl substituent in the 13-position. They have diminished androgenic activity relative to the estranes. These two classes of 19-nortestosterone derivatives are the progestational components of most oral and some long-acting injectable contraceptives. The remaining oral contraceptives contain a class of progestins derived from...
Agents Similar to Progesterone (Pregnanes)

Agents Similar to 19-Nortestosterone (Estranes)

Agents Similar to 19-Norgestrel (Gonanes)

Figure 40–5. Structural features of various progestins.

spironolactone (e.g., drospirenone) that have anti-mineralocorticoid and anti-androgenic properties.

History. Corner and Allen originally isolated a hormone in 1933 from the corpora lutea of sows and named it “progestin.” The next year, several European groups independently isolated the crystalline compound and called it “luteo-sterone,” unaware of the previous name. This difference in nomenclature was resolved in 1935 at a garden party in London given by Sir Henry Dale, who helped persuade all parties that the name “progesterone” was a suitable compromise.

Two major advances overcame the early difficulties and expense of obtaining progesterone from animal sources. The first was the synthesis of progesterone by Russel Marker from the plant product diosgenin in the 1940s, which provided a relatively inexpensive and highly pure product. The second was the synthesis of 19-nor compounds, the first orally active progestins, in the early 1950s by Carl Djerassi, who synthesized norethindrone at Syntex, and Frank Colton, who synthesized the isomer norethynodrel at Searle. These advances led to the development of effective oral contraceptives.

Chemistry. The structural features of several progestins are shown in Figure 40–5. Unlike the ER, which requires a phenolic A ring for high-affinity binding, the progesterone receptor (PR) favors a Δ4,3-one A-ring structure in an inverted 1β, 2α-conformation (Duax et al., 1988). Other steroid hormone receptors also bind this nonphenolic A-ring structure, although the optimal conformation differs from that for the PR. Thus, some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors, a property that probably accounts for some of their nonprogestational activities. The spectrum of activities of these compounds is highly dependent on specific substituent groups, especially the nature of the C17 substituent in the D ring, the presence of a C19 methyl group, and the presence of an ethyl group at position C13.

One major class of agents is similar to progesterone and its metabolite 17α-hydroxyprogesterone (Figure 40–5). Compounds such as hydroxyprogesterone caproate have progestational activity but must be used parenterally due to first-pass hepatic metabolism. However, further substitutions at the 6-position of the B ring yield orally active compounds such as medroxyprogesterone acetate and megestrol acetate with selective progestational activity. The second major class of agents is 19-nor testosterone derivatives. These testosterone derivatives, lacking the C19 methyl group, display primarily progestational rather than androgenic activity. An ethinyl substituent at C17 decreases hepatic metabolism and yields orally active 19-nortestosterone analogs such as norethindrone, norethindrone acetate, norethynodrel, and ethynodiol diacetate. The activity of the latter three compounds is due primarily to their rapid in vivo conversion to norethindrone. These compounds are less selective than the 17α-hydroxyprogesterone derivatives just mentioned and have varying degrees of androgenic activity and, to a lesser extent, estrogenic and anti-estrogenic activities.

Replacement of the 13-methyl group of norethindrone with a 13-ethyl substituent yields the gonane norgestrel, which is a more potent progestin than the parent compound but has less androgenic activity. Norgestrel is a racemic mixture of an inactive dextrorotatory isomer and the active levorotatory isomer, levonorgestrel. Preparations containing half as much levonorgestrel as norgestrel thus have equivalent pharmacological activity. Other gonanes—including norgestimate, desogestrel, and gestodene (not available in the U.S.)—have very little if any androgenic activity at therapeutic doses.

Other steroidal progestins include the gonane dienogest; 19-norprogestin derivatives (e.g., nomegestrol, Nestorone, and trimogestone), which have increased selectivity for the progesterone receptor and less androgenic activity than estranes; and the spironolactone derivative drospirenone, which is used in combination with oral contraceptives. Like spironolactone, drospirenone is also a mineralocorticoid and androgen receptor antagonist.

Biosynthesis and Secretion. Progesterone is secreted by the ovary, mainly from the corpus luteum, during the second half of the menstrual cycle (Figure 40–3). LH, acting via its G protein-coupled receptor, stimulates progesterone secretion during the normal cycle.

After fertilization, the trophoblast secretes hCG into the maternal circulation, which then stimulates the LH receptor to sustain the corpus luteum and maintain progesterone production. During the second or third month of pregnancy, the developing placenta begins to secrete estrogen and progesterone in collaboration...
with the fetal adrenal glands, and thereafter the corpus luteum is not essential to continued gestation. Estrogen and progesterone continue to be secreted in large amounts by the placenta up to the time of delivery.

**PHYSIOLOGICAL AND PHARMACOLOGICAL ACTIONS**

**Neuroendocrine Actions.** As discussed earlier in this chapter, progesterone produced in the luteal phase of the cycle has several physiological effects including decreasing the frequency of GnRH pulses. This progesterone-mediated decrease in GnRH pulse frequency is critical for suppressing gonadotropin release and resetting the hypothalamic-pituitary-gonadal axis to transition from the luteal back to the follicular phase. Furthermore, GnRH suppression is the major mechanism of action of progestin-containing contraceptives.

**Reproductive Tract.** Progesterone decreases estrogen-driven endometrial proliferation and leads to the development of a secretory endometrium (Figure 40–3), and the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. If the duration of the luteal phase is artificially lengthened, either by sustaining luteal function or by treatment with progesterone, decidual changes in the endometrial stroma similar to those seen in early pregnancy can be induced. Under normal circumstances, estrogen antecedes and accompanies progesterone in its action on the endometrium and is essential to the development of the normal menstrual pattern.

Progesterone also influences the endocervical glands, and the abundant watery secretion of the estrogen-stimulated structures is changed to a scant viscid material. As noted previously, these and other effects of progestins decrease penetration of the cervix by sperm.

The estrogen-induced maturation of the human vaginal epithelium is modified toward the condition of pregnancy by the action of progesterone, a change that can be detected in cytological alterations in the vaginal smear. If the quantity of estrogen concurrently acting is known to be adequate, or if it is assured by giving estrogen, the cytological response to a progestin can be used to evaluate its progestational potency.

Progesterone is very important for the maintenance of pregnancy. Progesterone suppresses menstruation and uterine contractility, but other effects also may be important. These effects to maintain pregnancy led to the historical use of progestins to prevent threatened abortion. However, such treatment is of questionable benefit, probably because spontaneous abortion infrequently results from diminished progesterone.

**Mammary Gland.** Development of the mammary gland requires both estrogen and progesterone. During pregnancy and to a minor degree during the luteal phase of the cycle, progesterone, acting with estrogen, brings about a proliferation of the acini of the mammary gland. Toward the end of pregnancy, the acini fill with secretions and the vasculature of the gland notably increases; however, only after the levels of estrogen and progesterone decrease at parturition does lactation begin.

During the normal menstrual cycle, mitotic activity in the breast epithelium is very low in the follicular phase and then peaks in the luteal phase. This pattern is due to progesterone, which triggers a *single* round of mitotic activity in the mammary epithelium. This effect is transient because continued exposure to the hormone is rapidly followed by arrest of growth of the epithelial cells. Importantly, progesterone may be responsible for the increased risk of breast cancer associated with estrogen-progestin use in postmenopausal women, although controlled studies with only progesterin have not been performed (Anderson et al., 2004; Rossouw et al., 2002).

**Central Nervous System Effects.** During a normal menstrual cycle, an increase in basal body temperature of ~0.6°C (1°F) may be noted at mid-cycle; this correlates with ovulation. This increase is due to progesterone, but the exact mechanism of this effect is unknown. Progesterone also increases the ventilatory response of the respiratory centers to carbon dioxide and leads to reduced arterial and alveolar Pco2 in the luteal phase of the menstrual cycle and during pregnancy. Progesterone also may have depressant and hypnotic actions in the CNS, possibly accounting for reports of drowsiness after hormone administration. This potential untoward effect may be abrogated by giving progesterone preparations at bedtime, which may even help some patients sleep.

**Metabolic Effects.** Progestins have numerous metabolic actions. Progesterone itself increases basal insulin levels and the rise in insulin after carbohydrate ingestion, but it does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogs such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. The 19-norprogestins may have more pronounced effects on plasma lipids because of their androgenic activity.

In this regard, a large prospective study has shown that MPA decreases the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but it does not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly alter beneficial estrogen effects on either HDL or LDL profiles.
Group for the PEPI Trial, 1995); the spironolactone derivative drosperone may actually have advantageous effects on the cardiovascular system due to its anti-androgenic and anti-mineralocorticoid activities. Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

**Mechanism of Action**

A single gene that encodes two isoforms of the progesterone receptor, PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A; this occurs by use of two distinct estrogen-dependent promoters in the PR gene (Giangrande and McDonnell, 1999). The ratios of the individual isoforms vary in reproductive tissues as a consequence of tissue type, developmental status, and hormone levels. Both PR-A and PR-B have AF-1 and AF-2 transactivation domains, but the longer PR-B also contains an additional AF-3 that contributes to its cell- and promoter-specific activity. Because the ligand-binding domains of the two PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR is present primarily in the nucleus in an inactive monomeric state bound to heat-shock proteins (HSP-90, HSP-70, and p59). When receptors bind progesterone, the heat-shock proteins dissociate, and the receptors are phosphorylated and subsequently form dimers (homo- and heterodimers) that bind with high selectivity to PREs (progesterone response elements) located on target genes (Giangrande and McDonnell, 1999). Transcriptional activation by PR occurs primarily via recruitment of co-activators such as SRC-1, NcoA-1, or NcoA-2 (Collingwood et al., 1999). The receptor–co-activator complex then favors further interactions with additional proteins such as CBP and p300, which mediate other processes including histone acetylation activity. Histone acetylation causes a remodeling of chromatin that increases the accessibility of general transcriptional proteins, including RNA polymerase II, to the target promoter. Progesterone antagonists also facilitate receptor dimerization and DNA binding, but, as with ER, the conformation of antagonist-bound PR is different from that of agonist-bound PR. This different conformation favors PR interaction with co-repressors such as NCoR/SMRT, which recruit histone deacylases. Histone deacylation increases DNA interaction with nucleosomes and renders a target promoter inaccessible to the general transcription apparatus.

The biological activities of PR-A and PR-B are distinct and depend on the target gene in question. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this action of PR-B and is also a transcriptional inhibitor of other steroid receptors (McDonnell and Goldman, 1994). Current data suggest that co-activators and co-repressors interact differentially with PR-A and PR-B (e.g., the co-repressor SMRT binds much more tightly to PR-A than to PR-B) (Giangrande et al., 2000), and this may account, at least in part, for the differential activities of the two isoforms. Female PR-A knockout mice are infertile, with impaired ovulation and defective decidualization and implantation. Several uterine genes appear to be regulated exclusively by PR-A, including calcitonin and amphiregulin (Mucal-Jericevic et al., 2000), and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium is lost in PR-A knockout mice. In contrast, knockout studies suggest that PR-B is largely responsible for mediating hormone effects in the mammary gland (Mucal-Jericevic et al., 2003).

Certain effects of progesterone, such as increased Ca2+ mobilization in sperm, can be seen in as little as 3 minutes (Blackmore, 1999) and are therefore considered transcription independent. Similarly, progesterone can promote oocyte maturation (meiotic resumption) independent of transcription (Hammes, 2004). There is debate regarding the identity of the receptors mediating these progestin-induced processes, as well as their physiological importance in humans.

**Absorption, Fate, and Excretion**

Progesterone undergoes rapid first-pass metabolism, but high-dose (e.g., 100-200 mg) preparations of micronized progesterone (PROGESTRIN) are available for oral use. Although the absolute bioavailability of these preparations is low (Fotherby, 1996), efficacious plasma levels nevertheless may be obtained. Progesterone also is available in oil solution for injection, as a vaginal gel (CRINONE, PROCHIEVE), as a slow-release intrauterine device (PROGESTASAERT) for contraception, and as a vaginal insert (ENDOMETRIN) for assisted reproductive technology.

Esters such as MPA (DEPO-PROVERA) are available for intramuscular administration, and MPA (PROVERA, others) and megestrol acetate (MEGACE, others) may be used orally. The 19-nor steroids have good oral activity because the ethinyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time (see later section on contraceptives).

In the plasma, progesterone is bound by albumin and corticosteroid-binding globulin but is not appreciably bound to SHBG. 19-Nor compounds, such as norethindrone, norgestrel, and desogestrel, bind to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of all these synthetic compounds to plasma proteins is extensive, ≤90%, but the proteins involved are compound specific.

The elimination t 1/2 of progesterone is ~5 minutes, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3α, 20α-diol-i; its measurement in urine and plasma is used as an index of endogenous progesterone secretion. The synthetic progestins have much longer half-lives (e.g., ~7 hours for norethindrone, 16 hours for norgestrel, 12 hours for gestodene, and 24 hours for MPA). The metabolism of synthetic progestins is thought to be primarily hepatic, and elimination is generally via the urine as conjugates and various polar metabolites, although their metabolism is not as clearly defined as that of progesterone.
Therapeutic Uses

The two most frequent uses of progestins are for contraception, either alone or with an estrogen (Chapter 66; see also later in this chapter), and in combination with estrogen for hormone therapy of postmenopausal women.

Progestins also are used diagnostically for secondary amenorrhea. An oral progestin is given to an amenorrheic woman for 5-7 days. If endogenous estrogens are present, withdrawal bleeding will occur. Combinations of estrogens and progestins can also be given to test for endometrial responsiveness in patients with amenorrhea.

In addition, progestins are highly efficacious in decreasing the occurrence of endometrial hyperplasia and carcinoma caused by unopposed estrogens; when used in this setting, there appears to be less irregular uterine bleeding with sequential rather than continuous administration. Local intrauterine application via a hormone-releasing intrauterine device (IUD) containing levonorgestrel can be used to decrease estrogen-induced endometrial hyperplasia while reducing untoward effects (e.g., unfavorable lipid profiles and incidence of breast cancer) of systemically administered progestins.

Finally, levonorgestrel is used as so-called emergency contraception after known or suspected unprotected intercourse. The medication is given orally within 72 hours after intercourse as either a single 1.5-mg dose (PLAN B ONE STEP) or as two 0.75-mg doses (PLAN B) separated by 12 hours. The mechanism of action may involve several factors, including the prevention of ovulation, fertilization, and implantation.

ANTI-PROGESTINS AND PROGESTERONE-RECEPTOR MODULATORS

The first report of an anti-progestin, RU 38486 (often referred to as RU-486) or mifepristone, appeared in 1981; this drug is available for the termination of pregnancy (Christin-Maitre et al., 2000). In 2010, the FDA approved ulipristal acetate [ella (U.S.), ellaOne (E.U.)], a partial agonist at the progesterone receptor, for emergency contraception. Anti-progestins also have several other potential applications, including to prevent conception, to induce labor, and to treat uterine leiomyomas, endometriosis, meningiomas, and breast cancer (Spitz and Chwalisz, 2000).

Mifepristone

Chemistry. Mifepristone is a derivative of the 19-norprogestin norethindrone containing a dimethyl-aminophenol substituent at the 11β-position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone was initially thought to be a pure anti-progestin, although it is now considered a progesterone-receptor modulator (PRM) due to its context-dependent activity.

Other PRMs and pure progesterone antagonists now have been synthesized, and most contain an 11β-aromatic group. Another widely studied anti-progestin is onapristone (or ZK 98299), which is similar in structure to mifepristone but contains a methyl substituent in the 13α rather than 13β orientation. More selective progesterone-receptor modulators, such as asoprisnil, are being studied experimentally (DeManno et al., 2003).

Pharmacological Actions. Mifepristone acts primarily as a competitive receptor antagonist for both progesterone receptors, although it may have some agonist activity in certain contexts. In contrast, onapristone appears to be a pure progesterone antagonist. PR complexes of both compounds antagonize the actions of progesterone-PR complexes and also appear to preferentially recruit corepressors (Leonhardt and Edwards, 2002).

When administered in the early stages of pregnancy, mifepristone causes decidual breakdown by blockade of uterine progesterone receptors. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of progesterone receptors in the uterus increases uterine prostaglandin levels and sensitizes the myometrium to their contractile actions. Mifepristone also causes cervical softening, which facilitates expulsion of the detached blastocyst.

Mifepristone can delay or prevent ovulation depending on the timing and manner of administration. These effects are due largely to actions on the hypothalamus and pituitary rather than the ovary, although the mechanisms are unclear.
If administered for one or several days in the mid- to late luteal phase, mifepristone impairs the development of a secretory endometrium and produces menses. Progesterone-receptor blockade at this time is the pharmacological equivalent of progesterone withdrawal, and bleeding normally ensues within several days and lasts for 1-2 weeks after anti-progestin treatment.

Mifepristone also binds to glucocorticoid and androgen receptors and exerts anti-glucocorticoid and anti-androgenic actions. A predominant effect in humans is blockade of the feedback inhibition by cortisol of adrenocorticotropic hormone secretion from the pituitary, thus increasing both corticotropin and adrenal steroid levels in the plasma.

Absorption, Fate, and Excretion. Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours, and the drug is slowly cleared with a plasma t1/2 of 20-40 hours. In plasma, it is bound by α1-acid glycoprotein, which contributes to the drug’s long t1/2. Metabolites are primarily the mono- and di-demethylated products (thought to have pharmacological activity) formed via CYP3A4-catalyzed reactions and, to a lesser extent, hydroxylated compounds. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces (Jang and Benet, 1997).

Therapeutic Uses and Prospects. Mifepristone (MIFEPREX), in combination with misoprostol or other prostaglandins, is available for the termination of early pregnancy.

When mifepristone is used to produce a medical abortion, a prostaglandin is given 48 hours after the anti-progestin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular sulprostone, intravaginal gemeprost, and oral misoprostol have been used. The success rate with such regimens is >90% among women with pregnancies of ≤49 days’ duration. The most severe untoward effect is vaginal bleeding, which most often lasts 8-17 days but is only rarely (0.1% of patients) severe enough to require blood transfusions. High percentages of women also have experienced abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the prostaglandin. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its anti-glucocorticoid activity. In fact, due to its high affinity for the glucocorticoid receptor, high doses of mifepristone can result in adrenal insufficiency; thus mifepristone is being considered as a chemical treatment for diseases of excess adrenal cortisol secretion.

Ulipristal

Chemistry. Ulipristal, a derivative of 19-norpregesterone, functions as a selective progesterone receptor modulator (SPRM), acting as a partial agonist at progesterone receptors. It has a dimethylaminophenol group at the 11β position, as does mifepristone, with an additional acetoxy group at the C17. Unlike mifepristone, ulipristal appears to be a relatively weak glucocorticoid antagonist.

Pharmacological Actions. In high doses, ulipristal has anti-proliferative effects in the uterus; however, its most relevant actions to date involve its capacity to inhibit ovulation. Ulipristal’s anti-ovulatory actions likely occur due to progesterone regulation at many levels, including inhibition of LH release through the hypothalamus and pituitary, and inhibition of LH-induced follicular rupture within the ovary.

A 30-mg dose of ulipristal can inhibit ovulation when taken up to five days after intercourse. Ulipristal can block ovarian rupture at or even just after the time of the LH surge, confirming that at least some of its effects are directly in the ovary. Ulipristal may also block endometrial implantation of the fertilized egg, although whether this contributes to its effects as an emergency contraceptive (see below) is not clear.

Therapeutic Uses. Ulipristal acetate [ella, ellaOne] has recently been licensed in the E.U. and the U.S. as an emergency contraceptive. Studies comparing ulipristal to levonorgestrel (progesterone-only emergency contraception, or POEC) demonstrate that ulipristal is at least as effective when taken up to 72 hours after unprotected sexual intercourse. In addition, ulipristal remains effective up to 120 hours (5 days) after intercourse, making ulipristal a more versatile emergency contraceptive than levonorgestrel, which does not work well beyond 72 hours after unprotected intercourse. The most severe side effect in clinical trials using ulipristal has been a self-limited headache and some abdominal pain.

HORMONAL CONTRACEPTIVES

The incredible growth of the earth’s human population stands out as one of the fundamental events of the last two centuries. The Old Testament dictum “Be fruitful and multiply” (Genesis 9:1) has been followed too religiously by readers and nonreaders of the Bible alike. In 1798, Malthus started a great controversy by opposing the prevailing view of unlimited progress for humankind by making two postulates and a conclusion. Malthus postulated “that food is necessary for the existence of man” and that sexual attraction between female and male is necessary and likely to persist, since “toward the extinction of the passion between the sexes, no progress whatever has hitherto been made,” barring “individual exceptions.” Malthus concluded that “the power of populations is infinitely greater than the power of the earth to produce subsistence for man,” producing a “natural inequality” that would someday loom “insurmountable in the way to perfectibility of society.”

Malthus was right: The passion between the sexes has persisted, and the power of populations is very great indeed, so much so that our sheer numbers have increased to the point that they are straining the earth’s
capacity to supply food, energy, and raw materials, and to absorb the detritus of its human burden. Marine fisheries are being depleted, forests and aquifers are disappearing, and the atmosphere is accumulating greenhouse gases from combustion of the fossil fuels that provide the energy needs of almost 7 billion people. Perhaps some of the blame can be laid at the feet of medical science: Advances in public health and medicine have led to a significant decline in mortality and an increased life expectancy. However, medical science has also begun to assume a portion of the responsibility for overpopulation and its adverse effects. To this end, drugs in the form of hormones and their analogs have been developed to control human fertility.

Types of Hormonal Contraceptives

Combination Oral Contraceptives. The most frequently used agents in the U.S. are combination oral contraceptives containing both an estrogen and a progestin. Their theoretical efficacy generally is considered to be 99.9%. Combination oral contraceptives are available in many formulations. Monophasic, biphasic, or triphasic pills are generally provided in 21-day packs. (Virtually all preparations come as 28-day packs, with the pills for the last 7 days containing only inert ingredients.) For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day “pill-free” period. The biphasic and triphasic preparations provide two or three different pills containing varying amounts of active ingredients, to be taken at different times during the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. With these preparations, predictable menstrual bleeding generally occurs during the 7-day “off” period each month. However, several oral contraceptives are now available whereby progestin withdrawal is only induced every 3 months.

The estrogen content of current preparations ranges from 20 to 50 μg; most contain 30-35 μg. Preparations containing ≤35 μg of an estrogen are generally referred to as “low-dose” or “modern” pills. The dose of progestin is more variable because of differences in potency of the compounds used. For example, monophasic pills currently available in the U.S. contain 0.4-1.5 mg of norethindrone, 0.09-0.15 mg of levonorgestrel, 0.3-0.5 mg of norgestrel, 1 mg of ethynodiol diacetate, 0.25 mg of norgestimate, or 0.15 mg of desogestrel, with slightly different dose ranges in biphasic and triphasic preparations. In contrast, most first-generation preparations (circa 1966) contained 50-100 μg of an estrogen and 2-10 mg of a progestin. These large differences in doses complicate extrapolation of data from early epidemiological studies on the side effects of “high-dose” oral contraceptives to the “low-dose” preparations now used.

A transdermal preparation of norelgestromin and ethinyl estradiol (ORTHO EVRA) is marketed for weekly application to the buttock, abdomen, upper arm, or torso for the first 3 consecutive weeks followed by a patch-free week for each 28-day cycle. A similar 3-week on/1-week off cycle is employed for the intravaginal ring containing ethinyl estradiol and etonogestrel (NUVARING).
**Progestin-Only Contraceptives.** Several agents are available for progestin-only contraception, with theoretical efficacies of 99%. Specific preparations include the “minipill”; low doses of progestins (e.g., 350 μg of norethindrone [NOR-QD, ORTHO MICRONOR, others]) taken daily without interruption; subdermal implants of 216 mg of norgestrel (NORPLANT II, JADELLE) for long-term contraceptive action (e.g., up to 5 years) or 68 mg of etonogestrel (IMPLANON) for contraception lasting 3 years; and crystalline suspensions of medroxypregesterone acetate for intramuscular injection of 104 mg (DEPO-SUBQ PROVERA 104) or 150 mg (DEPO-PROVERA, others) of drug; each provides effective contraception for 3 months.

An IUD (PROGESTASERT) that releases low amounts of progesterone locally is available for insertion on a yearly basis. Its effectiveness is considered to be 97-98%, and contraceptive action probably is due to local effects on the endometrium. An intrauterine device (MIRENA) releases levonorgestrel for up to 5 years. It inhibits ovulation in some women but is thought to act primarily by producing local effects.

**Mechanism of Action**

**Combination Oral Contraceptives.** Combination oral contraceptives act by preventing ovulation (Lobo and Stanczyk, 1994). Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a mid-cycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. Although either component alone can be shown to exert these effects in certain situations, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Given the multiple actions of estrogens and progestins on the hypothalamic-pituitary-ovarian axis during the menstrual cycle and the extraordinary efficacy of these agents, several effects probably contribute to the blockade of ovulation.

Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progesterone diminishes the frequency of GnRH pulses. Because the proper frequency of LH pulses is essential for ovulation, this effect of progesterone likely plays a major role in the contraceptive action of these agents. In monkeys and women with normal menstrual cycles, estrogens do not affect the frequency of the pulse generator. However, in the prolonged absence of a menstrual cycle (e.g., in ovariectomized monkeys and postmenopausal women; Hotchkiss and Knobil, 1994), estrogens markedly diminish pulse-generator frequency, and progesterone enhances this effect. In theory, this hypothalamic effect of estrogens could come into play when oral contraceptives are used for extended time periods.

Multiple pituitary effects of both estrogen and progestin components are thus likely to contribute to oral contraceptive action. Oral contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. The progestin component may also inhibit the estrogen-induced LH surge at mid-cycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation. However, it is difficult to assess quantitatively the contributions of these effects because the drugs block ovulation so effectively.

**Progestin-Only Contraceptives.** Progestin-only pills and levonorgestrel implants are highly efficacious but block ovulation in only 60-80% of cycles. Their effectiveness is thus thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of IUDs that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

**Untoward Effects**

**Combination Oral Contraceptives.** Shortly after the introduction of oral contraceptives, reports of adverse side effects associated with their use began to appear. Many of the side effects were found to be dose dependent, and this led to the development of current low-dose preparations. Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects, including hypertension, myocardial infarction, hemorrhagic or ischemic stroke, and venous thrombosis and embolism; breast, hepatocellular, and cervical cancers; and a number of endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing risk factors, and these drugs also provide many beneficial health effects (Burkman et al., 2004).

**Cardiovascular Effects.** The question of cardiovascular side effects has been reexamined for the newer low-dose oral contraceptives (Burkman et al., 2004; Sherif, 1999). For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these
events in women without other predisposing factors is low (e.g., roughly half that associated with the risk of venous thromboembolism in pregnancy). Nevertheless, the risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism (Castelli, 1999). Of note, postmarketing epidemiologic studies indicate that women using transdermal contraceptives have a higher than expected exposure to estrogen and are at increased risk for the development of venous thromboembolism.

Early high-dose combination oral contraceptives caused hypertension in 4-5% of normotensive women and increased blood pressure in 10-15% of those with preexisting hypertension. This incidence is much lower with newer low-dose preparations, and most reported changes in blood pressure are not significant. The cardiovascular risk associated with oral contraceptive use does not appear to persist after use is discontinued. As noted previously, estrogens increase serum HDL and decrease LDL levels, and progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant changes in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have been reported.

**Cancer.** Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. These concerns were further heightened in the late 1960s by reports of endometrial changes caused by sequential oral contraceptives, which have since been removed from the market in the U.S. However, it is now clear that there is not a widespread association between oral contraceptive use and cancer (Burkman et al., 2004; Westhoff, 1999).

Epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about 2-fold but only in long-term users (>5 years) with persistent human papilloma virus infection (Moodley, 2004).

There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users. Current estimates indicate there is about a doubling in the risk of liver cancer after 4-8 years of use. However, these are rare cancers, and the absolute increases are small.

The major present concern about the carcinogenic effects of oral contraceptives is focused on breast cancer. Numerous studies have dealt with this issue, and the following general picture has emerged. The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1-1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. In addition, breast cancers diagnosed in women who have ever used oral contraceptives are more likely to be localized to the breast and thus easier to treat (i.e., are less likely to have spread to other sites) (Westhoff, 1999). Thus overall there is no significant difference in the cumulative risk of breast cancer between those who have ever used oral contraceptives and those who have never used them.

Combination oral contraceptives do not increase the incidence of endometrial cancer but actually cause a 50% decrease in the incidence of this disease, which lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer, and decreased ovarian stimulation by gonadotropins provides a logical basis for this effect. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer (Fernandez et al., 2001).

**Metabolic and Endocrine Effects.** The effects of sex steroids on glucose metabolism and insulin sensitivity are complex (Godsland, 1996) and may differ among agents in the same class (e.g., the 19-nor progestins). Early studies with high-dose oral contraceptives generally reported impaired glucose tolerance as demonstrated by increases in fasting glucose and insulin levels and responses to glucose challenge. These effects have decreased as steroid dosages have been lowered, and current low-dose combination contraceptives may even improve insulin sensitivity. Similarly, the high-dose progestins in early oral contraceptives did raise LDL and reduce HDL levels, but modern low-dose preparations do not produce unfavorable lipid profiles (Sherif, 1999). There also have been periodic reports that oral contraceptives increase the incidence of gallbladder disease, but any such effect appears to be weak and limited to current or very long-term users (Burkman et al., 2004).

The ethinyl estradiol present in oral contraceptives appears to cause a dose-dependent increase in several serum factors known to increase coagulation. However, in healthy women who do not smoke, there also is an increase in fibrinolytic activity, which exerts a counter effect so that overall there is a minimal effect on hemostatic balance. In women who smoke, however, this compensatory effect is diminished, which may shift the hemostatic profile toward a hypercoagulable condition (Fruzzetti, 1999).

**Miscellaneous Effects.** Nausea, edema, and mild headache occur in some individuals, and more severe migraine headaches may be precipitated by oral contraceptive use in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day “off” period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-nor progestins.

**Progestin-Only Contraceptives.** Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of all three types of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases, especially...
with the long-acting preparations, and amenorrhea becomes common after a year or more of use.

No evidence indicates that the progestin-only minipill preparations increase thromboembolic events, which are thought to be related to the estrogenic component of combination preparations; blood pressure does not appear to be elevated, and nausea and breast tenderness do not occur. Acne may be a problem, however, because of the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Aside from bleeding irregularities, headache is the most commonly reported untoward effect of depot MPA. Mood changes and weight gain also have been reported, but controlled clinical studies of these effects are not available. It is of more concern that many studies have found decreases in HDL levels and increases in LDL levels, and there have been several reports of decreased bone density. These effects may be due to reduced estrogenic estrogens because depot MPA is particularly effective in lowering gonadotropin levels. Numerous human studies have not found any increases in breast, endometrial, cervical, or ovarian cancer in women receiving MPA (Westhoff, 2003). Because of the time required to completely eliminate the drug, the contraceptive effect of this agent may remain for 6-12 months after the last injection.

Implants of norethindrone may be associated with infection, local irritation, pain at the insertion site, and, rarely, expulsion of the inserts. Headache, weight gain, and mood changes have been reported, and acne is seen in some patients. A number of metabolic studies have been performed in users of norplant (no longer marketed in the U.S.), and in most cases only minimal changes have been observed in lipid, carbohydrate, and protein metabolism. In women desiring pregnancy, ovulation occurs fairly soon after implant removal, reaching 50% in 3 months and almost 90% within 1 year.

Contraindications

Although the use of modern oral contraceptives is considered generally safe in most healthy women, these agents can contribute to the incidence and severity of cardiovascular, thromboembolic, or malignant disease, particularly if other risk factors are present. The following conditions are thus considered absolute contraindications for combination oral contraceptive use: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. The risk of serious cardiovascular side effects is particularly marked in women >35 years of age who smoke heavily (e.g., >15 cigarettes per day); even low-dose oral contraceptives are contraindicated in such patients.

Several other conditions are relative contraindications and should be considered on an individual basis. These include migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians recommend discontinuation of oral contraceptives for several weeks to a month to minimize the possibility of thromboembolism after surgery. These agents should be used with care in women with prior gestational diabetes or uterine fibroids, and low-dose pills should generally be used in such cases.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer. Depot MPA and levonorgestrel inserts are contraindicated in women with a history or predisposition to thrombophlebitis or thromboembolic disorders.

Choice of Contraceptive Preparations

Treatment should generally begin with preparations containing the minimum dose of steroids that provides effective contraceptive coverage. This is typically a pill with 30-35 μg of estrogen, but preparations with 20 μg may be adequate for lighter women or >40 years of age with perimenopausal symptoms; a preparation containing 50 μg of estrogen may be required for heavier women.

In women for whom estrogens are contraindicated or undesirable, progestin-only contraceptives may be an option. The progestin-only minipill may have enhanced effectiveness in several such types of women (e.g., nursing mothers and women >40 years of age, in whom fertility may be decreased).

The choice of a preparation also may be influenced by the specific 19-nor progestin component because this component may have varying degrees of androgenic and other activities. The androgenic activity of this component may contribute to untoward effects such as weight gain, acne due to increased sebaceous gland secretions, and unfavorable lipoprotein profiles. These side effects are greatly reduced in newer low-dose contraceptives that contain progestins with little to no androgenic activity.

In summary, for a given individual, both the efficacy and side effects of hormonal contraceptives may vary considerably among preparations. A number of choices are available to counter the development of side effects and improve patient tolerance, both in terms of specific components and routes of administration, without decreasing contraceptive efficacy. Risks for serious side effects as enumerated earlier should be considered before initiating contraceptives in any individual patient.

Noncontraceptive Health Benefits

It is generally accepted that combination oral contraceptives have substantial health benefits unrelated to their contraceptive use. Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, and the incidence is decreased 50% after 2 years of use. Depot MPA injections also reduce very substantially the incidence of uterine cancer. Furthermore, this protective effect persists for up to 15 years after oral contraceptive use.
is discontinued. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation in many women. These include more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of pelvic inflammatory disease and ectopic pregnancies, and endometriosis may be ameliorated. Some women also may obtain these benefits with progestin-only contraceptives. There are suggestions that MPA may improve hematological parameters in women with sickle-cell disease (Cullins, 1996).

From a purely statistical perspective, fertility regulation by oral contraceptives is substantially safer than pregnancy or childbirth for most women, even without considering the additional health benefits of these agents.

**CLINICAL SUMMARY**

Estrogens are most commonly used to treat vasomotor disturbances (“hot flashes”) in postmenopausal women. Other important benefits are amelioration of the effects of urogenital atrophy, a decreased incidence of colon cancer, and prevention of bone loss. A variety of preparations, including oral, transdermal, and vaginal, are available. Regardless of the specific drug(s) selected, treatment should use the minimum dose and duration for the desired therapeutic end point.

In postmenopausal women with an intact uterus, a progestin is included to prevent endometrial cancer. Medroxyprogesterone acetate is used in the U.S., but micronized progesterone is preferred; norethindrone and norgestrel/levonorgestrel are also commonly used. Women without a uterus are administered estrogen alone. Postmenopausal hormone therapy and contraception are the most frequent uses of progestins.

Tamoxifen, a selective estrogen receptor modulator or SERM, is widely used for the adjuvant treatment of breast cancer and for prophylaxis of the disease in high-risk women, but treatment should be limited to 5 years. The drug is most effective in the treatment of estrogen-receptor positive disease, and untoward effects include hot flashes as well as an increase in blood clots and uterine cancer. Another SERM, raloxifene, is used to prevent osteoporosis and decreases the incidence of vertebral fractures in postmenopausal women. Raloxifene is also licensed for reduction of risk of breast cancer in high-risk patients. Raloxifene does not increase the risk of uterine cancer but does increase the incidence of thromboembolic events and hot flashes.

The pure estrogen antagonist fulvestrant is also used to treat breast cancer, especially in patients who become refractory to tamoxifen. Another estrogen antagonist, clomiphene, is used to treat infertility in anovulatory women. Both compounds may cause hot flashes.

Aromatase inhibitors, including letrozole, anastrozole, and exemestane, are highly effective for both adjuvant and metastatic treatment of breast cancer in postmenopausal subjects, and their prophylactic use is being explored. Untoward effects include hot flashes; potential long-term effects of these agents on osteoporosis and bone fractures remain to be established.

Mifepristone is used therapeutically as an anti-progestin for medical abortion, and it is administered with a prostaglandin for this purpose.

Estrogens and progestins are widely used as “combination” contraceptives and are 99% effective in preventing ovulation. These combinations are most often used orally, although transdermal preparations, once-monthly injections, and vaginal rings are available. Ethinyl estradiol (or mestranol) and 19-nor steroids such as norgestrel/levonorgestrel, norethindrone, or another synthetic progestin are commonly used. The greatest concern with these agents is the risk of stroke or other thromboembolic events; consequently, they should not be used in older women (>35 years of age) who smoke or have other risk factors (e.g., hypertension) for cardiovascular disease.

Several progestin-only contraceptives are available, including low-dose pills, long-lasting (e.g., 3-month) depot injections, and subdermal implants. These agents are also highly efficacious and exert a number of actions, including decreased frequency of ovulation and effects on cervical mucus, ovum transport, and implantation. They may be used in nursing mothers and in some women with contraindications for combined estrogen-progestin combinations. The most common untoward effect is unpredictable vaginal bleeding.

A levonorgestrel-only pill and high-dose estrogen-progestin oral contraceptives are available and effective for postcoital or emergency contraception within 72 hours of unprotected intercourse. These preparations are ineffective in cases of established pregnancy and should not be used to terminate pregnancy.

TESTOSTERONE AND OTHER ANDROGENS

In men, testosterone is the principal secreted androgen. The Leydig cells synthesize the majority of testosterone by the pathways shown in Figure 41–1. In women, testosterone also is probably the principal androgen and is synthesized both in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors androstenedione and dehydroepiandrosterone are weak androgens that can be converted peripherally to testosterone.

Secretion and Transport of Testosterone. The magnitude of testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains many of the other differences between men and women. In the first trimester in utero, the fetal testes begin to secrete testosterone, which is the principal factor in male sexual differentiation, probably stimulated by human chorionic gonadotropin (hCG) from the placenta. By the beginning of the second trimester, the serum testosterone concentration is close to that of mid-puberty, ~250 ng/dL (Figure 41–2) (Dawood and Saxena, 1977; Forest, 1975). Testosterone production then falls by the end of the second trimester, but by birth the value is again ~250 ng/dL, possibly due to stimulation of the fetal Leydig cells by luteinizing hormone (LH) from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at ~250 ng/dL at 2-3 months after birth and falls to <50 ng/dL by 6 months, where it remains until puberty (Forest, 1975).

During puberty, from ~12 to 17 years of age, the serum testosterone concentration in males increases to a much greater degree than in females, so that by early adulthood the serum testosterone concentration is 500 ng/dL to 700 ng/dL in men, compared to 30 ng/dL to 50 ng/dL in women. The magnitude of the testosterone concentration in the male is responsible for the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.

LH, secreted by the pituitary gonadotropes (Chapter 38), is the principal stimulus of testosterone secretion in men, perhaps potentiated by follicle-stimulating hormone (FSH), also secreted by gonadotropes. The secretion of LH by gonadotropes is positively regulated by hypothalamic gonadotropin-releasing hormone (GnRH), and testosterone directly inhibits LH secretion in a negative feedback loop. LH is secreted in pulses, which occur approximately every 2 hours and are greater in magnitude in the morning. The pulsatility appears to result from pulsatile secretion of GnRH from the hypothalamus. Pulsatile administration of GnRH to men who are hypogonadal due to hypothalamic disease results in normal LH pulses and testosterone secretion, but continuous administration does not (Crowley et al., 1985). Testosterone secretion is likewise pulsatile and diurnal, the highest plasma concentrations occurring at ~8 a.m. and the lowest at ~8 p.m. The morning peaks diminish as men age (Bremner et al., 1983).

In women, LH stimulates the corpus luteum (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, estradiol and progesterone, not testosterone, are the principal inhibitors of LH secretion in women. Sex hormone-binding globulin (SHBG) binds ~40% of circulating testosterone with high affinity, rendering the bound hormone unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving ~2% unbound or free. In some testosterone assays, the latter two components are considered as “bioavailable” testosterone.

Metabolism of Testosterone to Active and Inactive Compounds. Testosterone has many different effects in many tissues. One mechanism by which the varied effects are mediated is the metabolism of testosterone to two other active steroids, dihydrotestosterone and estradiol (Figure 41–3). Some effects of testosterone appear
to be mediated by testosterone itself, some by dihydrotestosterone, and some by estradiol. The enzyme 5α-reductase catalyzes the conversion of testosterone to dihydrotestosterone. Although both testosterone and dihydrotestosterone act via the androgen receptor, dihydrotestosterone binds with higher affinity (Wilbert et al., 1983) and activates gene expression more efficiently (Deslypere et al., 1992). As a result, acting via dihydrotestosterone and in tissues expressing 5α-reductase, testosterone is able to affect tissues that would otherwise not be affected by circulating levels of testosterone. Two forms of 5α-reductase...
Physiological and Pharmacological Effects of Androgens

The biological effects of testosterone are mediated by the receptor it activates and by the tissues in which the receptor and responses occur at various stages of life. Testosterone can act as an androgen either directly, by binding to the androgen receptor, or indirectly by conversion to dihydrotestosterone, which also binds to the androgen receptor. Testosterone also can act as an estrogen by conversion to estradiol, which binds to the estrogen receptor (Figure 41–4).

Effects That Occur via the Androgen Receptor. Testosterone and dihydrotestosterone act as androgens via a single androgen receptor (Figure 41–5). The androgen receptor—officially designated NR3A—is a member of the nuclear receptor superfamily, which includes steroid hormone receptors, thyroid hormone receptors, and orphan receptors that lack a known ligand (Chapter 3).

The androgen receptor has an amino-terminal domain that contains a polyglutamine repeat of variable length, a DNA-binding domain consisting of two Zn finger motifs, and a carboxyterminal ligand-binding domain. The polyglutamine repeat of variable length is unique to the androgen receptor; a shorter length appears to increase its activity. In the absence of a ligand, the androgen receptor is located in the cytoplasm associated with a heat-shock protein complex. When testosterone or dihydrotestosterone binds to the ligand-binding domain, the androgen receptor dissociates from the heat-shock protein complex, dimerizes, and translocates to the nucleus. The dimer then binds via the DNA-binding domains to androgen response elements on certain responsive genes. The ligand-receptor complex recruits coactivators and acts as a transcription factor complex, stimulating or repressing expression of those genes (Agoulnik and Weigel, 2008; Brinkmann and Trapman, 2000).

The mechanisms by which androgens have different actions in diverse tissues have become clearer in recent years. One mechanism is the higher affinity with which dihydrotestosterone binds to and activates the
androgen receptor compared to testosterone (Deslypere et al., 1992). Another mechanism involves transcription cofactors, both coactivators and corepressors, which are tissue specific. At this time, the roles of cofactors are better described for other nuclear receptors than for the androgen receptor (Smith and O’Malley, 2004).

The importance of the androgen receptor is illustrated by the consequences of its mutations. Predictably, mutations that either alter the primary sequence of the protein or cause a single amino acid substitution in the hormone- or DNA-binding domains result in resistance to the action of testosterone, beginning in utero (McPhaul and Griffin, 1999). Male sexual differentiation therefore is incomplete, as is pubertal development.

Another kind of mutation occurs in patients who have spinal and bulbar muscular atrophy, known as Kennedy’s disease. These patients have an expansion of the CAG repeat, which codes for glutamine, at the amino terminus of the molecule (Walcott and Merry, 2002). The result is very mild androgen resistance, manifest primarily by gynecomastia (Dejager, 2002), and progressively severe motor neuron atrophy. The mechanism by which the neuronal atrophy occurs is unknown but pharmacological induction of autophagy in a model cell system degrades the mutant AR and rescues the cells from damage (Montie et al, 2009). Other trinucleotide repeats are also associated with neurological disorders (Molla et al., 2009).

Other kinds of androgen receptor mutations may explain why prostate cancer that is treated by androgen deprivation eventually becomes androgen-independent. At the time of its clinical presentation, prostate cancer is usually androgen-sensitive, and this sensitivity forms the basis for the initial treatment of metastatic prostate cancer by androgen deprivation. Metastatic prostate cancer often regresses initially in response to this treatment but then becomes unresponsive to continued deprivation. The androgen receptor not only continues to be expressed in androgen-independent prostate cancer, but its signaling remains active, as indicated by expression of the androgen receptor-dependent prostate-specific antigen (PSA). It has been postulated that these observations can be explained by mutations in the androgen receptor gene or changes in androgen receptor co-regulatory proteins. In some patients resistant to standard androgen deprivation therapy, the tumor responds to further depletion of androgens by inhibitors of adrenal androgen synthesis, such as abiraterone, a drug in late stages of clinical development (Chapter 63) (Heinlein and Chang, 2004).

Effects That Occur via the Estrogen Receptor. The effects of testosterone on at least one tissue are mediated by its conversion to estradiol, catalyzed by the aromatase enzyme complex. In the rare cases in which a male does not express aromatase or the estrogen receptor (Smith, 1994), the epiphyses do not fuse and long-bone growth continues indefinitely; moreover, such patients are osteoporotic. Administration of estradiol corrects the bone abnormalities in patients with aromatase deficiency but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone expresses the androgen receptor (Colvard et al., 1989), testosterone also may have an effect on bone via the androgen receptor. The effect of testosterone on male libido also may be mediated by conversion to estradiol: administration of estradiol to a man with aromatase deficiency increased his libido (Rochira and Carani, 2009).

Effects of Androgens at Different Stages of Life.

In Utero. When the fetal testes, stimulated by hCG, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby Wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens, and seminal vesicles. Further away, in the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia: the penis, scrotum, and prostate. The increase in testosterone at the end of gestation may result in further phallic growth.

Infancy. The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

Puberty. Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotropes, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes; not surprisingly, the first sign of puberty is an increase in testicular size. The increase in testosterone production by Leydig cells and the effect of FSH on the Sertoli cells stimulate the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues virtually simultaneously, and the changes in most of them occur gradually during the course of several years. The phallus enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow, initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Full development of the latter two may not occur until 10 years after the start of puberty and marks the completion of puberty. Muscle mass and strength, especially of the shoulder girdle, increase, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to a slowing and then cessation of growth. Bone also becomes thicker. The increase in muscle mass and bone result in a pronounced increase in weight. Erythropoiesis increases, resulting in higher hematocrit and hemoglobin concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops.
CHAPTER 41

ANDROGENS

Other changes also may result from the increase in testosterone during puberty. Men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

Adulthood. The serum testosterone concentration and the characteristics of the adult man are maintained largely during early adulthood and midlife. One change during this time is the gradual development of male pattern baldness, beginning with recession of hair at the temples and/or at the vertex.

Two changes that can occur in the prostate gland during adulthood are of much greater medical significance. One is the gradual development of benign prostatic hyperplasia, which occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate. This development is mediated by the conversion of testosterone to dihydrotestosterone by 5α-reductase II within prostatic cells (Wilson, 1980).

The other change that can occur in the prostate during adulthood is the development of cancer. Although no direct evidence suggests that testosterone causes the disease, prostate cancer depends on androgen stimulation. This dependency is the basis of treating metastatic prostate cancer by lowering the serum testosterone concentration or by blocking its action at the receptor.

Senescence. As men age, the serum testosterone concentration gradually declines (Figure 41–2), and the SHBG concentration gradually increases, so that by age 80, the total testosterone concentration is ~80% and the free testosterone is ~40% of those at age 20 (Harman et al., 2001). This fall in serum testosterone could contribute to several other changes that occur with increasing age in men, including decreases in energy, libido, muscle mass (Forbes, 1976) and strength (Murray et al., 1980), and bone mineral density. Androgen deprivation also leads to insulin resistance, truncal obesity, and abnormal serum lipids, as observed in patients with metastatic prostate cancer receiving this treatment (see also Chapter 63). A causal role is suggested by the occurrence of similar changes when men develop hypogonadism at a younger age caused by known diseases, as discussed later in this chapter.

Consequences of Androgen Deficiency
The consequences of androgen deficiency depend on the stage of life during which the deficiency first occurs and on the degree of the deficiency.

During Fetal Development. Testosterone deficiency in a male fetus during the first trimester in utero causes incomplete sexual differentiation. Testosterone deficiency in the first trimester results only from testicular disease, such as deficiency of 17α-hydroxylase (CYP17); deficiency of LH secretion because of pituitary or hypothalamic disease does not result in testosterone deficiency during the first trimester, presumably because Leydig cell secretion of testosterone at that time is regulated by placental hCG. Complete deficiency of testosterone secretion results in entirely female external genitalia; less severe testosterone deficiency results in incomplete virilization of the external genitalia proportionate to the degree of deficiency. Testosterone deficiency at this stage of development also leads to failure of the wolffian ducts to differentiate into the male internal genitalia, such as the vas deferens and seminal vesicles, but the müllerian ducts do not differentiate into the female internal genitalia as long as testes are present and secrete müllerian inhibitory substance. Similar changes occur if testosterone is secreted normally, but its action is diminished because of an abnormality of the androgen receptor or of the 5α-reductase enzyme. Abnormalities of the androgen receptor can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization in utero and result only in impaired spermatogenesis in adulthood (McPhaul and Griffin, 1999). Abnormal 5α-reductase results in incomplete virilization of the external genitalia in utero but normal development of the male internal genitalia, which requires only testosterone (Wilson et al., 1993).

Testosterone deficiency during the third trimester, caused either by a testicular disease or a deficiency of fetal LH secretion, has two known consequences. First, the phallus fails to grow as much as it would normally. The result, called microphallus, is a common occurrence in boys later discovered to be unable to secrete LH due to abnormalities of GnRH synthesis. Second, the testes fail to descend into the scrotum; this condition, called cryptorchidism, occurs commonly in boys whose LH secretion is subnormal (Chapter 38).

Before Completion of Puberty. When a boy can secrete testosterone normally in utero but loses the ability to do so before the anticipated age of puberty, the result is failure to complete puberty. All of the pubertal changes previously described, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. In addition, if growth hormone secretion is normal when testosterone secretion is subnormal during the years of expected puberty, the long bones continue to lengthen because the epiphyses do not close. The result is longer arms and legs relative to the trunk; these proportions are referred to as eunuchoid. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue, called gynecomastia.
After Completion of Puberty. When testosterone secretion becomes impaired after puberty (e.g., castration or anti-androgen treatment), regression of the pubertal effects of testosterone depends on both the degree and the duration of testosterone deficiency. When the degree of testosterone deficiency is substantial, libido and energy decrease within a week or two, but other testosterone-dependent characteristics decline more slowly. Decreases in muscle mass and strength probably can be detected by testing groups of men within a few months, but a clinically detectable decrease in muscle mass in an individual does not occur for several years. A pronounced decrease in hematocrit and hemoglobin will occur within several months. A decrease in bone mineral density probably can be detected by dual energy absorptiometry within 2 years, but an increase in fracture incidence would not be likely to occur for many years. A loss of sexual hair takes many years.

In Women. Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Androgens may have other important effects in women, and the loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) may result in the loss of these effects. Testosterone preparations that can yield serum testosterone concentrations in the physiological range in women currently are being developed. The availability of such preparations will allow clinical trials to determine if testosterone replacement in androgen-deficient women improves their libido, energy, muscle mass and strength, and bone mineral density.

Therapeutic Androgen Preparations

The need for a creative approach to pharmacotherapy with androgens arises from the fact that ingestion of testosterone is not an effective means of replacing testosterone deficiency. Even though ingested testosterone is readily absorbed into the hepatic circulation, the rapid hepatic catabolism ensures that hypogonadal men generally cannot ingest it in sufficient amounts and with sufficient frequency to maintain a normal serum testosterone concentration. Most pharmaceutical preparations of androgens, therefore, are designed to bypass hepatic catabolism of testosterone.

Testosterone Esters. Esterifying a fatty acid to the 17α hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as testosterone enanthate (heptanoate) or cypionate (cyclopentylpropionate) (Figure 41–6) is dissolved in oil and administered intramuscularly every 2–4 weeks to hypogonadal men, the ester hydrolyzes in vivo and results in serum testosterone concentrations that range from higher than normal in the first few days after the injection to low normal just before the next injection (Figure 41–7). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone (Figure 41–6), when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic catabolism. Testosterone undecanoate in oil also can be injected and produces stable serum testosterone concentrations for 2 months (Schubert et al., 2004). The undecanoate ester of testosterone is not currently marketed in the U.S.

Alkylated Androgens. Several decades ago, chemists found that adding an alkyl group to the 17α position of testosterone (Figure 41–6) retarded its hepatic catabolism. Consequently, 17α-alkylated androgens are androgenic when administered orally; however, they are less androgenic than testosterone itself, and they cause hepatotoxicity (Cabasso, 1994), whereas native testosterone does not.

Transdermal Delivery Systems. Recent attempts to avoid the “first pass” inactivation of testosterone by the liver have employed novel delivery systems; chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. The first such preparations were patches, one of which (ANDRODERM) is still available. Newer preparations include gels (ANDROGEL, TESTIM) and a buccal tablet (STRIANT). These preparations produce mean serum testosterone concentrations within normal range in hypogonadal men (Figure 41–7).

Attempts to Design Selective Androgens

Alkylated Androgens. Decades ago, investigators attempted to synthesize analogs of testosterone that possessed greater anabolic effects than androgenic effects compared to native testosterone. Several compounds appeared to have such differential effects, based on a greater effect on the levator ani muscle compared to the ventral prostate of the rat. These compounds were called anabolic steroids, and most are 17α-alkylated androgens. None of these compounds, however, has been convincingly demonstrated to have such a differential effect in human beings. Nonetheless, they have
Figure 41–6. Structures of androgens available for therapeutic use.
enjoyed popularity among athletes who seek to enhance their performance. Another alkylated androgen, 7α-methyl-19-nortestosterone, is poorly converted to dihydrotestosterone.

Selective Androgen-Receptor Modulators. Stимulated by the development of selective estrogen receptor modulators, which have estrogenic effects in some tissues but not others (Chapter 40), investigators are attempting to develop selective androgen receptor modulators. Another stimulus is the desirable effects of testosterone in some tissues, such as muscle and bone, and the undesirable effects in other tissues, such as the prostate. Nonsteroidal molecules have been developed that bind to the androgen receptor and have greater effect on muscle and bone than on the prostate. Some of these compounds have begun trials in humans (Narayanan et al., 2008).

Therapeutic Uses of Androgens

Male Hypogonadism. The best established indication for administration of androgens is testosterone deficiency in men (i.e., treatment of male hypogonadism). Any of the testosterone preparations or testosterone esters just described can be used to treat testosterone deficiency. Monitoring treatment for beneficial and deleterious effects differs somewhat in adolescents and the elderly from that in other men.

Monitoring for Efficacy. The goal of administering testosterone to a hypogonadal man is to mimic as closely as possible the normal serum concentration. Therefore, measuring the serum testosterone concentration during treatment is the most important aspect of monitoring testosterone treatment for efficacy. When the serum testosterone concentration is measured depends on the testosterone preparation used (Figure 41–7). Occasional random fluctuations can occur, however, so measurements should be repeated for any dose. When the enanthate or cypionate esters of testosterone are administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation (Findlay et al., 1989; Snyder and Lawrence, 1980).

Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years (Snyder et al., 2000).

Monitoring for Deleterious Effects. When testosterone itself is administered, as in one of the transdermal preparations or as an ester that is hydrolyzed to testosterone, it has no “side effects” (i.e., no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Modified testosterone compounds, such as the 17α-alkylated androgens, do have undesirable effects even when dosages are targeted at physiological replacement. Some of these

---

**Figure 41–7. Pharmacokinetic profiles of three testosterone preparations during their chronic administration to hypogonadal men.** Doses of each were given at time 0. Shaded areas indicate range of normal levels. [Data adapted from A. Snyder and Lawrence (1980); B. Dobs et al. (1999); C. Swerdloff et al. (2000)]
undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration from prepubertal or mid-pubertal levels to that of an adult male at any age can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins. Replacement of physiological levels of testosterone occasionally may have undesirable effects in the presence of concomitant illnesses. For example, stimulation of erythropoiesis would increase the hematocrit from subnormal to normal in a healthy man but would raise the hematocrit above normal in a man with a predisposition to erythrocytosis, such as in chronic pulmonary disease. Similarly, the mild degree of sodium and water retention with testosterone replacement would have no clinical effect in a healthy man but would exacerbate preexisting congestive heart failure. If the testosterone dose is excessive, erythrocytosis and, uncommonly, salt and water retention and peripheral edema occur even in men who have no predisposition to these conditions. When a man’s serum testosterone concentration has been in the normal adult male range for many years, whether from endogenous secretion or exogenous administration, and he is >40 years of age, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer.

The principal adverse effects of the 17α-alkylated androgens are hepatic, including cholestasis and, uncommonly, peliosis hepatis, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. Case reports of cancer regression after androgen cessation do not appear to affect serum lipids or apolipoproteins. Replacement of physiological levels of testosterone occasionally may have undesirable effects in the presence of concomitant illnesses. For example, stimulation of erythropoiesis would increase the hematocrit from subnormal to normal in a healthy man but would raise the hematocrit above normal in a man with a predisposition to erythrocytosis, such as in chronic pulmonary disease. Similarly, the mild degree of sodium and water retention with testosterone replacement would have no clinical effect in a healthy man but would exacerbate preexisting congestive heart failure. If the testosterone dose is excessive, erythrocytosis and, uncommonly, salt and water retention and peripheral edema occur even in men who have no predisposition to these conditions. When a man’s serum testosterone concentration has been in the normal adult male range for many years, whether from endogenous secretion or exogenous administration, and he is >40 years of age, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer.

**Monitoring at the Anticipated Time of Puberty.** Administration of testosterone to testosterone-deficient boys at the anticipated time of puberty should be guided by the considerations just described but also by the fact that testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth-hormone status of the boy must be considered. Boys who are short because of growth-hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

**Male Senescence.** Preliminary evidence suggests that increasing the serum testosterone concentration of men whose serum levels are subnormal for no reason other than their age will increase their bone mineral density and lean mass and decrease their fat mass (Amory et al., 2004; Kenny et al., 2001; Snyder et al., 1999a, 1999b). It is entirely uncertain at this time, however, if such treatment will worsen benign prostatic hyperplasia or increase the incidence of clinically detectable prostate cancer.

**Female Hypogonadism.** Little data exist regarding whether increasing the serum testosterone concentrations of women whose serum testosterone concentrations are below normal will improve their libido, energy, muscle mass and strength, or bone mineral density. In a study of women with low serum testosterone concentrations due to panhypopituitarism, increasing the testosterone concentration to normal was associated with small increases in bone mineral density, fat-free mass, and sexual function compared to placebo (Miller et al., 2006).

**Enhancement of Athletic Performance.** Some athletes take drugs, including androgens, to attempt to improve their performance. Because androgens for this purpose usually are taken surreptitiously, information about their possible effects is not as complete as that for androgens taken for treatment of male hypogonadism. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2009).

**Kinds of Androgens Used.** Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When use by athletes began more than two decades ago, 17α-alkylated androgens and other compounds that were thought to have greater anabolic effects than androgen effects relative to testosterone (so-called anabolic steroids) were used most commonly. Because these compounds can be detected readily by organizations that govern athletic competitions, preparations that increase the serum concentration of testosterone itself, such as the testosterone esters or hCG, have increased in popularity. Testosterone precursors, such as androstenedione and dehydroepiandrosterone (DHEA), also have increased in popularity recently because they are treated as nutritional supplements and thus are not regulated by national governments or athletic organizations.

A new development in use of androgens by athletes is represented by tetrahydrogestrinone (THG), a potent androgen that appears to have been designed and synthesized in order to avoid detection by antidoping laboratories on the basis of its novel structure (Figure 41-6) and rapid catabolism.

**Efficacy.** There have been few controlled studies of the effects of pharmacological doses of androgens on muscle strength. In one controlled study, 43 normal young men were randomized to one of four groups: strength training ± 600 mg of testosterone enanthate once a week (more than six times the replacement dose); or no exercise ± testosterone. The men who received testosterone experienced an increase in muscle strength compared to those who received placebo, and the men who exercised simultaneously experienced even greater increases (Bhasin et al., 1996). In another study, normal young men were treated with a GnRH analog to reduce endogenous testosterone secretion severely and in a random blinded fashion, weekly doses of testosterone enanthate from 25 mg to 600 mg. There was a dose-dependent effect of testosterone on muscle strength (Bhasin et al., 2001). In a double-blind study of androstenedione, men who took 100 mg three times a day for 8 weeks did not experience an increase in muscle strength compared to men who took placebo. Failure of this treatment to increase muscle strength is not surprising because it also did not increase the mean serum testosterone concentration (King et al., 1999).
Side Effects. All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis (Drinka et al., 1995).

When administered in high doses, androgens that can be converted to estrogens, such as testosterone itself, cause gynecomastia. Androgens whose A ring has been modified so that it cannot be aromatized, such as dihydrotestosterone, do not cause gynecomastia even in high doses.

The 17α-alkylated androgens are the only androgens that cause hepatotoxicity. These androgens also appear to be much more likely than others, when administered in high doses, to affect serum lipid concentrations, specifically to decrease high-density lipoprotein (HDL) cholesterol and increase low-density lipoprotein (LDL) cholesterol. Other side effects have been suggested by many anecdotes but have not been confirmed, including psychological disorders and sudden death due to cardiac disease, possibly related to changes in lipids or to coagulation activation.

Certain side effects occur specifically in women and children. Both experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience virilization, including facial and body hirsutism, acne, and changes in lipids or to coagulation activation.

Detection. An androgen other than testosterone can be detected by gas chromatography and mass spectroscopy if the athlete is still taking it when he is tested. Exogenous testosterone itself can be detected by one of two methods. One is the T/E ratio, the ratio of testosterone glucuronide to its endogenous epimer, epitestosterone glucuronide, in urine. Administration of exogenous testosterone suppresses secretion of both testosterone and epitestosterone and replaces them with only testosterone, so the T/E ratio is higher than normal. This technique is limited, however, by heterozygosity in the UDP-glucuronosyl transferase that converts testosterone to epitestosterone glucuronide. An athlete who has a deletion of one or both copies of the gene coding for this enzyme and who takes exogenous testosterone will have a much lower T/E ratio than one who has both copies (Schulze, 2008).

A second technique for detecting administration of exogenous testosterone employs gas chromatography-combustion-isotope ratio mass spectrometry to detect the presence of 13C and 12C compounds. Urinary steroids with a low 13C/12C ratio are likely to have originated from pharmaceutical sources as opposed to endogenous physiological sources (Aguilera et al., 2001).

Male Contraception. Androgens inhibit LH secretion by the pituitary and thereby decrease endogenous testosterone production. Based on these observations, scientists have tried for more than a decade to use androgens, either alone or in combination with other drugs, as a male contraceptive. Because the concentration of testosterone within the testes, ~100 times that in the peripheral circulation, is necessary for spermatogenesis, suppression of endogenous testosterone production greatly diminishes spermatogenesis. Initial use of testosterone alone, however, required supraphysiologic doses, and addition of GnRH antagonists required daily injections. A more promising approach is the combination of a progestin with a physiological dose of testosterone to suppress LH secretion and spermatogenesis but provide a normal serum testosterone concentration (Bebb et al., 1996). One trial employed injections of testosterone undecanoate with a depot progestin every 2 months (Gu et al., 2004). Another androgen being tested as part of a male contraceptive regimen is 7α-methyl-19-nortestosterone, a synthetic androgen that cannot be metabolized to dihydrotestosterone (Cummings et al., 1998).

Catabolic and Wasting States. Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with acquired immunodeficiency syndrome (AIDS), which often is accompanied by hypogonadism. Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength (Bhasin et al., 2000).

Angioedema. Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it (Cicardi et al., 1998). The 17α-alkylated androgens, such as stanozolol and danazol, stimulate the hepatic synthesis of the esterase inhibitor. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal closure prevent chronic use of androgens for prophylaxis, although they are used occasionally to treat acute episodes. As an alternative to prophylactic androgens, concentrated C1-esterase inhibitor derived from human plasma (CINRYZE) may be used for protection in patients with hereditary angioedema.

Blood Dyscrasias. Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens, such as danazol, still are used occasionally as adjunctive treatment for hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

ANTI-ANDROGENS

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be antian- drogens and now are used intentionally for this indication. See Chapter 63 for a more detailed discussion of androgen deprivation therapy for prostate cancer.

Inhibitors of Testosterone Secretion. Analogs of GnRH effectively inhibit testosterone secretion by inhibiting LH secretion. GnRH “superactive” analogs, given repeatedly, downregulate the GnRH receptor and are available for treatment of prostate cancer. An extended-release form of the GnRH antagonist, abarelix (PLENAXIS; no longer available in the U.S.) is used for treating prostate cancer (Trachtenberg et al., 2002). Because it
does not transiently increase sex steroid production, this preparation may be especially useful in prostate cancer patients in whom any stimulus to tumor growth might have serious adverse consequences, such as patients with metastases impinging on the spinal cord, in whom further tumor growth could cause paralysis.

Some antifungal drugs of the imidazole family, such as ketoconazole (Chapter 57), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis but sometimes are employed in cases of glucocorticoid excess (Chapter 42).

**Inhibitors of Androgen Action**

These drugs inhibit the binding of androgens to the androgen receptor or inhibit 5α-reductase.

**Androgen Receptor Antagonists.**

*Flutamide, Bicalutamide, and Nilutamide.* These relatively potent androgen receptor antagonists have limited efficacy when used alone because the increased LH secretion stimulates higher serum testosterone concentrations. They are used primarily in conjunction with a GnRH analog in the treatment of metastatic prostate cancer (Chapter 63). In this situation, they block the action of adrenal androgens, which are not inhibited by GnRH analogs. Flutamide also has been used to treat hirsutism in women, and it appears to be as effective as other treatments for this purpose (Venturoli et al., 1999); however, its association with hepatotoxicity warrants caution against its use for this cosmetic purpose.

**Spironolactone.** Spironolactone (ALDACTONE; Chapter 25) is an inhibitor of aldosterone that also is a weak inhibitor of the androgen receptor and a weak inhibitor of testosterone synthesis. When the agent is used to treat fluid retention or hypertension in men, gynecomastia is a common side effect (Caminos-Torres et al., 1977). In part because of this adverse effect, the selective mineralocorticoid receptor antagonist eplerenone (INSPIRA) was developed. Spironolactone can be used in women to treat hirsutism; it is moderately effective (Cumming et al., 1982) but may cause irregular menses.

**Cyproterone Acetate.** Cyproterone acetate is a progestin and a weak antiandrogen by virtue of binding to the androgen receptor. It is moderately effective in reducing hirsutism alone or in combination with an oral contraceptive (Venturoli et al., 1999) but is not approved for use in the U.S.

**5α-Reductase Inhibitors.** Finasteride (PROSCAR) is an antagonist of 5α-reductase, especially the type II; dutasteride (AVODART) is an antagonist of both type I and type II. Both agents block the conversion of testosterone to dihydrotestosterone, especially in the male external genitalia. These drugs were developed to treat benign prostatic hyperplasia, and they are approved in the U.S. and many other countries for this purpose. When they are administered to men with moderately severe symptoms due to obstruction of urinary tract outflow, serum and prostatic concentrations of dihydrotestosterone decrease, prostatic volume decreases, and urine flow rate increases (McConnell et al., 1998). Impotence is a well-documented, albeit infrequent, side effect of this use, although the mechanism is not understood. Gynecomastia is an even less common side effect (Thompson, 2003).

Finasteride also is approved for use in the treatment of male pattern baldness under the trade name PROPECIA, even though that effect is presumably mediated via the type I enzyme. It appears to be as effective as flutamide and the combination of estrogen and cyproterone in the treatment of hirsutism (Venturoli et al., 1999).

**CLINICAL SUMMARY**

Testosterone is the principal circulating androgen in men. The varied effects of testosterone are due to its ability to act by at least three mechanisms: by binding to the androgen receptor; by conversion in certain tissues
to dihydrotestosterone, which also binds to the androgen receptor; and by conversion to estradiol, which binds to the estrogen receptor. Consequences of testosterone deficiency depend on whether the deficiency occurs in utero, before puberty, or in adulthood.

Testosterone delivery systems are designed to avoid the rapid hepatic catabolism that occurs when native testosterone is ingested orally. Available delivery systems include injectable esters of testosterone, implants, and several transdermal preparations. The major therapeutic indication for testosterone treatment is male hypogonadism. Treatment should be monitored for efficacy by measurement of the serum testosterone concentration and for deleterious effects by evaluating for obstruction to urine flow due to benign prostatic hyperplasia, for prostate cancer, and for erythrocytosis.

Forest MG. Differentiation and development of the male. *Clin Endocrinol Metab*, 1975, 4:569–596.

Adrenocorticotropic hormone (ACTH, corticotropin) and the steroid hormone products of the adrenal cortex are considered together because the major physiological and pharmacological effects of ACTH result from its action to increase the circulating levels of adrenocortical steroids. Synthetic derivatives of ACTH are used principally in the diagnostic assessment of adrenocortical function. Because all known therapeutic effects of ACTH can be achieved with corticosteroids, synthetic steroid hormones generally are used therapeutically instead of ACTH.

Corticosteroids and their biologically active synthetic derivatives differ in their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are employed at physiological doses for replacement therapy when endogenous production is impaired. In addition, glucocorticoids potently suppress inflammation, and their use in a variety of inflammatory and autoimmune diseases makes them among the most frequently prescribed classes of drugs. Because glucocorticoids exert effects on almost every organ system, the clinical use of and withdrawal from corticosteroids are complicated by a number of serious side effects, some of which are life threatening. Therefore, the decision to institute therapy with systemic corticosteroids always requires careful consideration of the relative risks and benefits in each patient.

Agents that inhibit steps in the steroidogenic pathway and thus alter the biosynthesis of adrenocortical steroids are discussed in this chapter, as are synthetic steroids that inhibit glucocorticoid action. Agents that inhibit the action of aldosterone are presented in Chapter 25; agents used to inhibit growth of steroid-dependent tumors are discussed in Chapters 60-62.

**History.** Addison described fatal outcomes in patients with adrenal destruction in a presentation to the South London Medical Society in 1849. These studies were soon extended when Brown-Séquard demonstrated that bilateral adrenalectomy was fatal in laboratory animals. It later was shown that the adrenal cortex, rather than the medulla, was essential for survival in these ablation experiments and that the adrenal cortex regulated both carbohydrate metabolism and fluid and electrolyte balance. The isolation and identification of the adrenal steroids by Reichstein and Kendall and the effects of these compounds on carbohydrate metabolism (hence the term glucocorticoids) culminated with the synthesis of cortisone, the first pharmacologically effective glucocorticoid to become readily available. Subsequently, Tait and colleagues isolated and characterized a distinct corticosteroid, aldosterone, which potently affected fluid and electrolyte balance and therefore was termed a mineralocorticoid. The isolation of distinct corticosteroids that regulated carbohydrate metabolism or fluid and electrolyte balance led to the concept that the adrenal cortex comprises two largely independent units: an outer zone that produces mineralocorticoids and an inner region that synthesizes glucocorticoids and androgen precursors.

Studies of adrenocortical steroids also played a key part in delineating the role of the anterior pituitary in endocrine function. As early as 1912, Cushing described patients with hypercorticism, and later he recognized that pituitary basophilism caused the adrenal overactivity, thus establishing the link between the anterior pituitary and adrenal function. These studies led to the purification of ACTH and the determination of its chemical structure. ACTH was further shown to be essential for maintaining the structural integrity and steroidogenic capacity of the inner cortical zones. Harris established
the role of the hypothalamus in pituitary control and postulated that a soluble factor produced by the hypothalamus activated ACTH release. These investigations culminated with the determination of the structure of corticotropin-releasing hormone (CRH), a hypothalamic peptide that, together with arginine vasopressin, regulates secretion of ACTH from the pituitary.

Shortly after synthetic cortisone became available, Hench and colleagues demonstrated its dramatic effect in the treatment of rheumatoid arthritis. These studies set the stage for the clinical use of corticosteroids in a wide variety of diseases, as discussed in this chapter.

ADRENOCORTICOTROPIC HORMONE (ACTH; CORTICOTROPIN)

As summarized in Figure 42–1, ACTH is synthesized as part of a larger precursor protein, pro-opiomelanocortin (POMC), and is liberated from the precursor through proteolytic cleavage at dibasic residues by the serine endoprotease, prohormone convertase 1 (also known as prohormone convertase 3). The importance of this enzyme in POMC processing is best illustrated in a rare group of patients with prohormone convertase 1 mutations who present with impaired POMC processing, secondary hypocortisolism, childhood obesity, hypogonadotropic hypogonadism, diabetes, and neonatal onset enteropathy (Farooqi et al., 2007). A number of other biologically important peptides, including endorphins, lipotropins, and the melanocyte-stimulating hormones (MSH), also are produced by proteolytic processing of the same POMC precursor (Chapter 18).

Human ACTH is a peptide of 39 amino acids (Figure 42–1). Whereas removal of a single amino acid at the amino terminus considerably impairs biological activity, a number of amino acids can be removed from the carboxyl-terminal end without a marked effect. The structure–activity relationships of ACTH have been studied extensively, and it is believed that a stretch of four basic amino acids at positions 15-18 is an important determinant of high-affinity binding to the ACTH receptor, whereas amino acids 6-10 are important for receptor activation.

The actions of ACTH and the other melanocortins liberated from POMC are mediated by their specific interactions with five melanocortin receptor (MC1-5R) subtypes comprising a distinct subfamily of G protein-coupled receptors. The well-known effects of MSH on pigmentation result from interactions with the MC1R on melanocytes. MC1Rs also are found on cells of the immune system and are thought to mediate the anti-inflammatory effects of α-MSH in experimental models of inflammation. ACTH, which is identical to α-MSH in its first 13 amino acids (Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val), exerts its effects on the adrenal cortex through the MC2R. The affinity of ACTH for the MC1R is much lower than for the MC2R; however, under pathological conditions in which ACTH levels are persistently elevated, such as primary adrenal insufficiency, ACTH also can signal through the MC1R and cause hyperpigmentation. Recent studies have defined key roles for β-MSH (Lee et al., 2006) and possibly other melanocortins acting via the MC4R (Farooqi et al., 2003) and MC3R (Mencarelli et al., 2008) in the hypothalamic regulation of appetite and body weight, and they therefore are the subject of considerable investigation as possible targets for drugs that affect appetite. The role of MC5R is less well defined, but studies in rodents suggest that MSH triggers aggressive, pheromone-related behavior via the MC5R (Morgan and Cone, 2006).

**Actions on the Adrenal Cortex.** Acting via MC2R, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and the androgen precursor dehydroepiandrosterone (DHEA) that can be converted peripherally into more potent androgens. The adrenal cortex histologically and functionally can be separated into three zones that produce different steroid products under different regulatory influences. The outer zona glomerulosa secretes the mineralocorticoid aldosterone, the middle zona fasciculata secretes the glucocorticoid cortisol, and the inner zona reticularis secretes DHEA (Figure 42–2) and its sulfated derivative DHEAS, which circulates at concentrations 1000 times greater than DHEA. DHEAS can be converted to DHEA in the periphery by DHEA sulfatase.
Mechanism of Action. ACTH stimulates the synthesis and release of adrenocortical hormones. Because specific mechanisms for steroid hormone secretion have not been defined and steroids do not accumulate appreciably in the gland, it is believed that the actions of ACTH to increase steroid hormone production are mediated predominantly at the level of de novo biosynthesis.

ACTH, binding to MC2R (a GPCR), activates the Gα-subunit, which then activates adenyl cyclase, leading to increased cyclic AMP (cAMP) production. Cyclic AMP activates protein kinase A (PKA), which then phosphorylates and activates the transcription factor CREB, leading to increased transcription of steroidogenic enzymes. In the adrenal cortex, this process is mediated by the Gαq pathway, which activates phospholipase C (PLC), leading to increased intracellular calcium and activation of calcineurin, which dephosphorylates and activates the transcription factor CREB.

The mechanisms by which ACTH stimulates the translocation of cholesterol to the inner mitochondrial matrix are not fully defined. A 37,000-Da phosphoprotein—designated the steroidogenic acute regulatory protein (STAR)—clearly plays essential roles in cholesterol transport from the outer mitochondrial membrane to the inner mitochondrial matrix, where it is used as a substrate for steroid hormone biosynthesis. Mutations in the gene encoding this phosphoprotein are found in patients with congenital lipoid adrenal hyperplasia, a rare syndrome of familial resistance to ACTH (Clark et al., 2005).

Temporal, the response of adrenocortical cells to ACTH has two phases. The acute phase, which occurs within seconds to minutes, primarily reflects increased supply of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes. A summary of the pathways of adrenal steroid biosynthesis and the structures of the major steroid intermediates and products of the human adrenal cortex is shown in Figure 42–3. The rate-limiting step in steroid hormone production is the conversion of cholesterol to pregnenolone, a reaction catalyzed by CYP11A1, the cholesterol side-chain cleavage enzyme. Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily of mixed-function oxidases that play important roles in the metabolism of xenobiotics such as drugs and environmental pollutants, as well as in the biosynthesis of such endogenous compounds as steroid hormones, vitamin D, bile acids, fatty acids, prostaglandins, and biogenic amines (Chapter 6). The rate-limiting components in this reaction regulate the mobilization of substrate cholesterol and its delivery to CYP11A1 in the inner mitochondrial matrix.

To ensure an adequate supply of substrate for steroidogenesis, the adrenal cortex uses multiple sources of cholesterol (Kraemer, 2007), including:
- circulating cholesterol and cholesterol esters taken up via the low-density lipoprotein and high-density lipoprotein receptor pathways
- endogenous cholesterol liberated from cholesterol ester stores via activation of cholesterol esterase
- endogenous cholesterol from de novo biosynthesis.
Figure 42–3. Pathways of corticosteroid biosynthesis. The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The pathways unique to the zona glomerulosa are shown in orange box, whereas those that occur in the inner zona fasciculata and zona reticularis are shown in gray box. The zona reticularis does not express 3β-HSD and thus preferentially synthesizes DHEA. CYP11A1, cholesterol side-chain cleavage enzyme; 3β-HSD, 3β-hydroxy-steroid dehydrogenase; CYP17, steroid 17α-hydroxylase; CYP21, steroid 21-hydroxylase; CYP11B2, aldosterone synthase; CYP11B1, steroid 11β-hydroxylase.
increases in the steroidogenic capacity of the gland. Myriad transcriptional regulators participate in the induction of steroid hydroxylases by ACTH. Among these is the nuclear receptor NR5A1 (steroidogenic factor 1), a transcription factor required for the development of the adrenal cortex and for the expression of most of the steroidogenic enzymes (Parker et al., 2002).

**Extra-Adrenal Effects of ACTH.** In large doses, ACTH causes a number of metabolic changes in adrenalectomized animals, including ketosis, lipolysis, hypoglycemia (immediately after treatment), and resistance to insulin (later after treatment). Given the large doses of ACTH required, the physiological significance of these extra-adrenal effects is questionable. ACTH also reportedly improves learning in experimental animals, an effect postulated to be mediated via distinct receptors in the CNS.

**Regulation of ACTH Secretion.**

**Hypothalamic-Pituitary-Adrenal Axis.** The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotropes. These corticotropes are regulated by corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP), peptide hormones released by specialized neurons of the endocrine hypothalamus, which, in turn, are regulated by several neurotransmitters from the CNS. These three organs collectively are referred to as the hypothalamic-pituitary-adrenal (HPA) axis, an integrated system that maintains appropriate levels of glucocorticoids (Figure 42–4). The three characteristic modes of regulation of the HPA axis are diurnal rhythm in basal steroidogenesis, negative feedback regulation by adrenal corticosteroids, and marked increases in steroidogenesis in response to stress. The diurnal rhythm is entrained by higher neuronal centers in response to sleep-wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at ~8 A.M. As discussed later, negative feedback regulation occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

Following release into the hypophyseal plexus, CRH is transported via this portal system to the anterior pituitary, where it binds to specific membrane receptors on corticotropes. Upon CRH binding, the CRH receptor activates the G<sub>3</sub>-adenylyl cyclase–cyclic AMP pathway within corticotropes, ultimately stimulating both ACTH biosynthesis and secretion. CRH and CRH-related peptides called urocortins also are produced at other sites, including the amygdala and hindbrain, gut, skin, adrenal gland, adipose tissue, placenta, and additional sites in the periphery. The classical CRH receptor, now designated CRF<sub>1</sub> receptor, belongs to the class II family of G protein-coupled receptors that includes receptors for calcitonin, parathyroid hormone, growth hormone-releasing hormone, secretin, glucagon, and glucagon-like peptide. A second CRH receptor, designated CRF<sub>2</sub> receptor, shares 70% homology at the amino acid level and is distinguished from the CRF<sub>1</sub> receptor in its binding specificities for CRH and the urocortins. In mice, the CRF<sub>2</sub> receptor opposes those effects mediated by the CRF<sub>1</sub> receptor thereby, providing a highly complex neural network that modulates the adaptive response to stress (Bale and Vale, 2004). The finding that the HPA axis often is altered in patients suffering from major depressive disorders illustrates the complex relationships between stress and mood and has stimulated considerable interest in the possible use of CRH antagonists in disorders such as anxiety and depression (Holsboer and Ising, 2008).

**Arginine Vasopressin.** Arginine vasopressin (AVP) also acts as a secretagogue for corticotropes, significantly potentiating the effects of CRH. Animal studies suggest that the potentiation of CRH action by AVP probably contributes to the full magnitude of the stress response in vivo. Like CRH, AVP is produced in the parvocellular neurons of the paraventricular nucleus and secreted into the pituitary plexus from the median eminence. After binding to V<sub>1b</sub> receptors, AVP activates the
G_{\text{q}}$-PLC-IP_{3}-Ca^{2+} pathway to enhance the release of ACTH. In contrast to CRH, AVP apparently does not increase ACTH synthesis (Surget and Belzung, 2008).

**Negative Feedback of Glucocorticoids.** Glucocorticoids inhibit ACTH secretion via direct and indirect actions on CRH neurons to decrease CRH mRNA levels and CRH release and via direct effects on corticotropes. The indirect inhibitory effects on CRH neurons appear to be mediated by specific corticosteroid receptors in the hippocampus. At lower cortisol levels, the mineralocorticoid receptor (MR), which has a higher affinity for glucocorticoids than classical glucocorticoid receptors (GR), is the major receptor species occupied. As glucocorticoid concentrations rise and saturate the MR, the GR becomes increasingly occupied. Both the MR and GR apparently control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominantly involves the GR.

In the pituitary, glucocorticoids act through the GR to inhibit the release of ACTH from corticotropes and the expression of POMC. These effects are both rapid (occurring within seconds to minutes) and delayed (requiring hours and involving changes in gene transcription mediated through the GR).

**The Stress Response.** Stress overcomes negative feedback regulation of the HPA axis, leading to a marked rise in corticosteroid production. Examples of stress signals include injury, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Although the precise mechanisms that underlie this stress response and the essential actions played by corticosteroids are not fully defined, it is clear that their increased secretion is vital to maintain homeostasis in these stressful settings. As discussed later, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response (Elenkov and Chrousos, 2006).

**Assays for ACTH.** Initially, ACTH levels were assessed by bioassays that measured induced steroid production or the depletion of adrenal ascorbic acid. Immunochemiluminescent assays that use two separate antibodies directed at distinct epitopes on the ACTH molecule now are widely available. These assays increase considerably the ability to differentiate patients with primary hypoadrenalism due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from those with secondary forms of hypoadrenalism, due to low ACTH levels resulting from hypothalamic or pituitary disorders. The immunochemiluminescent ACTH assays also are useful in differentiating between ACTH-dependent and ACTH-independent forms of hypercorticism: High ACTH levels are seen when the hypercorticism results from pituitary adenomas (e.g., Cushing’s disease) or nonpituitary tumors that secrete ACTH (e.g., the syndrome of ectopic ACTH), whereas low ACTH levels are seen in patients with excessive glucocorticoid production due to primary adrenal disorders. Despite their considerable utility, one problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can secrete aberrantly processed forms of ACTH that have biological activity but do not react in the antibody assays.

**Therapeutic Uses and Diagnostic Applications of ACTH.** There are anecdotal reports that selected conditions respond better to ACTH than to corticosteroids (e.g., multiple sclerosis), and some clinicians continue to advocate therapy with ACTH. Despite this, ACTH currently has only limited utility as a therapeutic agent. Therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. In addition, ACTH stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. Although ACTH and the corticosteroids are not pharmacologically equivalent, all proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids with a lower risk of side effects.

**Testing the Integrity of the HPA Axis.** The major clinical use of ACTH is in testing the integrity of the HPA axis. Other tests used to assess the HPA axis include the insulin tolerance test (Chapter 38) and the metyrapone test (discussed later in this chapter). Cosyntropin (CORTROSYN, SYNACTHEN) is a synthetic peptide that corresponds to residues 1-24 of human ACTH. At the considerably supraphysiological dose of 250 μg, cosyntropin maximally stimulates adrenocortical steroidogenesis. In the standard cosyntropin stimulation test, 250 μg of cosyntropin is administered either intramuscularly or intravenously, with cortisol measured just before administration (baseline) and 30-60 minutes after cosyntropin administration. An increase in the circulating cortisol to a level greater than 18-20 μg/dL indicates a normal response. Some accept an increase of 9 μg/dL over the baseline value as a positive response. In patients with pituitary or hypothalamic disease of recent onset or shortly after surgery for pituitary tumors, the standard cosyntropin stimulation test may be misleading because the duration of ACTH deficiency may have been insufficient to cause significant adrenal atrophy with frank loss of steroidogenic capacity. For these patients, some experts advocate a “low-dose” cosyntropin stimulation test, in which 1 μg of cosyntropin is administered intravenously, and cortisol is measured just before and 30 minutes after cosyntropin administration; the cutoff for a normal response is the same as that for the standard test. Care must be taken to avoid adsorption of the cosyntropin to plastic tubing and to measure the plasma cortisol precisely at 30 minutes after the cosyntropin injection. Although some studies indicate that the low-dose test is more sensitive than the standard 250-μg test, others report that this test also may fail to detect secondary adrenal insufficiency.

As already noted, primary adrenocortical insufficiency and secondary adrenocortical insufficiency are reliably distinguished by available sensitive assays for ACTH. More protracted ACTH stimulation tests rarely are used to differentiate between these disorders.

**CRH Stimulation Test.** Ovine CRH (corticorelin [ACTREL]) and human CRH are available for diagnostic testing of the HPA axis, with the former used in the U.S. and the latter preferred in Europe. In patients with documented ACTH-dependent hypercorticism, CRH testing may help differentiate between a pituitary source (i.e.,
Cushing’s disease) and an ectopic source of ACTH. After two baseline blood samples are obtained 15 minutes apart, CRH (1 μg/kg) is administered intravenously over a 30- to 60-second interval, and peripheral blood samples are obtained at 15, 30, and 60 minutes for ACTH measurement. It is important that the blood samples be handled as recommended for the ACTH assay. At the recommended dose, CRH generally is well tolerated, although flushing may occur, particularly if the dose is administered as a bolus. Patients with Cushing’s disease respond to CRH with either a normal or an exaggerated increase in ACTH, whereas ACTH levels generally do not increase in patients with ectopic sources of ACTH. This test is not perfect: ACTH levels are induced by CRH in occasional patients with ectopic ACTH, and ~5-10% of patients with Cushing’s disease fail to respond.

To improve the diagnostic accuracy of the CRH stimulation test, many authorities advocate sampling of blood from the inferior petrosal sinuses and the peripheral circulation after peripheral administration of CRH. In this test, an inferior petrosal/peripheral ratio of >2.5 supports a pituitary source of ACTH. When performed by a skilled neuroradiologist, this procedure increases diagnostic accuracy with a tolerable risk of complications from the catheterization procedure (Arnoldi et al., 2003).

**Absorption and Fate.** ACTH is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans, the t1/2 in plasma is ~15 minutes, primarily due to rapid enzymatic hydrolysis.

**Toxicity of ACTH.** Aside from rare hypersensitivity reactions, the toxicity of ACTH is primarily attributable to the increased secretion of corticosteroids. Cosyntropin generally is less antigenic than native ACTH; thus, cosyntropin is the preferred agent for clinical use.

### ADRENOCORTICAL STEROIDS

The adrenal cortex synthesizes two classes of steroids: the **corticosteroids** (glucocorticoids and mineralocorticoids), which have 21 carbon atoms, and the **androgens**, which have 19 carbons (Figure 41–3). The actions of corticosteroids historically were described as glucocorticoid (reflecting their carbohydrate metabolism–regulating activity) and mineralocorticoid (reflecting their electrolyte balance–regulating activity). In humans, **cortisol** (hydrocortisone) is the main glucocorticoid and aldosterone is the main mineralocorticoid. Table 42–1 shows typical rates of secretion of cortisol and aldosterone, as well as their normal circulating concentrations.

Although the adrenal cortex is an important source of androgen precursors in women, patients with adrenal insufficiency can be restored to normal life expectancy by replacement therapy with glucocorticoids and mineralocorticoids. Adrenal androgens are not essential for survival. The levels of dehydroepiandrosterone (DHEA) and its sulfated derivative DHEA-S peak in the third decade of life and decline progressively thereafter. Moreover, patients with a number of chronic diseases have very low DHEA levels, leading some to propose that DHEA treatment might at least partly alleviate the loss of libido, the decline in cognitive function, the decreased sense of well-being, and other adverse physiological consequences of aging. Whereas some studies have shown that addition of DHEA to the standard replacement regimen in women with adrenal insufficiency improved subjective well-being and sexuality, others have failed to show any benefit of DHEA replacement in either men or women (Chang et al., 2008). Nevertheless, DHEA is widely used as an over-the-counter nutritional supplement for its alleged health benefits, despite the absence of definitive data.

**Physiological Functions and Pharmacological Effects**

**Physiological Actions.** Corticosteroids have numerous and widespread effects, which include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist such stressful circumstances as noxious stimuli and environmental changes. In the absence of the adrenal cortex, survival is made possible only by maintaining an optimal environment, including adequate and regular feeding, ingestion of relatively large amounts of sodium chloride, and maintenance of an appropriate environmental temperature; stresses such as infection, trauma, and extremes in temperature in this setting can be life threatening.

Traditionally, the effects of administered corticosteroids have been viewed as physiological (reflecting actions of corticosteroids at doses corresponding to normal daily production levels) or pharmacological (representing effects seen only at doses exceeding the normal daily production of corticosteroids). More recent concepts suggest that the anti-inflammatory and immunosuppressive actions...
of corticosteroids—one of the major “pharmacological” uses of this class of drugs—also provide a protective mechanism in the physiological setting. Many of the immune mediators associated with the inflammatory response decrease vascular tone and could lead to cardiovascular collapse if unopposed by the adrenal corticosteroids. This hypothesis is supported by the fact that the daily production rate of cortisol can rise at least 10-fold in the setting of severe stress. In addition, the pharmacological actions of corticosteroids in different tissues and the physiological effects are mediated by the same receptor. Thus the various glucocorticoid derivatives used as pharmacological agents generally have side effects on physiological processes that parallel their therapeutic effectiveness.

The actions of corticosteroids are related to those of other hormones. For example, in the absence of lipolytic hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Likewise, in the absence of glucocorticoids, epinephrine and norepinephrine have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed permissive and most likely reflect steroid-induced changes in protein synthesis that, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are grouped according to their relative potencies in Na⁺ retention, effects on carbohydrate metabolism (i.e., hepatic deposition of glycogen and gluconeogenesis), and anti-inflammatory effects. In general, potencies of steroids as judged by their ability to sustain life in adrenalectomized animals closely parallel those determined for Na⁺ retention, whereas potencies based on effects on glucose metabolism closely parallel those for anti-inflammatory effects. The effects on Na⁺ retention and the carbohydrate/anti-inflammatory actions are not closely related and reflect selective actions at distinct receptors.

Based on these differential potencies, the corticosteroids traditionally are divided into mineralocorticoids and glucocorticoids. Estimates of potencies of representative steroids in these actions are listed in Table 42–2. Some steroids that are classified predominantly as glucocorticoids (e.g., cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency, the mineralocorticoid effects of these “glucocorticoids” are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na⁺ retention but has only modest potency for effects on carbohydrate metabolism. At normal rates of secretion by the adrenal cortex or in doses that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

### General Mechanisms for Corticosteroid Effects.

Corticosteroids bind to specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive genes, thereby changing the levels and array of proteins synthesized by the various target tissues (Figure 42–5). As a consequence of the time required to modulate gene expression and protein synthesis, most effects of corticosteroids are not immediate but become

*This agent is not used for glucocorticoid effects.
Regulation of Gene Expression by Glucocorticoids. After ligand binding, the GR dissociates from its associated proteins and translocates apparent after several hours. This fact is of clinical significance because a delay generally is seen before beneficial effects of corticosteroid therapy become manifest. Although corticosteroids predominantly act by increasing gene transcription, there are well-documented examples in which glucocorticoids decrease gene transcription, as discussed later. In addition, corticosteroids may exert some of their immediate effects by nongenomic mechanisms (Stahn and Buttgereit, 2008).
to the nucleus. There, it interacts with specific DNA sequences within the regulatory regions of affected genes. The short DNA sequences that are recognized by the activated GR are called glucocorticoid responsive elements (GREs) and provide specificity to the induction of gene transcription by glucocorticoids. The consensus GRE sequence is an imperfect palindrome (GGTACAnnnTGTTCT, where n is any nucleotide) to which the GR binds as a receptor dimer. The mechanisms by which GR activates transcription are complex and not completely understood, but they involve the interaction of the GR with transcriptional coactivators and with proteins that make up the basal transcription apparatus. Genes that are negatively regulated by glucocorticoids also have been identified. One well-characterized example is the pro-opiomelanocortin gene. In this case, the GR appears to inhibit transcription by a direct interaction with a GRE in the POMC promoter, thereby contributing to the negative feedback regulation of the HPA axis. Other genes negatively regulated by glucocorticoids include genes for cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (NOS2), and inflammatory cytokines.

In some cases, the inhibitory effects of glucocorticoids on gene expression have been linked to protein–protein interactions between the GR and other transcription factors rather than to negative effects of the GR at specific GREs. Indeed, protein–protein interactions have been observed between the GR and the transcription factors NF-κB and AP-1, which regulate the expression of a number of components of the immune system (De Bosscher et al., 2003). Such interactions repress the expression of genes encoding a number of cytokines—regulatory molecules that play key roles in the immune and inflammatory networks—and enzymes, such as collagenase and stromelysin, that are proposed to play key roles in the joint destruction seen in inflammatory arthritis. Thus, these protein–protein interactions and their consequent negative effects on gene expression appear to contribute significantly to the anti-inflammatory and immunosuppressive effects of the glucocorticoids.

The recognition that the metabolic effects of glucocorticoids generally are mediated by transcriptional activation, whereas the anti-inflammatory effects largely are mediated by transrepression, suggests that selective GR ligands may maintain the anti-inflammatory actions while lessening the metabolic side effects (McMaster and Ray, 2008). Recent reports describing steroidal and nonsteroidal compounds that exhibit anti-inflammatory actions but have little effect on blood glucose suggest that selective glucocorticoid agonists may emerge from ongoing research.

### Regulation of Gene Expression by Mineralocorticoids

Like the GR, the MR also is a ligand-activated transcription factor and binds to a very similar, if not identical, hormone-responsive element. Although its actions have been studied in less detail than the GR, the basic principles of action appear to be similar; in particular, the MR also associates with HSP90 and activates the transcription of discrete sets of genes within target tissues. Studies have not yet identified differences in the DNA recognition motifs for the GR and the MR that would explain their differential capacities to activate discrete sets of target genes. The GR and MR differ in their ability to inhibit AP-1–mediated gene activation, suggesting that differential interactions with other transcription factors may underlie their distinct effects on cell function. The MR has a restricted expression: it is expressed in epithelial tissues involved in electrolyte transport (i.e., the kidney, colon, salivary glands, and sweat glands) and in nonepithelial tissues (e.g., hippocampus, heart, vasculature and adipose tissue) where its functions are less well understood.

Aldosterone exerts its effects on Na⁺ and K⁺ homeostasis primarily via its actions on the principal cells of the distal renal tubules and collecting ducts, whereas the effects on H⁺ secretion largely are exerted in the intercalated cells. The binding of aldosterone to the MR in the kidney initiates a sequence of events that includes the rapid induction of serum- and glucocorticoid-regulated kinase, which in turn phosphorylates and activates amiloride-sensitive epithelial Na⁺ channels in the apical membrane. Thereafter, increased Na⁺ influx stimulates the Na⁺, K⁺-ATPase in the basolateral membrane. In addition to these rapid genomic actions, aldosterone also increases the synthesis of the individual components of these membrane proteins as part of a more delayed effect.

### Receptor-Independent Mechanism for Corticosteroid Specificity

The availability of cloned genes encoding the GR and MR led to the surprising finding that aldosterone (a classic mineralocorticoid) and cortisol (generally viewed as predominantly glucocorticoid) bind the MR with equal affinity. This raised the question of how the apparent specificity of the MR for aldosterone was maintained in the face of much higher circulating levels of glucocorticoids. We now know that the type 2 isozyme of 11β-hydroxysteroid dehydrogenase (11βHSD2) plays a key role in corticosteroid specificity, particularly in the kidney, colon, and salivary glands (Hammer and Stewart, 2006). This enzyme metabolizes glucocorticoids such as cortisol to receptor-inactive 11-keto derivatives such as cortisone (Figure 42–6). Because its predominant form in physiological settings is the hemiacetal derivative (Figure 42–7), which is resistant to 11βHSD action, aldosterone escapes this inactivation and maintains mineralocorticoid activity. In the absence of 11βHSD2, as occurs in an inherited disease called the syndrome of apparent mineralocorticoid excess, the MR is activated by cortisol, leading to severe hypokalemia and mineralocorticoid-related hypertension. A state of mineralocorticoid excess also can be induced by inhibiting 11βHSD
with **glycyrrhizic acid**, a component of licorice implicated in licorice-induced hypertension.

**Carbohydrate and Protein Metabolism.** Corticosteroids profoundly affect carbohydrate and protein metabolism, which can be viewed as protecting glucose-dependent tissues (e.g., the brain and heart) from starvation. They stimulate the liver to form glucose from amino acids and glycerol and to store glucose as liver glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Because of their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of hyperglycemia in susceptible patients.

The mechanisms whereby glucocorticoids inhibit glucose utilization in peripheral tissues are not fully understood. Glucocorticoids decrease glucose uptake in adipose tissue, skin, fibroblasts, thymocytes, and polymorphonuclear leukocytes; these effects are postulated to result from translocation of the glucose transporters from the plasma membrane to an intracellular location. These peripheral effects are associated with a number of catabolic actions, including atrophy of lymphoid tissue, decreased muscle mass, negative nitrogen balance, and thinning of the skin.

Similarly, the mechanisms by which the glucocorticoids promote gluconeogenesis are not fully defined. Amino acids mobilized from a number of tissues in response to glucocorticoids reach the liver and provide substrate for the production of glucose and glycogen. In the liver, glucocorticoids induce the transcription of a number of enzymes involved in gluconeogenesis and amino acid metabolism, including phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase, and the bifunctional enzyme fructose-2,6-bisphosphatase. Analyses of the molecular basis for regulation of PEPCK gene expression have identified complex regulatory influences involving an interplay among glucocorticoids, insulin, glucagon, and catecholamines. The effects of these hormones and amines on PEPCK gene expression mirror the complex regulation of gluconeogenesis in the intact organism.

**Lipid Metabolism.** Two effects of corticosteroids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in settings of endogenous or pharmacologically induced hypercorticism, such as Cushing’s syndrome. In this setting, there is increased fat in the back of the neck (“buffalo hump”), face (“moon facies”), and supraclavicular area, coupled with a loss of fat in the extremities. The other is the permissive facilitation of the lipolytic
effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration.

One hypothesis for the redistribution of body fat is that peripheral and truncal adipocytes differ in their relative sensitivities to insulin and to glucocorticoid-facilitated lipolytic effects. Truncal adipocytes respond predominantly to elevated levels of insulin resulting from glucocorticoid-induced hyperglycemia, whereas peripheral adipocytes are less sensitive to insulin and respond mostly to the glucocorticoid-facilitated effects of other lipolytic hormones. This differential sensitivity may reflect differences in the expression of 11βHSD1 that converts inactive cortisone into active cortisol in target tissues (Figure 42–6). Consistent with this idea, overexpression of 11βHSD1 in adipocytes causes obesity in a transgenic mouse model. The potential role of this enzyme in adipocyte function has prompted speculation that 11βHSD1 inhibitors may have a role in the treatment of obesity.

**Electrolyte and Water Balance.** Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Thus, electrolyte balance is relatively normal in patients with adrenal insufficiency due to pituitary disease, despite the loss of glucocorticoid production by the inner cortical zones. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na+ from the tubular fluid; they also increase the urinary excretion of K+ and H+. Conceptually, it is useful to think of aldosterone as stimulating a renal exchange between Na+ and K+ or H+, although this does not involve a simple 1:1 exchange of cations in the renal tubule.

These actions on electrolyte transport, in the kidney and in other tissues (e.g., colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralocorticoids. Thus, the primary features of hyperaldosteronism are positive Na+ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na+ concentration, normal or low plasma K+, and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na+ wasting and contraction of the extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Indeed, mineralocorticoid-deficient patients are especially predisposed to Na+ loss and volume depletion through excessive sweating in hot environments. Chronically, hyperaldosteronism causes hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse.

Further insights into the roles of aldosterone target genes in fluid and electrolyte balance have emerged from analyses of patients with rare genetic disorders of mineralocorticoid action, such as pseudohypoaldosteronism and pseudoaldosteronism. Despite elevated levels of mineralocorticoids, patients with classical pseudohypoaldosteronism (i.e., type 1 disease) present with clinical manifestations suggestive of deficient mineralocorticoid action (i.e., volume depletion, hypotension, hyperkalemia, and metabolic acidosis). Molecular analyses have defined discrete subpopulations of patients with this disorder. One form of the disease is caused by autosomal dominant mutations in the MR that impair its activity. A second, autosomal recessive form results from loss-of-function mutations in genes encoding subunits of the amiloride-sensitive epithelial Na+ channel. A nonclassical pseudohypoaldosteronism (type 2, also known as Gordon’s syndrome) presents with hyperkalemia, mild metabolic acidosis, and familial hypertension. In some of these patients, the disease is caused by autosomal dominant mutations in the protein kinase genes WNK1 and WNK4 that inhibit the sodium chloride cotransporter. Pseudoaldosteronism, also termed Liddle’s syndrome, is an autosomal dominant disease that results from mutations in subunits of the amiloride-sensitive Na+ channel that interfere with its downregulation. The constitutive activity of this channel leads to hypertension, hyperkalemia, and metabolic alkalosis, despite low levels of plasma renin and aldosterone.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney.

In addition to their effects on monovalent cations and water, glucocorticoids also exert multiple effects on Ca2+ metabolism. Steroids lower Ca2+ uptake from the gut and increase Ca2+ excretion by the kidney. These effects collectively lead to decreased total body Ca2+ stores.

**Cardiovascular System.** The most striking effects of corticosteroids on the cardiovascular system result from mineralocorticoid-induced changes in renal Na+, as is evident in primary aldosteronism. Studies have shown direct effects of MR activation on the heart and vessel wall; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis is proposed to result from direct mineralocorticoid actions in the heart rather than from the effect of hypertension because treatment with spironolactone, a MR antagonist, blocks the development of fibrosis without altering blood pressure. Indeed, in age-, sex-, and blood pressure-matched hypertensive patients, those with primary aldosteronism have a higher prevalence of atrial fibrillation, stroke, and myocardial infarction, indicating direct effects of increased aldosterone on the cardiovascular system. Similar cardiac effects of MR activation in human beings may explain the beneficial effects of spironolactone in patients with congestive heart failure (Chapter 28).

The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity
to other vasoactive substances. Hypoadrenalism is associated with reduced responsiveness to vasoconstrictors such as norepinephrine and angiotensin II, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing’s syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

The underlying mechanisms in glucocorticoid-induced hypertension also are unknown; the hypertension related to the endogenous secretion of cortisol, as seen in patients with Cushing’s syndrome, likely results from multiple effects mediated by the GR and MR. Unlike hypertension caused by high aldosterone levels, the hypertension secondary to excess glucocorticoids is generally resistant to Na+ restriction (Magiakou et al., 2006).

**Skeletal Muscle.** Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison’s disease, weakness and fatigue are frequent symptoms. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, either secondary to glucocorticoid therapy or endogenous hypercorticism, causes skeletal muscle wasting. This effect, termed *steroid myopathy*, accounts in part for weakness and fatigue in patients with glucocorticoid excess and is discussed in more detail later.

**Central Nervous System.** Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability.

Patients with adrenal insufficiency exhibit a diverse array of neurological manifestations, including apathy, depression, and irritability; some patients are frankly psychotic. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as mania, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids become anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing’s syndrome. These abnormalities usually disappear after cessation of glucocorticoid therapy or treatment of the Cushing’s syndrome.

The mechanisms whereby corticosteroids affect neuronal activity are unknown, but it has been proposed that steroids produced locally in the brain (termed neurosteroids) may regulate neuronal excitability. In rodent models, very high doses of glucocorticoids decrease survival and function of hippocampal neurons; in association with these changes, memory also is diminished. In one study in human subjects, basal cortisol levels correlated directly with hippocampal atrophy and memory deficits. To the extent that these results are confirmed, they may have important prognostic implications for age-related memory decline, and for therapeutic approaches directed at diminishing the negative effects of glucocorticoids on hippocampal neurons with aging.

**Formed Elements of Blood.** Glucocorticoids exert minor effects on hemoglobin and erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing’s syndrome and of normochromic, normocytic anemia in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish the self-destruction of erythrocytes.

Corticosteroids also affect circulating white blood cells. Addison’s disease is associated with an increased mass of lymphoid tissue and lymphocytosis. In contrast, Cushing’s syndrome is characterized by lymphocytopenia and decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone leads to a decline of these circulating cells within 4-6 hours; this effect persists for 24 hours and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and decreased adherence to vascular walls. Finally, certain lymphoid malignancies are destroyed by glucocorticoid treatment, an effect that may relate to the ability of glucocorticoids to activate programmed cell death.

**Anti-inflammatory and Immunosuppressive Actions.** In addition to their effects on lymphocyte number, corticosteroids profoundly alter the immune responses of lymphocytes. These effects are an important facet of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Glucocorticoids can prevent or suppress inflammation in response to multiple inciting events, including radiant, mechanical, chemical, infectious, and immunological stimuli. Although the use of glucocorticoids as anti-inflammatory agents does not address the underlying cause of the disease, the
suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of immense value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (Chapter 65), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (Chapter 35). The immunosuppressive and anti-inflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. Glucocorticoids inhibit the production by multiple cells of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemoattractive factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of pro-inflammatory cytokines, as well as COX-2 and NOS2. Some of the cell types and mediators that are inhibited by glucocorticoids are summarized in Table 42–3. The net effect of these actions on various cell types is to diminish markedly the inflammatory response.

The influence of stressful conditions on immune defense mechanisms is well documented, as is the contribution of the HPA axis to the stress response (Elenkov and Chrousos, 2006). This has led to a growing appreciation of the importance of glucocorticoids as physiological modulators of the immune system, where glucocorticoids appear to protect the organism against life-threatening consequences of a full-blown inflammatory response (Chrousos, 1995).

Stresses such as injury, infection, and disease result in the increased production of cytokines, a network of signaling molecules that integrate actions of macrophages/monocytes, T lymphocytes, and B lymphocytes in mounting immune responses. Among these cytokines, interleukin (IL)-1, IL-6, and tumor necrosis factor α (TNF-α) stimulate the HPA axis, with IL-1 having the broadest range of actions. IL-1 stimulates the release of CRH by hypothalamic neurons, interacts directly with the pituitary to increase the release of ACTH, and may directly stimulate the adrenal gland to produce glucocorticoids. As detailed earlier, the increased production of glucocorticoids, in turn, profoundly inhibits the immune system at multiple sites. Factors that are inhibited include components of the cytokine network, including interferon γ (IFN-γ), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukins (IL-1, IL-2, IL-3, IL-6, IL-8, and IL-12), and TNF-α. Thus, the HPA axis and the immune system are capable of bidirectional interactions in response to stress, and these interactions appear to be important for homeostasis (Chrousos, 1995).

### Absorption, Transport, Metabolism, and Excretion

#### Absorption

Hydrocortisone and numerous congeners, including the synthetic analogs, are orally effective. Certain water-soluble esters of hydrocortisone and its

synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action.

Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

Transport, Metabolism, and Excretion. After absorption, ≥90% of cortisol in plasma is reversibly bound to protein under normal circumstances. Only the fraction of corticosteroid that is unbound is active and can enter cells. Two plasma proteins account for almost all of the steroid-binding capacity: corticosteroid-binding globulin (CBG; also called transcortin), and albumin. CBG is an α-globulin secreted by the liver that has high affinity for steroids (estimated dissociation constant of ~1.3 × 10⁻⁹ M) but relatively low total binding capacity, whereas albumin, also produced by the liver, has a relatively large binding capacity but low affinity (estimated dissociation constant of 1 × 10⁻³ M). Because of its higher dissociation constant, albumin-bound corticosteroid makes a greater contribution to the active corticosteroid fraction in tissues that have a slow capillary transit time (e.g., liver and spleen) than in tissues with rapid capillary transit times (e.g., kidney). At normal or low concentrations of corticosteroids, most of the hormone is protein bound. At higher steroid concentrations, the capacity of protein binding is exceeded, and a greater fraction of the steroid exists in the free state. Corticosteroids compete with each other for binding sites on CBG. CBG has relatively high affinity for cortisol and some of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these latter steroids are found in the free form.

A special state of physiological hypercorticism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase severalfold. The physiological significance of these changes remains to be established.

All of the biologically active adrenocortical steroids and their synthetic congeners have a double bond in the 4,5 position and a ketone group at C3 (Figure 42–7). As a general rule, the metabolism of steroid hormones involves sequential additions of oxygen or hydrogen atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxyl derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring–reduced steroids are conjugated through the 3-hydroxyl group with sulfate or glucuronide by enzymatic reactions that take place in the liver and, to a lesser extent, in the kidney. The resultant sulfate esters and glucuronides are water soluble and the predominant forms excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans.

Synthetic steroids with an 11-keto group, such as cortisone and prednisone, must be enzymatically reduced to the corresponding 11β-hydroxy derivative before they are biologically active. The type 1 isozyme of 11β-hydroxysteroid dehydrogenase (11βHSD1) catalyzes this reduction, predominantly in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin. In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (e.g., hydrocortisone or prednisolone rather than cortisol or prednisone). Such settings include severe hepatic failure and patients with the rare condition of cortisone reductase deficiency, who are unable to activate the 11-keto steroids because of a defect in the enzyme hexose-6-phosphate dehydrogenase, which regulates the activity of 11β-hydroxysteroid dehydrogenase by supplying required reducing equivalents (Lavery et al., 2008).

Structure–Activity Relationships

Chemical modifications to the cortisol molecule have generated derivatives with greater separations of glucocorticoid and mineralocorticoid activity; for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used (Table 42–2). In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. Some of these agents are summarized in Table 42–4. None of these currently available derivatives effectively separates anti-inflammatory effects from effects on carbohydrate, protein, and fat metabolism, or from suppressive effects on the HPA axis.

The structures of hydrocortisone (cortisol) and some of its major derivatives are shown in Figure 42–7. Changes in chemical structure may alter the specificity and/or potency due to changes in affinity and intrinsic activity at corticosteroid receptors, and alterations in absorption, protein binding, rate of metabolic transformation, rate of excretion, or membrane permeability. The effects of various substitutions on glucocorticoid and mineralocorticoid activity and on duration of action are summarized in Table 42–2. The 4,5 double bond and the 3-keto group on ring A are essential for glucocorticoid and mineralocorticoid activity; an 11β-hydroxyl group on ring C is required for glucocorticoid activity but not mineralocorticoid activity; a hydroxyl group at C21 on ring D is present on all natural corticosteroids and on most of the active synthetic analogs, and seems to be an absolute requirement for mineralocorticoid but not glucocorticoid activity. The 17α-hydroxy group on ring D is a substituent on cortisol and on all of the currently used synthetic glucocorticoids. Although steroids without the 17α-hydroxyl group
(e.g., corticosterone) have appreciable glucocorticoid activity, the 17α-hydroxyl group gives optimal potency.

Introduction of an additional double bond in the 1,2 position of ring A, as in prednisolone or prednisone, selectively increases glucocorticoid activity, and results in an enhanced glucocorticoid/mineralocorticoid potency ratio. This modification also results in compounds that are metabolized more slowly than hydrocortisone.

Fluorination at the 9α position on ring B enhances both glucocorticoid and mineralocorticoid activity, possibly related to an electron-withdrawing effect on the nearby 11β-hydroxyl group. Fludrocortisone (9α-fluorocortisol) has enhanced activity at the GR (10 times relative to cortisol) but even greater activity at the MR (125 times relative to cortisol). It is used in mineralocorticoid replacement therapy and has no appreciable glucocorticoid effect at usual daily doses of 0.05-0.2 mg. When combined with the 1,2 double bond in ring A plus other substitutions at C16 on ring D (Figure 42–7), the 9α-fluoro derivatives formed (e.g., triamcinolone, dexamethasone, and betamethasone) have marked glucocorticoid activity—the substitutions at C16 virtually eliminate mineralocorticoid activity.

Other Substitutions. 6α Substitution on ring B has somewhat unpredictable effects. 6α-Methylcortisol has increased glucocorticoid and mineralocorticoid activity, whereas 6α-methylprednisolone has somewhat greater glucocorticoid activity and somewhat less mineralocorticoid activity than prednisolone. A number of modifications convert the glucocorticoids to more lipophilic molecules with enhanced topical/systemic potency ratios. Examples include the introduction of an acetonide between hydroxyl groups at C16 and C17, esterification of the hydroxyl group with valerate at C17, esterification of hydroxyl groups with propionate at C17 and C21, and substitution of the hydroxyl group at C21 with chlorine. Other approaches to achieve local glucocorticoid activity while minimizing systemic effects involve the formation of analogs that are rapidly inactivated after absorption (e.g., C21 carboxylate or carbothioate glucocorticoid esters, which are rapidly metabolized to inactive 21-carboxylic acids) or the formation of inactive analogs that are selectively activated at their site of action (e.g., glucocorticoid C21 isobutyryl or propionyl esters that are hydrolyzed to active C21 alcohols by airway-specific esterases).

Toxicity of Adrenocortical Steroids

Two categories of toxic effects result from the therapeutic use of corticosteroids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life threatening and require a careful assessment of the risks and benefits in each patient.

Withdrawal of Therapy. The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. Several other complications are associated with steroid withdrawal. The most severe complication of steroid cessation, acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has suppressed the HPA axis. The therapeutic approach to acute adrenal insufficiency is detailed later. There is significant variation among patients with respect to the degree and duration of adrenal suppression after glucocorticoid therapy, making it difficult to establish the relative risk in any given patient. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to recovery can be a year or longer.

In an effort to diminish the risk of iatrogenic acute adrenal insufficiency, protocols for discontinuing corticosteroid therapy in patients receiving long-term treatment with corticosteroids have been proposed, generally without rigorous documentation of their efficacy. Patients who have received supraphysiological doses of glucocorticoids for a period of 2-4 weeks within the preceding year should be considered to have some degree of HPA impairment in settings of acute stress and should be treated accordingly.

In addition to this most severe form of withdrawal, a characteristic glucocorticoid withdrawal syndrome consists of fever, myalgia, arthralgia, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted (Hochberg et al., 2003). Finally, pseudotumor cerebri, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

Continued Use of Supraphysiological Glucocorticoid Doses. Besides the consequences that result from the suppression of the HPA axis, a number of other complications result from prolonged therapy with corticosteroids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

Fluid and Electrolyte Handling. Alterations in fluid and electrolyte handling can cause hypokalemic alkalosis and hypertension, particularly in patients with primary hyperaldosteronism secondary to an adrenal adenoma or in patients treated with potent mineralocorticoids. Similarly, hypertension is a relatively common manifestation of glucocorticoid excess, even in patients treated with glucocorticoids lacking appreciable mineralocorticoid activity.

Metabolic Changes. The effects of glucocorticoids on intermediary metabolism have already been described. Hyperglycemia with glycosuria usually can be managed with diet and/or insulin, and its occurrence should not be a major factor in the decision to continue corticosteroid therapy or to initiate therapy in diabetic patients.

Immune Responses. Because of their multiple effects to inhibit the immune system and the inflammatory response, glucocorticoid use is associated with an increased susceptibility to infection and a risk for reactivation of latent tuberculosis. In the presence of known infections of some consequence, glucocorticoids should be administered only if absolutely necessary and concomitantly with appropriate and effective antimicrobial or antifungal therapy.

Possible Risk of Peptic Ulcers. There is considerable debate about the association between peptic ulcers and glucocorticoid therapy. The possible onset of hemorrhage and perforation in these ulcers and their insidious onset make peptic ulcers a serious therapeutic problem (Chapter 45); estimating the degree of risk from corticosteroids has received much study. Most patients who develop gastrointestinal bleeding while receiving corticosteroids also receive nonsteroidal anti-inflammatory agents, which are known to promote ulceration, such that the pathogenic role of corticosteroids remains open to debate. Nonetheless, it is prudent to be especially vigilant for peptic ulcer formation in patients receiving therapy with corticosteroids, especially if administered concomitantly with nonsteroidal anti-inflammatory drugs.

Myopathy. Myopathy, characterized by weakness of proximal limb muscles, can occur in patients taking large doses of corticosteroids and also is part of the clinical picture in patients with endogenous Cushing’s syndrome. It can be of sufficient severity to impair ambulation and is an indication for withdrawal of therapy. Attention also has focused on steroid myopathy of the respiratory muscles in patients with asthma or chronic obstructive pulmonary disease (Chapter 36); this complication can diminish respiratory function. Recovery from the steroid myopathies may be slow and incomplete.

Behavioral Changes. Behavioral disturbances are common after administration of corticosteroids and in patients who have Cushing’s syndrome secondary to endogenous hypercorticism; these disturbances may take many forms, including nervousness, insomnia, changes in mood or psyche, and overt psychosis. Suicidal tendencies are not uncommon. A history of previous psychiatric illness does not preclude the use of steroids in patients for whom they are otherwise indicated. Conversely, the absence of a history of previous psychiatric illness does not guarantee that a given patient will not develop psychiatric disorders while on steroids.

*Fludrocortisone acetate is intended for use as a mineralocorticoid.

Note: Topical preparations include agents for application to skin or mucous membranes in creams, solutions, ointments, gels, pastes (for oral lesions), and aerosols; ophthalmic preparations include solutions, suspensions, and ointments; inhalation preparations include agents for nasal or oral inhalation.
**Cataracts.** Cataracts are a well-established complication of glucocorticoid therapy and related to dosage and duration of therapy. Children appear to be particularly at risk. Cessation of therapy may not lead to complete resolution of opacities, and the cataracts may progress despite reduction or cessation of therapy. Patients on long-term glucocorticoid therapy at doses of prednisolone of ≥10-15 mg/day should receive periodic slit-lamp examinations to detect glucocorticoid-induced posterior subcapsular cataracts.

**Osteoporosis.** Osteoporosis, a frequent serious complication of glucocorticoid therapy, occurs in patients of all ages and is related to dosage and duration of therapy (Woolf, 2007). A reasonable estimate is that 30-50% of all patients who receive chronic glucocorticoid therapy ultimately will develop osteoporotic fractures. Glucocorticoids preferentially affect trabecular bone and the cortical rim of the vertebral bodies; the ribs and vertebrae are the most frequent sites of fracture. Glucocorticoids decrease bone density by multiple mechanisms, including inhibition of gonadal steroid hormones, diminished gastrointestinal absorption of Ca²⁺, and inhibition of bone formation due to suppressive effects on osteoblasts and stimulation of resorption by osteoclasts via changes in the production of osteoprotegerin and RANK ligand. In addition, glucocorticoid inhibition of intestinal Ca²⁺ uptake may lead to secondary increases in parathyroid hormone, thereby increasing bone resorption.

The considerable morbidity of glucocorticoid-related osteoporosis has led to efforts to identify patients at risk for fractures and to prevent or reverse bone loss in patients requiring chronic glucocorticoid therapy. The initiation of glucocorticoid therapy—that is, ≥5 mg/day prednisone (or its equivalent) for ≥3 months—is considered an indication for bone densitometry to detect abnormalities in trabecular bone. Because bone loss associated with glucocorticoids predominantly occurs within the first 6 months of therapy, densitometric evaluation, preferably with techniques such as dual-energy x-ray absorptiometry of the lumbar spine and hip, along with prophylactic measures should be initiated with therapy or shortly thereafter. Most authorities advocate maintaining a Ca²⁺ intake of 1500 mg/day by diet plus Ca²⁺ supplementation and vitamin D intake of 800 IU/day, assuming that these measures do not increase urinary calcium excretion above the normal range. Although gonadal hormone replacement therapy has been widely used in specific groups of patients receiving chronic glucocorticoid therapy, this is the subject of considerable debate based on recently published results from randomized placebo-controlled trials (Chapter 40). Recombinant parathyroid hormone 1-34 (teriparatide, FORTEO) also has received considerable attention as a potential therapy of glucocorticoid-induced osteoporosis.

The most important advance to date in the prevention of glucocorticoid-related osteoporosis is the successful use of bisphosphonates, which have been shown to decrease the decline in bone density and the incidence of fractures in patients receiving glucocorticoid therapy. Additional discussion of these issues is found in Chapters 40 and 44.

**Osteonecrosis.** Osteonecrosis (also known as avascular or aseptic necrosis) is a relatively common complication of glucocorticoid therapy. The femoral head is affected most frequently, but this process also may affect the humeral head and distal femur. Joint pain and stiffness usually are the earliest symptoms, and this diagnosis should be considered in patients receiving glucocorticoids who abruptly develop hip, shoulder, or knee pain. Although the risk increases with the duration and dose of glucocorticoid therapy, osteonecrosis also can occur when high doses of glucocorticoids are given for short periods of time. Osteonecrosis generally progresses, and most affected patients ultimately require joint replacement.

**Regulation of Growth and Development.** Growth retardation in children can result from administration of relatively small doses of glucocorticoids. Although the precise mechanism is unknown, there are reports that collagen synthesis and linear growth in these children can be restored by treatment with growth hormone; further studies are needed to define the role of concurrent treatment with growth hormone in this setting. Further studies also are needed to explore the possible effects of exposure to corticosteroids in utero. In experimental animals, antenatal exposure to glucocorticoids is clearly linked to cleft palate and altered neuronal development, ultimately resulting in complex behavioral abnormalities. Thus, although the actions of glucocorticoids to promote cellular differentiation play important physiological roles in human development in late gestation and in the neonatal period (e.g., production of pulmonary surfactant and induction of hepatic gluconeogenic enzymes), the possibility remains that antenatal steroids can lead to subtle abnormalities in fetal development.

**Therapeutic Uses**

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Based on extensive clinical experience, a number of therapeutic principles can be proposed. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the appropriate dose to achieve a given therapeutic effect must be determined by trial and error and must be reevaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond 1 week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects. Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.

These principles have several implications for clinical practice. When glucocorticoids are to be given over long periods, the dose must be determined by trial
and error and must be the lowest that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal anti-inflammatory drugs, may facilitate tapering the glucocorticoid dose once the initial benefit of therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent accurate observations of the patient. It is always essential to weigh carefully the relative dangers of therapy and of the disease being treated.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies their administration to critically ill patients who may have adrenal insufficiency. If the underlying condition does result from deficiency of glucocorticoids, then a single intravenous injection of a soluble glucocorticoid may prevent immediate death and allow time for a definitive diagnosis to be made. If the underlying disease is not adrenal insufficiency, the single dose will not harm the patient.

In the absence of specific contraindications, short courses of high-dose systemic glucocorticoids may be given for diseases that are not life threatening, but the general rule is that long courses of therapy at high doses should be reserved for life-threatening disease. In selected settings, as when a patient is threatened with permanent disability, this rule is justifiably violated.

In an attempt to dissociate therapeutic effects from undesirable side effects, various regimens of steroid administration have been used. To diminish HPA axis suppression, the intermediate-acting steroid preparations (e.g., prednisone or prednisolone) should be given in the morning as a single dose. Alternate-day therapy with the same glucocorticoids also has been employed because certain patients obtain adequate therapeutic responses on this regimen. Alternatively, pulse therapy with higher glucocorticoid doses (e.g., doses as high as 1 to 1.5 g/day of methylprednisolone for 3 days) frequently is used to initiate therapy in patients with fulminant, immunologically related disorders such as acute transplantation rejection, necrotizing glomerulonephritis, and lupus nephritis. The benefit of such pulse therapy in long-term maintenance regimens remains to be defined.

**Replacement Therapy.** Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison’s disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in developing countries. Other causes include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, acquired immunodeficiency syndrome, inherited disorders of the steroidogenic enzymes, and X-linked adrenoleukodystrophy (Carey, 1997). Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

**Acute Adrenal Insufficiency.** This life-threatening disease is characterized by GI symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus, and it sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic sodium chloride solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiac function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone (cortisol) should be given by continuous infusion at a rate of 50-100 mg every 8 hours. At this dose, which approximates the maximum daily rate of cortisol secretion in response to stress, hydrocortisone alone has sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6-8 hours. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency.

For the treatment of suspected but unconfirmed acute adrenal insufficiency, 4 mg of dexamethasone sodium phosphate can be substituted for hydrocortisone because dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin stimulation test). A failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency. Often, a sample for the measurement of plasma ACTH also is obtained because it will provide information about the underlying etiology if the diagnosis of adrenocortical insufficiency is established.

**Chronic Adrenal Insufficiency.** Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis but with lesser severity. These patients require daily treatment with corticosteroids (Coursin and Wood, 2002).
Traditional replacement regimens have used hydrocortisone in doses of 20-30 mg/day. Cortisone acetate, which is inactive until converted to cortisol by 11β-HSD1, also has been used in doses ranging from 25-37.5 mg/day. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Based on revised estimates of daily cortisol production and clinical studies showing that subtle degrees of glucocorticoid excess can decrease bone density in patients on conventional replacement regimens, many authorities advocate a lower hydrocortisone dose of 15-20 mg/day divided into either two doses (e.g., 10-15 mg on awakening and 5 mg in late afternoon) or three doses (e.g., 10 mg on awakening, 5 mg at lunch, and 5 mg in late afternoon). Others prefer to use intermediate- (e.g., prednisone) or long-acting (e.g., dexamethasone) glucocorticoids because no regimen employing shorter-acting steroids can reproduce the peak serum glucocorticoid levels that normally occur before awakening in the morning. The superiority of any one of these regimens has not been rigorously demonstrated. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; fludrocortisone acetate generally is used in doses of 0.05-0.2 mg/day. For patients with secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate because the zona glomerulosa, which makes mineralocorticoids, is intact. When initiating treatment in patients with panhypopituitarism, it is important to administer glucocorticoids before initiating treatment with thyroid hormone because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing the metabolism of cortisol.

The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overtreatment may cause manifestations of Cushing’s syndrome in adults and decreased linear growth in children. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency; the early-morning ACTH level should not be suppressed but should be <100 pg/mL (22 pmol/L). Although advocated by some endocrinologists, assessments of daily profiles of cortisol based on multiple blood samples or measurements of urinary free cortisol have been used more frequently as research tools than as a routine part of clinical practice.

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (e.g., phenytoin, barbiturates, or rifampin). Dosage adjustments also are needed to compensate for the stress of intercurrent illness, and proper patient education is essential for the execution of these adjustments. All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen. During minor illness, the glucocorticoid dose should be doubled. Patients should be instructed to contact their physician if nausea and vomiting preclude the retention of oral medications. The patient and family members should also be trained to administer parenteral dexamethasone (4 mg subcutaneously or intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Based largely on empirical data, glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo either elective or emergency surgery (Axelrod, 2003). In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/day; a standard regimen is hydrocortisone, 100 mg parenterally every 8 hours. Following surgery, the dose is halved each day until it is reduced to routine maintenance levels. Although some data suggest that increases in dose to this degree are not essential for survival even in major surgery, this approach remains the standard clinical practice.

**Congenital Adrenal Hyperplasia.** This term denotes a group of genetic disorders in which the activity of one of the several enzymes required for the biosynthesis of glucocorticoids is deficient. The impaired production of cortisol and the consequent lack of negative feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. Congenital adrenal hyperplasia (CAH) includes a spectrum of disorders for which precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient.

In ~90% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (Figure 42–3). Clinically, patients are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH, if not treated in utero with glucocorticoids, frequently are born with virilized external genitalia (female pseudohermaphroditism), which results from elevated production of adrenal androgen precursors at critical stages of sexual differentiation in utero. Males appear normal at birth and later may have precocious development of secondary sexual characteristics (isosexual precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses.

A subset of patients with classical CAH are unable to conserve Na⁺ normally and thus are called “salt wasters.” These patients can present with cardiovascular collapse secondary to volume depletion. In an effort to prevent such life-threatening events, especially in males who appear normal at birth, many centers routinely screen all newborn babies for elevated levels of 17-hydroxyprogesterone, the immediate steroid precursor to the enzymatic block.

All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of hydrocortisone is ~0.6 mg/kg daily in two or three divided doses. The
mineralocorticoid used is fludrocortisone acetate (0.05-0.2 mg/day). Many experts also administer table salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

The ability to detect classical CAH (21-hydroxylase deficiency) prenatally has made possible the treatment of affected females with glucocorticoids in utero, potentially eliminating the need for genital surgery to correct the virilization of the external genitalia. To suppress fetal adrenal androgen production effectively and consequent virilization, glucocorticoid therapy (e.g., dexamethasone, 20 µg/kg taken daily orally by mothers at risk) must be initiated before 10 weeks of gestation, before a definitive diagnosis of CAH can be made. The genotype and sex of the fetus then are determined, and steroid therapy is stopped if the sex is male or there is at least one wild-type allele for 21-hydroxylase. If genotyping reveals an affected female, steroid therapy is continued until delivery. A large-scale study currently is in progress to determine if exposure to glucocorticoids in utero has developmental consequences. To date, no adverse effects on developmental milestones and cognitive development have been noted; however, increased shyness and internalization behavior have been observed in small pilot study and will need to be reevaluated in the larger trial. Potential maternal side effects include hypertension, weight gain, edema, and mood changes.

**Therapeutic Uses in Nonendocrine Diseases.** Outlined next are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed are not inclusive; rather, they illustrate the principles governing glucocorticoid use in selected diseases for which glucocorticoids are more frequently employed. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. For convenience, approximate doses of a representative glucocorticoid (generally prednisone) are provided. This choice is not an endorsement of one particular glucocorticoid preparation over other congeners but is made for illustrative purposes only.

**Rheumatic Disorders.** Glucocorticoids are used widely in the treatment of a variety of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener’s granulomatosis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, prednisone (1 mg/kg per day in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by the clinical picture.

Although they are an important component of treatment of rheumatic diseases, glucocorticoids are often used in conjunction with other immunosuppressive agents such as cyclophosphamide and methotrexate, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Although glucocorticoids are indicated in these cases, there is at least a theoretical concern that glucocorticoids may complicate the course of the viral infection by suppressing the immune system. To facilitate drug tapering and/or conversion to alternate-day treatment regimens, the intermediate-acting glucocorticoids such as prednisone and methylprednisolone are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with chronic use, glucocorticoids are used as stabilizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory agents. In this case, glucocorticoids provide relief until other, slower-acting antirheumatic drugs, such as methotrexate or agents targeted at tumor necrosis factor, take effect. A typical starting dose is 5-10 mg of prednisone per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20-40 mg/day of prednisone or equivalent), with rapid taper thereafter. Complete relief of symptoms is not sought, and the symptomatic effect of small reductions in dose (decreases of perhaps 1 mg/day of prednisone every 2-3 weeks) should be tested frequently while concurrent therapy with other measures is continued, to maintain the lowest possible prednisone dose. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5-20 mg of triamcinolone acetonide or its equivalent.

In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to use a glucocorticoid that does not require bioactivation (e.g., prednisolone rather than prednisone) and to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling Charcot’s arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

**Renal Diseases.** Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids clearly are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1-2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6-8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2-3 weeks in 85% of patients, and >95% of patients have remission within 3 months. Cessation of steroid therapy frequently is complicated by disease relapse, as manifested by recurrent proteinuria. Patients who relapse repeatedly are termed steroid-resistant and often are treated with other immunosuppressive drugs such as azathioprine or cyclophosphamide. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids.
Studies with other forms of renal disease, such as membranous and membranoproliferative glomerulonephritis and focal sclerosis, have provided conflicting data on the role of glucocorticoids. In clinical practice, patients with these disorders often are given a therapeutic trial of glucocorticoids with careful monitoring of laboratory indices of response. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8-10 weeks (e.g., prednisone, 120 mg every other day), followed by a 1- to 2-month period of tapering.

**Allergic Disease.** The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine. The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioneurotic edema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone, 125 mg intravenously every 6 hours, or equivalent) are appropriate. In less severe disease, antihistamines are the drugs of first choice. In allergic rhinitis, intranasal steroids are now viewed as the drug of choice by many experts.

**Bronchial Asthma and Other Pulmonary Conditions.** Corticosteroids frequently are used in bronchial asthma (Chapter 36). Although they sometimes are employed in chronic obstructive pulmonary disease (COPD), particularly when there is some evidence of reversible obstructive disease, data supporting the efficacy of corticosteroids are much less convincing than for bronchial asthma. The increased use of corticosteroids in asthma reflects an increased appreciation of the role of inflammation in the immunopathogenesis of this disorder. In severe asthma attacks requiring hospitalization, treatment with high-dose parenteral glucocorticoids is essential. Symptomatic relief sometimes is very rapid; however, the onset of a maintained response may take up to 6-12 hours. Intravenous administration of 60-120 mg methylprednisolone (or equivalent) every 6 hours is used initially, followed by daily oral doses of prednisone (30-60 mg) as the acute attack resolves. The dose then is tapered gradually, with withdrawal planned for 10 days to 2 weeks after initiation of steroid therapy. In general, patients subsequently can be managed on their prior medical regimen.

Less severe acute exacerbations of asthma (as well as acute flares of COPD) often are treated with brief courses of oral glucocorticoids. In adult patients, 30-60 mg prednisone is administered daily for 5 days; an additional week of therapy at lower doses also may be required. Upon resolution of the acute exacerbation, the glucocorticoids generally can be rapidly tapered without significant deleterious effects. Any suppression of adrenal function usually dissipates within 1-2 weeks. In the treatment of severe chronic bronchial asthma (or, less frequently, COPD) that is not controlled by other measures, the long-term administration of glucocorticoids may be necessary. As with other long-term uses of these agents, the lowest effective dose is used, and care must be exercised when withdrawal is attempted. Given the risks of long-term treatment with glucocorticoids, it is especially important to document objective evidence of a response (e.g., an improvement in pulmonary function tests). In addition, these risks dictate that long-term glucocorticoid therapy be reserved for those patients who have failed to respond to adequate regimens of other medications (Chapter 36).

In many patients, inhaled steroids (see Table 42–4) can either reduce the need for oral corticosteroids or replace them entirely. Many physicians prefer inhaled glucocorticoids over previously recommended oral theophylline in the treatment of children with moderately severe asthma, in part because of the behavioral toxicity associated with chronic theophylline administration. The oral bioavailability of inhaled corticosteroids varies considerably; however, when used as recommended, inhaled glucocorticoids are effective in reducing bronchial hyperreactivity and are less likely to suppress adrenal function than are the oral glucocorticoids. Dysphonia or oropharyngeal candidiasis may develop, but the incidence of such side effects can be reduced substantially by maneuvers that reduce drug deposition in the oral cavity, such as spacers and mouth rinsing or by using corticosteroids with low oral bioavailability. For example, ciclesonide (ALVESCO, OMNARIS) and beclomethasone dipropionate (BECONASE AQ, QVAR), are inactive compounds that are activated on site by lung esterases; therefore they are less likely to adversely affect the oral cavity (Derendorf et al., 2006). The status of glucocorticoids in asthma therapy is discussed in Chapter 36.

Antenatal glucocorticoids are used frequently in the setting of premature labor, decreasing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely. Betamethasone (12 mg intramuscularly every 24 hours for two doses) or dexamethasone (6 mg intramuscularly every 12 hours for four doses) is administered to women with definitive signs of premature labor between 26 and 34 weeks of gestation (Roberts and Dalziel, 2006). Due to evidence of decreased birthweight and adrenal suppression in infants whose mothers were given repeated courses of glucocorticoids, only a single course of glucocorticoids should be administered.

**Infectious Diseases.** Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. One dramatic example of such beneficial effects is seen in AIDS patients with Pneumocystis carinii pneumonia and moderate to severe hypoxemia; addition of glucocorticoids to the antibiotic regimen increases oxygenation and lowers the incidence of respiratory failure and mortality. Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with Haemophilus influenzae type b meningitis in infants and children ≥2 months of age.

A long-standing controversy in medicine is the use of glucocorticoids in septic shock (Sprung et al., 2008). Supraphysiological doses of glucocorticoids had been used routinely as adjunctive therapy in subjects with septic shock associated with gram-negative bacteremia until it was recognized that glucocorticoid therapy in supraphysiologic doses actually increased mortality. Subsequent studies then examined the benefit of somewhat lower doses of glucocorticoids (e.g., 100 mg hydrocortisone every 8 hours) administered to patients early in the course of their disease. In one multicenter randomized placebo-controlled trial, beneficial effects of hydrocortisone plus fludrocortisone were seen only in subjects with adrenal insufficiency as determined by the rapid cosyntropin stimulation test. Although a second large study using hydrocortisone alone failed to demonstrate a beneficial effect regardless of adrenal status, current guidelines suggest that hydrocortisone be used in adult patients with septic shock whose blood pressure fails to respond adequately to fluids and vasopressors (Dellinger et al., 2008).
Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. As a result, a large number of different preparations and concentrations of topical glucocorticoids of varying potencies are available. A typical regimen for an eczematous eruption is 1% hydrocortisone ointment applied locally twice daily. Effectiveness is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to the eye for >2 weeks.

Topical glucocorticoid therapy frequently increases intracutaneous pressure in normal eyes and exacerbates intraocular hypertension in patients with antecedent glaucoma. The glaucoma is not always reversible on cessation of glucocorticoid therapy. Intracameral pressure should be monitored when glucocorticoids are applied to the eye for >2 weeks.

Topical administration of glucocorticoids to patients with bacterial, viral, or fungal conjunctivitis can mask evidence of progression of the infection until sight is irreversibly lost. Glucocorticoids are contraindicated in herpes simplex keratitis because progression of the disease may lead to irreversible clouding of the cornea. Topical steroids should not be used in treating mechanical lacerations and abrasions of the eye because they delay healing and promote the development and spread of infection.

**Skin Diseases.** Glucocorticoids are of value in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic. Although corticosteroids are frequently used for the treatment of cerebral edema caused by trauma or cerebrovascular accidents, controlled clinical trials do not support their use in these settings.

**Gastrointestinal Diseases.** Glucocorticoid therapy is indicated in selected patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn’s disease; Chapter 47). Patients who fail to respond to more conservative management (i.e., rest, diet, and sulfasalazine) may benefit from glucocorticoids; steroids are most useful for acute exacerbations. In mild ulcerative colitis, hydrocortisone (100 mg) can be administered as a retention enema with beneficial effects. In more severe acute exacerbations, oral prednisone (10-30 mg/day) frequently is employed. For severely ill patients—with fever, anorexia, anemia, and impaired nutritional status—larger doses should be used (40-60 mg prednisone per day). Major complications of ulcerative colitis or Crohn’s disease may occur despite glucocorticoid therapy, and glucocorticoids may mask signs and symptoms of complications such as intestinal perforation and peritonitis.

Budesonide, a highly potent synthetic glucocorticoid that is inactivated by first-pass hepatic metabolism, reportedly exhibits diminished systemic side effects commonly associated with glucocorticoids. Oral administration of budesonide in delayed-release capsules (ENTOCORT, 9 mg/day) facilitates drug delivery to the ileum and ascending colon; the drug also has been used as a retention enema in the treatment of ulcerative colitis.

**Hepatic Diseases.** The use of corticosteroids in hepatic disease has been highly controversial. Glucocorticoids clearly are of benefit in autoimmune hepatitis, where as many as 80% of patients show histological remission when treated with prednisone (40-60 mg daily initially, with tapering to a maintenance dose of 7.5-10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent meta-analysis of previously published reports failed to establish a beneficial role of corticosteroids, even in patients with severe disease (Rambaldi et al., 2008). Further studies are needed to confirm or refute the role of steroids in this setting. In the setting of severe hepatic disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active.

**Malignancies.** Glucocorticoids are used in the chemotherpay of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects. Most commonly, glucocorticoids are one component of combination chemotherapy administered under scheduled protocols. Glucocorticoids once were frequently employed in the setting of hypercalcemia of malignancy, but more effective agents, such as the bisphosphonates, now are the preferred therapy.

**Cerebral Edema.** Corticosteroids are of value in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic. Although corticosteroids are frequently used for the treatment of cerebral edema caused by trauma or cerebrovascular accidents, controlled clinical trials do not support their use in these settings.

**Miscellaneous Diseases and Conditions.** Sarcoidosis. Corticosteroids are indicated therapy for patients with debilitating symptoms or life-threatening forms of sarcoidosis. Patients with severe pulmonary involvement are treated with 10-20 mg per day of prednisone, or an equivalent dose of alternative steroids, to induce remission. Higher doses may be required for other forms of this disease. Maintenance doses, which often are required for long periods of time, may be as low as 5 mg/day of prednisone. These patients, like all patients who require chronic glucocorticoid therapy at doses exceeding the normal daily production rate, are at increased risk of secondary tuberculosis; therefore, patients with a positive tuberculin reaction or other evidence of tuberculosis should receive prophylactic antituberculosis therapy.

**Thrombocytopenia.** In thrombocytopenia, prednisone (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases, and for initiation of treatment of idiopathic thrombocytopenia, daily doses of prednisone (1-1.5 mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed high-dose glucocorticoid therapy.

**Autoimmune Destruction of Erythrocytes.** Patients with autoimmune destruction of erythrocytes (i.e., hemolytic anemia with a positive
Coordinated to make this distinction. I prefer to use inferior petrosal sinus sampling after CRH administra-

tionally with tumors such as bronchial carcinoids, and many experts prefer to use inferior petrosal sinus sampling after CRH administration to make this distinction.

Organ Transplantation. In organ transplantation, high doses of prednison (50-100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (Chapter 35). For some solid organ transplants (e.g., pancreas), protocols that either withdraw corticosteroids early after transplantation or that avoid them completely are becoming more common (Meier-Kriesche et al., 2006).

Spinal Cord Injury. A meta-analysis of several randomized, controlled trials (Bracken, 2002) demonstrated significant decreases in neurological defects in patients with acute spinal cord injury treated within 8 hours of injury with large doses of methylprednisolone sodium succinate (30 mg/kg initially followed by an infusion of 5.4 mg/kg per hour for 23 hours). One trial showed further improvement with an additional 24 hours of treatment. The ability of corticosteroids at these high doses to decrease neuro-

ological injury may reflect inhibition of free radical–mediated cellular injury, as occurs following ischemia and reperfusion. Potential side effects include increased susceptibility to infection and other wound complications.

Diagnostic Applications of Adrenocortical Steroids

In addition to its therapeutic uses, dexamethasone is used as a first-

t-line agent to diagnose hypercortisolism and to differentiate among the different causes of Cushing’s syndrome (Arnaldi et al., 2003).

To determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increased cor-

tisol biosynthesis, an overnight dexamethasone suppression test has been devised. Patients are given 1 mg of dexamethasone orally at 11 P.M., and cortisol is measured at 8 A.M. the following morning. Suppression of plasma cortisol to <1.8 μg/dL suggests strongly that the patient does not have Cushing’s syndrome. Drugs such as barbi-

turates that enhance dexamethasone metabolism or drugs (estrogens) or conditions (pregnancy) that increase the concentrations of corti-

costeroid binding globulin can interfere with suppression and com-

promise the test. The formal dexamethasone suppression test is used in the differential diagnosis of biochemically documented Cushing’s syndrome. Following determination of baseline cortisol levels for 48 hours, dexamethasone (0.5 mg every 6 hours) is administered orally for 48 hours. This dose markedly suppresses cortisol levels in normal subjects, including those who have nonspecific elevations of cortisol due to obesity or stress, but it does not suppress levels in patients with Cushing’s syndrome. In the high-dose phase of the test, dexamethasone is administered orally at 2 mg every 6 hours for 48 hours. Patients with pituitary-dependent Cushing’s syndrome (i.e., Cushing’s disease) generally respond with decreased cortisol levels. In contrast, patients with ectopic production of ACTH or with adrenocortical tumors generally do not exhibit decreased cortisol levels. Despite these generalities, dexamethasone may suppress cortisol levels in some patients with ectopic ACTH production, particularly with tumors such as bronchial carcinoids, and many experts prefer to use inferior petrosal sinus sampling after CRH administra-

tion to make this distinction.

INHIBITORS OF THE BIOSYNTHESIS AND ACTION OF ADRENOCORTICAL STEROIDS

Hypercortisolism with its attendant morbidity and mort-

tality is most frequently caused by corticotroph adenomas that overproduce ACTH (Cushing’s disease) or by adrenocortical tumors or bilateral hyperplasias that overproduce cortisol (Cushing’s syndrome). Less fre-

quently, hypercortisolism may result from adrenocortical carcinomas or ectopic ACTH- or CRH-producing tumors. Although surgery is the treatment of choice, it is not always effective, and adjuvant therapy with inhibitors of steroidogenesis becomes necessary (Biller et al., 2008). In these settings, ketoconazole, metyrapone, etomidate, and mitotane are clinically useful. Ketoconazole, etomidate, and mitotane are discussed in more detail in other chapters. All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient’s HPA axis must be carefully monitored. Agents that act as glucocorticoid receptor antagonists (antiglucocorticoids) are discussed later in this chapter; mineralocorticoid antagonists are discussed in Chapter 25.

Ketoconazole. Ketoconazole (NIZORAL) is an antifungal agent, and this remains its most important clinical role (Chapter 57). In doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis, primarily because of its inhibition of the activity of CYP17 (17α-hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is the best tolerated and most effective inhibitor of steroid hormone biosynthesis in patients with hypercortisolism. In most cases, a dosage regimen of 600-800 mg/day (in two divided doses) is required, and some patients may require up to 1200 mg/day given in two to three doses. Side effects include hepatic dysfunction, which ranges from asymptomatic elevations of transaminase levels to severe hepatic injury. The potential of ketoconazole to interact with CYP isoforms can lead to drug interactions of serious conse-

quence (Chapter 6). Further studies are needed to define the precise role of ketoconazole in the medical management of patients with excessive steroid hormonal production, and the FDA has not approved this indication for ketoconazole use.

Metyrapone. Metyrapone (METOPRONE) is a relatively selective inhibitor of CYP11B1 (11β-hydroxylase), which converts 11-deoxycorticisol to cortisol in the terminal reaction of the glucocorticoid biosynthetic pathway. Because of this inhibition, the biosynthesis of cortisol is markedly impaired, and the levels of steroid precursors (e.g., 11-

deoxycorticisol) are markedly increased. Although the biosynthesis of aldosterone also is impaired, the elevated levels of 11-deoxycorticisol sustain mineralocorticoid-dependent functions. In a diagnostic test of the entire HPA axis, metyrapone (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol
and 11-deoxycortisol are measured at 8 A.M. the next morning. A plasma cortisol <8 μg/dL validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycortisol level <7 μg/dL is highly suggestive of impaired hypothalamic-pituitary-adrenal function. An abnormal response does not identify the site of the defect; hypothalamic CRH release, ACTH production, or adrenal biosynthetic capacity could be impaired. Some authorities avoid overnight metyrapone testing in outpatients thought to have a reasonable probability of impaired HPA function because there is some risk of precipitating acute adrenal insufficiency. Others believe that the ability to assess the entire HPA axis with a relatively easy test justifies the use of metyrapone testing in outpatients.

Metyrapone also is used to diagnose patients with Cushing’s syndrome who respond equivocally to the formal dexamethasone suppression test. Those with pituitary-dependent Cushing’s syndrome exhibit a normal response, whereas those patients with ectopic secretion of ACTH exhibit no changes in ACTH or 11-deoxycortisol levels.

Therapeutically, metyrapone has been used to treat the hypercorticism resulting from either adrenal neoplasms or tumors producing ACTH ectopically. Maximal suppression of steroidogenesis requires doses of 4 g/day. More frequently, metyrapone is used as adjunctive therapy in patients who have received pituitary irradiation or in combination with other agents that inhibit steroidogenesis. In this setting, a dose of 500-750 mg three or four times daily is employed. The use of metyrapone in the treatment of Cushing’s syndrome secondary to pituitary hypersecretion of ACTH is more controversial. Chronic administration of metyrapone can cause hirsutism, which results from increased synthesis of adrenal androgens upstream from the enzymatic block, and hypertension, which results from elevated levels of 11-deoxycortisol. Other side effects include nausea, headache, sedation, and rash.

Etomidate. Etomidate (AMIDATE), a substituted imidazole used primarily as an anaesthetic agent and sedative, inhibits cortisol secretion at subhypnotic doses primarily by inhibiting CYP11B1 activity. It is administered intravenously and has been used off-label to treat hypercortisolism when rapid control is required in a patient who cannot take medication by the oral route. An international consensus panel recommends that etomidate be administered as a bolus of 0.03 mg/kg intravenously, followed by an infusion of 0.1 mg/kg per hour to a maximum of 0.3 mg/kg per hour (Billter et al., 2008).

Mitotane. Mitotane (o,p’-DDD; LYSODREN) is an adrenocorticolytic agent used to treat inoperable adrenocortical carcinoma. Its cytolytic action is due to its metabolic conversion to a reactive acyl chloride by adrenal mitochondrial CYPs and subsequent reactivity with cellular proteins. In a few centers, it has been used for long-term control of hypercortisolism. Doses range from 0.5-3 g administered three times daily. Its onset of action takes weeks to months, and GI disturbances and ataxia are its major toxicities.

Aminoglutethimide. Aminoglutethimide (α-ethyl-p-aminophenylglutarimide; CYTADREN) primarily inhibits CYP11A1, which catalyzes the initial and rate-limiting step in the biosynthesis of all physiological steroids and also inhibits CYP11B1 and CYP19 (aromatase). As a result, the production of all classes of steroid hormones is impaired. Although used at one time to treat hypercortisolism and advanced cancer of the breast and prostate, aminoglutethimide recently has been withdrawn from the market by the manufacturer and is no longer available.

Trilostane. Trilostane (4α,5α,17β-4,5-epoxy-3,17-dihydroxyandrostan-2-ene-2-carbonitrile), a competitive inhibitor of the type II 3β-hydroxysteroid dehydrogenase (Figure 42–3), also interferes with the synthesis of both adrenal and gonadal hormones, but it is more effective in dogs than in humans. For this reason, trilostane is not used in humans but still has a place in veterinary medicine.

ANTIGLUCOCORTICOIDS

The progesterone receptor antagonist mifepristone (MIFEPREX; RU-486; 11β-[p-(dimethylamino)phenyl]-17β-hydroxy-17-(1-propynyl)estra-4,9-dien-3-one) has received considerable attention because of its use as an antiprogestogen that can terminate early pregnancy (Chapter 66). At higher doses, mifepristone also inhibits the GR, blocking feedback regulation of the HPA axis and secondarily increasing endogenous ACTH and cortisol levels. Because of its ability to inhibit glucocorticoid action, mifepristone also has been studied as a potential therapeutic agent in a small number of patients with hypercortisolism (Johanssen and Allolio, 2007). Currently, its use for this purpose is considered investigational and is restricted to patients with inoperable causes of cortisol excess that have not responded to other agents.

CLINICAL SUMMARY

Glucocorticoids are administered in multiple formulations (e.g., oral, parenteral, and topical) for disorders that share an inflammatory or immunological basis. Except in patients receiving replacement therapy for adrenal insufficiency, glucocorticoids are neither specific nor curative, but rather are palliative because of their anti-inflammatory and immunosuppressive actions. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. After therapy is initiated, the minimal dose needed to achieve a given therapeutic effect must be determined by trial and error and must be reevaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week) is unlikely to cause harm in the absence of specific contraindications. As the duration of glucocorticoid therapy increases beyond 1 week, adverse effects increase in a time- and dose-related manner. Abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency due to suppression of the HPA axis, and it may be fatal.

BIBLIOGRAPHY

Diabetes mellitus is a spectrum of common metabolic disorders, arising from a variety of pathogenic mechanisms, all resulting in hyperglycemia. The number of individuals with diabetes is rising rapidly throughout the world. Both genetic and environmental factors contribute to its pathogenesis, which involves insufficient insulin secretion, reduced responsiveness to endogenous or exogenous insulin, increased glucose production, and/or abnormalities in fat and protein metabolism. The resulting hyperglycemia may lead to both acute symptoms and metabolic abnormalities. However, the major sources of the morbidity of diabetes are the chronic complications that arise from prolonged hyperglycemia, including retinopathy, nephropathy, neuropathy, and cardiovascular disease. Fortunately, these chronic complications can be mitigated in many patients by sustained control of the blood glucose. There are now a wide variety of treatment options for hyperglycemia that target different processes involved in glucose regulation or dysregulation.

Following a brief review of glucose homeostasis and the pathogenesis of diabetes, this chapter discusses the general approaches and specific agents used in the therapy of diabetes. The last section describes agents used for hypoglycemia.

**PHYSIOLOGY OF GLUCOSE HOMEOSTASIS**

**Regulation of Blood Glucose.** In healthy humans, blood glucose is tightly maintained despite wide fluctuations in glucose consumption, utilization, and production. The maintenance of glucose homeostasis, generally termed glucose tolerance, is a highly developed systemic process involving the integration of several major organs through multilayered communication (Figure 43–1). Although endocrine control of blood glucose, primarily through the actions of insulin, is of central importance, myriad levels of inter-organ communication, via other hormones, nerves, local factors and substrates, also play a vital role. The pancreatic β cell is central in this homeostatic process, adjusting the amount of insulin secreted very precisely to promote glucose uptake after meals and to regulate glucose output from the liver during fasting.

In the fasting state (Figure 43–1A), most of the fuel demands of the body are met by the oxidation of fatty acids. Importantly, the brain does not effectively utilize fatty acids to meet energy needs and in the fasting state requires glucose for normal function; glucose requirements are ~2 mg/kg per minute in adult humans, largely to supply the central nervous system (CNS) with an energy source. Fasting glucose requirements are primarily provided by the liver, with a minor contribution from the kidney. Liver glycogen stores provide some of this glucose; conversion of gluconeogenic precursors, primarily lactate, alanine and glycerol, into glucose accounts for the remainder. The dominant regulation of hepatic glycogenolysis and gluconeogenesis are the pancreatic islet hormones insulin and glucagon. Insulin inhibits hepatic glucose production at several levels, and the decline of circulating insulin concentrations in the postabsorptive state (fasting) is permissive for higher rates of glucose output. Glucagon maintains blood glucose concentrations at physiological levels in the absence of exogenous carbohydrate (overnight and in between meals) by stimulating gluconeogenesis and glycogenolysis by the liver.

Ingestion of a meal provides a substantial challenge to glucose homeostasis (Figure 43–1B). Adults
typically consume 30-90 g of carbohydrate in a single meal, considerably more than the extracellular glucose pool, which typically contains 15-20 g of glucose. Therefore, uptake and disposition of meal-derived glucose requires effective coordination of a range of processes, from digestion and absorption to intracellular glycolysis and glycogen synthesis, to prevent major shifts in plasma glucose concentrations. Regulation of nutrient disposition after meals is under the primary control of insulin. Insulin secretion is stimulated by food ingestion, nutrient absorption, and increases in blood glucose, and insulin promotes glucose, lipid, and protein anabolism. The centrality of insulin in glucose metabolism is emphasized by the fact that all the forms of human diabetes have as a root cause some abnormality of insulin secretion or action.

In healthy humans, β cell function is primarily controlled by plasma glucose concentrations. Elevations of blood glucose are necessary for insulin release above basal levels, and other stimuli are relatively ineffective when plasma glucose is in the fasting range (4.4-5.5 mM or 80-100 mg %). These other stimuli include nutrient substrates, insulinotropic hormones released from the gastrointestinal (GI) tract, and autonomic neural pathways. As a result, the pancreatic β cell is stimulated from the time of food presentation, through nutrient absorption, and until blood glucose returns to fasting levels. Neural stimuli cause some increase of insulin secretion prior to food consumption. In addition to these cephalic responses, neural stimulation of insulin secretion occurs throughout the meal and contributes significantly to glucose tolerance. Arrival of nutrient chyme to the intestine leads to the release of insulinotropic peptides from specialized endocrine cells in the intestinal mucosa. Glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1), together termed incretins, are the essential gut hormones contributing to glucose tolerance. They are secreted in

---

**Figure 43–1. Insulin, glucagon, and glucose homeostasis.**

**A. Fasting State**—In healthy humans plasma glucose is maintained in a range from 4.4-5.5 mM, and fatty acids near 400 μM. In the absence of nutrient absorption from the GI tract, glucose is supplied primarily from the liver and fatty acids from adipose tissue. With fasting, plasma insulin levels are low, and plasma glucagon is elevated, contributing to increased hepatic glycogenolysis and gluconeogenesis; low insulin also releases adipocytes from inhibition, permitting increased lipogenesis. Most tissues oxidize primarily fatty acids during fasting, sparing glucose for use by the CNS. **B. Prandial State**—During feeding, nutrient absorption causes an increase in plasma glucose, resulting in release of incretins from the gut and neural stimuli that promote insulin secretion. Under the control of insulin, the liver, skeletal muscle and adipose tissue actively take up glucose. Hepatic glucose production and lipolysis are inhibited, and total body glucose oxidation increases. The brain senses plasma glucose concentrations and provides regulatory inputs contributing to fuel homeostasis. The boldness of the arrows reflects relative intensity of action; a dashed line indicates little or no activity.
proportion to the nutrient load ingested and relay this information to the islet as part of a feed-forward mechanism that allows an insulin response appropriate to meal size. Insulin secretion rates in healthy humans are highest in the early digestive phase of meals, preceding and limiting the peak in blood glucose. This pattern of premonitory insulin secretion is an essential feature of normal glucose tolerance. How to mimic this pattern is one of the key challenges for successful insulin therapy in diabetic patients.

Elevated circulating insulin concentrations lower glucose in blood by inhibiting hepatic glucose production and stimulating the uptake and metabolism of glucose by muscle and adipose tissue. These two important effects occur at different concentrations of insulin. Production of glucose is inhibited half-maximally by an insulin concentration of \(~120\) pmol/L, whereas glucose utilization is stimulated half-maximally at \(~300\) pmol/L. Some of the effects of insulin on the liver occur rapidly, within the first 20 minutes of meal ingestion, whereas stimulation of peripheral glucose uptake may require up to an hour to reach significant rates. This is probably due to the quick access of insulin to hepatocytes, via the hepatic-portal circulation and the liver sinusoids, and the slower passage of insulin to its receptors on muscle and adipose cells. Insulin has potent effects to reduce lipolysis from adipocytes, primarily through the inhibition of hormone-sensitive lipase, and increases lipid storage by promoting lipoprotein lipase synthesis and adipocyte glucose uptake. Finally, insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation in muscle and other tissues; it thus causes a decrease in the circulating concentrations of most amino acids.

The demand for glucose as an energy source for skeletal muscle increases dramatically during exercise. Glycogen stored in skeletal muscle is mobilized for some of these needs, but there are limited supplies that are used, mostly at the onset of activity. Most of the glucose support of exercise comes from hepatic gluconeogenesis. The dominant regulation of hepatic glucose production during exercise comes from epinephrine and norepinephrine. The catecholamines stimulate glycogenolysis and gluconeogenesis, inhibit insulin secretion, and enhance release of glucagon, all contributing to increased hepatic glucose output. In addition, catecholamines promote lipolysis, freeing fatty acids for oxidation in exercising muscle and glycerol for hepatic gluconeogenesis.

Pancreatic Islet Physiology and Insulin Secretion. The pancreatic islets comprise 1-2% of the pancreatic volume and are scattered throughout the exocrine pancreas. The pancreatic islet is a highly vascularized, highly innervated mini-organ containing five endocrine cell types: \(\alpha\) cells that secrete glucagon, \(\beta\) cells that secrete glucose, \(\delta\) cells that secrete somatostatin, cells that secrete pancreatic polypeptide, and \(\epsilon\) cells that secrete ghrelin. The endocrine, exocrine, and ductal cells of the pancreas share a common embryologic heritage but in the adult are functionally distinct. Insulin and glucagon are important pharmacological agents in the treatment of diabetes, and an understanding of their synthesis, secretion, and action are important in the therapeutic efforts related to diabetes.

Insulin is initially synthesized as a single polypeptide chain, preproinsulin (110 amino acids), which is processed first to proinsulin and then to insulin and C-peptide (Figure 43–2). This complex and highly regulated process involves the Golgi complex, the endoplasmic reticulum, and importantly the distinctive secretory granules of the \(\beta\) cell. Secretory granules are critical not only in bringing insulin to the cell surface for exocytosis, but also in the cleavage and processing of the prohormone to the final secretion products, insulin and C-peptide. The structure of insulin is discussed in the section describing its therapeutic use. Equimolar quantities of insulin and C-peptide (31 amino acids) are co-secreted. Insulin has a \(t_{1/2}\) of 5-6 minutes due to extensive hepatic clearance. C-peptide, in contrast, with no known physiological function or receptor, has a \(t_{1/2}\) of \(~30\) minutes. Because almost all of the C-peptide released into the portal vein reaches the peripheral circulation where it can be measured, this peptide is useful in assessment of \(\beta\)-cell secretion, and to distinguish endogenous and exogenous hyperinsulinemia (for example in the evaluation of insulin-induced hypoglycemia). Importantly, the \(\beta\) cell also synthesizes and secretes islet amyloid polypeptide (IAPP) or amylin, a 37–amino acid peptide. IAPP is not essential for life but influences GI motility and the speed of glucose absorption. Pramlintide is an agent used in the treatment of diabetes that mimics the action of IAPP. As reflected by its name, IAPP forms amyloid fibrils in the islets of individuals with type 2 diabetes; whether this is a cause or a consequence of the islet dysfunction of type 2 diabetes is not yet clear.

Insulin secretion is a tightly regulated process designed to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated
interplay of various nutrients, GI hormones, pancreatic hormones, and autonomic neurotransmitters. Glucose, amino acids (arginine, etc.), fatty acids, and ketone bodies promote the secretion of insulin. Glucose is the primary insulin secretagogue, and insulin secretion is tightly coupled to the extracellular glucose concentration. Insulin secretion is much greater when the same amount of glucose is delivered orally compared to intravenously (incretin effect). Islets are richly innervated by both adrenergic and cholinergic nerves. Stimulation of α2 adrenergic receptors inhibits insulin secretion, whereas β2 adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (such as hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α2 adrenergic receptors. Predictably, α2 adrenergic receptor antagonists increase basal concentrations of insulin in plasma, and β2 adrenergic receptor antagonists decrease them. Glucagon and somatostatin inhibit insulin secretion.

The pancreatic β cell is a highly specialized cell that has considerable structural and functional similarities to a sensory neuron: Both cell types quickly sense and respond to external stimuli. The molecular events controlling glucose-stimulated insulin secretion begin with the transport of glucose into the β cell via a facilitative glucose transporter (Figure 43–3). In rodents, this is the GLUT2, which has a distinctive, low affinity for glucose and is also the primary glucose transporter in hepatocytes. Human β cells express primarily GLUT1 but little GLUT2. Upon entry into the β cell, glucose is quickly phosphorylated by glucokinase (GK; hexokinase IV); this phosphorylation is the rate-limiting step in glucose metabolism in the β cell. GK’s distinctive affinity for glucose leads to a marked increase in glucose metabolism over the range of 5–10 mM glucose, where glucose-stimulated insulin secretion is most pronounced. The glucose-6-phosphate produced by GK activity enters the glycolytic pathway, producing changes in NADPH and the ratio of ADP/ATP. Elevated ATP inhibits an ATP-sensitive K+ channel (KATP channel), leading to cell membrane depolarization. This KATP channel is a heteromeric protein that consists of an inward rectifying K+ channel (Kir6.2) and a closely associated protein known as the sulfonylurea receptor (SUR), which was identified originally because of its interaction with this class of drugs. Mutations in the KATP channel are responsible for some types of neonatal diabetes or hypoglycemia. Membrane depolarization then leads to opening of a voltage-dependent Ca2+ channel and increased intracellular Ca2+, resulting in exocytotic release of insulin from storage vesicles. These intracellular events are modulated by a number of processes, such as changes in cAMP production, amino acid metabolism, and the level of transcription factors. GPCRs for glucagon, GIP, and GLP-1 couple to Gs to stimulate adenylyl cyclase and insulin secretion; receptors for somatostatin and α2 adrenergic agonists couple to Gi to reduce cellular cAMP production and secretion.

**Figure 43–3. Regulation of insulin secretion from a pancreatic β cell.** The pancreatic β cell in a resting state (fasting blood glucose) is hyperpolarized. Glucose, entering via GLUT transporters (primarily GLUT1 in humans, GLUT2 in rodents), is metabolized and elevates cellular ATP, which inhibits K+ entry through the KATP channel; the decreased K+ conductance results in depolarization, leading to Ca2+-dependent exocytosis of stored insulin. The KATP channel, actually a hetero-octamer composed of SUR1 and Kir 6.2 subunits, is the site of action of several classes of drugs: ATP binds to and inhibits Kir 6.2; sulfonylureas and meglitinides bind to and inhibit SUR1; all 3 agents thereby promote insulin secretion. Diazoxide and ADP-Mg2+ (low ATP) bind to and activate SUR1, thereby inhibiting insulin secretion. Incretins enhance insulin secretion.
The pancreatic α cell, which has considerable similarity to the β cell, secretes glucagon, primarily in response to hypoglycemia. Glucagon biosynthesis begins with preproglucagon, which is processed in a cell-specific fashion to several biologically active peptides such as glucagon, GLP-1, and glucagon-like peptide-2 (GLP-2) (Figure 43-9). The molecular mechanisms that control glucagon secretion are unclear but may involve paracrine regulation by the β cell and neural input. In general, glucagon and insulin secretion are regulated in a reciprocal fashion; that is, the agents or processes that stimulate insulin secretion inhibit glucagon secretion. Notable exceptions are arginine and somatostatin: arginine stimulates and somatostatin inhibits the secretion of both hormones.

Insulin Action. The insulin receptor is expressed on virtually all mammalian cell types, explaining the broad array of biological responses to insulin. The tissues that are considered critical for regulation of blood glucose are liver, skeletal muscle, and fat (Figure 43-1). However, recent evidence suggests that specific regions of the brain and the pancreatic islet are also important targets for insulin. Systemically, the actions of insulin are anabolic, and insulin signaling is critical for promoting the uptake, use, and storage of the major nutrients: glucose, lipids, and amino acids. Importantly, while insulin action stimulates glycogenesis, lipogenesis, and protein synthesis, it also inhibits the catabolism of these compounds. On a cellular level, insulin stimulates transport of substrates and ions into cells, promotes translocation of proteins between cellular compartments, regulates the action of specific enzymes, and controls gene transcription and mRNA translation. Some effects of insulin occur within seconds or minutes, such as activation of glucose and ion transport systems and phosphorylation or dephosphorylation of specific enzymes. Other effects, such as those promoting protein synthesis and regulating gene transcription, manifest over minutes to hours. The effects of insulin on cell proliferation and differentiation occur over days. Metabolic effects such as inhibition of lipolysis or hepatic glucose production occur rapidly, within minutes of increasing concentrations of plasma insulin; detectable increases in glucose clearance from the blood may take nearly an hour. The variability in the kinetics of insulin action probably relate to variable access to insulin receptors in different tissues, distinct intracellular signaling pathways, and the inherent kinetics of the various processes controlled by insulin.

The Insulin Receptor. Insulin action is transmitted through a receptor tyrosine kinase that bears functional similarity to the insulin-like growth factor 1 (IGF-1) receptor (Taniguchi et al., 2006). The insulin receptor is composed of linked (α/β subunit dimers that are products of a single gene; dimers linked by disulfide bonds form a transmembrane heterotetramer glycoprotein composed of two extracellular α-subunits and two membrane-spanning β-subunits (Figure 43–4). The number of receptors varies from as few as 40 per cell on the relatively insulin-insensitive erythrocytes, to 300,000 per cell on adipocytes and hepatocytes, cell types that are highly responsive to insulin.

The α-subunits inhibit the inherent tyrosine kinase activity of the β-subunits. Insulin binding to the α-subunits releases this inhibition and allows transphosphorylation of one β-subunit by the other, and autophosphorylation at specific sites from the juxtamembrane region to the intracellular tail of the receptor. There are two splice variants of the α-subunits, which lead to insulin receptors with differential expression and ligand binding. In addition, insulin receptor dimers can form complexes with IGF-1 receptor α/β dimers, creating another distinct receptor isoform. Activation of the insulin receptor initiates signaling by phosphorylating a set of intracellular proteins such as the insulin receptor substrates (IRS) and Src-homology-2-containing protein (Shc). These insulin receptor substrates interact with effectors that amplify and extend the signaling cascade. As an example, binding of Shc to IRS1 leads to activation of the GTPase Ras and initiation of the protein kinase cascade involving MAPK and ERK that are involved in insulin-mediated gene transcription and cell growth.

Insulin action, at least for glucose transport, is critically dependent on the activation of phosphatidylinositol-3-kinase (PI3K). PI3K is activated by interaction with IRS proteins and generates phosphatidylinositol 3,4,5-trisphosphate (PIP3), which regulates the localization and activity of several downstream kinases, including Akt, atypical isoforms of protein kinase C (PKCζ and λc), and mammalian target of rapamycin (mTOR) (Huang and Czech, 2007). The isoform Akt2 appears to control the downstream steps that are important for glucose uptake in skeletal muscle and adipose tissue, and to regulate glucose production in the liver. Substrates of Akt2 coordinate the translocation of the glucose transporter 4 (GLUT4) to the plasma membrane through processes involving actin remodelling and other membrane trafficking systems (Zaid et al., 2008). Despite the centrality of PI3K/Akt2 in mediating insulin signaling in key target tissues, it seems likely that there are additional effects mediated by the insulin receptor that do not directly involve these enzymes. Actions of small G-proteins, such as Rac and TC10, have been implicated in the actin remodeling necessary for GLUT4 translocation.

GLUT4 is expressed in insulin-responsive tissues such as skeletal muscle and adipose tissue that constitute important sites of glucose disposal after meal ingestion. GLUT4 is one of a family of 13 glucose transporters in humans that share 12 membrane-spanning domains. GLUT4 is noteworthy among these transporters as the most dependent on discrete stimuli by insulin or other effectors; in the basal state, most GLUT4 resides in the intracellular space; following activation of insulin receptors, GLUT4 is shifted rapidly and
in abundance to the plasma membrane, where it facilitates inward transport of glucose from the circulation. Insulin signaling also reduces GLUT4 endocytosis, increasing the residence time of the protein in the plasma membrane.

Following the facilitated diffusion into cells along a concentration gradient, glucose is phosphorylated to glucose-6-phosphate (G-6-P) by a family of hexokinases. Hexokinase II is found in association with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin. G-6-P is a branch-point substrate that can enter several pathways. G-6-P can be isomerized to G-1-P by phosphoglucomutase, and then the G-1-P can be stored as glycogen (insulin enhances the activity of glycogen synthase); G-6-P can enter the glycolytic pathway (leading to ATP production); G-6-P can also enter the pentose phosphate pathway.

**Figure 43–4. Pathways of insulin signaling.** The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P) of the receptor’s β subunits and a small number of specific substrates (yellow shapes): the Insulin Receptor Substrate (IRS) proteins, Gab-1 and SHC; within the membrane, a caveolar pool of insulin receptor phosphorylates caveolin (Cav), APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades via SH2 and SH3 domains to mediate the effects of insulin, with specific effects resulting from each pathway. In target tissues such as skeletal muscle and adipocytes, a key event is the translocation of the Glut4 glucose transporter from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and non-caveolar pathways. In the non-caveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by PIP3) and/or an atypical form of PKC is involved. In the caveolar pathway, caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein, TC10. The pathways are inactivated by specific phosphoprotein phosphatases (eg, PTB1B). In addition to the actions shown, insulin also stimulates the plasma membrane Na⁺,K⁺-ATPase by a mechanism that is still being elucidated; the result is an increase in pump activity and a net accumulation of K⁺ in the cell.

**PATHOPHYSIOLOGY AND DIAGNOSIS OF DIABETES MELLITUS**

**Glucose Homeostasis and the Diagnosis of Diabetes**

Broad categories of glucose homeostasis as defined by the fasting blood glucose or the glucose level following an oral glucose challenge include:

- Normal glucose homeostasis: Fasting plasma glucose <5.6 mmol/L (100 mg/dL)
- Impaired fasting glucose (IFG): 5.6-6.9 mmol/L (100-125 mg/dL)
• Impaired glucose tolerance (IGT): Glucose level between 7.8 and 11.1 mmol/L (140-199 mg/dL) 120 minutes after ingestion of 75 g liquid glucose solution
• Diabetes mellitus (see Table 43–1)

The diagnosis of diabetes mellitus is currently based on the correlation of a diabetes-specific complication with a particular level of glycemia, that is, the level of glycemia at which a diabetes-specific complication like retinopathy begins to appear. The boundaries between normal glucose homeostasis, abnormal glucose homeostasis, and diabetes are described as abrupt transitions, but the data are best viewed as a spectrum.

Organizations such as the American Diabetes Association (ADA) and the World Health Organization (WHO) have adopted criteria for the diagnosis of diabetes, based on the fasting blood glucose, the glucose value following an oral glucose challenge, or the level of hemoglobin A1c (HbA1c; exposure of proteins to elevated glucose) produces nonenzymatic glycation of proteins including Hb. Thus the level of HbA1c represents a measure of the average glucose concentration to which the Hb has been exposed) (Table 43–1). Fasting plasma glucose is most widely used because of its convenience and low cost. The diagnostic criteria have recently (2009) been changed to also include a hemoglobin A1c (A1C) value ≥6.5%. Impaired fasting glucose (IFG) and impaired glucose tolerance (IGT), previously termed prediabetes, or an A1C of 5.7-6.4% portend a markedly increased risk of progressing to type 2 diabetes. An A1C of 5.7-6.4%, IFG, and IGT do not identify the same group of individuals, but all are associated with increased risk of cardiovascular disease.

The four broad categories of diabetes include type 1 diabetes, type 2 diabetes, other forms of diabetes, and gestational diabetes (Table 43–2). Although hyperglycemia is common to all forms of diabetes, the pathogenic mechanisms leading to diabetes are quite distinct. As our current understanding of the molecular pathogenesis of the hyperglycemia improves, these categories will likely be subdivided into a number of other types of diabetes.

### Screening for Diabetes and Categories of Increased Risk Of Diabetes

Many individuals with type 2 diabetes are asymptomatic at the time of diagnosis, and diabetes is often found on routine blood testing as an outpatient or upon admission to the hospital for nonglucose-related reasons. A long, asymptomatic phase in type 2 diabetes (up to a decade) is likely responsible for the observation that up to 50% of individuals with diabetes may have a diabetes-related complication at the time of diagnosis. For these reasons, the ADA recommends widespread screening for type 2 diabetes of these individuals with the following features:

- >45 years of age or
- Body mass index >25 kg/m² with one of these additional risk factors: hypertension, low high-density lipoprotein, family history of type 2 diabetes, high-risk ethnic group (African American, Latino, Native American, Asian American, and Pacific Islander), abnormal glucose testing (IFG, IGT, A1C of 5.7-6.4%), cardiovascular disease, and women with polycystic ovary syndrome or who have previously delivered a large infant.

Earlier diagnosis and treatment of type 2 diabetes should delay diabetes-related complications and reduce the burden of the disease. Many also feel that earlier treatment may alter the natural history of the disease, but conclusive proof of this hypothesis is lacking. Likewise, informing individuals who are at increased risk for developing diabetes provides impetus to take steps to slow the progression to diabetes. A number of interventions including pharmacological agents and lifestyle modification are effective. Screening for type 1 diabetes is not currently recommended.

### Pathogenesis of Type 1 Diabetes

Type 1 diabetes accounts for 5-10% of diabetes and results from autoimmune-mediated destruction of the β cells of the islet leading to total or near total insulin deficiency (von Herrath et al., 2007). Prior terminology included juvenile-onset diabetes mellitus or insulin-dependent diabetes mellitus. Although traditionally considered a disease of children and adolescents, type 1 diabetes resulting from autoimmune β cell destruction can occur at any age. In fact, in some reports, more than one-third of individuals developed type 1 diabetes after adolescence. Individuals with type 1 diabetes and their families have an increased prevalence of autoimmune diseases such as celiac disease, inflammatory bowel disease, pernicious anemia, Addison’s disease, and type 1 diabetes itself.

### Table 43–1

<table>
<thead>
<tr>
<th>Criteria for the Diagnosis of Diabetes</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Symptoms of diabetes plus random blood glucose concentration ≥11.1 mM (200 mg/dL) (^a) or</td>
</tr>
<tr>
<td>• Fasting plasma glucose ≥7.0 mM (126 mg/dL) (^b) or</td>
</tr>
<tr>
<td>• Two-hour plasma glucose ≥11.1 mM (200 mg/dL) during an oral glucose tolerance test (^c)</td>
</tr>
<tr>
<td>• HbA1c ≥6.5%</td>
</tr>
</tbody>
</table>

\(^a\)Random is defined as without regard to time since the last meal.
\(^b\)Fasting is defined as no caloric intake for at least 8 h.
\(^c\)The test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water; this test is not recommended for routine clinical use.

Note: In the absence of unequivocal hyperglycemia and acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.

Adapted from Diabetes Care, 2010; 33:S62-S69.
Diabetes (~75%) do not have a family member with type 1 diabetes, and the genes conferring genetic susceptibility are found in a significant fraction of the nondiabetic population. Genetically susceptible individuals are thought to have a normal $\beta$-cell number or mass until $\beta$-cell-directed autoimmunity develops and $\beta$-cell loss begins. The first physiological abnormality that is detectable in affected subjects is loss of the first phase of glucose-stimulated insulin secretion. Prior to this, islet cell autoantibodies can be detected in the serum (known autoantigens include insulin, glutamate decarboxylase, protein tyrosine phosphatase IA-2 [ICA-512], and zinc transporter 8 [SLC30A8]). The initiating or triggering stimulus for the autoimmune process is not known, but most favor exposure to viruses (enterovirus, etc.) or other ubiquitous environmental agents. Histological examinations of human pancreata during the prediabetic period and at presentation are quite limited, but animal models of type 1 diabetes show a T cell infiltrate and the concordance of type 1 diabetes in genetically identical twins is 40-60%, indicating a significant genetic component. The major genetic risk (~40-50%) is conferred by HLA class II genes encoding HLA-DR and HLA-DQ (and possibly other genes with the HLA locus). Candidate gene association studies and recently genome-wide association studies have identified >20 additional loci that confer genetic susceptibility to type 1 diabetes (INS, PTPN22, CTLA4, and IL2RA, among others) (Concannon et al., 2009). However, there clearly is a critical interaction of genetics and an environmental or infectious agent. Most individuals with type 1 diabetes (~75%) do not have a family member with type 1 diabetes, and the genes conferring genetic susceptibility are found in a significant fraction of the nondiabetic population.

predominance of CD8+ cells (insulitis). The β cell destruction is cell mediated, and there is also evidence that infiltrating cells produce local inflammatory agents such as TNF-α, IFN-γ, and IL-1, all of which can lead to β cell death. The β cell destruction occurs over a period of months to years and when >80% of the β cells are destroyed, hyperglycemia ensues and the clinical diagnosis of type 1 diabetes is made. Sometimes the clinical presentation of type 1 diabetes is with a concurrent illness (viral syndrome) and this may result in diabetic ketoacidosis; at other times, the typical symptoms of diabetes lead to the diagnosis. Most patients report several weeks of polyuria and polydipsia, fatigue, and often abrupt and significant weight loss. Some adults with the phenotypic appearance of type 2 diabetes (obese, not insulin-requiring initially) have islet cell autoantibodies suggesting autoimmune-mediated β cell destruction and are diagnosed as expressing latent-autoimmune diabetes of adults (LADA).

**Pathogenesis of Type 2 Diabetes.** The pathogenesis of type 2 diabetes mellitus is complex, and the condition is best thought of as a heterogeneous syndrome of dysregulated glucose homeostasis associated with impaired insulin secretion and insulin action (Das and Elbein, 2006; Doria et al., 2008; Taylor, 2008). Overweight or obesity is a common correlate of type 2 diabetes that occurs in ~ 80% of affected individuals. Increased lipid accumulation in depots in the abdomen, skeletal muscle cells, and hepatocytes has been linked to some of the common impairments. For the vast majority of persons developing type 2 diabetes, there is no clear inciting incident, but rather the condition is thought to develop gradually over years with progression through identifiable prediabetic stages.

In fundamental terms, type 2 diabetes results when there is insufficient insulin action to maintain plasma glucose levels in the normal range. Insulin action is the composite effect of plasma insulin concentrations (determined by islet β cell function) and insulin sensitivity of key target tissues (liver, skeletal muscle, and adipose tissue). These sites of regulation are all impaired to variable extents in patients with type 2 diabetes (Figure 43–5).

The etiology of type 2 diabetes has a strong genetic component (Das and Elbein, 2006; Grant et al., 2009). It is a heritable condition with a relative 4-fold increased risk of disease for persons having a diabetic parent or sibling, increasing to 6-fold if both parents have type 2 diabetes. Consistent with this, the concordance rates of diabetes in monozygotic twins are 2- to 3-fold those in dizygotic twins. Based on linkage analysis, candidate gene searches, and genome-wide association studies, type 2 diabetes appears to be a complex multigenic condition, with many loci of susceptibility contributing to the ultimate phenotype. Although more than 20 genetic loci with clear associations to type 2 diabetes have been identified through recent genome-wide association studies, the contribution of each is relatively small. The genetic locus with the largest relative risk is the transcription factor TCF7L2. Of note, most of the genes currently associated with type 2 diabetes have a relevant connection to β cell function, with fewer linked to the action of insulin in target cells.

**Impaired β Cell Function.** In persons with type 2 diabetes, the sensitivity of the β cell to glucose is impaired, and there is also a loss of responsiveness to other stimuli such as insulinotropic GI hormones and neural signaling. This results in delayed secretion of insufficient amounts of insulin, allowing the blood glucose to rise dramatically after meals, and failure to restrain liver glucose release during

![Figure 43–5. Pathophysiology of type 2 diabetes mellitus.](image-url) Graphs show data from diabetic (---) and non-diabetic (---) patients, comparing postprandial insulin and glucagon secretion and hepatic glucose production, and the sensitivities of muscle glucose use and adipocyte lipolysis to insulin.
fasting. Beyond the defect in functional properties of the β cell, the absolute mass of β cells is reduced in type 2 diabetes patients. It is estimated that persons with early type 2 diabetes have >50% of the normal complement of β cells (Butler et al., 2003). This deficit is compounded by a gradual loss of β cell mass over time, potentially related to toxic effects of hyperglycemia. Progressive reduction of β cell mass and function explains the natural history of type 2 diabetes in most patients who require steadily increasing therapy to maintain glucose control.

Type 2 diabetic patients frequently have elevated levels of fasting insulin. This is not a reflection of accentuated β cell function but a result of their higher fasting glucose levels and insulin resistance. Another factor contributing to apparently high insulin levels early in the course of the disease is the presence of increased amounts of proinsulin. Proinsulin, the precursor to insulin, is inefficiently processed in the diabetic islet. Whereas healthy subjects have only 2-4% of total circulating insulin as proinsulin, type 2 diabetic patients can have 10-20% of the measurable plasma insulin in this form. Proinsulin has a considerably attenuated effect for lowering blood glucose compared to insulin.

**Insulin Resistance.** Insulin sensitivity is a quantifiable parameter that is measured as the amount of glucose cleared from the blood in response to a dose of insulin. The failure of normal amounts of insulin to elicit the expected response is referred to as insulin resistance. This is a relative term because there is inherent variability of insulin sensitivity among cells, tissues, and individuals. Insulin sensitivity is affected by many factors including age, body weight, physical activity levels, illness, and medications. Furthermore, insulin sensitivity varies within individuals over time and across groups or populations of subjects, even among healthy adults. Thus, insulin resistance is a relative designation but has considerable pathological significance because persons with type 2 diabetes or glucose intolerance have reduced responses to insulin and can easily be distinguished from groups with normal glucose tolerance.

The major insulin-responsive tissues are skeletal muscle, adipose tissue, and liver. Insulin resistance in muscle and fat is generally marked by a decrease in transport of glucose from the circulation. Hepatic insulin resistance generally refers to a blunted ability of insulin to suppress glucose production. Insulin resistance in adipocytes causes increased rates of lipolysis and release of fatty acids into the circulation, which can contribute to insulin resistance in liver and muscle, hepatic steatosis, and dyslipidemia. More generally the role of obesity in the etiology of type 2 diabetes is related to the insulin resistance in skeletal muscle and liver that comes with increased amounts of lipid storage, particularly in specific fat depots. The sensitivity of humans to the effects of insulin administration is inversely related to the amount of fat stored in the abdominal cavity; more visceral adiposity leads to more insulin resistance (Kahn, 2003). Similarly, intrahepatic steatocyte or intramuscular fat, both commonly associated with obesity, are strongly linked to insulin resistance. Intracellular lipid or its byproducts may have direct effects to impede insulin signaling (Savage et al., 2007). Enlarged collections of adipose tissue, visceral or otherwise, is often infiltrated with macrophages and can become a site of chronic inflammation. Adipocytokines, secreted from adipocytes and immune cells, including TNF-α, IL-6, resistin, and retinol-binding protein 4, can also cause systemic insulin resistance. Insulin resistance is even more severe in obese persons with type 2 diabetes who have further reductions of insulin-stimulated glucose uptake into skeletal muscle and relatively low rates of nonoxidative glucose metabolism (glycogen synthesis), and impaired suppression of hepatic glucose production and adipocyte lipolysis, despite insulin concentrations that are often elevated.

Another important variable in determining insulin sensitivity is activity level. Sedentary persons are more insulin resistant than active ones, and physical training can improve insulin sensitivity. Physical activity can decrease the risk of developing diabetes and improve glycemic control in persons who have diabetes (Crandall et al., 2008). Insulin resistance is more common in the elderly; within populations, insulin sensitivity decreases linearly with age. Older individuals tend to be less physically active, which can contribute to insulin resistance. In addition, over the normal course of aging there is a decrease in muscle mass and an increase in fat mass, with an increased percentage of fat stored in the abdominal cavity.

At the cellular level, insulin resistance involves blunted steps in the cascade from the insulin receptor tyrosine kinase to translocation of GLUT4 transporters, but the molecular mechanisms are incompletely defined. There have been >75 different mutations in the insulin receptor discovered, most of which cause significant impairment of insulin action. These mutations affect insulin receptor number, movement to and from the plasma membrane, binding, and phosphorylation. Mutations involving the insulin binding domains of the extracellular α-chain cause the most severe syndromes, but specific variants in the intracellular portions of the receptor also cause severe insulin resistance. However, most insulin resistance associated with obesity and type 2 diabetes is not due to abnormalities of the insulin receptor. A central feature of the more common forms of insulin resistance is increased phosphorylation of serine, rather than tyrosine, in the insulin receptor and IRS proteins, inhibiting their activation and signaling. This process is mediated by protein serine/threonine kinases, which respond to an increased intracellular flux of fatty acids, specific lipid products, particularly diacylglycerol and ceramide, inflammatory mediators such as TNFα, and endoplasmic reticulum stress. In addition, chronic hyperinsulinemia, the typical correlate of insulin resistance, seems to increase IRS protein catabolism. It is known that insulin sensitivity is under genetic control, but it is unclear whether insulin-resistant individuals have mutations in specific components of the insulin signaling cascade or whether they have a complement of signaling effectors that operate at the lower range of normal. Regardless, it is apparent that insulin resistance clusters in families and is a major risk factor for the development of diabetes.

**Dysregulated Hepatic Glucose Metabolism.** In type 2 diabetes, hepatic glucose output is excessive in the fasting state and inadequately suppressed after meals. These are key components to the abnormal glycemic profile in diabetic patients, who have elevated glucose levels in the postabsorptive state and accentuated postprandial rises. Abnormal secretion of the islet hormones, both insufficient insulin and excessive glucagon, accounts for a significant portion of dysregulated hepatic glucose metabolism in type 2 diabetes. Increased concentrations of glucagon, especially in conjunction with hepatic insulin resistance, can lead to excessive hepatic gluconeogenesis and glycolysis, and abnormally high fasting glucose concentrations.

The liver is also resistant to insulin action in type 2 diabetes. This contributes to the reduced potency of insulin to suppress hepatic
Pathogenesis of Other Forms of Diabetes. Mutations in key genes involved in glucose homeostasis cause monogenic diabetes, which is inherited in an autosomal dominant fashion. These fall in two broad categories: diabetes onset in the immediate neonatal period (<6 months of age) and diabetes in children or adults (Murphy et al., 2008; Vaxillaire and Froguel, 2008). Some forms of neonatal diabetes are caused by mutations in the sulfonylurea receptor or its accompanying inward rectifying K⁺ channel and mutations in the insulin gene. Monogenic diabetes beyond the first year of life may appear clinically similar to type 1 or type 2 diabetes. In other instances, young individuals (adolescence to young adulthood) may have monogenic forms of diabetes known as maturity onset diabetes of the young (MODY). Phenotypically, these individuals are not obese and are not insulin resistant, or they may initially have modest hyperglycemia. The most common causes are mutations in key islet-enriched transcription factors or glucokinase (see discussion about molecular mechanisms of insulin secretion; Table 43–2 and Figure 43–3). Most individual with MODY are treated similarly to those with type 2 diabetes. Importantly, sulfonylureas may be a particularly effective treatment of individuals with MODY-3 or neonatal diabetes caused by a mutation in the K⁺ channel complex.

Diabetes may also be the result of other pathological processes such as acromegaly and Cushing’s disease (Table 43–2). A number of medications promote hyperglycemia or lead to diabetes by either impairing insulin secretion or insulin action (Table 43–3). Most notable are asparaginase, glucocorticoids, pentamidine, nicotinic acid, α-interferon, protease inhibitors, and in particular, atypical antipsychotics (Chapter 16).

Epidemiology of Diabetes. The number of individuals with diabetes is increasing worldwide. Although the annual rate of type 1 diabetes has increased modestly over the past decade, the increased frequency of type 2 diabetes has been dramatic. In the U.S., 7-10% of adults are affected, with up to three times that many at risk. There is clear ethnic variability in the prevalence of type 2 diabetes. Among adults living in the U.S., there is a spectrum of prevalence with Native Americans (15%), Hispanics (12%), and African Americans (12%) having greater rates than persons of European ancestry (8%). While the upward trends in the industrialized world have been similar in many countries, there are now alarming increases in rates of type 2 diabetes worldwide. Most notable are China, India, and other countries in the Far East where the disease was previously uncommon (Chan et al., 2009). The largest increase in the number of people with diabetes is predicted to take place in the regions or countries with developing economies. Parallel increases in obesity rates and changes in diet and activity appear to be the major factors in this marked increase in diabetes.

Diabetes-Related Complications. Diabetes can cause metabolic derangements or acute complications, such as the life-threatening metabolic disorders of diabetic ketoacidosis and hyperglycemic hyperosmolar state. These require hospitalization for insulin administration, rehydration with intravenous fluids, and careful monitoring of electrolytes and metabolic parameters. Chronic complications of diabetes have been described in all forms of the disease and are commonly divided into microvascular and macrovascular complications. Microvascular complications occur only in individuals with diabetes, whereas macrovascular complications occur more frequently in individuals with diabetes but are not diabetes specific. The common microvascular complications include retinopathy, nephropathy and neuropathy. Macrovascular complications refer to increased atherosclerosis-related events such as myocardial infarction and stroke. The pharmacological management of diabetes-related complications is discussed elsewhere (e.g., Chapters 25, 28, 31, 64).

In the U.S., diabetes is the leading cause of blindness in adults, the leading reason for renal failure requiring dialysis or renal transplantation, and the leading cause of nontraumatic lower extremity amputations. Fortunately, most of these diabetes-related complications can be prevented, delayed, or reduced by near normalization of the blood glucose on a consistent basis. How chronic hyperglycemia causes these complications is unclear. For microvascular complications, current hypothesis are that hyperglycemia leads to advanced glycosylation end products (AGEs), increased glucose metabolism via the sorbitol pathway, increased formation of diacylglycerol leading to PKC activation, and increased flux through the hexosamine pathway. Growth factors such as vascular endothelial growth factor α may be involved in diabetic retinopathy and TGF-β in diabetic nephropathy.
Therapy of Diabetes

Goals of Therapy. The goals of therapy for diabetes are to alleviate the symptoms related to hyperglycemia (fatigue, polyuria, etc.) and to prevent or reduce the acute and chronic complications of diabetes. Accomplishment of these goals requires a multidisciplinary team (physicians, nurse educators, pharmacists) with expertise in pharmacology, nutrition, and patient education. Central to the treatment plan is the patient who must actively participate in the care of his or her diabetes.

Glycemic control is assessed using both short-term (blood glucose self-monitoring) and long-term metrics (A1C, fructosamine). Using capillary blood glucose measurements, the patient assesses capillary blood glucose on a regular basis (fasting, before meals, or postprandially) and reports these values to the diabetes management team. A1C reflects glycemic control over the prior 3 months; glycosylated albumin (fructosamine) is a measure of glycemic control over the preceding 2 weeks.

Approaches to diabetes care are sometimes termed intensive insulin therapy, intensive glycemic control, and tight control. This chapter use the term comprehensive diabetes care to describe optimal therapy, which involves more than glucose management and includes aggressive treatment of abnormalities in blood pressure and lipids and detection and management of diabetes-related complications (Figure 43–6). Table 43–4 shows the ADA-recommended treatment goals for comprehensive diabetes care, for glucose, blood pressure, and lipids (Bruzell et al., 2008). Improved glycemic control reduces the complications when started relatively early in the course of both type 1 and type 2 diabetes, but very intensive glucose control reduces the complications when started relatively early in the course of both type 1 and type 2 diabetes, but very intensive glucose control is not physiological, and this may alter the influence of insulin on hepatic metabolic processes.

Insulin Therapy

Insulin is the mainstay for treatment of virtually all type 1 and many type 2 diabetes patients. Insulin may be administered intravenously, intramuscularly, or subcutaneously. Long-term treatment relies predominantly on subcutaneous injection. Subcutaneous administration of insulin differs from physiological secretion of insulin in two major ways:

- The absorption kinetics do not reproduce the rapid rise and decline of endogenous insulin in response to glucose following intravenous or oral administration.
- Injected insulin is delivered into the peripheral circulation instead of being released into the portal circulation. Thus the portal/peripheral insulin concentration is not physiological, and this may alter the influence of insulin on hepatic metabolic processes.

Nonetheless, insulin delivered into the peripheral circulation can lead to normal or near-normal glycemia.

History. The discovery of insulin is a dramatic story. The discovery is attributed to Frederick Banting, Charles Best, J.J.R. Macleod, and J.B. Collip at the University of Toronto, but others provided important observations and techniques that made it possible (Bliss, 2005). In 1869, a German medical student, Paul Langerhans, noted that the pancreas contains two distinct groups of cells—the acinar cells, which secrete digestive enzymes, and cells that are clustered in islands, or islets, which he suggested served a second function. Direct evidence for this function came in 1889, when Minkowski and von Mering showed that pancreatectomized dogs exhibit a syndrome similar to human diabetes mellitus. Thereafter, there were numerous attempts to extract the pancreatic substance responsible for regulating blood glucose. Between 1903 and 1909, the Romanian
physiologist Nicolas Paulesco found that injections of pancreatic extracts reduced urinary sugar and ketones in diabetic dogs and published results clearly indicating isolation of a glucose-lowering compound. The significance of these findings was recognized only years later.

Unaware of much of this work, Frederick Banting, a young Canadian surgeon, convinced J.J.R. Macleod, a professor of physiology in Toronto, to allow him access to a laboratory to search for the antidiabetic principle of the pancreas. Banting began work on the assumption that the islets secreted a glucose-lowering hormone that was destroyed by proteolytic digestion prior to or during extraction. Together with Charles Best, a fourth-year medical student, he attempted to overcome the problem by ligating the pancreatic ducts so that the acinar tissue degenerated, leaving the islets undisturbed. Using an ethanol and acid extraction procedure, Banting and Best obtained a pancreatic isolate that decreased the concentration of blood glucose in diabetic dogs. Under the guidance of Macleod, Banting and Best received help from J.B. Collip, a chemist with expertise in extraction and purification of epinephrine. The first patient to receive the active extracts was Leonard Thompson, age 14. He presented at the Toronto General Hospital with a blood glucose level of 500 mg/dL (28 mM). Despite rigid control of his diet (450 kcal/day), he continued to excrete large quantities of glucose, and, without insulin, would likely have died within a few months. The administration of the pancreatic extracts reduced the plasma concentration and urinary excretion of glucose, and the patient demonstrated marked clinical improvement. Replacement therapy with the newly discovered hormone, insulin, had interrupted what was clearly an otherwise fatal metabolic disorder. Stable extracts eventually were obtained, and patients in many parts of North America soon were being treated with insulin from porcine and bovine sources. The first of several Nobel Prizes associated with insulin was awarded to Banting and Macleod in 1923. A furor over credit followed immediately, and Banting announced that he would share his prize with Best; Macleod did the same with Collip (Bliss, 2005). Frederick Sanger established the amino acid sequence of insulin and received the Nobel Prize in 1958. Dorothy Hodgkin (Nobel prize for chemistry, 1964) and coworkers elucidated insulin’s three-dimensional structure. Insulin was the hormone for which Yalow and Berson first developed the radioimmunoassay, which was recognized with the Nobel Prize in 1977.

### Insulin Preparation and Chemistry

Human insulin, produced by recombinant DNA technology, is soluble in aqueous solution. Most preparations are supplied at neutral pH, which improves stability and permits short-term storage at room temperature. Beginning shortly after its discovery in 1921, patients were treated with insulin preparations prepared from porcine or bovine pancreatic extracts for >70 years. With the advent of human insulin, beef and pork insulin are no longer produced. A number of other insulin preparations that once were widely used such as lente, ultralente, and protamine zinc insulin are no longer available.

Doses and concentration of clinically used insulin preparations are expressed in international units. This tradition dates to a time when preparations of hormones were impure and the concentration of the hormone was standardized by bioassay. One unit of insulin is defined as the amount required to reduce the blood glucose concentration in a fasting rabbit to 45 mg/dL (2.5 mM).

$^a$As recommended by the ADA goals should be individualized for each patient. Goals may be different for certain patient populations.

$^b$A1C is primary goal.

$^c$While the ADA recommends an A1C <7.0% in general, in the individual patient it recommends that an appropriate goal for the individual patient based on age, duration of diabetes, life expectancy, other medical conditions, cardiovascular disease).

$^{d}$One to two hours after beginning of a meal.

$^e$In decreasing order of priority

$^f$In individuals with coronary artery disease, an LDL <1.8 mmol (70 mg/dL) is the goal.

$^g$For women, some suggest a goal that is 0.25 mmol/L (10 mg/dL) higher.

Adapted from *Diabetes Care* 33:S11, 2010.
Commercial preparations of insulin are supplied in solution or suspension at a concentration of 100 units/mL, which is ~3.6 mg insulin per milliliter (0.6 mM) and termed U-100. Insulin also is available in a more concentrated solution (500 units/mL or U-500) for patients who are resistant to the hormone. In the past, other concentrations of insulin such as U-40 were available. Other insulin formulations such as inhaled insulin and injected human proinsulin were tested but either were not clinically useful or were used for only a brief period of time. Work is ongoing to develop delivery approaches that do not involve injection.

**Insulin Formulations.** Preparations of insulin are classified according to their duration of action into short-acting and long-acting (Table 43–5). Within the short-acting acting category, some distinguish the very rapid-acting insulins (aspart, glulisine, lispro) from regular insulin. Likewise, some distinguish formulations with a longer duration of action (detemir, glargine) from NPH insulin. Two approaches are used to modify the absorption and pharmacokinetic profile of insulin. The first approach, which has been used for >70 years to alter the absorption profile of native insulin, is based on formulations that slow the absorption following subcutaneous injection. The other approach is to alter the amino acid sequence or protein structure of human insulin so that it retains its ability to bind the insulin receptor, but its behavior in solution or following injection is either accelerated or prolonged in comparison to native or regular insulin (Figure 43–7).

The wide variability in the kinetics of insulin action between and even within individuals must be emphasized. The time to peak hypoglycemic effect and insulin levels can vary by 50%. This variability is caused, at least in part, by large variations in the rate of subcutaneous absorption.

**Short-Acting Regular Insulin.** Native or regular insulin molecules associate as hexamers in aqueous solution at a neutral pH and this aggregation slows absorption following subcutaneous injection. Regular insulin should be injected 30-45 minutes before a meal. Regular insulin also may be given intravenously or intramuscularly.

**Short-Acting Insulin Analogs.** The development of short-acting insulin analogs that retain a monomeric or dimeric configuration is a major advance in insulin therapy (Figures 43–7 and 43–8; Table 43–5). These analogs are absorbed more rapidly from subcutaneous sites than regular insulin. Consequently, there is a more rapid increase in plasma insulin concentration and an earlier response. Insulin analogs should be injected ≤15 minutes before a meal. Insulin lispro (HUMALOG) is identical to human insulin except at positions B28 and B29, where the sequence of the two residues has been reversed to match the sequence in IGF-1 (which does not self-associate). Like regular insulin, lispro exists as a hexamer in commercially available formulations. Unlike regular insulin, lispro

<sup>a</sup>Glargine and detemir have minimal peak activity.

<sup>b</sup>Dual: two peaks - one at 2-3 h; the second one several hours later.

Figure 43–7. Insulin analogs. Modifications of native insulin can alter its pharmacokinetic profile. Reversing amino acids 28 and 29 in the B chain (lispro) or substituting Asp for Pro28B (aspart) gives analogs with reduced tendencies for molecular self-association that are faster acting. Altering Asp30B to Lys and Lys29B to Glu produces an insulin (glulisine) with a more rapid onset and a shorter duration of action. Substituting Gly for ε-amino group of Lys 29B (detemir) enhances reversible binding to albumin, thereby slowing transport across vascular endothelium to tissues and providing prolonged action. Deleting Thr30B and adding a myristoyl group to the ε-amino group of Lys29B (detemir) enhances reversible binding to albumin, thereby slowing transport across vascular endothelium to tissues and providing prolonged action.

Insulin aspart (NovoLog) is formed by the replacement of proline at B28 with aspartic acid. This reduces self-association to a degree similar to lispro. Like lispro, insulin aspart dissociates rapidly into monomers following injection. Comparison of a single subcutaneous dose of aspart and lispro in a group of type 1 diabetes patients revealed similar plasma insulin profiles. In clinical trials, insulin aspart and insulin lispro have had similar effects on glucose control and hypoglycemia frequency, with lower rates of nocturnal hypoglycemia as compared with regular insulin.

Insulin glulisine (APIDRA) is formed when glutamic acid replaces lysine at B29, and lysine replaces asparagine at B23; these substitutions result in a reduction in self-association and rapid dissociation into active monomers. The time–action profile of insulin glulisine is similar to that of insulin aspart and insulin lispro. Similar to insulin aspart, insulin glulisine has been approved in the U.S. for continuous subcutaneous insulin infusion (CSII) pump use.

Long-Acting Insulins. Neutral protamine hagedorn (NPH; insulin isophane) is a suspension of native insulin complexed with zinc and protamine in a phosphate buffer. This produces a cloudy or whitish solution in contrast to the clear appearance of other insulin solutions. Because of this formulation, the insulin dissolves more gradually when injected subcutaneously and thus its duration of action is prolonged. NPH insulin is usually given either once a day (at bedtime) or twice a day in combination with short-acting insulin. In patients with type 2 diabetes, long-acting insulin is often given at bedtime to help normalize fasting blood glucose. It should be noted that the use of long-acting basal insulin alone will not control postprandial glucose elevation in insulin-deficient type 1 or type 2 diabetes.

Insulin glargine (LANTUS) is a long-acting analog of human insulin that is produced following two alterations of human insulin. Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position 21 on the A chain is replaced with glycine. Insulin glargine is a clear solution with a pH of 4.0,
which stabilizes the insulin hexamer. When injected into the neutral pH of the subcutaneous space, aggregations occur, resulting in prolonged, but predictable, absorption from the injection site. Owing to insulin glargine’s acidic pH, it cannot be mixed with short-acting insulin preparations (i.e., regular insulin, aspart, or lispro) that are formulated at a neutral pH.

In clinical studies glargine has a sustained peakless absorption profile, and provides a better once-daily 24-hour insulin coverage than NPH insulin. Evidence from clinical trials also suggests that glargine has a lower risk of hypoglycemia, particularly overnight compared to NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and does not accumulate after several injections. Glargine has been shown in clinical studies to normalize fasting (postabsorptive) glucose levels following once-daily administration in patients with type 2 diabetes. Sometimes, splitting the dose of glargine may be needed in very insulin-sensitive type 1 diabetes patients to achieve fasting (basal) glucose levels in the target range and avoid hypoglycemia. Unlike traditional insulin preparations that are absorbed more rapidly from the abdomen than from the arm or leg, the site of administration does not influence the time–action profile of glargine. Similarly, exercise does not influence glargine’s unique absorption kinetics, even when the insulin is injected into a working limb.

Glargine binds with a slightly greater affinity to IGF-1 receptors as compared with human insulin. However, this slightly increased binding is still approximately two log scales lower than that of IGF-1. Controversy currently exists whether glargine insulin is associated with an increased chance of malignancy or an acceleration of underlying malignancy, but most feel that the available evidence is circumstantial and not sufficiently convincing to change prescribing patterns (Pocock and Smeeth, 2009; Smith and Gale, 2009; Weinstein et al., 2009).

Insulin detemir (LEVEIR) is an insulin analog modified by the addition of a saturated fatty acid to the ε amino group of LysB29, yielding a myristoylated insulin. When insulin detemir is injected subcutaneously, it binds to albumin via its fatty acid chain. Clinical studies in patients with type 1 diabetes have demonstrated that when insulin detemir is administered twice a day, it has a smoother time–action profile and produces a reduced prevalence of hypoglycemia than NPH insulin. The absorption profiles of glargine and detemir insulin are similar, but detemir often requires twice-daily administration.

**Other Insulin Formulations.** Stable, mixed combinations (Table 43–5) of NPH and regular insulin in proportions of 70:30 combinations are available. Combinations of lispro protamine/lispro (50/50 and 75/25) and aspart protamine/aspart (70/30) are also available in the U.S.

**Insulin Delivery.** Most insulin is injected subcutaneously. Pen devices containing prefilled regular, lispro, NPH, glargine, premixed lispro protamine-lispro, or pre-mixed aspart protamine-aspart have proven to be popular with many diabetic patients. Jet injector systems that enable patients to receive subcutaneous insulin injections without a needle are available. Intravenous infusions of insulin are useful in patients with ketoacidosis or when requirements for insulin may change rapidly, such as during the perioperative period, during labor and delivery, and in intensive care situations.

**Continuous Subcutaneous Insulin Infusion.** Short-acting insulins are the only form of the hormone used in subcutaneous infusion pumps. A number of pumps are available for continuous subcutaneous insulin infusion (CSII) therapy. CSII, or pump, therapy is not suitable for all patients because it demands considerable attention. However, for patients interested in intensive insulin therapy, a pump may be an attractive alternative to several daily injections. Insulin pumps provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the dawn phenomenon (rise in blood glucose that occurs just prior to awakening from sleep) and bolus injections that are programmed according to the size and nature of a meal.

Glucose sensors that measure the interstitial glucose are now available and may be helpful in patients with labile blood glucose and frequent hypoglycemia (Juvenile Diabetes Research Foundation Continuous Glucose Monitoring Study Group, 2008). Although patients can use both a pump and a sensor, these devices are not yet integrated into a closed-loop system. Similar to the collected evidence with CSII, the benefits of continuous glucose monitoring have not been conclusively demonstrated, nor have clear selection criteria for appropriate patient groups been developed. However, the results from recent studies suggest that real-time glucose monitoring may lead to modest improvements in glycemic control and improved patient/family quality of life.

Pump therapy presents some unique problems. Because all the insulin used is short acting and there is a minimal amount of insulin in the subcutaneous pool at any given time, insulin deficiency and ketoacidosis may develop rapidly if therapy is interrupted accidentally. Although modern pumps have warning devices that detect changes in line pressure, mechanical problems such as pump failure, dislodgement of the needle, aggregation of insulin in the infusion line, or accidental kinking of the infusion catheter may occur. There also is a possibility of subcutaneous abscesses and cellulitis. Selection of the most appropriate patients is extremely important for success with pump therapy. Offsetting these potential problems, pump therapy is capable of producing a more physiological profile of insulin replacement during exercise (where insulin production is decreased) and therefore less hypoglycemia than do traditional subcutaneous insulin injections.

**Factors That Affect Insulin Absorption.** Factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (insulin has a more rapid onset of action if delivered intramuscularly rather than subcutaneously). Increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption.

Insulin usually is injected into the subcutaneous tissues of the abdomen, buttok, anterior thigh, or dorsal arm. Absorption is usually most rapid from the abdominal wall, followed by the arm, buttock, and thigh. If a patient is willing to inject into the abdomen, injections can be rotated throughout the entire area, thereby eliminating the injection site as a cause of variability in the rate of absorption. The
abdomen currently is the preferred site of injection in the morning because insulin is absorbed 20-30% faster from that site than from the arm. If the patient refuses to inject into the abdominal area, it is preferable to select a consistent injection site for each component of insulin treatment (e.g., before-breakfast dose into the thigh, evening dose into the arm). Rotation of insulin injection sites traditionally has been advocated to avoid lipohypertrophy or lipatrophy, although these conditions are infrequent with current preparations of insulin. In a small group of patients, subcutaneous degradation of insulin has been observed, and this has necessitated the injection of large amounts of insulin for adequate metabolic control.

**Insulin Dosing and Regimens.** In most patients, insulin-replacement therapy includes long-acting insulin (basal) and a short-acting insulin to provide postprandial needs. In a mixed population of type 1 diabetes patients, the average dose of insulin is usually 0.6-0.7 units/kg body weight per day, with a range of 0.2-1 units/kg per day. Obese patients generally and pubertal adolescents require more (~1-2 units/kg per day) because of resistance of peripheral tissues to insulin. Patients who require less insulin than 0.5 units/kg per day may have some endogenous production of insulin or may be more sensitive to the hormone because of good physical conditioning. The basal dose suppresses lipolysis, proteolysis, and hepatic glucose production; it is usually 40-50% of the total daily dose with the remainder as prandial or pre-meal insulin. The insulin dose at meal time should reflect the anticipated carbohydrate intake (many patients with type 1 diabetes calculate a ratio of the insulin dose to the number of grams of carbohydrate). A supplemental scale of short-acting insulin is added to the prandial insulin dose to allow correction of the BG. With all insulin dosing, the provider should consider the insulin sensitivity of the patient and adjust the insulin dosing accordingly. **Insulin administered as a single daily dose of long-acting insulin, alone or in combination with short-acting insulin, is rarely sufficient to achieve euglycemia. More complex regimens that include multiple injections of long-acting or short-acting insulin are needed to reach this goal. In all patients, careful monitoring of therapeutic end points directs the insulin dose used. This approach is facilitated by self-glucose monitoring and measurements of A1C.**

A number of commonly used dosage regimens that include mixtures of insulin given in two or more daily injections are depicted in Figure 43–8. An effective regimen involving multiple daily injections consisting of basal administration of long-acting insulin (e.g., insulin glargine or detemir) either before breakfast or at bedtime and prandial injections of a short-acting insulin (Weng et al., 2008). This method is called basal/bolus and is very similar to the pattern of insulin administration achieved with a subcutaneous infusion pump. Another regimen used is the split-mixed regimen involving the pre-breakfast and pre-supper injection of a mixture of short- and long-acting insulins. When the pre-supper NPH insulin is not sufficient to control hyperglycemia throughout the night, the evening dose may be divided into a pre-supper dose of regular insulin followed by NPH insulin at bedtime.

Individuals with diabetes may sometimes consume smaller amounts of food than originally planned. This, in the presence of a previously injected dose of insulin that was based on anticipation of a larger meal, could result in postprandial hypoglycemia. Thus, in patients who have gastroparesis or loss of appetite, injection of a short-acting analog postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

**Adverse Events.** The most common adverse reaction during insulin therapy is hypoglycemia. Hypoglycemia is the major risk that must be weighed against benefits of efforts to normalize glucose control. Additional information about hypoglycemia and its treatment is provided later in this chapter. Insulin is an anabolic hormone, and insulin treatment of both type 1 and type 2 diabetes is associated with modest weight gain. Paradoxically, improved glycemic control may initially lead to the deterioration of retinopathy in rare patients, but this is followed by a long-term reduction in diabetes-related complications. There has been a dramatic decrease in the incidence of allergic reactions to insulin with the transition to recombinant human insulin; these may still occur as a result of reaction to the small amounts of aggregated or denatured insulin in preparations, to minor contaminants, or because of sensitivity to one of the components added to insulin in its formulation (prolamines, Zn²⁺, etc.). Human insulin, as delivered to patients with diabetes, is immunogenic as reflected by the observation that many patients have circulating anti-insulin antibodies, but these do not alter insulin pharmacokinetics or action. Atrophy of subcutaneous fat at the site of insulin injection (lipoatrophy) was a rare side effect of older insulin preparations. Lipohypertrophy (enlargement of subcutaneous fat depots) has been ascribed to the lipogenic action of high local concentrations of insulin.

**Insulin Treatment of Ketoacidosis and Other Special Situations.** Acutely ill diabetic patients may have metabolic disturbances that are sufficiently severe or labile to justify intravenous administration of insulin (Kitabchi et al., 2009). Such treatment is most appropriate in patients with ketoacidosis or severe hyperglycemia with a hyperosmolar state. Insulin infusion inhibits lipolysis and gluconeogenesis completely and produces near-maximal stimulation of glucose uptake. In most patients with diabetic ketoacidosis, blood glucose concentrations will fall by ~10% per hour; the acidosis is corrected more slowly. As treatment proceeds, it often is necessary to administer glucose along with the insulin to prevent hypoglycemia but to allow clearance of all ketones. Some physicians prefer to initiate therapy with a loading dose of insulin, but this tactic appears unnecessary because steady-state concentrations of the hormone are achieved within 30 minutes with a constant infusion. Patients with nonketotic hyperglycemic hyperosmolar state may be more sensitive to insulin than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes is an integral part of the therapy in both situations because there is always a major deficit. **Regardless of the insulin regimen, the key to effective therapy is careful and frequent monitoring of the patient’s clinical status, glucose, and electrolytes.** A frequent error in the management of such patients is the failure to administer long-acting insulin subcutaneously before the insulin infusion is discontinued.

**Treatment of Diabetes in Children or Adolescents.** Diabetes is one of the most common chronic diseases of childhood, and rates of type 1 diabetes in American youth are estimated at 1 in 300, with an increasing incidence over the past 20 years. One of the unfortunate corollaries of the growing rates of obesity over the past three decades is an increase in the numbers of children and adolescents with nonautoimmune, or type 2, diabetes. Current estimates are that 15-20% of
new cases of pediatric diabetes may in fact be type 2 diabetes; rates vary by ethnicity, with disproportionately high rates in Native Americans, African Americans, and Latinos. Because of a paucity of clinical trials performed in children, there is only limited information on which to base decisions for appropriate therapy. Thus the results in the Diabetes Control and Complications Trial with young and middle-aged adults have been extrapolated to the pediatric population such that current practice is for more intensive, physiologically based insulin replacement with a goal of tight glucose control (Diabetes Control Complications Trial Research Group, 1993). This is achieved with combinations of basal and prandial insulin replacement. The primary limiting factor of more aggressive insulin therapy is hypoglycemia, a problem with special concerns in young children. Diabetic patients <5 years old are at greater risk for hypoglycemia, have increased rates of severe hypoglycemia with seizures and coma, and may suffer permanent cognitive dysfunction as a result of repeated episodes of low blood glucose. Older children and adolescents do not seem to have demonstrable cognitive impairment related to hypoglycemia; good glycemic control is associated with better mental function (Kodl and Seaquist, 2008).

The treatment of type 1 diabetes in children and adolescents has changed with the availability of newer technologies. The standard for insulin treatment now includes multiple dose regimens with three to five injections per day or CSII. Split/mixed regimens using NPH and regular insulin have been increasingly supplanted by regimens using insulin analogs because they offer more flexibility in dosing and meal patterns. Similarly, CSII is used with increasing frequency in the pediatric diabetic population. Moreover, recent studies show that this approach is applicable to young children as well as older children and adolescents.

Because of the nearly uniform association of type 2 diabetes with obesity in the pediatric age group, lifestyle management is the recommended first step in therapy. Goals of reducing body weight while maintaining normal linear growth, and increasing physical activity, are broadly recommended and can be effective when patients are compliant. There have been few clinical trials of glucose lowering therapy in pediatric type 2 diabetes. The only medication currently approved by the FDA specifically for medical treatment of type 2 diabetes is metformin. Metformin is approved for children as young as 10 years of age and is available in a liquid formulation (100 mg/mL). Results from clinical trials have shown that both metformin and glimepiride effectively lower blood glucose in affected patients. Insulin is the typical second line of therapy after metformin; basal insulin can be added to oral agent therapy or multiple daily injections can be used when simpler regimens are not successful. Weight gain is a more significant problem than hypoglycemia with insulin treatment in pediatric type 2 diabetes. Other diabetes medications, such as thiazolidinediones, α-glucosidase inhibitors, DPP-4 inhibitors, and exenatide, have been tried empirically in type 2 diabetic adolescents, but there is no systematically collected data on efficacy or safety of these agents in the pediatric population.

Management of Diabetes in Hospitalized Patients. Hyperglycemia is common in hospitalized patients. Depending on how hyperglycemia is defined, prevalence estimates of elevated blood glucose among inpatients with and without a prior diagnosis of diabetes range between 20% and 100% for patients treated in intensive care units (ICUs) and 30% and 83% outside the ICU. Although most of these individuals will have known diabetes, ~30% of hospitalized patients will have elevated blood glucose levels without a prior diagnosis of diabetes (Falciglia, 2007). Patients admitted to the hospital often have a number of challenges to glucose regulation in addition to those faced by diabetic outpatients (Donner and Flammer, 2008). Stress of illness has been associated with insulin resistance, possibly the result of counterregulatory hormone secretion, cytokines, and other inflammatory mediators. Food intake is often variable due to concurrent illness or preparation for diagnostic testing. Medications used in the hospital, such as glucocorticoids or dextrose-containing intravenous solutions, can exacerbate tendencies toward hyperglycemia. Finally, fluid balance and tissue perfusion can affect the absorbance of subcutaneous insulin and the clearance of glucose. Therapy of hyperglycemia in hospitalized patients needs to be adjusted for these variables.

There is an emerging body of information indicating that hyperglycemia portends poor outcomes in hospitalized patients, most notably in the critically ill, and that this effect is independent of severity of illness (Finfer et al., 2009; van den Berge et al., 2001). The mechanisms for this association have not been fully explained, and controversy persists about the optimal level of glycemia in hospitalized patients. The ADA currently suggests these blood glucose targets: 140-180 mg/dL (7.8-10.0 mM) in critically ill patients and random glucose of 180 mg/dL (10 mM) or pre-meal glucose of 140 mg/dL (7.8 mM) in noncritically ill patients. Great emphasis should be placed on steps taken to minimize hypoglycemia in both settings.

Insulin is the cornerstone of treatment of hyperglycemia in hospitalized patients (Moghissi et al., 2009). For critically ill patients and those with variable blood pressure, edema, and tissue perfusion, intravenous insulin is the treatment of choice. This method of insulin administration has been firmly established in the care of critically ill patients with elevated blood glucose and provides the most flexible and precise means of treatment. A number of algorithms have been adapted to allow rapid titration with adjustments to maintain blood glucose in a target range. For patients who are more stable, subcutaneous insulin regimens using combinations of basal and prandial insulin is the standard. There is considerable evidence that reactive treatment, using sliding scale regimens, is inferior and associated with wider fluctuations in blood glucose and greater rates of both hyper- and hypoglycemia. Oral agents have a limited place in treatment of hyperglycemic patients in the hospital because of slow onset of action, insufficient potency, need for intact GI function, and side effects. In general, oral glucose-lowering medications should be discontinued on hospital admission and can be restarted at discharge.

Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth. There is debate, however, about the optimal route of insulin administration during surgery. Although some clinicians advocate subcutaneous insulin administration, most recommend intravenous insulin infusion. Some physicians give patients half their normal daily dose of insulin as long-acting insulin subcutaneously on the morning of an operation and then administer 5% dextrose infusions during surgery to maintain glucose concentrations. This approach provides less minute-to-minute control than is possible with intravenous regimens and also may increase the likelihood of hypoglycemia. For patients with type 1 diabetes, failure to provide some basal insulin at all times can precipitate diabetic ketoacidosis.
INSULIN SECRETAGOGUES AND ORAL HYPOGLYCEMIC AGENTS

A variety of sulfonylureas, meglitinides, GLP-1 agonists, and inhibitors of dipeptidyl peptidase-4 (DPP-4) are used as secretagogues to stimulate insulin release (Table 43–6).

**K<sub>ATP</sub> Channel Modulators: Sulfonylureas**

*Chemistry.* All members of this class of drugs are substituted arylsulfonylureas. They differ by substitutions at the para position on the benzene ring and at one nitrogen residue of the urea moiety. The sulfonylureas are divided into two groups or generations of agents. The first generation sulfonylureas (tolbutamide, tolazamide, and chlorpropamide) are rarely used now in the treatment of type 2 diabetes and are not discussed (information is available in prior editions of this book). The second, more potent generation of hypoglycemic sulfonylureas includes glyburide (glibenclamide; DIABET, others), glipizide (GLUCOTROL, others), and glimepiride (AMARYL, others) (Table 43–7). Some are available in an extended-release (glipizide) or a micronized (glyburide) formulation.

<sup>a</sup>Dose may be lower in some patients

Mechanism of Action. Sulfonylureas stimulate insulin release by binding to a specific site on the β cell K<sub>ATP</sub> channel complex (the sulfonylurea receptor, SUR) and inhibiting its activity. K<sub>ATP</sub> channel inhibition causes cell membrane depolarization and the cascade of events leading to insulin secretion (Figure 43–3). The acute administration of sulfonylureas to type 2 diabetes patients increases insulin release from the pancreas. Sulfonylureas may also reduce hepatic clearance of insulin, further increasing plasma insulin levels. In the initial months of sulfonylurea treatment, fasting plasma insulin levels and insulin responses to oral glucose challenges are increased. With chronic administration, circulating insulin levels decline to those that existed before treatment, but despite this reduction in insulin levels, reduced plasma glucose levels are maintained. The explanation for this is not clear, but it may relate to the fact that chronic hyperglycemia *per se* impairs insulin secretion (glucose toxicity), and with the initial
correction of plasma glucose circulating insulin has improved effects on its target tissues. The absence of acute stimulatory effects of sulfonylureas on insulin secretion during chronic treatment is attributed to downregulation of cell surface receptors for sulfonylureas on the pancreatic β cell. If chronic sulfonylurea therapy is discontinued, pancreatic β cell response to acute administration of the drug is restored.

Absorption, Distribution, and Elimination. Although the rates of absorption of the different sulfonylureas vary, all are effectively absorbed from the GI tract. However, food and hyperglycemia can reduce absorption. Sulfonylureas in plasma are largely (90-99%) bound to protein, especially albumin; plasma protein binding is greatest for glyburide. The volumes of distribution of most of the sulfonylureas are ~0.2 L/kg. Although their half-lives are short (3-5 hours), their hypoglycemic effects are evident for 12-24 hours, and they often can be administered once daily. The reason for the discrepancies between their half-lives and duration of action is not clear. The liver metabolizes all sulfonylureas, and the metabolites are excreted in the urine. Thus, sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

Adverse Effects and Drug Interactions. Not unexpectedly, sulfonylureas may cause hypoglycemic reactions, including coma. This is a particular concern in elderly patients with impaired hepatic or renal function who are taking longer-acting sulfonylureas (a major reason first-generation agents are rarely used). Because of the long t½ of some sulfonylureas, it may be necessary to monitor or treat elderly hypoglycemic patients for 24-48 hours with an intravenous glucose infusion in the in-patient setting. Weight gain of 1-3 kg is a common side effect of improving glycemic control with sulfonylurea treatment.

Less frequent side effects of sulfonylureas include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. Rarely, patients treated with these drugs develop an alcohol-induced flush similar to that caused by disulfiram or hyponatremia. A long-running debate has centered on whether treatment with sulfonylureas is associated with increased cardiovascular mortality (Bell, 2006). This likely reflects the expression of the sulfonylurea receptor on vascular smooth muscle cells and cardiac myocytes, where activation of the sulfonylurea prevents the beneficial effects of ischemic preconditioning. Glyburide, but not glimepiride, interacts with the sulfonylurea receptor in these non-islet sites and may be associated with increased cardiovascular risk. However, a recent randomized trial of glyburide, metformin, and rosiglitazone found a slightly lower cardiovascular mortality in individuals treated with glyburide (Kahn et al., 2006).

The hypoglycemic effect of sulfonylureas may be enhanced by various mechanisms (decreased hepatic metabolism or renal excretion, displacement from protein-binding sites). For example, some drugs (sulfonamides, clofibrate, and salicylates) displace the sulfonylureas from binding proteins, thereby transiently increasing the concentration of free drug. Ethanol may enhance the action of sulfonylureas and cause hypoglycemia. In addition, hypoglycemia

may be more frequent in patients taking a sulfonylurea and one of these agents: androgens, anticoagulants, azole antifungals, chloramphenicol, fenfluramine, fluconazole, gemfibrozil, histamine H1 antagonists, magnesium salts, methyldopa, monoamine oxidase inhibitors (MAOIs), probenecid, sulfipyrazone, sulfonamides, tricyclic antidepressants, and urinary acidifiers. Other drugs may decrease the glucose-lowering effect of sulfonylureas by increased hepatic metabolism, increased renal excretion, or inhibiting insulin secretion (β-blockers, Ca2+ channel blockers, cholestyramine, diazoxide, estrogens, hydantoins, isoniazid, nicotinic acid, phenothiazines, rifampin, sympathomimetics, thiazide diuretics, and urinary alkalinizers).

**Dosage Forms Available.** Treatment is initiated at lower end of the dose range and titrated upward based on the patient’s glycemic response. Some have a longer duration of action and can be prescribed in a single daily dose (glimepiride), whereas others are formulated as extended-release or micronized formulations to extend their duration of action (Table 43–7). The dose for the extended-release glipizide or micronized glyburide is lower. Glyburide is not recommended when the creatinine clearance is < 50 mL/minute or in elderly individuals because reduced drug and metabolite clearance greatly increases the risk of hypoglycemia. Other sulfonylureas such as glipizide or glimepiride appear safer in elderly individuals with type 2 diabetes.

**Therapeutic Uses.** Sulfonylureas are used to treat hyperglycemia in type 2 diabetes. Between 50% and 80% of properly selected patients respond to this class of agents. All members of the class appear be equally efficacious. A significant number of patients who respond initially later cease to respond to the sulfonylurea and develop unacceptable hyperglycemia (secondary failure). This may occur as a result of a change in drug metabolism or more likely from a progression of β-cell failure. A recent randomized trial found that the initial improvement in glycemic control was less durable with glyburide monotherapy (compared to metformin or rosiglitazone monotherapy), suggesting that the secondary failure rate is higher with this class of drugs (Kahn et al., 2006). Some individuals with neonatal diabetes or MODY-3 respond to these agents (this is an off-label use). Combinations of insulin and sulfonylureas and other oral agents are discussed later. Contraindications to the use of these drugs include type 1 diabetes, pregnancy, lactation, and, for the older preparations, significant hepatic or renal insufficiency.

**K$_{ATP}$ Channel Modulators: Non-Sulfonylureas**

**Repaglinide.** Repaglinide (PRANDIN) is an oral insulin secretagogue of the meglitinide class (Table 43–6). It is a benzoic acid derivative structurally unrelated to the sulfonylureas, but like sulfonylureas, it stimulates insulin release by closing K$_{ATP}$ channels in pancreatic β cells. The drug is absorbed rapidly from the GI tract, and peak blood levels are obtained within 1 hour. The t$_{1/2}$ is ~1 hour. These features allow for multiple preprandial use as compared with the classical once- or twice-daily dosing of sulfonylureas.

Repaglinide is metabolized primarily by the liver (CYP3A4) to inactive derivatives. Repaglinide should be used cautiously in patients with hepatic insufficiency. Because a small proportion (~10%) is metabolized by the kidney, dosing of the drug in patients with renal insufficiency also should be performed cautiously. As with sulfonylureas, the major side effect of repaglinide is hypoglycemia. Like sulfonylureas, repaglinide is associated with a decline in efficacy (secondary failure) after initially improving glycemic control. Certain drugs may potentiate the action of repaglinide by displacing it from plasma protein binding sites (β-blockers, chloramphenicol, coumarins, MAOIs, nonsteroidal anti-inflammatory drugs [NSAIDs], probenecid, salicylates, and sulfonamide) or altering its metabolism (gemfibrozil, itraconazole, trimethoprim, cyclosporine, simvastatin, clarithromycin).

**Nateglinide.** Nateglinide (STARLIX) is an orally effective insulin secretagogue derived from d-phenylalanine. Like sulfonylureas and repaglinide, nateglinide stimulates insulin secretion by blocking K$_{ATP}$ channels in pancreatic β cells (Rosenstock et al., 2004). Nateglinide promotes a more rapid but less sustained secretion of insulin than other available oral antidiabetic agents. The drug’s major therapeutic effect is reducing postprandial glycemic elevations in type 2 diabetes patients. Nateglinide is approved by the FDA for use in type 2 diabetes. It is most effective when administered in a dose of 120 mg, 1-10 minutes before a meal.
Nateglinide is metabolized primarily by hepatic CYPs [2C9, 70%; 3A4, 30%] and thus should be used cautiously in patients with hepatic insufficiency. About 16% of an administered dose is excreted by the kidney as unchanged drug. Dosage adjustment is unnecessary in renal failure. Some drugs reduce the glucose-lowering effect of nateglinide (corticosteroids, rifamycins, sympathomimetics, thiazide diuretics, thyroid products); others (alcohol, NSAIDs, salicylates, MAOIs, and nonselective β blockers) may increase the risk of hypoglycemia with nateglinide. Nateglinide therapy may produce fewer episodes of hypoglycemia than other currently available oral insulin secretagogues including repaglinide. As with sulfonylureas and repaglinide, secondary failure occurs.

**A\textsubscript{MPK} and PPAR \textgamma activators**

**Metformin**

Mechanism of Action. Metformin (GLUCOPHAGE, others) is the only member of the biguanide class of oral hypoglycemic drugs available for use today (Bailey and Turner, 1996). Metformin increases the activity of the AMP-dependent protein kinase (AMPK) (Zhou et al., 2001). AMPK is activated by phosphorylation when cellular energy stores are reduced (i.e., lower concentrations of ATP and phosphocreatine). Activated AMPK stimulates fatty acid oxidation, glucose uptake, and nonoxidative metabolism, and it reduces lipogenesis and gluconeogenesis. The net result of these actions is increased glycogen storage in skeletal muscle, lower rates of hepatic glucose production, increased insulin sensitivity, and lower blood glucose levels.

Metformin causes a similar profile of effects and is dependent on AMPK activation (Shaw et al., 2005). Although the molecular mechanism by which metformin activates AMPK is not known, it is thought to be indirect, possibly by reducing intracellular energy stores. Consistent with this, metformin has been shown to inhibit cellular respiration by specific actions on mitochondrial complex I. Metformin has little effect on blood glucose in normoglycemic states and does not affect the release of insulin or other islet hormones and rarely causes hypoglycemia. However, even in persons with only mild hyperglycemia, metformin lowers blood glucose by reducing hepatic glucose production and increasing peripheral glucose uptake. This effect is at least partially mediated by reducing insulin resistance at key target tissues. The hepatic effect is probably the dominant mode of action and involves primarily suppression of gluconeogenesis. Table 43–8 compares metformin and thiazolidinediones (glitazones).

HGP = hepatic glucose production
Absorption, Distribution, and Elimination. Metformin is absorbed primarily from the small intestine. The drug is stable, does not bind to plasma proteins, and is excreted unchanged in the urine. It has a $t_{1/2}$ in the circulation of ~2 hours. The transport of metformin into cells is mediated in part by organic cation transporters (see Chapter 5). Organic cation transporter 1 (OCT 1) is believed to carry the drug into cells such as hepatocytes and myocytes where it is pharmacologically active. Organic cation transporter 2 (OCT 2) is thought to transport metformin into renal tubules for excretion. There is recent evidence suggesting that genetic variation in OCT 1 among humans may affect the response to metformin.

Therapeutic Uses and Dosage. Metformin is currently the most commonly used oral agent to treat type 2 diabetes and is generally accepted as the first-line treatment for this condition. Metformin is effective as monotherapy and in combination with nearly every other therapy for type 2 diabetes, and its utility is supported by data from a large number of clinical trials. Fixed-dose combinations of metformin in conjunction with glipizide, glyburide, pioglitazone, repaglinide, rosiglitazone, and sitagliptin are available. Metformin is available as an immediate-release form, and treatment is best started with low doses and titrated over days to weeks to minimize side effects. The currently recommended dosing is 0.5-1.0 g twice daily, with a maximum dose of 2550 mg; there is no advantage of thrice-daily administration. A sustained-release preparation is available that is effective for once-daily dosing; the maximum dose for this compound is 2 g.

Metformin has superior or equivalent efficacy of glucose lowering compared to other oral agents used to treat diabetes, and reduces diabetes-related complications in patients with type 2 diabetes. Unlike many of the other oral agents, metformin does not typically cause weight gain and in some cases causes weight reduction. Metformin is not effective in the treatment of type 1 diabetes. Several observational studies suggest that diabetic patients treated with metformin may have lower rates of cardiovascular disease and mortality, compared to individuals treated with alternative therapies (Evans et al., 2006; Johnson et al., 2005). The results of the Diabetes Prevention Program indicate that in persons with impaired glucose tolerance, treatment with metformin delays the progression to diabetes. Metformin has been used as a treatment for infertility in women with the polycystic ovarian syndrome. Although not formally approved for this purpose, metformin has demonstrable effects to improve ovulation and menstrual cyclicity and reduce circulating androgens and hirsutism.

Adverse Effects and Drug Interactions. The most common side effects of metformin are gastrointestinal. Approximately 10-25% of patients starting this medication report nausea, indigestion, abdominal cramps or bloating, diarrhea, or some combination of these. Metformin has direct effects on GI function including glucose and bile salt absorption. Use of metformin is associated with 20-30% lower blood levels of vitamin B$_{12}$ (DeFronzo et al., 1995), probably due to malabsorption, but neurological or hematological consequences of this have not been reported. Most GI adverse effects of metformin abate over time with continued use of the drug, and can be minimized by starting at low doses and gradually titrating to a target dose over several weeks, and by having patients take it with meals.

Like phenformin, metformin has been associated with lactic acidosis. The most concrete evidence of this is from cases of metformin overdose where very high circulating levels of the drug were associated with high plasma lactate and acidemia. However, the estimated incidence of lactic acidosis attributable to metformin use is 3-6 per 100,000 patient-years of treatment (Lalau and Race, 2001; Scarpello and Howlett, 2008), which is comparable to rates in type 2 diabetic patients not using metformin. Moreover, several recent analyses of this association have raised doubts as to whether the association of lactic acidosis with metformin is causal (Kamber et al., 2008). Many cases of lactic acidosis associated with the use of metformin have been reported in patients with concurrent conditions that can cause poor tissue perfusion such as sepsis, myocardial infarction, and congestive heart failure. Renal failure is another common comorbidity reported in patients having lactic acidosis associated with metformin use, and decreased glomerular filtration rates are thought to increase plasma metformin levels by reducing clearance of drug from the circulation. There are no consensus guidelines for renal contraindications for metformin use; because clearance of the drug is not altered significantly until the creatinine clearance drops below 50 mL/minute, metformin is probably safe in patients with this level of renal function (Herrington and Levy, 2008). It is important to assess renal function before starting metformin and to monitor function at least annually. Metformin should be discontinued preemptively in situations where renal function could decline precipitously, such as before radiographic procedures that use contrast dyes and during admission to hospital for severe illness. Metformin should not be used in severe pulmonary disease, decompensated heart failure, severe liver disease, or chronic alcohol abuse.

Cationic drugs that are eliminated by renal tubular secretion have the potential for interaction with metformin by competing for common renal tubular transport systems. Careful patient monitoring and dose adjustment of metformin is recommended in patients who are taking cationic medications such as cimetidine, furosemide, and nifedipine, excreted via the proximal renal tubular secretory system.

Thiazolidinediones

Chemistry and Mechanism of Action. Thiazolidinediones are ligands for the peroxisome proliferation activating receptor γ (PPARγ) receptors, a group of nuclear hormone receptors that are involved in the regulation of genes related to glucose and lipid metabolism (Yki-Jarvinen, 2004). Two thiazolidinediones are currently available to treat patients with type 2 diabetes, rosiglitazone (AVANDIA) and pioglitazone (ACTOS). These compounds are generally similar but have several important differences. Although much is understood about the molecular mechanisms of action of the thiazolidinediones, they have complex effects on a wide variety of tissues, and much remains to be learned about their overall clinical impact.
and their specific role in therapeutics. Table 43–8 compares metformin and thiazolidinediones.

![ROSIGLITAZONE](image1)

![PIOGLITAZONE](image2)

PPARγ is expressed primarily in adipose tissue with lesser expression in cardiac, skeletal, and smooth muscle cells, islet β cells, macrophages, and vascular endothelial cells. The endogenous ligands for PPARγ include small lipophilic molecules such as oxidized linoleic acid, arachidonic acid and the prostaglandin metabolite 15d-PGJ2; rosiglitazone and pioglitazone are synthetic ligands for PPARγ. Ligand binding to PPARγ causes heterodimer formation with the retinoid X receptor and interaction with PPAR response elements on specific genes, an interaction that is modulated by complex interactions with co-repressors and co-activators. The principal response to PPARγ activation is adipocyte differentiation. Preclinical gain-of-function models show increased numbers of adipocytes and expansion of fat mass; loss-of-function models demonstrate lipodystrophy. Along with adipocyte differentiation, PPARγ activity promotes uptake of circulating fatty acids into fat cells and shifts of lipid stores from extra-adipose to adipose tissue. One consequence of the concerted cellular responses to PPARγ activation is increased tissue sensitivity to insulin, and this is the basis for the pharmacological application of thiazolidinediones to clinical medicine.

Pioglitazone and rosiglitazone are insulin sensitizers and increase insulin-mediated glucose uptake by 30-50% in patients with type 2 diabetes. Although adipose tissue seems to be the primary target for PPARγ agonists, both clinical and preclinical models support a role for skeletal muscle, the major site for insulin-mediated glucose disposal, in the response to thiazolidinediones. It is still not clear whether thiazolidinedione-induced improvement of insulin resistance is due to direct effects on key target tissues (skeletal muscle and liver), indirect effects mediated by secreted products of adipocytes (e.g., adiponectin), or some combination of these. In addition to promoting glucose uptake into muscle and adipose tissue, the thiazolidinediones reduce hepatic glucose production and increase hepatic glucose uptake.

Beyond effects on insulin sensitivity and blood glucose, thiazolidinediones also affect lipid metabolism. Treatment with rosiglitazone or pioglitazone reduces plasma levels of fatty acids by increasing clearance and reducing lipolysis. These drugs also cause a shift of triglyceride stores from nonadipose to adipose tissues, and from visceral to subcutaneous fat depots. In clinical trials, pioglitazone reduces plasma triglycerides by 10-15%, and raises HDL-cholesterol levels. This has been attributed to a dual effect on PPARα as well as PPARγ; rosiglitazone does not interact with PPARα and has minimal effects on plasma triglycerides and cholesterol. Because of these actions on plasma lipids, and beneficial effects on inflammatory markers, coagulation, and endothelial function, thiazolidinediones were predicted to reduce macrovascular complications of diabetes and insulin resistance. However, recently completed randomized clinical trials demonstrated a questionable benefit of pioglitazone (Dormandy et al., 2005), and no effect of rosiglitazone on major events related to atherosclerosis (Home et al., 2009). Because thiazolidinediones reduce hepatic triglyceride, they have been applied to the treatment of nonalcoholic fatty liver disease. Although results of these studies have been encouraging (Kashi et al., 2008), the thiazolidinediones are not yet approved for this use.

**Absorption, Distribution, and Elimination.** Both agents are absorbed within 2-3 hours, and bioavailability does not seem to be affected by food. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency, but should not be used if there is active hepatic disease or significant elevations of serum liver transaminases. The thiazolidinediones are metabolized by hepatic CYPs. CYPs 2C8 and 3A4 metabolize pioglitazone; rosiglitazone is metabolized by CYPs 2C9 and 2C8. Rifampin induces these enzymes and causes a significant decrease in plasma concentrations of rosiglitazone and pioglitazone; gemfibrozil impedes metabolism of the thiazolidinediones and can increase plasma levels by ~2-fold. It may be prudent to reduce the doses of the thiazolidinediones when they are used in conjunction with gemfibrozil. Rosiglitazone and pioglitazone do not seem to significantly affect the pharmacokinetics of other drugs.

**Therapeutic Uses and Dosage.** Rosiglitazone and pioglitazone are dosed once daily. The starting dose of rosiglitazone is 4 mg and should not exceed 8 mg daily. The starting dose of pioglitazone is 15-30 mg, up to a maximum of 45 mg daily. Thiazolidinediones have proven effects to enhance insulin action on liver, adipose tissue, and skeletal muscle. These composite effects on glucose metabolism confer improvements in glycemic control in persons with type 2 diabetes and cause average reductions in A1C of 0.5-1.4%. Thiazolidinediones require the presence of insulin for pharmacological activity and are not indicated to treat type 1 diabetes. Both pioglitazone and rosiglitazone are effective as monotherapy and as additive therapy to metformin, sulfonylureas, or insulin. The onset of action of thiazolidinediones is relatively slow; maximal effects on glucose homeostasis develop gradually over the course of 1-3 months.

There is evidence in drug-naive diabetic subjects that the glucose-lowering effect of primary treatment with rosiglitazone is more durable than that of metformin or glyburide (Kahn et al., 2006). Treatment with rosiglitazone also reduced progression from prediabetes to type 2 diabetes (Gerstein et al., 2006).

**Adverse Effects and Drug Interactions.** The most common adverse effects of the thiazolidinediones are weight gain and edema. Edema attributable to thiazolidinedione treatment occurs in up to 10% of
patients in clinical trials and has been reported equally with pioglitazone and rosiglitazone. Beyond the effects of edema, treatment with thiazolidinediones causes an increase in body adiposity and an average weight gain of 2-4 kg over the first year of treatment. Importantly, in both preclinical models and in human studies the gain of body weight occurs peripherally, in subcutaneous adipose tissue, and visceral fat changes little or is reduced. The use of insulin with thiazolidinedione treatment roughly doubles the incidence of edema and amount of weight gain, compared with either drug alone.

Macular edema has been reported in patients using both rosiglitazone and pioglitazone (Ryan et al., 2006), usually in association with more general fluid retention. Beyond regular annual retinal exams, diabetic patients taking thiazolidinediones should be observed for visual changes.

Of greatest concern among the adverse effects of thiazolidinediones is the increased incidence of congestive heart failure. This has generally been attributed to the effect of the drugs to cause plasma volume expansion in type 2 diabetic patients who have significantly increased risk for heart failure. There does not appear to be an acute effect of pioglitazone or rosiglitazone to reduce myocardial contractility or ejection fraction. Yet exposure to these drugs over several years in clinical trials has been associated with an increased incidence of heart failure of up to 2-fold (Home et al., 2009). The use of thiazolidinediones in diabetic patients without a history of heart failure, or with compensated heart failure, can be initiated, but monitoring for signs and symptoms of congestive heart failure is important, especially when insulin is also used. Thiazolidinediones should not be used in patients with moderate to severe heart failure, and they should be discontinued in those who develop clinically apparent heart failure while being treated (Nesto et al., 2003).

Recent evidence suggests that rosiglitazone, but not pioglitazone, increases the risk of cardiovascular events (myocardial infarction, stroke). While the degree of the risk remains controversial, an expert panel reviewing this question for the FDA recommended caution in the use of rosiglitazone, but did not recommend its removal from the market (Rosen, 2010). Rather, as of September, 2010, the FDA requires that new prescriptions for rosiglitazone be issued under a risk evaluation and mitigation strategy and be limited to patients whose diabetes could not be adequately controlled by other medications (including pioglitazone). The European Medicines Agency has suspended marketing of rosiglitazone-containing formulations and recommended removal of rosiglitazone and rosiglitazone-containing formulations from the European market.

Evidence from clinical trials indicates that treatment with thiazolidinediones can increase the risk of bone fracture in women (Home et al., 2009; Kahn et al., 2006; Meier et al., 2008). This effect has been proposed to result from increased shunting of mesenchymal stem cells into the adipocyte lineage, and away from osteogenesis, as a result of increased PPARγ activity. Treatment with thiazolidinediones has also been associated with a small but consistent reduction in the hematocrit. This has generally been attributed to hemodilution due to plasma volume expansion, but thiazolidinediones may conceivably shunt erythroid precursors into adipose tissue development.

The first thiazolidinedione released for treatment of diabetic patients, troglitazone, was removed from the market because of rare but severe, and sometimes fatal, hepatic failure. There have been few cases of severe hepatocellular damage attributable to the newer thiazolidinediones, and these have not caused death or required transplantation. In general, pioglitazone and rosiglitazone have been associated with a lowering of transaminases, probably reflective of reductions in hepatic steatosis. It is recommended that thiazolidinediones be withheld from patients with clinically apparent liver disease and that liver function be monitored intermittently during treatment.

**GLP-1-Based Agents**

Incretins are GI hormones that are released after meals and stimulate insulin secretion. The two best known incretins are GLP-1 and GIP. Although these peptides share many similarities, they differ in that GIP is not effective for stimulating insulin release and lowering blood glucose in persons with type 2 diabetes, whereas GLP-1 is effective. Consequently, the GLP-1 signaling system has been a successful drug target.

Both GLP-1 and glucagon are products derived from proglucagon, a 180–amino acid precursor with five separately processed domains (Figure 43–9; Drucker, 2006). An amino-terminal signal peptide is followed by glicentin-related pancreatic peptide, glucagon, GLP-1, and glucagon-like peptide 2 (GLP-2). Processing of the protein is sequential and occurs in a tissue-specific fashion. Pancreatic α-cells cleave proglucagon into glucagon and a large C-terminal peptide that includes both of the GLPs. Intestinal L-cells and specific hindbrain neurons process proglucagon into a large N-terminal peptide that includes glucagon or GLP-1 and GLP-2. GLP-2 impacts the proliferation of epithelial cells lining the GI tract. Teduglutide, a GLP-2 analog, is under development as a treatment for short bowel syndrome and has received orphan drug designation for the treatment of short bowel syndrome from the U.S. FDA and the European Medicines Agency.

Given intravenously to diabetic subjects in supraphysiologic amounts, GLP-1 stimulates insulin secretion, inhibits glucagon release, delays gastric emptying, reduces food intake, and normalizes fasting and postprandial insulin secretion. The insulinotrophic effect of GLP-1 is glucose dependent in that insulin secretion at fasting glucose concentrations, even with high levels of circulating GLP-1, is minimal. The effects of GLP-1 to promote glucose homeostasis and the glucose dependence of these effects are beneficial aspects of this signaling system for treating type 2 diabetes. GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase IV (DPP-4), with a plasma t½ of 1-2 minutes; thus, the natural peptide, itself, is not a useful therapeutic agent.

Two broad strategies have been taken to applying GLP-1 to therapeutics, the development of injectable, DPP-4 resistant peptide agonists of the GLP-1 receptor, and the creation of small molecule inhibitors of DPP-4 (Figure 43–10; Table 43–6).

**GLP-1 Receptor Agonists.** There are currently two GLP-1 receptor agonists that have been approved for
treatment diabetic patients in the U.S. and several others in advanced phases of development. Exendin-4 is a naturally occurring reptilian peptide of 39 amino acids with considerable homology to GLP-1. It is a potent GLP-1 receptor agonist that shares many of the physiological and pharmacological effects of GLP-1. It is not metabolized by DPP-4 and so has a plasma t$_{1/2}$ of 2-3 hours following subcutaneous injection. Importantly,

Figure 43–9. Processing of proglucagon to glucagon, GLP1, GLP-2, and GRPP. Proglucagon is synthesized in islet $\alpha$ cells, intestinal enteroendocrine cells (L cells) and a subset of neurons in the hindbrain. In $\alpha$ cells, prohormone processing is primarily by proconvertase 2, releasing glucagon, glicentin-related pancreatic polypeptide (GRPP), and a major proglucagon fragment, containing the two glucagon-like peptides (GLPs). In L cells and neurons, proglucagon cleavage is mostly through proconvertase 1/3, giving the larger C-terminal peptides, glicentin and oxyntomodulin, and the smaller GLP-1 and GLP-2. STN, solitary tract nucleus.

Figure 43–10. Pharmacological effects of DDP-4 inhibition. DPP-4, an ectoenzyme located on the luminal side of capillary endothelial cells metabolizes the incretins, glucagon-like peptide 1 (GLP-1), and glucose-dependent insulinotropic polypeptide (GIP), by removing the two N-terminal amino acids. The target for DPP-4 cleavage is a proline or alanine residue in the second position of the primary peptide sequence. The truncated metabolites GLP-1[9-36] and GIP[3-42] are the major forms of the incretins in plasma and are inactive as insulin secretagogues. Treatment with a DPP-4 inhibitor increases the concentrations of intact GLP-1 and GIP.
Exenatide (BYETTA), synthetic exendin-4, is approved for use as monotherapy and as adjunctive therapy for type 2 diabetes patients not achieving glycemic targets with metformin, sulfonylurea, the combination of metformin and sulfonylurea, or thiazolidinedione. In clinical trials, exenatide, alone or in combination with metformin, sulfonylurea, or thiazolidinedione, was associated with improved glycemic control, as reflected in an ~1% decrease in HbA1C, and weight loss that averaged 2.5-4 kg (Amori et al., 2007).

Liraglutide is a second GLP-1 receptor agonist. Structurally, liraglutide is nearly identical to native GLP-1, with Lys$^{34}$ to Arg substitution and addition of a α-glutamatic acid spacer coupled to a C16 fatty acyl group. The fatty acid side chain permits binding to albumin and other plasma proteins and accounts for an extended $t_{1/2}$ permitting once a day administration. The pharmacodynamic profile of liraglutide mimics GLP-1 and exenatide, and in clinical trials liraglutide caused both improvement in glycemic control and weight loss. In a single comparative trial, liraglutide reduced A1C~30% more than exenatide (Buse et al., 2009). Liraglutide is indicated for adjunctive therapy in patients not achieving glycemic control with metformin, sulfonylurea, or the combination of metformin/sulfonylurea or metformin/thiazolidinedione.

There are a number of other GLP-1 receptor agonists in development. A sustained-release form of exenatide, exenatide LAR, is being tested as a once-weekly injection. This compound is composed of exenatide in microspheres with the biodegradable polymer D.L lactico-co-glycolic acid. In phase 3 studies, exenatide LAR shares the pharmacodynamic properties of exenatide but may be more potent (Kim et al., 2007). Other long-acting GLP-1 receptor agonists in advanced stages of development include albglutide, a recombinant protein fusion of GLP-1 and albumin; taspoglutide, a modified GLP-1; lixisenatide, a modified exendin-4 based molecule; and CJC-1134, an exendin-4/albumin conjugate. These agonists all have extended half-lives relative to exenatide and liraglutide and may be suitable for once-weekly injection. The distinguishing feature among the drugs currently available or under investigation is their pharmacokinetics and the exposure time to the GLP-1 receptor.

**Mechanism of Action.** All GLP-1 receptor agonists share a common mechanism, activation of the GLP-1 receptor. GLP-1 receptors are expressed by β cells, cells in the peripheral and central nervous system, the heart and vasculature, kidney, lung, and GI mucosa. Binding of agonists to the GLP-1 receptor activates the cAMP-PKA pathway and several GEFs (guanine nucleotide exchange factors) (Drucker, 2006). GLP-1 receptor activation also initiates signals through PKC and PI3K, and it alters the activity of several ion channels. In β cells, the end result of these actions is increased insulin biosynthesis and exocytosis in a glucose-dependent manner (Figure 43-3).

**Absorption, Distribution, Metabolism, Excretion, and Dosing.** Exenatide is given as a subcutaneous injection twice daily, typically before meals. Exenatide is rapidly absorbed, reaches peak concentrations in ~2 hours, undergoes little metabolism in the circulation, and has a volume of distribution of nearly 30 L. Clearance of the drug occurs primarily by glomerular filtration, with tubular proteolysis and minimal reabsorption. Exenatide is marketed as a pen that delivers 5 or 10 μg; dosing is typically started at the lower amount and increased as the response to therapy warrants.

Liraglutide is given as a subcutaneous injection once daily. Peak levels occur in 8-12 hours and the elimination $t_{1/2}$ is 12-14 hours. There is little renal or intestinal excretion of liraglutide, and clearance is primarily through the metabolic pathways of large plasma proteins. Liraglutide is supplied in a pen injector that delivers 0.6, 1.2, or 1.8 mg of drug; the low dose is for treatment initiation and generally advanced to the two higher doses based on clinical response.

**Adverse Effects and Drug Interactions.** The side effects of GLP-1 receptor agonists mimic the pharmacology of native GLP-1. Intravenous or subcutaneous administration of GLP-1 causes nausea and vomiting in a dose-dependent manner; the doses above which GLP-1 causes GI side effects are higher than those needed to regulate blood glucose. Despite this therapeutic window that minimizes adverse effects, nausea, vomiting, and other problems related to GI function are common with these drugs. Based on data from clinical trials, up to 40-50% of subjects given a GLP-1 receptor agonist report nausea at the initiation of therapy. Because the GI side effects of these drugs wane over time, most affected patients are able to continue a course of therapy. The activation of the GLP-1 receptor can delay gastric emptying; thus exenatide and other drugs of this class should be used with caution with other compounds that affect gastric emptying. Moreover, GLP-1 agonists may alter the pharmacokinetics of drugs that require rapid GI absorption, such as oral contraceptives and antibiotics.

In the absence of other diabetes drugs that cause low blood glucose, hypoglycemia associated with GLP-1 agonist treatment is rare. The combination of exenatide or liraglutide with sulfonylurea drugs causes an increased rate of hypoglycemia compared to sulfonylurea treatment alone. Because of the high degree of renal clearance, exenatide should not be given to persons with moderate to severe renal failure (creatinine clearance <30 mL/minute). There is no current recommendation for dose adjustments of other GLP-1 receptor agonists for decreased renal function. Exenatide has also been rarely associated with acute renal failure. Based on surveillance data, there is a possible association of exenatide treatment with pancreatitis, including fatal and nonfatal hemorrhagic or necrotizing pancreatitis. There is currently no mechanism to explain this association, and cases linking exenatide to pancreatitis are rare.
DPP-4 inhibitors

**Mechanism of Action.** DPP-4 is a serine protease that is widely distributed throughout the body, expressed as an ectoenzyme on endothelial cells, on the surface of T-lymphocytes, and in a circulating form. DPP-4 cleaves the two N-terminal amino acids from peptides with a proline or alanine in the second position. Although there are many potential substrates for this enzyme, it seems to be especially critical for the inactivation of GLP-1 and GIP (glucose-dependent insulinotropic polypeptide; gastric inhibitory peptide) (Drucker, 2007). DPP-4 inhibitors increase the AUC of GLP-1 and GIP when their secretion is by a meal (Figure 43-10).

**Dosage Forms.** Several agents provide nearly complete and long-lasting inhibition of DPP-4, thereby increasing the proportion of active GLP-1 from 10-20% of total circulating GLP-1 immunoreactivity to nearly 100%. Two of these, sitagliptin (JANUVIA) and saxagliptin (ONGLYZA), are now available in the U.S.; a third, vildagliptin, is available in the E.U.; a fourth compound, alogliptin, is in advanced stages of clinical trials. Sitagliptin and alogliptin are competitive inhibitors of DPP-4, whereas vildagliptin and saxagliptin bind the enzyme covalently. Despite these differences, all four drugs can be given in doses that lower measurable activity of DPP-4 by >95% for 12 hours. This causes a greater than 2-fold elevation of plasma concentrations of active GIP and GLP-1 and is associated with increased insulin secretion, reduced glucagon levels, and improvements in both fasting and postprandial hyperglycemia. Inhibition of DPP-4 does not appear to have direct effects on insulin sensitivity, gastric motility, or satiety, nor does chronic treatment with DPP-4 inhibitors affect body weight. DPP-4 inhibitors, used as monotherapy in type 2 diabetic patients, reduced HbA1c levels by an average ~0.8%. These compounds are also effective in diabetes patients receiving metformin, thiazolidinediones, sulfonylureas, and insulin. The effects of DPP-4 inhibitors in combination regimens appear to be additive. The recommended dose of sitagliptin is 100 mg once daily. The recommended dose of saxagliptin is 5 mg once daily.

**Absorption, Distribution, Metabolism, and Excretion.** DPP-4 inhibitors are absorbed effectively from the small intestine. They circulate in primarily unbound form and are excreted mostly unchanged in the urine. DPP-4 inhibitors do not bind to albumin, nor do they affect the hepatic cytochrome oxidase system. Both sitagliptin and saxagliptin are excreted renally, and lower doses should be used in patients with reduced renal function. Sitagliptin has minimal metabolism by hepatic microsomal enzymes. Saxagliptin is metabolized by CYP 3A4/5 to an active metabolite. The dose saxagliptin should be lowered to 2.5 mg daily when co-administered with strong CYP3A4 inhibitors (e.g., ketoconazole, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, neflinavir, ritonavir, saquinavir, and telithromycin).

**Adverse Effects and Drug Interactions.** There are no consistent adverse effects that have been noted in clinical trials with any of the DPP-4 inhibitors. With few exceptions the incidence of adverse effects in drug-treated and placebo-treated patients has been similar. DPP-4 is expressed on lymphocytes; in the immunology literature, the enzyme is referred to as CD26. Although there is some evidence of minor effects on in vitro lymphocyte function with DPP-4 inhibitors, there is no evidence from clinical studies of major adverse effects in humans. This area bears scrutiny as more patients are treated with these compounds.

---

**OTHER HYPOGLYCEMIC AGENTS**

**Alpha Glucosidase Inhibitors**

**Mechanism of Action.** α-Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α-glucosidase in the intestinal brush border. Inhibition of this enzyme slows the absorption of carbohydrates from the GI tract and blunts the rate of rise of postprandial plasma glucose. These drugs also increase the release of the glucoregulatory hormone GLP-1 into the circulation, which may contribute to their glucose-lowering effects.

**Dosage Forms.** The drugs in this class are acarbose (PRECOSE, others), miglitol (GLYSET), and voglibose; only acarbose and miglitol are available in the U.S. Dosing of acarbose and miglitol is similar. Both are provided as 25, 50, or 100 mg tablets that are taken before meals. It is recommended that treatment start with lower doses and be titrated as indicated by balancing postprandial glucose, A1C, and GI symptoms. Acarbose and miglitol are most effective when given with a starchy, high-fiber diet with restricted amounts of glucose and sucrose.

**Absorption, Distribution, Metabolism, Excretion, and Dosing.** Acarbose is minimally absorbed and the small amount of drug reaching the systemic circulation is cleared by the kidney. Miglitol absorption is saturable, with 50-100% of any dose taken into the circulation. Miglitol is cleared almost entirely by the kidney, and dose reductions are recommended for patients with creatinine clearance <30 mL/minute.

**Adverse Effects and Drug Interactions.** The most prominent adverse effects related to α-glucosidase inhibitors are malabsorption, flatulence, diarrhea, and abdominal bloating. These side effects are dose dependent and related to the mechanism of action of the drugs, with greater amounts of carbohydrate available in the lower intestinal tract for metabolism by bacteria. Mild to moderate elevations of hepatic transaminases have been reported with acarbose, but asymptomatic liver disease is very rare. Cutaneous hypersensitivity has been described but is also rare. α-Glucosidase inhibitors do not stimulate insulin release and therefore do not result in hypoglycemia when given alone. Hypoglycemia has been described when α-glucosidase inhibitors are added to insulin or an insulin secretagogue. For hypoglycemia in the setting of α-glucosidase use, glucose rather than sucrose or more complex carbohydrates should be used for treatment. Acarbose can decrease the absorption of digoxin and miglitol can decrease the absorption of propranolol and ranitidine. Alpha glucosidase inhibitors are contraindicated in patients with stage 4 renal failure.
Therapeutic Uses. \(\alpha\)-Glucosidase inhibitors are indicated as adjuncts to diet and exercise in type 2 diabetic patients not reaching glycemic targets. They can also be used in combination with other oral antidiabetic agents and/or insulin. In clinical studies \(\alpha\)-glucosidase inhibitors reduce A1C by 0.5-0.8\%, fasting glucose by \(\sim\)1 mM and postprandial glucose by 2.0-2.5 mM. These agents do not cause weight gain or have significant effects on plasma lipids. \(\alpha\)-Glucosidase inhibitors have been demonstrated to reduce the progression from impaired glucose tolerance to type 2 diabetes.

Pramlintide

Mechanism of Action. Islet amyloid polypeptide (amylin), is a 37–amino acid peptide produced in the pancreatic \(\beta\) cell and secreted with insulin. A synthetic form of amylin with several amino acid modifications to improve bioavailability, pramlintide (SYMLIN), has been developed as a drug for the treatment of diabetes (Hoogwerf et al., 2008). It is thought to modulate its actions through specific binding to the amylin receptor in specific regions of the hindbrain. Activation of the amylin receptor cause reductions in glucagon release, delayed gastric emptying, and satiety.

Absorption, Distribution, Metabolism, Excretion, and Dosing. Pramlintide is administered as a subcutaneous injection prior to meals. Pramlintide is not extensively bound by plasma proteins and has a \(t_{1/2}\) of 50 minutes. Metabolism and clearance is primarily by the kidney. The doses in patients with type 1 diabetes start at 15 \(\mu\)g and are titrated upward to a maximum of 60 \(\mu\)g; in type 2 diabetes the starting dose is 60 \(\mu\)g and the maximum is 120 \(\mu\)g. Because of differences in the pH of the solution, pramlintide should not be administered in the same syringe as insulin.

Adverse Effects and Drug Interactions. The most common adverse events associated with pramlintide therapy are nausea and hypoglycemia. Although pramlintide alone does not lower blood glucose, addition to insulin at mealtimes has been noted to cause increased rates of hypoglycemia, occasionally severe. It is currently recommended that prandial insulin doses by reduced 30-50% at the time of pramlintide initiation and then titrated. Because of its effects on GI motility, pramlintide is contraindicated in patients with gastrointestinal or other disorders of motility. Because pramlintide can delay gastric emptying, it should be used with caution when combined with other compounds that affect GI motility. Moreover, the pharmacokinetics of drugs that require rapid GI absorption may be altered. Pramlintide is a pregnancy Category C drug. Pramlintide can be used in persons with moderaterenal disease (creatinine clearance >20 mL/minute).

Therapeutic Uses. Pramlintide is approved for treatment of types 1 and 2 diabetes as an adjunct in patients who take insulin with meals. In clinical trials of type 2 diabetic subjects, pramlintide reduced A1C by 0.5\%, lowered insulin requirements, and caused weight loss of 1.0-2.5 kg over 3-6 months. Results in studies of type 1 diabetic subjects were similar, with reductions in A1C of 0.3-0.5\%, weight loss of 1-2 kg, and insulin sparing. Pramlintide is now being evaluated as a drug for weight loss in nondiabetic persons.

Bile Acid Binding Resins

Mechanism of Action. Bile acid metabolism is abnormal in patients with type 2 diabetes, and there have been intermittent reports that bile acid binding resins lower plasma glucose in diabetic patients. The mechanism by which bile acid binding and removal from enterohepatic circulation lowers blood glucose has not been established. Bile acid sequestrants could reduce intestinal glucose absorption, although there is no direct evidence of this. Bile acids also act as signaling molecules through nuclear receptors, some of which may act as glucose sensors. The only bile acid sequestrant specifically approved for the treatment of type 2 diabetes is colesevelam (WELCHOL); other bile acid sequestrants likely are also effective.

Absorption, Distribution, Metabolism and Excretion. Colesevelam is provided as a powder for oral solution and as 625-mg tablets; typical usage is three tablets twice a day before lunch and dinner or six tablets prior to the patient’s largest meal. The drug is absorbed from the intestinal tract only in trace amounts, so that its distribution is limited to the GI tract.

Adverse Effects and Drug Interactions. The most common side effects of colesevelam are gastrointestinal, with constipation, dyspepsia, abdominal pain, and nausea affecting up to 10\% of treated patients. Intestinal obstruction has been reported in persons with previous intestinal surgery or obstruction. Like other bile acid binding resins, colesevelam can increase plasma triglycerides in persons with an inherent tendency to hypertriglyceridemia. In ~400 patient-year exposures in clinical trials, plasma triglycerides in treated patients did not exceed 1000 mg/dL, and no associated pancreatitis was documented; nonetheless, colesevelam should be used cautiously in patients with plasma triglycerides >200 mg/dL. Colesevelam has no effects on systemic drug metabolism but can interfere with the absorption of commonly used drugs like phenytoin, warfarin, verapamil, glyburide, L-thyroxine, and ethinyl estradiol; these medications should be given 4 hours prior to colesevelam. The drug may also interfere with the absorption of fat-soluble vitamins. Colesevelam is a pregnancy Category B drug that has no contraindications in patients with renal or liver disease.

Therapeutic Uses. The bile acid binding resin colesevelam, approved for treatment of hypercholesterolemia, may be used for treatment of type 2 diabetes as an adjunct to diet and exercise (Sonnett et al., 2009). In clinical trials, colesevelam reduced A1C by 0.5\% when added to metformin, sulfonylurea, or insulin treatment in type 2 diabetic patients. A new bile acid binding resin, col-
Hormones and Hormone Antagonists

SECTION V

Drugs in Development for Type 2 Diabetes. Inhibitors of the sodium glucose co-transporter 2 (SGLT2) are designed to reduce hyperglycemia by increasing urinary clearance of glucose. SGLT2 is expressed in the proximal renal tubule and functions to reabsorb filtered glucose from the tubule lumen to epithelial cells; glucose subsequently is returned to the circulation through the actions of the glucose transporters 1 and 2. SGLT2 is a low-affinity, high-capacity co-transporter that shuttles sodium and glucose in a 1:1 ratio and accounts for most of the recovery of filtered glucose in the nephron; SGLT1 located in the distal tubule plays a lesser role. Loss-of-function mutations in SGLT2 cause glucosuria. There are several orally available, highly specific SGLT2 inhibitors in clinical development. These compounds cause urinary losses of 50-100 g per day of glucose in the urine, reduce fasting glucose by 0.5-2.0 mM, lower A1C by 0.5-1.0%, and cause modest amounts of weight loss. In clinical trials, SGLT2 inhibitors have been generally well tolerated. There is a mild diuretic effect, rare instances of hypoglycemia, and a slight increase in urinary tract infection, including genital infections. Although there are yet no specific indications with this class of drugs, the novel mechanism, the general action to reduce glyceria in proportion to plasma levels and the blockade of reuptake of renally filtered solute, raise the possibility that SGLT2 inhibitors could have application as adjuncts to a wide range of other diabetes therapies.

Emerging Therapies for Diabetes

A number of immunomodulatory approaches are being investigated to prevent or block the autoimmune process that is central to type 1 diabetes. Interventions with immune modifying agents, such as monoclonal antibodies against the lymphocyte receptors CD3, CD20 and CD 25, and immunosuppressant mycophenolate (Chapter 35), are currently ongoing. The use of immunosuppressive agents, such as cyclosporine, glucocorticoids and azathioprine, has been tested in small numbers of patients with new-onset type 1 diabetes. Although some of these studies have demonstrated that immunosuppression can slow β cell loss, this approach has not been widely accepted because of the acute and long-term toxicities of these drugs.

Combined Pharmacological Approaches to Type 2 Diabetes

Progressive Management of Type 2 Diabetes

There are several useful algorithms or flow charts for the treatment of type 2 diabetes (Figure 43–11; Nathan et al., 2009). There are a number of pathways or combination of drugs that are used for treatment of type 2 diabetes if the glucose control does not reach the therapeutic target (Inzucchi,2002; Monami et al., 2008). For example, the addition of a second oral agent, such as an insulin sensitizer, either alone or in combination with an oral insulin secretagogue, also may provide good therapeutic results. Another approach is to introduce basal insulin (often at bedtime) in combination with oral hypoglycemic agents. This combination allows the oral agents to provide postprandial glycemic control while the basal insulin provides the foundation for normalizing fasting or basal glucose levels. Insulin can be combined with various oral antihyperglycemic agents. Combination of glargine with sulfonylureas and/or metformin can reduce both fasting (basal) and postprandial glucose levels. The exact combination of therapies can be guided by an estimation of the β cell secretory reserve in each patient (i.e., a measurement of circulating C peptide level). The progressive insulin deficiency in type 2 diabetes often makes it increasingly difficult to achieve tight glycemic control solely with oral antihyperglycemic agents (Bretzel et al., 2008; Lasserson et al., 2009). Table 43-9 summarizes available pharmacological agents for the treatment of diabetes.
relatively low affinity for glucose, the GK activators have muted action at fasting glycemia and a low risk for inducing hypoglycemia. In early phases of clinical trial, GK activators seem to lower blood glucose in diabetic humans.

The enzyme $^{11}\beta$-hydroxysteroid dehydrogenase 1 ($^{11}\beta$-HSD1) is expressed in the liver, adipose tissue, and skeletal muscle. $^{11}\beta$-HSD1 converts inactive cortisone into the active glucocorticoid cortisol (Figure 42-6). Cortisol plays an important role in normal counterregulation of insulin action, but excess activity is associated with weight gain, visceral adiposity, insulin resistance, inefficient proinsulin processing, and hyperglycemia. This has led to the strategy of inhibition of $^{11}\beta$-HSD1 to reduce cortisol levels in the visceral and splanchnic beds, potentially increasing insulin sensitivity and glucose metabolism. Potent, orally available, selective inhibitors of $^{11}\beta$-HSD1 that can inhibit the enzyme in liver and adipose tissue are under investigation. Inhibition of $^{11}\beta$-HSD1 improves glycemic control, insulin sensitivity, and total cholesterol in patients with type 2 diabetes.

Several intracellular enzymes serve as nutrient sensors, including SIRT1, AMPK, DGAT1, and ACC2. Compounds that stimulate the activities of these enzymes have the potential to increase glucose utilization, alter fatty acid metabolism, and increase energy expenditure, potentially resulting in improvements of both glucose and lipid metabolism as well as a decrease in body weight. A SIRT1 activator, resveratrol, has been reported to decrease glucose and insulin levels and improve glucose tolerance in subjects with type 2 diabetes. Activators of other peripheral nutrient sensors are in development.

**HYPOGLYCEMIA**

During prolonged fasting, the blood glucose levels may drop to 3-4 mM in healthy persons with no symptoms of hypoglycemia due to gradual shifts in fuel metabolism to increase the percentage of energy derived from stored lipids. In the absence of prolonged fasting, healthy humans almost never have blood glucose levels <3.5 mM (Cryer, 2008; Cryer et al., 2009). This is due to a highly adapted neuroendocrine counterregulatory

system that prevents acute hypoglycemia, a hazardous and potentially lethal situation. The two major clinical scenarios for hypoglycemia are:

- treatment of diabetes
- inappropriate production of endogenous insulin or an insulin-like substance by a pancreatic islet tumor (insulinoma) or a non-islet tumor

Hypoglycemia in the first scenario can occur either in the fasting or fed state, whereas in the second scenario, hypoglycemia occurs almost exclusively in the fasting or postabsorptive state. Some drugs not used for the treatment of diabetes promote hypoglycemia (Table 43–3; Murad et al., 2009). After a brief discussion of the physiological responses to hypoglycemia, agents used to treat hypoglycemia are discussed.

The most common and serious adverse event related to diabetes therapy is hypoglycemia. Although an adverse reaction to a number of oral therapies, it is most pronounced and serious with insulin therapy. Hypoglycemia may result from an inappropriately large dose, from a mismatch between the time of peak delivery of insulin and food intake, or from superimposition of additional factors that increase sensitivity to insulin (e.g., adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (e.g., exercise). The more vigorous the attempt to achieve euglycemia, the more frequent are the episodes of hypoglycemia (Cryer, 2008; Heller, 2008). In the Diabetes Control and Complications Trial, the incidence of severe hypoglycemic reactions was three times higher in the intensive insulin therapy group than in the conventional therapy group. Milder but significant hypoglycemic episodes were much more common than were severe reactions, and their frequency also increased with intensive therapy. Hypoglycemia is the major risk that always must be weighed against benefits of efforts to normalize glucose control.

There is a hierarchy of physiological responses to hypoglycemia. The first response is a reduction of endogenous insulin secretion, which occurs at a plasma glucose level of ~70 mg/dL (3.9 mM); thereafter, the counter-regulatory hormones—epinephrine, glucagon, growth hormone, cortisol, and norepinephrine—are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60-80 mg/dL (3.3-4.4 mM). Sweating, hunger, glucagon, growth hormone, cortisol, and norepinephrine—are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60-80 mg/dL (3.3-4.4 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (i.e., most important neuroglycopenic symptoms) usually occur at lower plasma glucose levels than do autonomic symptoms.

Glucagon and epinephrine are the most important counter-regulatory hormones in acute hypoglycemia in newly diagnosed diabetes patients and normal subjects. In patients with type 1 and type 2 diabetes of longer duration, the glucagon secretory response to hypoglycemia becomes deficient, but effective glucose counter-regulation still occurs because epinephrine plays a compensatory role. Diabetic patients thus become dependent on epinephrine for counter-regulation, and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases. This occurs in patients with diabetes of long duration who may also have autonomic neuropathy. The absence of both glucagon and epinephrine can lead to prolonged hypoglycemia, particularly during the night, when some individuals can have extremely low plasma glucose levels for several hours. Severe hypoglycemia can lead to convulsions and coma. In addition to autonomic neuropathy, several related syndromes of defective counter-regulation contribute to the increased incidence of severe hypoglycemia in intensively treated type 1 diabetes patients. These include hypoglycemic unawareness, altered thresholds for release of counter-regulatory hormones, and deficient secretion of counter-regulatory hormones. With the ready availability of home glucose monitoring, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect but should be suspected from a history of morning headaches, night sweats, or symptoms of hypothermia.

All diabetic patients who receive insulin or oral agents that can cause hypoglycemia should be aware of the symptoms of hypoglycemia, carry some form of easily ingested glucose, and carry an identification card or bracelet containing pertinent medical information. When possible, patients who suspect that they are experiencing hypoglycemia should document the glucose concentration with a measurement. Mild-to-moderate hypoglycemia may be treated simply by ingestion of glucose (15 g of carbohydrate). When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon (Figure 43–10).

Agents Used to Treat Hypoglycemia

Glucagon is a single-chain polypeptide of 29 amino acids and is produced by recombinant DNA technology. Glucagon interacts with a GPCR on the plasma membrane of target cells that signals through Gs. The primary effects of glucagon on the liver are mediated by cAMP. Glucagon is used to treat severe hypoglycemia, particularly in diabetic patients when the patient cannot safely consume oral glucose and intravenous glucose is not available (Figure 43–12). For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously, usually by the patient’s family member, who must be trained to administer this.

The intramuscular route is preferred in such an emergency. The hyperglycemic action of glucagon is transient and may be inadequate if hepatic stores of glycogen are depleted. After the initial response to glucagon, patients should be given glucose or urged to eat to prevent recurrent hypoglycemia. Glucagon also is sometimes used to relax the intestinal tract to facilitate radiographic examination of the upper and lower gastrointestinal tract with barium and retrograde ileography and in magnetic resonance imaging of the gastrointestinal tract. Nausea and vomiting are the most frequent adverse effects.

Diazoxide (PROGLYCEM) is an antihypertensive, diuretic benzothiadiazine derivative with potent hyperglycemic actions when given orally. Hyperglycemia
results primarily from inhibition of insulin secretion. Diazoxide interacts with the K_\text{ATP} channel on the β cell membrane and either prevents its closing or prolongs the open state; this effect is opposite to that of the sulfonylureas (Figure 43–3). Diazoxide has been used to treat patients with various forms of chronic or recurring hypoglycemia.

The usual oral dose is 3-8 mg/kg per day in adults and children and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide circulates largely bound to plasma proteins and has a \( t_{1/2} \) of ~48 hours. Thus the patient should be maintained at the chosen dosage for several days before evaluating the therapeutic result. Diazoxide has a number of adverse effects, including retention of Na\(^+\) and fluid, hyperuricemia, hypertrichosis (especially in children), thrombocytopenia, and leucopenia, which sometimes limit its use. Despite these side effects, the drug may be useful in patients with inoperable insulinomas and in children with neonatal hyperinsulinism (leucine sensitivity, islet cell hyperplasia, nesidioblastosis, extrapancreatic malignancy, or islet cell adenoma).

**OTHER PANCREATIC ISLET HORMONES**

Somatostatin was identified as an inhibitor of GH secretion from the pituitary. Somatostatin (SST) is produced by δ cells of the pancreatic islet, cells of the GI tract, and in the CNS. Somatostatin, produced as a 14–amino acid or a 28–aminoacid peptide molecule, acts through a family of five GPCRs, SSTR\(_{1-5}\). SST inhibits a wide variety of endocrine and exocrine secretions, including TSH and GH from the pituitary, gastrin, motilin, VIP, glicentin, and insulin, glucagon, and pancreatic polypeptide from the pancreatic islet. The physiological role of somatostatin has not been defined precisely, but its short \( t_{1/2} \) (3-6 minutes) prevents its use therapeutically. Longer-acting analogs such as octreotide (SANDOSTATIN) and lanreotide (SOMATULINE) are useful for treatment of carcinoid tumors, glucagonomas, VIPomas, and acromegaly (Chapter 38).

A depot form of octreotide or lanreotide can be administered intramuscularly every 4 weeks. Octreotide or lanreotide successfully controls excess secretion of growth hormone in most patients, and both have been reported to reduce the size of pituitary tumors in about one-third of cases. Octreotide has been used to treat severe hypoglycemia related to sulfonlurea ingestion (Cryer et al., 2009). Because octreotide also can decrease blood flow to the GI tract, it has been used to treat bleeding esophageal varices, peptic ulcers, and postprandial orthostatic hypotension. Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the somatostatin analogs, as do GI symptoms. Hypoglycemia, hyperglycemia, hypothyroidism, and goiter have been reported in patients being treated with somatostatin analogs for acromegaly.

**BIBLIOGRAPHY**

To understand why, when, and how to employ pharmacological agents that affect mineral ion homeostasis, one must first understand some basic physiology and pathophysiology of the subject. This chapter presents a primer on mineral ion homeostasis and the endocrinology of Ca\(^{2+}\) and phosphate metabolism, then some relevant pathophysiology, and, finally, pharmacotherapeutic options in treating disorders of mineral ion homeostasis.

**PHYSIOLOGY OF MINERAL ION HOMEOSTASIS**

**Calcium**

Elemental calcium is essential for a variety of micromolecular and macroscopic biological functions. Its ionized form, Ca\(^{2+}\), is an important component of current flow across excitable membranes. Ca\(^{2+}\) is vital for muscle contraction, fusion, and release of storage vesicles. In the submicromolar range, intracellular Ca\(^{2+}\) acts as a critical second messenger (Chapter 3). In extracellular fluid, millimolar concentrations of calcium promote blood coagulation and support the formation and continuous remodeling of the skeleton.

Ca\(^{2+}\) has an adaptable coordination sphere that facilitates binding to the irregular geometry of proteins. The capacity of an ion to cross-link two proteins requires a high coordination number, which dictates the number of electron pairs that can be formed and generally is six to eight for Ca\(^{2+}\). Unlike disulfide or sugar–peptide cross-links, Ca\(^{2+}\) linking is readily reversible. Cross-linking of structural proteins in bone matrix is enhanced by the relatively high extracellular concentration of calcium.

In the face of millimolar extracellular Ca\(^{2+}\), intracellular free Ca\(^{2+}\) is maintained at a low level, ~100 nM in cells in their basal state, by active extrusion by Ca\(^{2+}\)–ATPases and by Na\(^+\)/Ca\(^{2+}\) exchange. As a consequence, changes in cytosolic Ca\(^{2+}\) (whether released from intracellular stores or entering via membrane Ca\(^{2+}\) channels) can modulate effector targets, often by interacting with the Ca\(^{2+}\)-binding protein calmodulin. The rapid association–dissociation kinetics of Ca\(^{2+}\) and the relatively high affinity and selectivity of Ca\(^{2+}\)-binding domains permit effective regulation of Ca\(^{2+}\) over the 100 nM to 1 \(\mu\)M range.

The body content of calcium in healthy adult men and women, respectively, is ~1300 and 1000 g, of which >99% is in bone and teeth. Ca\(^{2+}\) is the major extracellular divalent cation. Although the portion of calcium in extracellular fluids is small, this fraction is stringently regulated within narrow limits. In adult humans, the normal serum calcium concentration ranges from 8.5–10.4 mg/dL (4.25–5.2 mEq/L, 2.1–2.6 mM) and includes three distinct chemical forms of Ca\(^{2+}\): ionized (50%), protein-bound (40%), and complexed (10%). Thus, whereas total plasma calcium concentration is ~2.54 mM, the concentration of ionized Ca\(^{2+}\) in human plasma is ~1.2 mM.

The various pools of calcium are illustrated schematically in Figure 44–1. Only diffusible calcium (i.e., ionized plus complexed) can cross cell membranes. Albumin accounts for some 90% of the serum calcium bound to plasma proteins. Smaller percentages are bound, albeit with greater affinity, to β-globulin, α\(_2\)-globulin, α\(_1\)-globulin, and γ-globulin. The remaining 10% of the serum calcium is complexed in ion pairs with small polyvalent anions, primarily phosphate and citrate. The degree of complex formation depends on the ambient pH and the concentrations of ionized calcium and complexing anions. Ionized Ca\(^{2+}\) is the physiologically relevant component, mediates calcium’s biological effects, and, when perturbed, produces the characteristic signs and symptoms of hypo- or hypercalcemia.
The total plasma calcium concentration can be interpreted only by correcting for the concentration of plasma proteins. A change of plasma albumin concentration of 1.0 g/dL from the normal value of 4.0 g/dL can be expected to alter total calcium concentration by ~0.8 mg/dL.

The extracellular Ca$^{2+}$ concentration is tightly controlled by hormones that affect calcium entry at the intestine and its exit at the kidney; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

**Calcium Stores.** The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite [Ca$_{10}$(PO$_4$)$_6$(OH)$_2$]; other ions, including Na$^+$, K$^+$, Mg$^{2+}$, and F$^-$, also are present in the crystal lattice. The steady-state content of calcium in bone reflects the net effect of bone resorption and bone formation, coupled with aspects of bone remodeling. In addition, a labile pool of bone Ca$^{2+}$ exchanges readily with interstitial fluid. This exchange is modulated by hormones, vitamins, drugs, and other factors that directly alter bone turnover or that influence the Ca$^{2+}$ level in interstitial fluid.

**Calcium Absorption and Excretion.** In the U.S., ~75% of dietary calcium is obtained from milk and dairy products. The adequate intake value for calcium is 1300 mg/day in adolescents and 1000 mg/day in adults. After age 50, the adequate intake is 1200 mg/day. This contrasts with median intakes of calcium for boys and girls ≥9 years of age of 865 and 625 mg, respectively, and a median daily calcium intake of 517 mg for women >50 years of age.

The total plasma calcium concentration can be interpreted only by correcting for the concentration of plasma proteins. A change of plasma albumin concentration of 1.0 g/dL from the normal value of 4.0 g/dL can be expected to alter total calcium concentration by ~0.8 mg/dL.

The extracellular Ca$^{2+}$ concentration is tightly controlled by hormones that affect calcium entry at the intestine and its exit at the kidney; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

**Calcium Stores.** The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite [Ca$_{10}$(PO$_4$)$_6$(OH)$_2$]; other ions, including Na$^+$, K$^+$, Mg$^{2+}$, and F$^-$, also are present in the crystal lattice. The steady-state content of calcium in bone reflects the net effect of bone resorption and bone formation, coupled with aspects of bone remodeling. In addition, a labile pool of bone Ca$^{2+}$ exchanges readily with interstitial fluid. This exchange is modulated by hormones, vitamins, drugs, and other factors that directly alter bone turnover or that influence the Ca$^{2+}$ level in interstitial fluid.

**Calcium Absorption and Excretion.** In the U.S., ~75% of dietary calcium is obtained from milk and dairy products. The adequate intake value for calcium is 1300 mg/day in adolescents and 1000 mg/day in adults. After age 50, the adequate intake is 1200 mg/day. This contrasts with median intakes of calcium for boys and girls ≥9 years of age of 865 and 625 mg, respectively, and a median daily calcium intake of 517 mg for women >50 years of age.

The efficiency of intestinal Ca$^{2+}$ absorption is inversely related to calcium intake. Thus, a diet low in calcium leads to a compensatory increase in fractional absorption owing partly to activation of vitamin D. In older persons, this response is considerably less robust. Disease states associated with steatorrhea, diarrhea, or chronic malabsorption promote fecal loss of calcium, whereas drugs such as glucocorticoids and phenytoin depress intestinal Ca$^{2+}$ transport.

Urinary Ca$^{2+}$ excretion is the net difference between the quantity filtered at the glomerulus and the amount reabsorbed. About 9 g of Ca$^{2+}$ are filtered each day. Tubular reabsorption is very efficient, with >98% of filtered Ca$^{2+}$ returned to the circulation. The efficiency of reabsorption is highly regulated by parathyroid hormone (PTH) but also is influenced by filtered Na$^+$, the presence of nonreabsorbed anions, and diuretic agents (Chapter 25). Sodium intake, and therefore sodium excretion, is directly related to urinary calcium excretion. Diuretics that act on the ascending limb of the loop of Henle (e.g., furosemide) increase calcium excretion. By contrast, thiazide diuretics uncouple the relationship between Na$^+$ and Ca$^{2+}$ excretion, increasing sodium excretion but diminishing calcium excretion (Friedman and Bushinsky, 1999). Urine Ca$^{2+}$ excretion is a direct function of dietary protein intake, presumably owing to the effect of sulfur-containing amino acids on renal tubular function.
Phosphate

Phosphate is an essential component of all body tissues, present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone tissue. More than 80% of total body phosphorus is found in bone, and ~15% is in soft tissue. Additionally, phosphate subserves roles as a dynamic constituent of intermediary and energy metabolism and as a key regulator of enzyme activity when transferred by protein kinases from ATP to phosphorylatable serine, threonine, and tyrosine residues.

Biologically, phosphorus (P) exists in both organic and inorganic (P\textsubscript{i}) forms. Organic forms include phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus is present as inorganic phosphate in the form of Na\textsubscript{2}HPO\textsubscript{4} and Na\textsubscript{2}HPO\textsubscript{4}; at pH 7.4, the ratio of disodium to monosodium phosphate is 4:1, so plasma phosphate has an intermediate valence of 1.8. Owing to its relatively low concentration in extracellular fluid, phosphate contributes little to buffering capacity. The aggregate level of inorganic phosphate (P\textsubscript{i}) modifies tissue concentrations of Ca\textsuperscript{2+} and plays a major role in renal H\textsuperscript{+} excretion. Within bone, phosphate is complexed with calcium as hydroxyapatites having the general formula Ca\textsubscript{10}(PO\textsubscript{4})\textsubscript{6}(OH)\textsubscript{2} and as calcium phosphate.

Absorption, Distribution, and Excretion. Phosphate is absorbed from and, to a limited extent, secreted into the GI tract. Phosphate is a ubiquitous component of ordinary foods; thus even an inadequate diet rarely causes phosphate depletion. Transport of phosphate from the intestinal lumen is an active, energy-dependent process that is regulated by several factors, primarily vitamin D, which stimulates absorption. In adults, about two-thirds of ingested phosphate is absorbed and is excreted almost entirely into the urine. In growing children, phosphate balance is positive, and plasma concentrations of phosphate are higher than in adults.

Phosphate excretion in the urine represents the difference between the amount filtered and that reabsorbed. More than 90% of plasma phosphate is freely filtered at the glomerulus, and 80% is actively reabsorbed, predominantly in the initial segment of the proximal convoluted tubule but also in the proximal straight tubule (pars recta). Renal phosphate absorption is regulated by a variety of hormones and other factors; the most important are PTH and dietary phosphate, with extracellular volume and acid–base status playing lesser roles. Dietary phosphate deficiency upregulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of any effect on plasma P\textsubscript{i}, Ca\textsuperscript{2+}, or PTH. PTH increases urinary phosphate excretion by blocking phosphate absorption. Expansion of plasma volume increases urinary phosphate excretion. Effects of vitamin D and its metabolites on proximal tubular phosphate are modest at best.

Role of Phosphate in Urine Acidification. Despite the fact that the concentration and buffering capacity of phosphate in extracellular fluid are low, phosphate is concentrated progressively in the renal tubule and becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H\textsuperscript{+} and Na\textsuperscript{+} in the tubular urine converts disodium hydrogen phosphate (Na\textsubscript{2}HPO\textsubscript{4}) to sodium dihydrogen phosphate (NaH\textsubscript{2}PO\textsubscript{4}), permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H\textsuperscript{+} transport.

Actions of Phosphate. If large amounts of phosphate are introduced into the GI tract by oral administration or enema, a cathartic action will result. Thus, phosphate salts are employed as mild laxatives (Chapter 46). If excessive phosphate salts are introduced either intravenously or orally, they may reduce the concentration of Ca\textsuperscript{2+} in the circulation and induce precipitation of calcium phosphate in soft tissues.

HORMONAL REGULATION OF CALCIUM AND PHOSPHATE HOMEOSTASIS

A number of hormones interact to regulate extracellular calcium and phosphate balance. The most important are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (calcitriol), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 44–3).
**Parathyroid Hormone**

Parathyroid hormone (PTH) is a polypeptide hormone that helps to regulate plasma Ca\(^{2+}\) by affecting bone resorption/formation, renal Ca\(^{2+}\) excretion/reabsorption, and calcitriol synthesis (thus GI Ca\(^{2+}\) absorption).

**History.** Sir Richard Owen, the curator of the British Museum of Natural History, discovered the parathyroid glands in 1852 while dissecting a rhinoceros that had died in the London Zoo. Credit for discovery of the human parathyroid glands usually is given to Sandstrom, a Swedish medical student who published an anatomical report in 1890. In 1891, von Recklinghausen reported a new bone disease, which he termed “osteitis fibrosa cystica,” which Askany subsequently described in a patient with a parathyroid tumor in 1904. The glands were rediscovered a decade later by Gley, who determined the effects of their extirpation with the thyroid. Vassalle and Generali then successfully removed only the parathyroids and noted that tetany, convulsions, and death quickly followed unless calcium was given postoperatively.

MacCallum and Voegtlin first noted the effect of parathyroidectomy on plasma Ca\(^{2+}\). The relation of low plasma Ca\(^{2+}\) concentration to symptoms was quickly appreciated, and a comprehensive picture of parathyroid function began to form. Active glandular extracts alleviated hypocalcemic tetany in parathyroidectomized animals and raised the level of plasma Cr\(^{2+}\) in normal animals. For the first time, the relation of clinical abnormalities to parathyroid hyperfunction was appreciated.

Whereas American and British investigators used physiological approaches to explore the function of the parathyroid glands, German and Austrian pathologists related the skeletal changes of osteitis fibrosa cystica to the presence of parathyroid tumors; these two investigational approaches arrived at the same conclusions, as has been recounted by Carney (1997).

**Chemistry.** PTH molecules of all species are all single polypeptide chains of 84 amino acids with molecular masses of ~9500 Da. Biological activity is associated with the N-terminal portion of the peptide; residues 1–27 are required for optimal binding to the PTH receptor and hormone activity. Derivatives lacking the first and second residue bind to PTH receptors but do not activate the cyclic AMP or IP\(_3\)–Ca\(^{2+}\) signaling pathways. The PTH fragment lacking the first six amino acids inhibits PTH action.

**Synthesis, Secretion, and Immunoassay.** PTH is synthesized as a 115-amino-acid translation product called proparathyroid hormone. This single-chain peptide is converted to parathyroid hormone by cleavage of 25 amino-terminal residues as the peptide is transferred to the intracisternal space of the endoplasmic reticulum. Parathyroid hormone then moves to the Golgi complex, where it is converted to PTH by cleavage of six amino acids. PTH(1-84) resides within secretory granules until it is discharged into the circulation. Neither proparathyroid hormone nor parathyroid hormone appears in plasma. The synthesis and processing of PTH have been reviewed (Jüppner et al., 2001).

A major proteolytic product of PTH is PTH(7–84). PTH(7–84) and other amino-truncated PTH fragments accumulate significantly during renal failure in part because they are normally cleared from the circulation predominantly by the kidneys, whereas intact PTH is also removed by extrarenal mechanisms. Rather than competing with PTH(1–84) binding at the receptor, PTH(7–84) may cause the PTH receptor to internalize from the plasma membrane in a cell-specific manner (Sneddon et al., 2003).

During periods of hypocalcemia, more PTH is secreted and less is hydrolyzed. In this setting, PTH(7–84) release is augmented. In prolonged hypocalcemia, PTH synthesis also increases, and the gland hypertrophies.

PTH(1–84) has a t\(_{1/2}\) in plasma of ~4 minutes; removal by the liver and kidney accounts for ~90% of its clearance. Proteinolysis of PTH (in the storage granule and in plasma) generates smaller fragments (e.g., a 33–36 amino acid N-terminal fragment that is fully active, a larger C-terminal peptide, and PTH(7–84)). Much of what circulates in the blood and is measured by older RIAs is the inactive C-terminal fragment that has a longer t\(_{1/2}\) than the active N-terminal fragment or the intact PTH(1–84). Second-generation enzyme-linked immunosorbent assays for PTH, by contrast, can distinguish among these forms, but the clinical value of such information and whether it should affect therapeutic intervention remains controversial (D’Amour, 2008; Herberth et al., 2009).

**Physiological Functions.** The primary function of PTH is to maintain a constant concentration of Ca\(^{2+}\) and P\(_i\) in the extracellular fluid. The principal processes regulated are renal Ca\(^{2+}\) and P\(_i\) absorption, and mobilization of bone Ca\(^{2+}\) (Figure 44–3). PTH also affects a variety of tissues not involved in mineral ion homeostasis that include cartilage, vascular smooth muscle, placenta, liver, pancreatic islets, brain, dermal fibroblasts, and lymphocytes. The actions of PTH on its target tissues are mediated by at least two receptors. The PTH receptor (PTH1R or PTH/PTHrP receptor) also binds PTH-related protein (PTHrP); the PTH\(_2\) receptor, found in vascular tissues, brain, pancreas, and placenta, binds only PTH. Both of these are GPCRs that can couple with G\(_s\) and G\(_i\) in cell-type specific manners; thus cells may show one, the other, or both types of responses. There is also evidence that PTH can activate phospholipase D through a G\(_{12/13}\)-RhoA pathway (Singh et al., 2005). A third receptor, designated the CPTH receptor, interacts with forms of PTH that are truncated in the amino-terminal region, contain most of the carboxyl terminus, and are inactive at the PTH\(_1\) receptor; these CPTH receptors reportedly are expressed on osteocytes (Selim et al., 2006).

**Regulation of Secretion.** Plasma Ca\(^{2+}\) is the major factor regulating PTH secretion. As the concentration of Ca\(^{2+}\) diminishes, PTH secretion increases. Sustained hypocalcemia induces parathyroid hyper trophy and hyperplasia. Conversely, if the concentration of Ca\(^{2+}\) is high, PTH secretion decreases. Studies of parathyroid cells in culture show that amino acid transport, nucleic acid and protein synthesis, cytoplasmic growth, and PTH secretion are all stimulated by low concentrations of Ca\(^{2+}\) and suppressed by high concentrations. Thus, Ca\(^{2+}\) itself appears to regulate parathyroid gland growth as well as hormone synthesis and secretion.

Changes in plasma Ca\(^{2+}\) regulate PTH secretion by the plasma membrane–associated calcium-sensing receptor (CaSR) on parathyroid cells. The CaSR is a GPCR that couples with G\(_s\) and G\(_i\). Occupancy of the CaSR by Ca\(^{2+}\) thus stimulates the G\(_i\)-PLC-IP\(_3\)-Ca\(^{2+}\) pathway leading to activation of PKC; this results in inhibition of PTH secretion, an unusual case in which elevation of cellular Ca\(^{2+}\) inhibits secretion (another being the granular cells in the juxtaglomerular complex of the kidney, where elevation of cellular Ca\(^{2+}\)
inhibits renin secretion). Simultaneous activation of the $G_i$ pathway by $Ca^{2+}$ reduces cAMP synthesis and lowers the activity of PKA, also a negative signal for PTH secretion. Conversely, reduced occupancy of CaSR by $Ca^{2+}$ reduces signaling through $G_i$ and $G_{q1}$, lessening inhibition of adenylyl cyclase and lowering activation of the $G_q$ pathway, thereby promoting PTH secretion. Thus, the extracellular concentration of $Ca^{2+}$ is controlled by a classical negative-feedback system, the afferent limb of which is sensitive to the ambient activity of $Ca^{2+}$ and the efferent limb of which releases PTH. Acting via the CaSR, hypercalcemia reduces intracellular cyclic AMP content and activates PKC, whereas hypocalcemia does the reverse. The precise links between these changes and alterations in PTH secretion remain to be defined. Other agents that increase parathyroid cell cyclic AMP levels, such as $\beta$-adrenergic receptor agonists and dopamine, also increase PTH secretion, but the magnitude of response is far less than that seen with hypocalcemia. The active vitamin D metabolite, 1,25-dihydroxyvitamin D ($calcitriol$), directly suppresses PTH gene expression. There appears to be no relation between physiological concentrations of extracellular phosphate and PTH secretion, except insofar as changes in phosphate concentration alter circulating $Ca^{2+}$. Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

**Effects on Bone.** PTH exerts both catabolic and anabolic effects on bone. Normally, these processes are tightly coupled. Chronically elevated PTH enhances bone resorption and thereby increases $Ca^{2+}$ delivery to the extracellular fluid, whereas intermittent exposure to PTH promotes anabolic actions. The primary skeletal target cell for PTH is the osteoblast, although evidence points to the presence of functional PTH receptors on osteocytes (O’Brien et al., 2008). PTH also recruits osteoclast precursor cells to form new bone remodeling units. Sustained increases in circulating PTH cause characteristic histological changes in bone that include an increase in the prevalence of osteoclastic resorption sites and in the proportion of bone surface that is covered with unmineralized matrix (Martin and Ng, 1994).

Direct effects of PTH on osteoblasts in vitro generally are inhibitory and include reduced formation of type I collagen, alkaline phosphatase, and osteocalcin. However, the response to PTH in vivo reflects not only hormone action on individual cells but also the increased total number of active osteoblasts, owing to initiation of new remodeling units. Thus, plasma levels of osteocalcin and alkaline phosphatase activity actually may be increased. No simple model can fully explain the molecular basis of PTH effects on bone. PTH stimulates cyclic AMP production in osteoblasts, but there also is evidence that intracellular $Ca^{2+}$ mediates some PTH actions.

**Effects on Kidney.** In the kidney, PTH enhances the efficiency of $Ca^{2+}$ reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of vitamin D to its biologically active form, calcitriol (Figure 44–3). As a result, filtered $Ca^{2+}$ is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized calcitriol interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal $Ca^{2+}$ absorption, thereby contributing to the increase in plasma ($Ca^{2+}$).

**Calcium.** PTH increases tubular reabsorption of $Ca^{2+}$ with concomitant decreases in urinary $Ca^{2+}$ excretion. The effect occurs at distal nephron sites. This action, along with mobilization of calcium from bone and increased absorption from the intestine, increases the concentration of $Ca^{2+}$ in plasma. Eventually, the increased glomerular filtration of $Ca^{2+}$ overwhelms the stimulatory effect of PTH on tubular reabsorption, and hypercalcemia ensues. Conversely, reduction of serum PTH depresses tubular reabsorption of $Ca^{2+}$ and thereby increases urinary $Ca^{2+}$ excretion. When the plasma $Ca^{2+}$ concentration falls below 7 mg/dL (1.75 mM), $Ca^{2+}$ excretion decreases as the filtered load of $Ca^{2+}$ reaches the point where the cation is almost completely reabsorbed despite reduced tubular capacity.

**Phosphate.** PTH increases renal excretion of inorganic phosphate by decreasing its reabsorption by proximal tubules. This action is mediated by retrieval of the luminal membrane Na–P̄ cotransport protein, NPT2a, rather than an effect on its activity. Patients with primary hyperparathyroidism therefore typically have low tubular phosphate reabsorption.

**Cyclic AMP apparently mediates the renal effects of PTH on proximal tubular phosphate reabsorption.** PTH-sensitive adenyl cyclase is located in the renal cortex, and cyclic AMP synthesized in response to the hormone affects tubular transport mechanisms. A portion of the cyclic AMP synthesized at this site, so-called nephrogenous cyclic AMP, escapes into the urine. Measurement of urinary cyclic AMP is used as a surrogate for parathyroid activity and renal responsiveness.

**Calcitriol Synthesis.** The final step in the activation of vitamin D to calcitriol occurs in kidney proximal tubule cells. Three primary regulators govern the enzymatic activity of the 25-hydroxyvitamin $D_3$-1α-hydroxylase that catalyzes this step: $P_i$, PTH, and $Ca^{2+}$ (see later for further discussion). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypocalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating $P_i$ and a more direct effect of the hormone on the 1α-hydroxylase lead to increased circulating concentrations of calcitriol.

**Integrated Regulation of Extracellular $Ca^{2+}$ Concentration by PTH.** Even modest reductions of serum $Ca^{2+}$ stimulate PTH secretion. For minute-to-minute regulation of $Ca^{2+}$, adjustments in renal $Ca^{2+}$ handling more than suffice to maintain plasma calcium homeostasis. With more prolonged hypocalcemia, the renal 1α-hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal calcium absorption (Figure 44–3). In addition, delivery of calcium from bone into the extracellular fluid is augmented. In the face of prolonged and severe hypocalcemia, new bone remodeling units are activated to restore circulating $Ca^{2+}$ concentrations, albeit at the expense of skeletal integrity.

When plasma $Ca^{2+}$ activity rises, PTH secretion is suppressed, and tubular $Ca^{2+}$ reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate depress calcitriol production and thereby decrease intestinal $Ca^{2+}$ absorption. Finally, bone remodeling is suppressed. These integrated physiological events ensure a coherent
response to positive or negative excursions of plasma Ca²⁺ concentrations. In humans, the importance of other hormones, such as FGF23 and calcitonin, to this scheme remains unsettled. They may modulate the Ca²⁺–parathyroid–vitamin D axis or, in the case of FGF23, serve as primary regulators (Razzaque, 2009).

Vitamin D

Vitamin D traditionally was viewed as a permissive factor in calcium metabolism because it was thought to permit efficient absorption of dietary calcium and to allow full expression of the actions of PTH. We know now that vitamin D exerts a more active role in calcium homeostasis. Vitamin D is actually a hormone rather than a vitamin; it is synthesized in mammals and, under ideal conditions, probably is not required in the diet. Receptors for the activated form of vitamin D are expressed in many cells that are not involved in calcium homeostasis, including hematopoietic cells, lymphocytes, epidermal cells, hair follicles, adipose tissue, pancreatic islets, muscle, and neurons.

History. Vitamin D is the name applied to two related fat-soluble substances, cholecalciferol (vitamin D₃) and ergocalciferol (vitamin D₂) (Figure 44–4), that share the capacity to prevent or cure rickets. Prior to the discovery of vitamin D, a high percentage of urban children living in temperate zones developed rickets. Some researchers believed that the disease was due to lack of fresh air and sunshine; others claimed a dietary factor was responsible. Mellanby and Huldschinsky showed both notions to be correct; addition of cod liver oil to the diet or exposure to sunlight prevented or cured the disease. In 1924, it was found that ultraviolet irradiation of animal rations was as efficacious at curing rickets as was irradiation of the animal itself. These observations led to the elucidation of the structures of chole- and ergocalciferol and eventually to the discovery that these compounds require further processing in the body to become active. The discovery of metabolic activation is attributable primarily to studies conducted in the laboratories of DeLuca and Kodicek (DeLuca, 1988). The biological actions of vitamin D are mediated by the vitamin D receptor (VDR), a nuclear receptor, that was cloned in 1987 (McDonnell et al., 1987).

Chemistry and Occurrence. Ultraviolet irradiation of several animal and plant sterols results in their conversion to compounds possessing vitamin D activity. The principal provitamin found in animal tissues is 7-dehydrocholesterol, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D₃) (Figure 44–4). Ergosterol, which is present only in plants and fungi, is the provitamin for vitamin D₂ (ergocalciferol). Ergosterol and vitamin D₂ differ from 7-dehydrocholesterol and vitamin D₃, respectively, by the presence of a double bond between C22 and C23 and a methyl group at C24. Vitamin D₂ is the active constituent of a number of commercial vitamin preparations and is in irradiated bread and irradiated milk. In humans there is no practical difference between the antirachitic potencies of vitamin D₂ and vitamin D₃. Therefore, “vitamin D” is used here as a collective term for vitamins D₂ and D₃.

Human Requirements and Units. Although sunlight provides adequate vitamin D supplies in the equatorial belt, in temperate climates insufficient cutaneous solar radiation especially in winter may necessitate dietary vitamin D supplementation. It was assumed that vitamin D deficiency had been eliminated as a significant medical problem in the U.S. However, upward adjustment of estimates of normal vitamin D levels, improved analytical methodology, and more comprehensive data collection have led to an appreciation of the common finding of low circulating levels of vitamin D and a re-emergence of vitamin D–dependent rickets. Potential factors contributing to the rise of vitamin D deficiency include diminished consumption of vitamin D–fortified foods owing to concerns about fat intake; reduced intake of calcium-rich foods, including milk, in adolescents and young women of reproductive age; increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging from exposure to ultraviolet radiation; and an increased prevalence and duration of exclusive breast-feeding (the combination of human milk, a poor source of vitamin D, and the high prevalence of low circulating vitamin D levels in U.S. women, particularly African-American mothers) (Bodnar et al., 2007).

There is no consensus regarding optimal vitamin D intake, and determination of vitamin D requirements is remarkably unsupported by clinical measurements. The recommended dietary allowance of vitamin D for infants and children is 400 IU, or 10 µg, daily. The basis for this dose was that it approximates that in a teaspoon (5 mL) of cod liver oil, which had long been considered safe and effective in preventing rickets (Vieth, 1999). Because adults require less vitamin D than infants, the adult dose was set arbitrarily at 200 IU.

The Food and Nutrition Board of the Institute of Medicine has developed Dietary Reference Intakes (DRI) for vitamins (Institute of Medicine, 2003). In both premature and normal infants, intake of 200 units per day of vitamin D from any source is considered adequate for optimal growth. Recently, the American Academy of Pediatrics recommended an intake of 400 IU of vitamin D per day from infants through adolescence (Wagner and Greer, 2008). Beyond adolescence, this amount probably may be sufficient, although nutritionists now recommend high daily intake, up to 4000 IU/day (Bischoff-Ferrari et al., 2009). There is some evidence that vitamin D requirements increase during pregnancy and lactation (Hollos and Wagner, 2004), where vitamin D doses of <1000 IU/day may be inadequate to maintain normal circulating 25-hydroxyvitamin D concentrations. Doses of ≤10,000 IU/day of vitamin D for up to 5 months do not elevate circulating 25-hydroxyvitamin D to concentrations >90 ng/mL.

Absorption, Fate, and Excretion. Vitamins D₂ and D₃ are absorbed from the small intestine, although vitamin D₃ may be absorbed more efficiently. Most of the vitamin appears first within chylomicrons in lymph. Bile is essential for adequate absorption of vitamin D; deoxycholic acid is the major constituent of bile in this regard (Chapter 46). The primary route of vitamin D₃ excretion is the bile; with a smaller percentage found in the urine. Patients who have intestinal bypass surgery or otherwise have severe shortening or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption.

Absorbed vitamin D circulates in the blood in association with vitamin D–binding protein, a specific α-globulin. The vitamin
disappears from plasma with a $t_{1/2}$ of 20–30 hours but is stored in fat depots for prolonged periods.

**Metabolic Activation.** Whether derived from diet or endogenously synthesized, vitamin D requires modification to become biologically active. The primary active metabolite of the vitamin is calcitriol [1α,25-dihydroxyvitamin D, 1,25(OH)$_2$D], the product of two successive hydroxylations of vitamin D (Figure 44–4).

25-Hydroxylation of Vitamin D. The initial step in vitamin D activation occurs in the liver, where cholecalciferol and ergocalciferol are hydroxylated in the 25-position to generate 25-OH-cholecalciferol.
(25-OHD, or calcifediol) and 25-OH-ergocalciferol, respectively. 25-OHD is the major circulating form of vitamin D; it has a biological $t_{1/2}$ of 19 days, and normal steady-state concentrations are 15-50 ng/mL. Reduced extracellular Ca$^{2+}$ levels stimulate $1\alpha$-hydroxylat-
ion of 25-OHD, increasing the formation of biologically active 1,25(OH)$_2$D$_3$. In contrast, when Ca$^{2+}$ concentrations are elevated, 25-OHD is inactivated by 24-hydroxylation. Similar reactions occur with 25-OH-ergocalciferol. Normal steady-state concentrations of 25-OHD in human beings are 15-50 ng/mL, although concentrations <25 ng/mL may be associated with increased circulating PTH and greater bone turnover.

$1\alpha$-Hydroxylation of 25-OHD. After production in the liver, 25-OHD enters the circulation and is carried by vitamin D–binding globulin. Final activation to calcitriol occurs primarily in the kidney but also takes place in other sites, including keratinocytes and macrophages (Hewison et al., 2004). The enzyme system responsible for $1\alpha$-hydroxyl-
ylation of 25-OHD (CYP1$\alpha$, 25-hydroxyvitamin D$_1$-$1\alpha$-hydroxylase, $1\alpha$-hydroxylase) is associated with mitochondria in proximal tubules.

Vitamin D $1\alpha$-hydroxylase is subject to tight regulatory controls that result in changes in calcitriol formation appropriate for optimal calcium homeostasis. Dietary deficiency of vitamin D, calcium, or phosphate enhances enzyme activity. $1\alpha$-Hydroxylase is potently stimulated by PTH and probably also by prolactin and estrogen. Conversely, high calcium, phosphate, and vitamin D intakes suppress $1\alpha$-hydroxylase activity. Regulation (Figure 44-5) is both acute and chronic, the latter owing to changes in protein synthesis. PTH increases calcitriol production rapidly via a cyclic AMP–dependent pathway. Hypocalcemia can activate the hydroxylase directly in addition to affecting it indirectly by eliciting PTH secretion (Bland et al., 1999). Hypophosphatemia greatly increases $1\alpha$-hydroxylase activity. Calcitriol controls $1\alpha$-hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma $t_{1/2}$ of calcitriol is estimated at 3-5 days in humans.

24-Hydroxylase. Calcitriol and 25-OHD are hydroxylated to 1,24,25(OH)$_3$D and 24,25(OH)$_2$D, respectively, by another renal enzyme, 24-hydroxylase, whose expression is induced by calcitriol and suppressed by factors that stimulate the 25-OHD-$1\alpha$-hydroxylase. Both 24-hydroxylated compounds are less active than calcitriol and presumably represent metabolites destined for excretion.

Physiological Functions and Mechanism of Action. Calcitriol augments absorption and retention of Ca$^{2+}$ and phosphate. Although regulation of Ca$^{2+}$ homeostasis is considered to be its primary function, accumulating evidence underscores the importance of calcitriol in a number of other processes.

Calcitriol acts to maintain normal concentrations of Ca$^{2+}$ and phosphate in plasma by facilitating their absorption in the small intestine, by interacting with PTH to enhance their mobilization from bone, and by decreasing their renal excretion. It also exerts direct physiological and pharmacological effects on bone mineralization (Suda et al., 2003).

The mechanism of action of calcitriol is mediated by its interaction with VDR. Calcitriol binds to cytosolic VDRs within target cells, and the receptor–hormone complex translocates to the nucleus and interacts with DNA to modify gene transcription. The VDR belongs to the steroid and thyroid hormone receptor superfamily. Calcitriol also exerts nongenomic effects. It is controversial whether the presence of a functional VDR is required for this action (Zanello and Norman, 2004).

**Figure 44-5. Regulation of $1\alpha$-hydroxylase activity.** Changes in the plasma levels of PTH, Ca$^{2+}$, and phosphate modulate the hydroxylation of 25-OH vitamin D to the active form, 1,25-dihydroxyvitamin D. 25-OHD, 25-hydroxycholecalciferol; 1,25-(OH)$_2$D, calcitriol; PTH, parathyroid hormone.
mucosal compartments. Thus, net calcium absorption is the difference between the two oppositely oriented vectorial processes. The complex mechanisms and the proteins mediating calcium absorption are still incompletely understood (Perez et al., 2008). Evidence implicates TRPV6 Ca$^{2+}$ channels in mediating mucosal calcium entry in the intestine (Bianco et al., 2007). In humans, TRPV6 is expressed in the duodenum and proximal jejunum. A calcium-poor diet upregulates intestinal TRPV6 expression in mice (Van Croomphaut et al., 2001). This effect is greatly reduced in VDR knockout mice, suggesting that TRPV6 mediates calcium entry and is vitamin D dependent.

Ca$^{2+}$ absorption is potently augmented by calcitriol. It is likely that calcitriol enhances all three steps involved in intestinal Ca$^{2+}$ absorption: entry across mucosal brush border membranes, diffusion through the enterocytes, and active extrusion across serosal plasma membranes. Calcitriol upregulates the synthesis of calbindin-D$_{9K}$ and calbindin-D$_{28K}$ and the serosal plasma membrane Ca--ATPase. Calbindin-D$_{9K}$ enhances the extrusion of Ca$^{2+}$ by the Ca--ATPase, whereas the precise function of calbindin-D$_{28K}$ is unsettled.

**Mobilization of Bone Mineral.** Although vitamin D–deficient animals show obvious deficits in bone mineral, there is little evidence that calcitriol directly promotes mineralization. Thus, even though VDR knockout mice exhibit severely impaired bone formation and mineralization, these deficiencies can be entirely corrected by a high-calcium diet. These results support the view that the primary role of calcitriol is to stimulate intestinal absorption of calcium, which, in turn, indirectly promotes bone mineralization. Indeed, children with rickets caused by mutations of the VDR have been treated successfully with intravenous infusions of Ca$^{2+}$ and phosphate. In contrast, physiological doses of vitamin D promote mobilization of Ca$^{2+}$ from bone, and large doses cause excessive bone turnover. Although calcitriol-induced bone resorption may be reduced in parathyroidectomized animals, the response is restored when hyperphosphatemia is corrected. Thus, PTH and calcitriol act independently to enhance bone resorption.

Calcitriol increases bone turnover by multiple mechanisms (Suda et al., 2007). Mature osteoclasts apparently lack the VDR. Acting by a non-VDR mechanism, calcitriol promotes the recruitment of osteoclast precursor cells to resorption sites, as well as the development of differentiated functions that characterize mature osteoclasts.

Osteoblasts, the cells responsible for bone formation, express the VDR, and calcitriol induces their production of several proteins, including osteocalcin, a vitamin K–dependent protein that contains γ-carboxyglutamic acid residues, and interleukin-1 (IL-1), a lymphokine that promotes bone resorption (Spear et al., 1988). Thus, the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone. Osteoporosis is a disease in which osteoclast responsiveness to calcitriol or other bone-resorbing agents is profoundly impaired, leading to deficient bone resorption.

**Renal Retention of Calcium and Phosphate.** The effects of calcitriol on the renal handling of Ca$^{2+}$ and phosphate are of uncertain importance. Calcitriol increases retention of Ca$^{2+}$ independently of phosphate. The effect on Ca$^{2+}$ is thought to proceed in distal tubules, whereas enhanced phosphate absorption occurs in proximal tubules.

**Other Effects of Calcitriol.** It now is evident that the effects of calcitriol extend well beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body (Pike and Shevde, 2005). Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function (Nagpal et al., 2005). One focus of research is the potential use of calcitriol to inhibit proliferation and to induce differentiation of malignant cells (van den Bemd et al., 2000). The possibility of dissociating the hypercalcemic effect of calcitriol from its actions on cell differentiation has encouraged the search for analogs that might be useful in cancer therapy. Calcitriol inhibits epidermal proliferation and promotes epidermal differentiation and therefore is a potential treatment for psoriasis vulgaris (Kragballe and Iversen, 1993) (Chapter 65). Calcitriol also affects the function of skeletal muscle, brain (Carswell, 1997), and blood pressure (Nagpal et al., 2005).

**Calcitonin**

Calcitonin is a hypocalcemic hormone whose actions generally oppose those of PTH.

**History and Source.** Copp observed in 1962 that perfusion of canine parathyroid and thyroid glands with hypercalcemic blood caused a transient hypocalcemia that occurred significantly earlier than that caused by total parathyroidectomy. He concluded that the parathyroid glands secreted a calcium-lowering hormone (calcitonin) in response to hypercalcemia and in this way normalized plasma Ca$^{2+}$ concentrations. The physiological relevance of calcitonin has been challenged vigorously: calcitonin normally circulates at remarkably low levels; surgical removal of the thyroids has no appreciable effect on calcium metabolism; and conditions associated with profound elevations of serum calcitonin concentration are not accompanied by hypocalcemia (Hirsch and Baruch, 2003). The primary interest in calcitonin arises from its pharmacological use in treating Paget’s disease and hypercalcemia and in its diagnostic use as a tumor marker for medullary carcinoma of the thyroid.

The thyroid parafollicular C cells are the site of production and secretion of calcitonin. Human C cells, which are derived from neural crest ectoderm, are distributed widely in the thyroid, parathyroid, and thymus. In non-mammalian vertebrates, calcitonin is found in ultimobranchial bodies, which are separate organs from the thyroid gland.

The calcitonin gene is localized on human chromosome 11p and contains six exons (Figure 44–6). The primary transcript is alternatively spliced in a tissue-specific manner. In thyroid C cells, the calcitonin/calcitonin gene–related peptide (CGRP) pre-mRNA is processed primarily with common exons 2 and 3 to include exon 4. This leads to production of the 32-amino-acid peptide calcitonin, along with a flanking 21-amino-acid peptide called katacalcin, whose physiological significance is unknown. In neuronal cells, in contrast, most of the calcitonin/CGRP pre-mRNA, is processed to exclude exon 4, resulting in inclusion of exons 5 and 6 with common exons 2 and 3, which ultimately gives rise to CGRP. This results in the production of the 37-amino-acid CGRP. Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of “calcium stress,” such as growth, pregnancy, and lactation. CGRP and the closely related peptide adrenomedullin are potent endogenous vasodilators.

**Chemistry and Immunoreactivity.** Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking the cysteine residues in positions 1 and 7 (Figure 44–7). In all species, 8 of the
32 residues are invariant, including the disulfide bridge and a carboxyl-terminal proline amide; both structural features are essential for biological activity. The residues in the middle portion of the molecule (positions 10–27) are more variable and apparently influence potency and/or duration of action. Calcitonins derived from salmon and eel differ from the human hormone by 13 and 16 amino acid residues, respectively, and are more potent than mammalian calcitonin. Salmon calcitonin is used therapeutically in part because it is cleared more slowly from the circulation.

**Regulation of Secretion.** The biosynthesis and secretion of calcitonin are regulated by the plasma Ca\(^{2+}\) concentration. Calcitonin secretion increases when plasma Ca\(^{2+}\) is high and decreases when plasma Ca\(^{2+}\) is low. Multiple forms of calcitonin are found in plasma, including high-molecular-weight aggregates or cross-linked products. Assays for the intact monomeric peptide are now available. The circulating concentrations of calcitonin are low, normally <15 and 10 pg/mL for males and females, respectively. The circulating \(t_{1/2}\) of calcitonin is ~10 minutes. Abnormally elevated levels of calcitonin are characteristic of thyroid C-cell hyperplasia and medullary thyroid carcinoma.

Calcitonin secretion is stimulated by a number of agents, including catecholamines, glucagon, gastrin, and cholecystokinin, but there is little evidence for a physiological role for secretion in response to these stimuli.

**Mechanism of Action.** Calcitonin actions are mediated by the calcitonin receptor (CTR), which is a member of the PTH/secretin subfamily of GPCRs (Lin et al., 1991). Six human CTR subtypes occur through alternative splicing of coding and noncoding exons (Purdue et al., 2002). These isoforms exhibit distinct ligand-binding specificity and/or signal-transduction pathways and are distributed in a tissue-specific pattern. Of the more abundant isoforms, hCTR1\(^{+}\), which lacks a 16-amino acid insert in the first intracellular loop, preferentially couples with the G\(_{i}\)-adenyl cyclase pathway (Gorn et al., 1995). The hCTR1\(^{+}\) isoform, which includes this cassette, does not couple with PLC (Naro et al., 1998) and therefore does not activate PKC or trigger an increase in Ca\(^{2+}\). Calcitonin receptors can dimerize with RAMPs (receptor-activity modifying proteins) to create receptors with high affinity for amylin (Hay et al., 2005) (Chapter 43).

The hypocalcemic and hypophosphatemic effects of calcitonin are caused predominantly by direct inhibition of osteoclastic bone resorption. Although calcitonin inhibits the effects of PTH on osteolysis, it inhibits neither PTH activation of bone cell adenyl cyclase nor PTH-induced uptake of Ca\(^{2+}\) into bone. Calcitonin interacts directly with receptors on osteoclasts to produce a rapid and profound decrease in ruffled border surface area, thereby diminishing resorptive activity.

Depressed bone resorption reduces urinary excretion of Ca\(^{2+}\), Mg\(^{2+}\), and hydroxyproline. Plasma phosphate concentrations are lowered owing also to increased urinary phosphate excretion. Direct renal effects of calcitonin vary with species. Acute administration of pharmacological doses of calcitonin increases urinary calcium excretion, whereas calcitonin inhibits renal calcium excretion at physiological concentrations. In humans, calcitonin increases fractional urinary calcium excretion in a dose-dependent manner in subjects given a modest calcium load (Carney, 1997).
Fibroblast Growth Factor 23 and Klotho

Fibroblast growth factor 23 (FGF23) is a hypophosphatemic hormone whose actions generally parallel those of PTH but with effects restricted to regulation of renal Pi absorption and vitamin D biosynthesis. Klotho is a membrane protein that serves as an essential cofactor in the transduction of FGF23 signaling.

FGF23 was discovered by positional cloning as the gene responsible for autosomal dominant hypophosphatemic rickets (ADHR). It was simultaneously cloned as one factor causing tumor-induced osteomalacia (TIO). FGF23, a protein of 251 amino acids, is produced primarily by several bone cells including osteoblasts, osteocytes, and lining cells.

FGF23 is secreted in response to dietary phosphorus load, and its main function is the promotion of urinary phosphate excretion and the suppression of active vitamin D production by the kidney. Emerging evidence suggests that FGF23 is the principal regulator of proximal renal tubule phosphate reabsorption and of 1,25-dihydroxyvitamin D synthesis. Serum levels of FGF23 rise precipitously in patients with chronic kidney disease and are inversely correlated with the degree of hyperphosphatemia. Elevated FGF23 may contribute to impaired production of 1,25-dihydroxyvitamin D.

Klotho was originally identified as a gene mutated in mice that developed accelerated aging. Further analysis revealed a pattern of altered mineral ion metabolism and diminished bone density similar to that found in FGF23 knockout mice or patients with ADHR. The similar phenotypes of Klotho-deficient and FGF23-null mice suggested that Klotho and FGF23 function in a common signaling pathway. Klotho acts as a cofactor in FGF signaling, facilitates the interactions of FGF23 with its receptor, and determines its tissue specificity (Razzaque, 2009). Exogenous FGF23 administration reduces serum Pi and calcitriol synthesis. Vitamin D analogs are commonly used in the management of chronic kidney disease. Although no clinical agents based on FGF23 have yet been developed, bioactive fragments or FGF23 inhibitors might become useful in counterbalancing the hyperphosphatemic actions of vitamin D therapy.

BONE PHYSIOLOGY

The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular compartment.

Skeletal Organization. It is useful to consider the appendicular, or peripheral, skeleton as separate from the axial, or central, skeleton because their turnover rates differ. Appendicular bones make up 80% of bone mass and are composed predominantly of compact cortical bone. Axial bones, such as the spine and pelvis, contain substantial amounts of trabecular bone within a thin cortex. Trabecular bone consists of highly connected bony plates that resemble a honeycomb. The intertrabecular interstices contain bone marrow and fat. Alterations in bone turnover are observed first and foremost in axial bone both because bone surfaces, where bone remodeling occurs, are more densely distributed in trabecular bone and because marrow precursor cells that ultimately participate in bone turnover lie in close proximity to trabecular surfaces.

Bone Mass. Bone mineral density (BMD) and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for ~60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Bone acquisition is largely complete by age 17 in girls and by age 20 in boys. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium.

Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. Similar trajectories occur for men and women of all ethnic groups. The fundamental accuracy of this model has been amply confirmed for cortical bone, although trabecular bone loss at some sites probably begins prior to age 50. In women, loss of estrogen at menopause accelerates the rate of bone loss. Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficiency in all three areas, and deficiency of one is not compensated by excessive attention to another.

Bone Remodeling. Growth and development of endochondral bone are driven by a process called modeling. Once new bone is laid down, it is subject to a continuous process of breakdown and renewal called remodeling, by which bone mass is adjusted throughout adult life (Ballock and O’Keefe, 2003). Remodeling is carried out by myriad independent “bone remodeling units” throughout the skeleton (Figure 44–8). Remodeling proceeds on bone surfaces, ~90% of which are normally inactive, covered by a thin layer of lining cells. In response to physical or biochemical signals, recruitment of marrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated osteoclasts that resorb, or excavate, a cavity into the bone.

Osteoclast production is regulated by osteoblast-derived cytokines such as IL-1 and IL-6. Studies have begun to clarify the mechanisms through which osteoclast production is regulated (Suda et al., 1999). The receptor for activating NF-κB (RANK) is an osteoclast protein whose expression is required for osteoclastic bone resorption. Its natural ligand, RANK ligand (RANKL; previously called osteoclast differentiation factor), is a membrane-spanning osteoblast protein. On binding to RANK, RANKL induces osteoclast formation (Khosla, 2001) (Figure 44–9). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce osteoprotegerin (OPG), which acts as a decoy ligand for RANKL. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK. In certain model systems, OPG is superior to bisphosphonates in suppressing bone resorption and hypercalcemia (Morony et al., 2005).

Completion of the resorption phase is followed by invasion of preosteoblasts derived from marrow stroma into the base of the resorption cavity. These cells develop the characteristic osteoblastic phenotype and begin to replace the resorbed bone by elaborating new bone matrix constituents, such as collagen and osteocalcin. Once the
newly formed osteoid reaches a thickness of ~20 μm, mineralization begins. A complete remodeling cycle normally requires ~6 months. If the replacement of resorbed bone precisely matched the amount that was removed, remodeling would not change net bone mass. However, small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary sufficiency, exercise, hormones, and drugs, affect bone balance. Changes in the hormonal milieu often lead to an increase in the activation of remodeling units. Examples include hyperthyroidism, hyperparathyroidism, and hypervitaminosis D. Other factors that may impair osteoblast function include high doses of corticosteroids or ethanol. Finally, estrogen deficiency augments osteoclastic resorptive capacity by a proapoptotic action (Manolagas et al., 2002).

At any given time, a transient deficit in bone, the remodeling space, represents sites of bone resorption that have not yet filled in. Stimuli that alter the rate of emergence of new remodeling units either increase or decrease the remodeling space until a new steady state is established at an increased or decreased bone mass.

**DISORDERS OF MINERAL HOMEOSTASIS AND BONE**

**Abnormal Calcium Metabolism**

**Hypercalcemia.** Moderate elevations of the concentration of Ca$^{2+}$ in the extracellular fluid may have no clinically detectable effects. The degree of hypercalcemia and the rate of onset of the elevation in the serum calcium concentration largely dictate the extent of symptoms.
Chronic elevation of serum Ca\(^{2+}\) to 12-14 mg/dL (3-3.5 mmol/L) generally causes few manifestations, whereas an acute rise to the same levels may cause marked neuromuscular manifestations owing to an increased threshold for excitation of nerve and muscle. Symptoms include fatigue, muscle weakness, anorexia, depression, diffuse abdominal pain, and constipation.

Hypercalcemia can result from a number of conditions. Ingestion of large quantities of calcium by itself generally does not cause hypercalcemia; exceptions are hyperthyroid subjects, who absorb Ca\(^{2+}\) with increased efficiency, and subjects with the uncommon milk-alkali syndrome, a condition caused by concurrent ingestion of large quantities of milk and absorbable alkali (e.g., certain antacids; Chapter 45), resulting in impaired renal Ca\(^{2+}\) excretion and attendant hypercalcemia.

In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by one or more parathyroid glands. Secondary hyperparathyroidism, in contrast, arises as a compensation for reductions of circulating Ca\(^{2+}\) and is not associated with hypercalcemia.

Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephro lithiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption. Some patients have renal calculi and peptic ulceration, and a few display classical parathyroid skeletal disease. However, most patients show few, if any, symptoms, and those that are present are often vague and nonspecific. Contemporary clinical assays that distinguish between full-length PTH(1–84) and “intact” PTH [PTH(1–84) + PTH(7–84)] obviate many of the difficulties with previous assays and, in conjunction with an elevated serum calcium, possess a diagnostic accuracy of >90% (Jüppner and Potts, 2002).

Familial benign hypercalcemia (or familial hypocalciuric hypercalcemia) is a genetic disorder generally accompanied by extremely low urinary calcium excretion. Familial benign hypercalcemia results from heterozygous mutations in the Ca\(^{2+}\)-sensing receptor (Pollak et al., 1996). Hypercalcemia usually is mild, and circulating PTH often is normal to slightly elevated. The importance of making this diagnosis lies in the fact that patients mistakenly diagnosed as having primary hyperparathyroidism may undergo surgical exploration without discovery of an adenoma and without therapeutic benefit. Patients do not experience long-term clinical consequences, except for homozygous infants, who may have severe, even lethal, hypercalcemia. Diagnosis is established by demonstrating hypercalcemia in first-degree family members and a decreased fractional excretion of calcium.

Newly diagnosed hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTH-related protein (PTHrP) is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue, particularly by squamous cell and other epithelial cancers. The substantial sequence homology of the amino-terminal portion of PTHrP with that of native PTH permits it to interact with the PTH-1 receptor in target tissues, thereby causing the hypercalcemia and hypophosphatemia seen in humoral hypercalcemia of malignancy (Grill et al., 1998). Other tumors release cytokines or prostaglandins that stimulate bone resorption. In some patients with lymphomas, hypercalcemia results from overproduction of 1,25-dihydroxyvitamin D by the tumor cells owing to expression of 1α-hydroxylase. A similar mechanism underlies the hypercalcemia that is seen occasionally in sarcoidosis and other granulomatous disorders.

Hypercalcemia associated with malignancy generally is more severe than in primary hyperparathyroidism (frequently with calcium levels that exceed 13 mg/dL) and may be associated with lethargy, weakness, nausea, vomiting, polydipsia, and polyuria. Assays for PTHrP may aid diagnosis.

Vitamin D excess may cause hypercalcemia if sufficient 25-hydroxyvitamin D is present to stimulate intestinal Ca\(^{2+}\) absorption, leading to hypercalcemia and suppressing PTH and 1,25-dihydroxyvitamin D levels. Measurement of 25-hydroxyvitamin D is diagnostic. Occasional patients with hyperthyroidism show mild hypercalcemia, presumably owing to increased bone turnover. Immobilization may lead to hypercalcemia in growing children and young adults but rarely causes hypercalcemia in older individuals unless bone turnover is already increased, as in Paget’s disease or hyperparathyroidism. Hypercalcemia sometimes is noted in adrenocortical deficiency, as in Addison’s disease, or following removal of a hyperfunctional adrenocortical tumor. Hypercalcemia occurs following renal transplantation owing to persistent hyperfunctioning parathyroid tissue that resulted from the previous renal failure.

The differential diagnosis of hypercalcemia may pose difficulties, but advances in serum assays for PTH, PTHrP, and
**Hypocalcemia.** Mild hypocalcemia (i.e., reduction in ionized serum \([\text{Ca}^{2+}]\)) from normal to concentrations above 3.2 mg/dL (0.8 mM), approximately equal to a total serum \([\text{Ca}^{2+}]\) of 8–8.5 mg/dL (2–2.1 mM), is usually asymptomatic. Again, the rapidity of change affects the clinical picture because patients exhibit greater signs and symptoms if the hypocalcemia develops acutely. The signs and symptoms of hypocalcemia include tetany and related phenomena such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic hypoparathyroidism, ectodermal changes—consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts—are encountered; calcification in the basal ganglia may be seen on routine skull radiographs. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present.

Combined deprivation of \(\text{Ca}^{2+}\) and vitamin D, as observed with malabsorption states or dietary deficiency, readily promotes hypocalcemia. When caused by malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mg\(^{2+}\) deficiency may accentuate the hypocalcemia by diminishing the secretion and action of PTH. In infants with malabsorption or inadequate calcium intake, \(\text{Ca}^{2+}\) concentrations usually are depressed, with attendant hypophosphatemia resulting in rickets.

**Hypoparathyroidism** is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disorders. In hypoparathyroidism, hypocalcemia is accompanied by hyperphosphatemia, reflecting decreased PTH action on renal phosphate transport.

**Pseudohypoparathyroidism** is a diverse family of hypocalcemic and hyperphosphatemic disorders. Pseudohypoparathyroidism results from resistance to PTH rather than PTH deficiency; this resistance is not due to mutations of the PTH receptor but rather to mutations in \(G_{\alpha} (GNAS1)\), which normally mediates hormone-induced adenyl cyclase activation (Yu et al., 1999). The variable phenotypes arising from \(GNAS1\) defects apparently are due to differential genomic imprinting of the maternal and paternal alleles (Levine et al., 2003). Multiple hormonal abnormalities have been associated with the \(GNAS1\) mutation, but none is as severe as the deficient response to PTH.

Hypocalcemia is not unusual in the first several days following removal of a parathyroid adenoma. If hyperphosphatemia is also present, the condition is one of functional hypoparathyroidism owing to temporary failure of the remaining parathyroid glands to compensate for the missing adenomatous tissue. In patients with parathyroid bone disease, postoperative hypocalcemia associated with hyperphosphatemia may reflect rapid uptake of calcium into bone, the “hungry bone” syndrome. In this setting, persistent, severe hypocalcemia may require administration of vitamin D and supplemental calcium for several months.

Neonatal tetany resulting from hypocalcemia sometimes occurs in infants of mothers with hyperparathyroidism; indeed, the tetany may call attention to the mother’s disorder. This problem disappears when the infant’s own parathyroid glands develop sufficiently to respond appropriately.

Hypocalcemia is associated with advanced renal insufficiency accompanied by hyperphosphatemia. Many patients with this condition do not develop tetany unless the accompanying acidosis is treated, which decreases the ionized calcium. High concentrations of phosphate in plasma inhibit the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol. Hypocalcemia also can occur following massive transfusions with citrated blood, which chelates calcium.

### Disturbed Phosphate Metabolism

Dietary inadequacy very rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (Chapter 45). **Osteomalacia,** as described later, is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the GI tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action.

Hyperphosphatemia is an important component of the bone disease seen in chronic renal failure. In this condition, phosphate retention is primary and reflects the degree of renal compromise. The increased phosphate level reduces the serum \(\text{Ca}^{2+}\) concentration, which, in turn, activates the parathyroid gland calcium-sensing receptor, stimulates PTH secretion, and exacerbates the hyperphosphatemia. The continuing hyperphosphatemia may be modified by vigorous administration of aluminum hydroxide gel or calcium carbonate supplements. As discussed later, the FDA recently approved therapeutic use of the calcium-sensing receptor agonist **cinacalcet** to suppress PTH secretion.

### Disorders of Vitamin D

**Hypervitaminosis D.** The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. The responses to vitamin D reflect endogenous vitamin D production, tissue reactivity, and vitamin D intake. Some infants may be hyperreactive to small doses of vitamin D. In adults, hypervitaminosis D results from overtreatment of hypoparathyroidism or secondary hyperparathyroidism of renal osteodystrophy and from faddist use of excessive doses. Toxicity in children also may occur following accidental ingestion of adult doses and from feeding premature infants with formula containing supplemental vitamin D.
The amount of vitamin D necessary to cause hypervitaminosis varies widely. As a rough approximation, continued daily ingestion of \( \geq 50,000 \) units by a person with normal parathyroid function and sensitivity to vitamin D may result in poisoning. Hypervitaminosis D is particularly dangerous in patients who are receiving digoxin because the toxic effects of the cardiac glycosides are enhanced by hypercalcemia (Chapter 28). The initial signs and symptoms of vitamin D toxicity are those associated with hypercalcemia. Because hypercalcemia in vitamin D intoxication generally is due to very high circulating levels of 25-OHD, the plasma concentrations of PTH and calcitriol typically (but not uniformly) are suppressed. In children, a single episode of moderately severe hypercalcemia may arrest growth completely for \( \geq 6 \) months, and the deficit in height may never be fully corrected. Vitamin D toxicity in the fetus is associated with excess maternal vitamin D intake or extreme sensitivity and may result in congenital supravalvular aortic stenosis. In infants, this anomaly frequently is associated with other stigmata of hypercalcemia.

**Vitamin D Deficiency.** Vitamin D deficiency results in inadequate absorption of Ca\(^{2+}\) and phosphate. The consequent decrease of plasma Ca\(^{2+}\) concentration stimulates PTH secretion, which acts to restore plasma Ca\(^{2+}\) at the expense of bone. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH. In children, the result is a failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as *rickets*. As a consequence of inadequate calcification, bones of individuals with rickets are soft, and the stress of weight bearing gives rise to bowing of the long bones.

In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Severe osteomalacia may be associated with extreme bone pain and tenderness. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations \(<8 \) ng/mL are highly predictive of osteomalacia.

**Metabolic Rickets and Osteomalacia.** These disorders are characterized by abnormalities in calcitriol synthesis or response.

**Hypophosphatemic vitamin D–resistant rickets,** in its most common form, is an X-linked disorder (XLH) of calcium and phosphate metabolism. Calcitriol levels are inappropriately normal for the observed degree of hypophosphatemia. Patients experience clinical improvement when treated with large doses of vitamin D, usually in combination with inorganic phosphate. Even with vitamin D treatment, calcitriol concentrations may remain lower than expected. The genetic basis for XLH has been defined. The affected protein, a phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEX), is a neutral endopeptidase. The substrate for this enzyme likely is involved in renal phosphate transport. Syndromes closely related to XLH, in which phosphate levels are altered without significant net changes in serum concentrations of calcium, PTH, or 1,25(OH)\(_2\)D, include *hereditary hypophosphatemic rickets with hypercalciuria* (HHHR) and autosomal dominant *hypophosphatemic rickets*. The latter disorder maps to chromosome 12p13.3 and is associated with mutations in the gene encoding fibroblast growth factor 23 (White et al., 2001; Bergwitz and Jüppner, 2010).

**Vitamin D–dependent rickets** (also called vitamin D–dependent rickets type I, VDDR-I or pseudovitamin D-deficiency rickets (PDDR)) is an autosomal recessive disease caused by an inborn error of vitamin D metabolism involving defective conversion of 25-OHD to calcitriol owing to mutations in CYP1α (1α-hydroxylase). The condition responds to physiological doses of calcitriol. An initial dose of 1-3 \( \mu \)g/day is used to heal rickets, after which a maintenance dose of 0.25-1 \( \mu \)g/day can be used. 1αOHD is also effective as slightly higher dosages (2-5 \( \mu \)g/day and 1-2 \( \mu \)g/day, respectively). Other vitamin D analogs upstream of the 1α-hydroxylase have little activity.

**Hereditary 1,25-dihydroxyvitamin D resistance** (HVDDR, also called vitamin D–dependent rickets type II) is an autosomal recessive disorder that is characterized by hypocalcemia, osteomalacia, rickets, and total alopecia. Multiple heterogenous mutations of the vitamin D receptor cause vitamin D–dependent rickets type II (Malloy et al., 2005). Absolute hormone resistance results from premature stop mutations, missense mutations in the zinc finger DNA-binding domain, mutations of the receptor ligand-binding domain, or mutations that affect heterodimerization of the VDR with the retinoid X receptor (RXR).

Serum abnormalities include low serum concentrations of calcium and phosphate and elevated serum alkaline phosphatase activity. The hypocalcemia leads to secondary hyperparathyroidism with elevated PTH levels and hypophosphatemia. The 25(OH)-vitamin D values are normal, whereas 1,25(OH)\(_2\)-vitamin D levels are elevated in type II vitamin D–dependent rickets. This clinical feature distinguishes hereditary vitamin D–dependent rickets type II from CYP1α deficiency (vitamin D–dependent rickets type I), where serum 1,25(OH)2-vitamin D values are depressed. Children affected by vitamin D–dependent rickets type II are refractory even to massive doses of vitamin D and calcitriol, and they may require prolonged treatment with parenteral Ca\(^{2+}\). Some remission of symptoms has been observed during adolescence, but the basis of remission is unknown. Notably, missense mutations in the ligand-binding domain have been described that result only in partial hormone resistance. Thus, the use of calcitriol analogs that bind to the VDR at different amino acids may provide therapeutic opportunities not otherwise available. This represents a prime application of pharmacogenetics, where “personalized” treatment based on the specific VDR mutations can be envisioned.

**Renal osteodystrophy (renal rickets)** refers to the disordered bone morphology that attends chronic kidney disease. It is characterized by abnormalities of bone turnover, mineralization, volume, linear growth, or strength, as well as underlying defects in mineral ion, PTH, or vitamin D metabolism. In the early phase of chronic renal failure, physiological concentrations of 1,25(OH)2D in circulation may become insufficient to regulate parathyroid cell function normally. As a result, the set point of PTH secretion to plasma Ca\(^{2+}\) concentration shifts to the right, PTH synthesis becomes enhanced at the transcriptional level, and parathyroid cells begin to proliferate. This resistance of the parathyroid cells to the physiological concentration of 1,25(OH)2D may be partially due to decreased conversion of 25-OHD to calcitriol. Phosphate retention and diminished serum calcium also increase PTH mRNA levels but at the post-transcriptional level. In addition, calcitriol deficiency impairs intestinal Ca\(^{2+}\) absorption and mobilization from bone. Hypocalcemia commonly results (although in some patients, prolonged and severe hyperparathyroidism eventually may lead to hypercalcemia). Aluminum
deposition in bone, once a cause of renal osteodystrophy, is no longer an issue since aluminum was removed from dialysis solutions.

Osteoporosis

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Osteoporosis is a major and growing public health problem in developed nations. Many women (30-50%) and men (15-30%) suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age, and spine and hip fractures are associated with reduced survival. Fractures of distal forearm, foot, or ankle are not associated with increased mortality (Teng et al., 2008).

Osteoporosis can be categorized as primary or secondary. In 1948, Albright and Reifenstein concluded that primary osteoporosis included two separate entities: one related to menopausal estrogen loss and the other to aging. This concept was extended by the recognition that primary osteoporosis represents two fundamentally different conditions: type I osteoporosis, characterized by loss of trabecular bone owing to estrogen lack at menopause, and type II osteoporosis, characterized by loss of cortical and trabecular bone in men and women due to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. It is not clear, however, that these two entities are truly distinct. Although many osteoporotic women undoubtedly have experienced excessive menopausal bone loss, it may be more appropriate to consider osteoporosis as the result of multiple physical, hormonal, and nutritional factors acting alone or in concert.

Secondary osteoporosis is due to systemic illness or medications such as glucocorticoids or phenytoin. The most successful approach to secondary osteoporosis is prompt resolution of the underlying cause or discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used.

Paget’s Disease. Paget’s disease is characterized by single or multiple sites of disordered bone remodeling. The etiology of the disease is uncertain but is thought to be the result of infection with the measles virus of the paramyxovirus family (Roodman and Windle, 2005). It affects up to 2-3% of the population >60 years of age. The primary pathologic abnormality is increased bone resorption followed by exuberant bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. Pagetic lesions contain many abnormal multinucleated osteoclasts associated with a disordered mosaic pattern of bone formation. Pagetic bone is thickened and has abnormal microarchitecture. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget’s disease.

Renal Osteodystrophy. Bone disease is a frequent consequence of chronic renal failure and dialysis. Pathologically, lesions are typical of hyperparathyroidism (osteitis fibrosa), vitamin D deficiency (osteomalacia), or a mixture of both. The underlying pathophysiology reflects increased serum phosphate and decreased calcium, leading to secondary events that strive to preserve circulating levels of mineral ions at the expense of bone.

PHARMACOLOGICAL TREATMENT OF DISORDERS OF MINERAL ION HOMEOSTASIS AND BONE METABOLISM

Hypercalcemia

Hypercalcemia can be life threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6-8 L/day). Agents that augment Ca²⁺ excretion, such as loop diuretics (Chapter 25), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted because they otherwise will aggravate volume depletion and hypercalcemia.

Corticosteroids administered at high doses (e.g., 40-80 mg/day of prednisone) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (Chapter 42). The response to steroid therapy is slow; from 1-2 weeks may be required before plasma Ca²⁺ concentration falls.

Calcitonin (CALCIUM, Miacalcin) may be useful in managing hypercalcemia. Reduction in Ca²⁺ can be rapid, although “escape” from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 hours; if there is no response within 1-2 days, the dose may be increased to a maximum of 8 units/kg every 12 hours. If the response after 2 more days still is unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 hours. Calcitonin can lower serum calcium by 1-2 mg/dL.

Intravenous bisphosphonates (pamidronate, zoledronate) have proven very effective in the management of hypercalcemia (see further discussion of bisphosphonates later in the chapter). These agents potentely inhibit osteoclastic bone resorption. Oral bisphosphonates are less effective for treating hypercalcemia. Therefore, pamidronate (AREDIA) is given as an intravenous infusion of 60-90 mg over 4-24 hours; the more prolonged infusion (>4 hours) is reserved primarily for patients with renal dysfunction. With pamidronate, resolution of hypercalcemia occurs over several days, and the effect usually persists for several weeks. Zoledronate (ZOMETA) has superseded pamidronate because of its more rapid normalization of serum calcium and longer duration of action.

Plicamycin (mithramycin, Mithracin) is a cytotoxic antibiotic that also decreases plasma Ca²⁺ concentrations by inhibiting bone resorption. Reduction in plasma Ca²⁺ concentrations occurs within 24-48 hours when a relatively low dose of this agent is given.
(15-25 μg/kg of body weight) to minimize the high systemic toxicity of the drug; indeed, its toxicity generally precludes its use.

Oral sodium phosphate lowers plasma Ca\(^{2+}\) concentrations and may offer short-term calcemic control of some patients with primary hyperparathyroidism who are awaiting surgery. However, the risk of precipitating calcium phosphate salts in soft tissues throughout the body is of concern. In light of satisfactory responses to other agents, administration of intravenous sodium phosphate is not recommended as a treatment for hypocalcemia.

Once the hypercalcemic crisis has resolved or in patients with milder calcium elevations, therapy turns to more durable resolution of the hypercalcemic state. Parathyroidectomy remains the only definitive treatment for primary hyperparathyroidism. Specific indications for surgery have been proposed (Bilezikian et al., 2002). In the hands of a skilled parathyroid surgeon, resection of a single adenoma (~80% of cases) or of the hyperplastic glands (~15% of cases) cures hyperparathyroidism. Complications include transient postoperative hypocalcemia, which may reflect temporary disruption of blood supply to the remaining parathyroid tissue or skeletal avidity for calcium, and permanent hypoparathyroidism. As described later, a calcium mimetic that stimulates the calcium-sensing receptor is a promising new therapy for hyperparathyroidism that may be used increasingly in the future.

Therapy of hypocalcemia of malignancy ideally is directed at the underlying cancer. When this is not possible, parenteral bisphosphonates often will maintain calcium levels within an acceptable range.

**Hypocalcemia and Other Therapeutic Uses of Calcium.**

Hypoparathyroidism is treated primarily with vitamin D. Dietary supplementation with Ca\(^{2+}\) also may be necessary.

Calcium is used in the treatment of calcium deficiency states and as a dietary supplement. Ca\(^{2+}\) salts are specific in the immediate treatment of hypocalcemic tetany regardless of etiology. In severe tetany, symptoms are best brought under control by intravenous medication. Calcium chloride (CaCl\(_2\) · 2H\(_2\)O) contains 27% Ca\(^{2+}\); it is valuable in the treatment of hypocalcemic tetany and laryngospasm. The salt is given intravenously and must never be injected into tissues. Injections of calcium chloride are accompanied by peripheral vasodilation and a cutaneous burning sensation. The salt usually is given intravenously in a concentration of 10% (equivalent to 1.36 mEq Ca\(^{2+}\)/mL). The rate of injection should be slow (not >1 mL/minute) to prevent cardiac arrhythmias from a high concentration of Ca\(^{2+}\). The injection may induce a moderate fall in blood pressure owing to vasodilation. Because calcium chloride is an acidifying salt, it is usually undesirable in the treatment of the hypocalcemia caused by renal insufficiency. Calcium gluconate injection (a 22% solution; 18 mg or 0.9 mEq of Ca\(^{2+}\)/mL) is administered intravenously at a dose of 5-20 mL for the treatment of severe hypocalcemic tetany; the injection produces a transient tingling sensation when given too rapidly. When the intravenous route is not possible, injections may be given intramuscularly in the gluteal region at a dose of up to 5 mL. A mild local reaction may result. Calcium gluconate injection (a 10% solution; 9.3 mg of Ca\(^{2+}\)/mL) given intravenously is the treatment of choice for severe hypocalcemic tetany. Patients with moderate-to-severe hypocalcemia may be treated by intravenous infusion of calcium gluconate at a dose of 10-15 mg of Ca\(^{2+}\)/kg of body weight over 4-6 hours. Because the usual 10-mL vial of a 10% solution contains only 93 mg Ca\(^{2+}\), many vials are needed. The intramuscular route should not be employed because abscess formation at the injection site may result.

For control of milder hypocalcemic symptoms, oral medication suffices, frequently in combination with vitamin D or one of its active metabolites. Calcium salts are acidifying, and different forms can be interchanged to avoid gastric irritation. Available Ca\(^{2+}\) salts include calcium carbonate, lactate, gluconate, phosphate, citrate, and hydroxyapatite. Calcium carbonate is prescribed most frequently, whereas calcium citrate may be absorbed more efficiently than other salts. However, absorption efficiency for most commonly prescribed calcium products is reasonable, and for many patients, cost and palatability outweigh modest differences in efficacy. Average doses for hypocalcemic patients are calcium gluconate, 15 g/day in divided doses; calcium lactate, 7.7 g plus 8 g lactose with each meal; and calcium carbonate or calcium phosphate, 1-2 g with meals.

Calcium carbonate and calcium acetate are used to restrict phosphate absorption in patients with chronic renal failure and oxalate absorption in patients with inflammatory bowel disease. Acute administration of calcium may be lifesaving in patients with extreme hyperkalemia (serum K\(^+\)>7 mEq/L). Calcium gluconate (10-30 mL of a 10% solution) can reverse some of the cardiotoxic effects of hyperkalemia, providing time while other efforts are taken to lower the plasma K\(^+\) concentration.

Additional FDA-approved uses of calcium include intravenous treatment for black widow spider envenomation and management of magnesium toxicity. Use of supplemental calcium in the prevention and treatment of osteoporosis is discussed later.

**THERAPEUTIC USES OF VITAMIN D**

**Clinical Forms of Vitamin D.**

Calcitriol (1,25-dihydroxycholecalciferol; CALCIEX, ROCALTROL) is available for oral administration or injection. Intravenous treatment regimens with high doses of calcitriol or one of its derivatives have become predominant for managing patients with chronic kidney disease and end-stage kidney disease. Its specific therapeutic uses are discussed later. Several derivatives of vitamin D (Figure 44–10) are of considerable therapeutic and experimental interest.

Doxercalciferol (1α-hydroxyvitamin D\(_{2}\), HECTOROL) is a prodrug that first must be activated by hepatic 25-hydroxylation to generate the biologically active compound, 1α,25-(OH)\(_2\)D\(_2\) (Figure 44–10). The FDA has approved oral and intravenous preparations of 1α-hydroxyvitamin D\(_2\) for use in treating secondary hyperparathyroidism, starting at 10 mg three times per week.

Dihydrotachysterol (DHT, ROXANE) is a reduced form of vitamin D\(_{3}\). In the liver DHT is converted to its active form, 25-hydroxydihydrotachysterol. DHT is <1% as active as calcitriol in antirachitic assays but is much more effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca\(^{2+}\) in hypoparathyroidism. DHT is well absorbed from the GI tract and maximally increases serum calcium concentration after 2 weeks of daily
administration. The hypercalcemic effects typically persist for 2 weeks but can last for up to 1 month. DHT is available for oral administration in doses ranging from 0.2-1 mg/day (average 0.6 mg/day).

1α-Hydroxycholecalciferol (1-OHD3, alphacalcidol; ONE-ALPHA) was introduced as a substitute for 1,25(OH)2D3; alphacalcidol is a synthetic vitamin D3 derivative that is already hydroxylated in the 1α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-(OH)2D3. It is equal to calcitriol in assays for stimulation of intestinal absorption of Ca2+ and bone mineralization and does not require renal activation. It therefore has been used to treat renal osteodystrophy and is available in the U.S. for experimental purposes.

Ergocalciferol (calciferol, DRISDOL) is pure vitamin D2. It is available for oral, intramuscular, or intravenous administration. Ergocalciferol is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypoparathyroidism, and vitamin D–resistant rickets type II, typically in doses of 50,000-200,000 units/day in conjunction with calcium supplements.

Analogs of Calcitriol. Several vitamin D analogs (Figure 44–10) suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism.

Calcipotriol (calcipotriene) is a synthetic derivative of calcitriol with a modified side chain that contains a 22–23 double bond, a 24(S)-hydroxy functional group, and carbons 25-27 incorporated into a cyclopropane ring. Calcipotriol has comparable affinity for the vitamin D receptor, but it is <1% as active as calcitriol in regulating calcium metabolism. This reduced calcemic activity largely reflects the pharmacokinetics of calcipotriol (Kissmeyer and Binderup, 1991). Calcipotriol has been studied extensively as a treatment for psoriasis (Chapter 65), although its mode of action is not known; a topical preparation (DOVONEX) is available for that purpose. In clinical trials, topical calcipotriol has been found to be slightly more effective than glucocorticoids with a good safety profile.

Paricalcitol (1,25-dihydroxy-19-norvitamin D2, ZEMPLAR) is a synthetic calcitriol derivative that lacks the exocyclic C19 and has a vitamin D2 rather than vitamin D3 side chain (Figure 44–10). It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus (Martin et al., 1998). In an animal model, paricalcitol prevented or reversed PTH-induced high-turnover bone disease (Slatopolsky et al., 2003). Paricalcitol administered intravenously is FDA-approved for treating secondary hyperparathyroidism in patients with chronic renal failure.

22-Oxacalcitriol (1,25-dihydroxy-22-oxavitamin D3, OCT, maxacalcitol, OXAROL) differs from calcitriol only in the substitution of C-22 with an oxygen atom. Oxacalcitriol has a low affinity for vitamin D–binding protein; as a result, more of the drug circulates in the free (unbound) form, allowing it to be metabolized more rapidly than calcitriol with a consequent shorter t1/2. Oxacalcitriol is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in chronic renal failure. It should be borne in mind that persuasive evidence supports the use of cinacalcet for treatment of secondary hyperparathyroidism (Drueke and Ritz, 2009). Indeed, emerging findings show the clinical efficacy of cinacalcet for managing primary hyperparathyroidism (Peacock et al., 2009).
Therapeutic Indications for Vitamin D

The major therapeutic uses of vitamin D may be divided into four categories:

- prophylaxis and cure of nutritional rickets
- treatment of metabolic rickets and osteomalacia, particularly in the setting of chronic renal failure
- treatment of hypoparathyroidism
- prevention and treatment of osteoporosis (discussed in the section on osteoporosis)

Vitamin D supplementation may help prevent fractures, but the relationship between blood vitamin D concentrations and fracture risk is unclear (Cauley et al., 2008).

Nutritional Rickets. Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The condition, once extremely rare in the U.S. and other countries where food fortification with the vitamin is practiced, is now increasing. Infants and children receiving adequate amounts of vitamin D–fortified food do not require additional vitamin D; however, breast-fed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement (Wagner and Greer, 2008). The usual practice is to administer vitamin A in combination with vitamin D. A number of balanced vitamin A and D preparations are available for this purpose. Because the fetus acquires >85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D.

Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca$^{2+}$ and phosphate concentrations in ~10 days, with radiographic evidence of healing within ~3 weeks. However, a larger dose of 3000–4000 units daily is often prescribed for more rapid healing, particularly when respiration is compromised by severe thoracic rickets.

Vitamin D may be given prophylactically in conditions that impair its absorption (e.g., diarrhea, steatorrhea, and biliary obstruction). Parenteral administration also may be used in such cases.

Treatment of Osteomalacia and Renal Osteodystrophy. Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with chronic renal disease are at risk for developing osteomalacia but also may develop a complex bone disease called renal osteodystrophy. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in bone mineralization that is due to decreased renal synthesis of calcitriol. In renal osteodystrophy, low bone mineral density may be accompanied by high-turnover bone lesions typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease. The therapeutic approach to the patient with renal osteodystrophy depends on its specific type. In high-turnover (hyperparathyroid) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended because phosphate restriction is limited by the need to provide adequate protein intake to maintain nitrogen balance. Although highly effective, aluminum is no longer used as a phosphate binder because it promotes adynamic bone disease, anemia, myopathy, and occasionally dementia. Calcium-containing phosphate binders along with calcitriol administration may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease and an increased incidence of vascular calcification. Highly effective non-calcium-containing phosphate binders have been developed. Sevelamer hydrochloride (RENAGEL), a nonabsorbable phosphate-binding polymer, effectively lowers serum phosphate concentration in hemodialysis patients, with a corresponding reduction in the calcium × phosphate product. Sevelamer hydrochloride consists of cross-linked poly[allylamine hydrochloride] that is resistant to digestive degradation. Its partially protonated amines spaced one carbon from the polymer backbone chelate phosphate ions. Sevelamer is modestly water soluble and only trace amounts are absorbed from the GI tract. However, with continued use, progressive accumulation has been reported in experimental animals. Side effects of sevelamer include vomiting, nausea, diarrhea, and dyspepsia. Sevelamer does not affect the bioavailability of digoxin, warfarin, enalapril, or metoprolol. Lanthanum carbonate (FOSRENL) is a poorly permeable trivalent cation that is useful in treating the hyperphosphatemia associated with renal osteodystrophy.

Renal osteodystrophy associated with low bone turnover (adynamic bone disease) is increasingly common and may be due to oversuppression of PTH with aggressive use of either calcitriol or other vitamin D analogs. Although PTH levels generally are low (<100 pg/mL), a high PTH level does not exclude the presence of adynamic bone disease, especially with PTH assays that do not distinguish between biologically active and inactive PTH fragments (Monier-Faugere et al., 2001). Current guidelines suggest that treatment with an active vitamin D preparation is indicated if serum 25-OHD levels are <30 ng/mL and serum calcium is <9.5 mg/dL (2.37 mM). However, if 25-OHD and serum calcium levels are elevated, vitamin D supplementation should be discontinued. If the serum calcium level is <9.5 mg/dL, treatment with a vitamin D analog is warranted irrespective of the 25-OHD level (Eknayan et al., 2003).

Hypoparathyroidism. Vitamin D and its analogs are a mainstay of the therapy of hypoparathyroidism. Dihydractychosterol (DHT) has a faster onset, shorter duration of action, and a greater effect on bone mineralization than does vitamin D and traditionally has been a preferred agent. Calcitriol also is effective in the management of hypoparathyroidism and certain forms of pseudohypoparathyroidism in which endogenous levels of calcitriol are abnormally low. However, most hypoparathyroid patients respond to any form of vitamin D. Calcitriol may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

Miscellaneous Uses of Vitamin D. Vitamin D is used to treat hypophosphatemia associated with Fanconi’s syndrome. Large doses of vitamin D (>10,000 units/day) are not useful in patients with osteoporosis and even can be dangerous. However, administration of 400-800 units/day of vitamin D to frail elderly men and women has been shown to suppress bone remodeling, protect bone mass, and reduce fracture incidence (see later section on osteoporosis). Clinical trials suggest that calcitriol may become an important agent for the treatment of psoriasis (Kowalzick, 2001). As such nontraditional
uses of vitamin D are discovered, it will become important to develop noncalcemic analogs of calcitriol that achieve effects on cellular differentiation without the risk of hypercalcemia.

### Adverse Effects of Vitamin D Therapy

The primary toxicity associated with calcitriol reflects its potent effect to increase intestinal calcium and phosphate absorption, along with the potential to mobilize osseous calcium and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates calcitriol therapy and may limit its use at doses that effectively suppress PTH secretion. As described earlier, noncalcemic vitamin D analogs provide alternative interventions, although they do not obviate the need to monitor serum calcium and phosphorus concentrations.

Hypervitaminosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support. As noted earlier under hypercalcemia, forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca\(^{2+}\) concentration falls to normal, and Ca\(^{2+}\) in soft tissue tends to be mobilized. Conspicuous improvement in renal function occurs unless renal damage has been severe.

### CALCITONIN

#### Diagnostic Uses of Calcitonin

Calcitonin is a sensitive and specific marker for the presence of medullary thyroid carcinoma (MTC), a neuroendocrine malignancy originating in thyroid parafollicular C cells. MTC can be hereditary (25%) or sporadic (75%) and is present in all patients with the multiple endocrine neoplasia type 2 (MEN2) syndromes. Because one form of MEN2 is inherited as a dominant trait, relatives of patients should be examined repeatedly by calcitonin measurements from early childhood. Because calcitonin levels may be low in early tumor stages or in premalignant C-cell hyperplasia, pentagastrin-induced calcitonin provides greater sensitivity and increased MTC detection. The identification of discrete mutations in the RET protooncogene in subjects with MEN2 offers hope that genetic screening will supplant reliance on testing serum calcitonin, which can give spurious results.

#### Therapeutic Uses

Calcitonin lowers plasma Ca\(^{2+}\) and phosphate concentrations in patients with hypercalcemia; this effect results from decreased bone resorption and is greater in patients in whom bone turnover rates are high. Although calcitonin is effective for up to 6 hours in the initial treatment of hypercalcemia, patients become refractory after a few days. This is likely due to receptor downregulation (Takahashi et al., 1995). Use of calcitonin does not substitute for aggressive fluid resuscitation, and the bisphosphonates are the preferred agents.

Calcitonin is effective in disorders of increased skeletal remodeling, such as Paget’s disease, and in some patients with osteoporosis. In Paget’s disease, chronic use of calcitonin produces long-term reductions of serum alkaline phosphatase activity and symptoms. Development of antibodies to calcitonin occurs with prolonged therapy, but this is not necessarily associated with clinical resistance. Side effects of calcitonin include nausea, hand swelling, urticaria, and, rarely, intestinal cramping. Side effects appear to occur with equal frequency with human and salmon calcitonin. *Salmon calcitonin* is approved for clinical use. The latter product also is available as a nasal spray, introduced for once-daily treatment of postmenopausal osteoporosis. For Paget’s disease, calcitonin generally is administered by subcutaneous injection because intranasal delivery is relatively ineffective owing to limited bioavailability. After initial therapy at 100 units/day, the dose typically is reduced to 50 units three times a week.

### BISPHOSPHONATES

Bisphosphonates are analogs of pyrophosphate (Figure 44-11) that contain two phosphate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate. Because they form a three-dimensional structure capable of chelating divalent cations such as Ca\(^{2+}\), the bisphosphonates have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling. Accordingly, they are used extensively in conditions characterized by osteoclast-mediated bone resorption, including osteoporosis, steroid-induced osteoporosis, Paget’s disease, tumor-associated osteolysis, breast and prostate cancer, and hypercalcemia. Calcium supplements, antacids, food or medications containing divalent cations, such as iron, may interfere with intestinal absorption of bisphosphonates. Recent evidence suggests that second- and third-generation bisphosphonates also may be effective anticancer drugs. For a review of the basic and clinical pharmacology of bisphosphonates, see Russell, 2007.

The clinical utility of bisphosphonates resides in their direct inhibition of bone resorption. First-generation bisphosphonates contain minimally modified side chains (R1 and R2 in Figure 44-11) (medronate, clodronate, and etidronate) or possess a chlorophenol group (tiludronate) (Figure 44-11). They are the least potent and in some instances cause bone demineralization. Second-generation amino bisphosphonates (e.g., alendronate and pamidronate) contain a nitrogen group in the side chain. They are 10-100 times more potent than first-generation compounds. Third-generation bisphosphonates (e.g., risedronate and zoledronate) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents.
Bisphosphonates concentrate at sites of active remodeling. Because they are highly negatively charged, bisphosphonates are membrane impermeable but are incorporated into the bone matrix by fluid-phase endocytosis (Stenbeck and Horton, 2000). Bisphosphonates remain in the matrix until the bone is remodeled and then are released in the acid environment of the resorption lacunae beneath the osteoclast as the overlying mineral matrix is dissolved. The importance of this process for the antiresorptive effect of bisphosphonates is evidenced by the fact that calcitonin blocks the antiresorptive action.

Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly physiochemical effects. The antiresorptive activity apparently involves two primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

The current model is that apoptosis accounts for the antiresorptive effect of first-generation bisphosphonates, whereas the inhibitory action of aminobisphosphonates proceeds through the latter mechanism. Consistent with this view, the antiresorptive effect of aminobisphosphonates such as alendronate and risedronate, but not of clodronate or etidronate, persists when apoptosis is suppressed (Halasy-Nagy et al., 2001). First-generation bisphosphonates are metabolized into a nonhydrolyzable ATP analog (AppCCl₂p) that accumulates within osteoclasts and induces apoptosis (Rogers, 2003). In contrast, the aminobisphosphonates such as alendronate and ibandronate directly inhibit multiple steps in the pathway from mevalonate to cholesterol and isoprenoid lipids, such as geranylgeranyl diphosphate, that are required for the prenylation of proteins that are important for osteoclast function. The potency of aminobisphosphonates for inhibiting farnesyl synthase correlates directly with their antiresorptive activity (Dunford et al., 2001).

Available Bisphosphonates

Several bisphosphonates are available in the U.S. (Figure 44–11). Etidronate sodium (Didronel) is used for treatment of Paget’s disease and may be used parenterally to treat hypercalcemia. Because etidronate is the only bisphosphonate that inhibits mineralization, it
has been supplanted largely by pamidronate and zoledronate for treating hypercalcemia. Pamidronate (AREDIA) is approved for management of hypercalcemia and for prevention of bone loss in breast cancer and multiple myeloma, but it also is effective in other skeletal disorders. Pamidronate is available in the U.S. only for parenteral administration. For treatment of hypercalcemia, pamidronate may be given as an intravenous infusion of 60-90 mg over 4-24 hours.

Several newer bisphosphonates have been approved for treatment of Paget’s disease. These include tiludronate (SKELID), alendronate (FOSAMAX), and risedronate (ACTONEL). Tiludronate is approved for treatment of Paget’s disease of bone. Standard dosing is 400 mg/day orally for 3 months. Tiludronate in recommended doses does not interfere with bone mineralization, unlike etidronate. Zoledronate (ZOMETA) is approved for treating Paget’s disease and administered as a single 5-mg infusion decreased bone turnover markers for 6 months with no loss of therapeutic effect (Reid et al., 2005). Zometa is widely used for prevention of osteoporosis in prostate and breast cancer patients receiving hormonal therapy. It is also approved for treating hypercalcemia of malignancies and for preventing fractures and skeletal complications in cancer patients with bone metastases. It is widely used to prevent osteoporosis and fractures in breast and prostate cancer patients receiving hormone-antagonist treatment.

The potent bisphosphonate ibandronate is approved for the prevention and treatment of postmenopausal osteoporosis. The recommended oral dose is 2.5 mg daily or 150 mg once monthly, which appears to be as effective as daily treatment and is well tolerated.

Absorption, Fate, and Excretion. All oral bisphosphonates are very poorly absorbed from the intestine and have remarkably limited bioavailability (<1% [alendronate, risedronate] to 6% [etidronate, tiludronate]). Hence these drugs should be administered with a full glass of water following an overnight fast and at least 30 minutes before breakfast. Oral bisphosphonates have not been used widely in children or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton.

Bisphosphonates are excreted primarily by the kidneys. Adjusted doses for patients with diminished renal function have not been determined; bisphosphonates currently are not recommended for patients with a creatinine clearance of <30 mL/minute.

Adverse Effects. Oral bisphosphonates, including alendronate, ibandronate, and risedronate, can cause heartburn, esophageal irritation, or esophagitis. Other GI side effects include abdominal pain and diarrhea. Symptoms often abate when patients take the medication after an overnight fast, with tap or filtered water (not mineral water), and remain upright. Esophageal complications are infrequent when the drug is taken as described. If symptoms persist despite these precautions, use of a nonsteroidal anti-inflammatory drug or acetaminophen can diminish these symptoms; a proton pump inhibitor at bedtime may be helpful (Chapter 45). Both drugs may be better tolerated on a once-weekly regimen with no reduction of efficacy. Patients with active upper GI disease should not be given oral bisphosphonates.

Serious osteonecrosis of the jaw is associated with use of bisphosphonates (Edwards et al., 2008). In 2008 the FDA issued an alert on the use of bisphosphonates (http://www.fda.gov/Drugs/ DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm124165.htm) and product labeling was modified to highlight the severe musculoskeletal pain that may occur and its relation to osteonecrosis of the jaw.

Owing to cytokine release, initial parenteral infusion of pamidronate, may cause skin flushing, flu-like symptoms, muscle and joint aches and pains, nausea and vomiting, abdominal discomfort and diarrhea (or constipation) but mainly when given in higher concentrations or at faster rates than those recommended. These symptoms are short lived and generally do not recur with subsequent administration.

Zoledronate has more potent effects on calcium than some other bisphosphonates and is capable of causing severe hypercalcemia. It has been associated with renal toxicity, deterioration of renal function, and potential renal failure. Thus, the infusion should be given over at least 15 minutes, and the dose should be 4 mg. Patients who receive zoledronate should have standard laboratory and clinical parameters of renal function assessed prior to treatment and periodically after treatment to monitor for deterioration in renal function.

Other Therapeutic Uses

Hypercalcemia. The use of pamidronate in the management of malignancy-associated hypercalcemia was described earlier. Zoledronate appears to be more effective than pamidronate and at least as safe, can be infused over 15 minutes rather than 2-4 hours, and is FDA-approved for this indication.

Postmenopausal Osteoporosis. Much interest is focused on the role of bisphosphonates in the treatment of osteoporosis. Clinical trials show that treatment is associated with increased bone mineral density and protection against fracture.

Cancer. Bisphosphonates may also have direct antitumor action by inhibiting oncogene activation and through their anti-angiogenic effects. Randomized clinical trials of bisphosphonates in patients with breast cancer suggest that they delay or prevent development of metastases as a component of endocrine adjuvant therapy (Gnant et al., 2009).

The use of bisphosphonates in cancer patients suggests that they delay or prevent development of metastases as a component of endocrine adjuvant therapy (Gnant et al., 2009).

**PARATHYROID HORMONE**

Continuous administration of parathyroid hormone (PTH) or high-circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, *intermittent* PTH administration promotes bone growth. Selye first described the anabolic action of PTH some 80 years ago, but this observation was largely ignored and generally forgotten. Beginning in the 1970s, studies focused on the anabolic action of PTH, culminating with FDA approval of synthetic human 34-amino-acid amino-terminal PTH fragment [hPTH(1-34), teriparatide (Forteo)] for use in treating severe osteoporosis (Hodsman et al., 2005).

Full-length human recombinant PTH(1-84) is in phase III trials for hypoparathyroidism, for which teriparatide is not approved. Intermittent PTH(1-84) may soon be approved for use in osteoporosis, but its benefits over PTH(1-34) remain to be established.
Absorption, Fate, and Excretion. Pharmacokinetics and systemic actions of teriparatide on mineral metabolism are the same as for PTH. Teriparatide is administered by once-daily subcutaneous injection of 20 μg into the thigh or abdomen. With this regimen, serum PTH concentrations peak at 30 minutes after the injection and decline to undetectable concentrations within 3 hours, whereas the serum calcium concentration peaks at 4-6 hours after administration. Based on aggregate data from different dosing regimens, teriparatide bioavailability averages 95%. Teriparatide clearance averages 62 L/hour in women and 94 L/hour in men, which exceeds normal liver plasma flow, consistent with both hepatic and extrhepatic PTH removal. The serum t 1/2 of teriparatide is ~1 hour when administered subcutaneously versus 5 minutes when administered intravenously. The longer t 1/2 following subcutaneous administration reflects the time required for absorption from the injection site. The elimination of PTH(1-34) and full-length PTH proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion.

Clinical Effects. In postmenopausal women with osteoporosis, teriparatide increases BMD and reduces the risk of vertebral and non-vertebral fractures. Several laboratories have examined the effects of intermittent PTH on BMD in patients with osteoporosis. In these studies, teriparatide increased axial bone mineral, although initial reports of effects on cortical bone were disappointing. Co-administration of hPTH(1-34) with estrogen or synthetic androgen led to impressive gains in vertebral bone mass or trabecular bone. However, in some early studies there was only maintenance or even loss of cortical bone. Vitamin D insufficiency in patients at baseline or pharmacokinetic differences involving bioavailability or circulating half-life may have contributed to observed differences on cortical bone. The most comprehensive studies to date established the value of daily hPTH(1-34) administration on total BMD, with significant elevations of BMD in lumbar spine and femoral neck and with significant reductions of vertebral and nonvertebral fracture risk in osteoporotic women (Neer et al., 2001) and men (Finkelstein et al., 2003).

Candidates for teriparatide treatment include women who have a history of osteoporotic fracture, who have multiple risk factors for fracture, or who failed or are intolerant of previous osteoporosis therapy. Men with primary or hypogonadal osteoporosis are also candidates for treatment with teriparatide. However, the effect on fracture incidence in this group has not been established.

Adverse Effects. In rats, teriparatide increased the incidence of osteosarcoma (Vahle et al., 2004). Because of these findings, a black box warning appears on the FORTEO package insert. The clinical relevance of this finding is unclear, especially because patients with primary hyperparathyroidism have marked elevation of serum PTH without a greater incidence of osteosarcoma. Nonetheless, teriparatide should not be used in patients who are at increased baseline risk for osteosarcoma (including those with Paget’s disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton). The safety and efficacy of FORTEO have not been evaluated for extended use beyond 2 years of treatment and therapy should be limited to no more than 2 years. A tumor registry-based analysis of the occurrence of osteosarcoma in teriparatide-treated patients is ongoing; cases of osteosarcoma associated with the drug should be reported to the FDA. Increases in bone density acquired during therapy with teriparatide can maintained or extended with subsequent use of bisphosphonates (Black et al., 2005).

Full-length PTH(1-84) has been associated with osteosarcomas in rats (Jolette et al., 2006) although not in humans. The significance and interpretation of the toxicological findings has been questioned (Tashjian and Goltzman, 2008). However, adverse effects include exacerbation of nephrolithiasis and elevation of serum uric acid levels.

CALCIUM SENSOR MIMETICS: CINACALCET

Calcimimetics are drugs that mimic the stimulatory effect of calcium on the calcium-sensing receptor (CaSR) to inhibit PTH secretion by the parathyroid glands. By enhancing the sensitivity of the CaSR to extracellular Ca 2+, calcimimetics lower the concentration of Ca 2+ at which PTH secretion is suppressed. Inorganic di- and trivalent cations, along with polycations such as spermine, aminoglycosides (e.g., streptomycin, gentamicin, and neomycin) and polybasic amino acids (e.g., polylysine) are full agonists and are referred to a type I calcimimetics. Phenylalkylamine derivatives that are allosteric CaSR modulators that require the presence of Ca 2+ or other full agonists to enhance the sensitivity of activation without altering the maximal response are designated type II calcimimetics. Cinacalcet (SENSIPAR) (Figure 44–12) is approved for the treatment of secondary hyperparathyroidism owing to chronic renal disease and for patients with hypercalcemia associated with parathyroid carcinoma. Cinacalcet lowers serum PTH levels in patients with normal or reduced renal function (Padhi and Harris, 2009).

In clinical trials, cinacalcet at 20- to 100-mg doses lowered PTH levels in a concentration-dependent manner by 15–50% and the serum calcium × phosphate product by 7% compared with placebo (Franceschini et al., 2003). Cinacalcet also effectively reduced PTH levels in patients with primary hyperparathyroidism and provided sustained normalization of serum calcium without altering bone mineral density (Shoback et al., 2003). Long-term control of PTH levels was achieved during a 3-year study of cinacalcet, suggesting that resistance does not develop. There currently is insufficient information to know whether reducing serum PTH levels with

![Figure 44–12. Structure of cinacalcet.](image)
cinacalcet improves outcomes such as risk of cardiovascular events, bone disease, or mortality (Evenepoel, 2008).

Absorption, Fate, and Excretion. Cinacalcet \((\alpha R)-(\alpha\text{-methyl-N-[3-[3\text{-trifluoromethylphenyl]propyl]-1-naphthalenemethanamine hydro-chloride})\) exhibits first-order absorption, with maximal serum concentrations achieved 2-6 hours after oral administration. Maximal effects, as defined by the nadir of serum PTH, occur 2-4 hours after administration. After absorption, plasma concentrations of cinacalcet decrease with a \(t_{1/2}\) of 30-40 hours. Cinacalcet is eliminated primarily by renal excretion, with some 85% recovered in the urine after oral administration; the drug is also metabolized by multiple hepatic cytochromes, including CYPs 3A4, 2D6, and 1A2.

Cinacalcet is available in 30-, 60-, and 90-mg tablets. Optimal doses have not been defined. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis is 30 mg once daily, with a maximum of 180 mg/day. For treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum of 90 mg four times daily. The starting dose is titrated upward every 2-4 weeks to maintain the PTH level between 150 and 300 pg/mL (secondary hyperparathyroidism) or to normalize serum calcium (parathyroid carcinoma).

Adverse Reactions. The principal adverse event with cinacalcet is hypocalcemia. Thus, the drug should not be used if the initial serum \([\text{Ca}^{2+}]\) is <8.4 mg/dL; serum calcium and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy or after changing dosage.

Hypocalcemia can be diminished by initiating therapy with a low dose and gradually titrating it as necessary or adjusting the dose when vitamin D and/or phosphate binders are administered concomitantly. Patients on hemodialysis with low-calcium dialysate need to be monitored closely for hypocalcemia. Seizure threshold is lowered by significant reductions in serum \([\text{Ca}^{2+}]\), so patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is <100 pg/mL, and the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/mL.

Drug Interactions. Potential drug interactions can be anticipated with drugs that interfere with calcium homeostasis or that hinder cinacalcet absorption. Based on these considerations, potentially interfering drugs may include vitamin D analogs, phosphate binders, bisphosphonates, calcitonin, glucocorticoids, gallium, and cisplatin. The other category of drug interactions is for compounds metabolized by CYPs. Caution is recommended when cinacalcet is co-administered with inhibitors of CYP3A4 (e.g., ketoconazole, erythromycin, or itraconazole), CYP2D6 (many \(\beta\) adrenergic receptor blockers, flecainide, vinblastine, and most tricyclic antidepressants), and many other drugs.

INTEGRATED APPROACH TO PREVENTION AND TREATMENT OF OSTEOPOROSIS

Osteoporosis is a major and growing public health problem in developed nations. Ten million Americans are afflicted with osteoporosis, and an estimated 44 million individuals >50 years of age have low bone mass placing them at risk for osteoporosis. Osteoporosis is associated with a significant risk for bone fracture, especially of the hip, spine, and wrist. Approximately 50% women and 25% of men >50 years of age will experience an osteoporosis-related fracture. However, important reductions in fracture risk can be achieved with appropriate lifelong attention to prevention. Regular weight-bearing and muscle-strengthening exercise of reasonable intensity is endorsed at all ages. For children and adolescents, adequate dietary calcium and vitamin D are important if peak bone mass is to reach the level appropriate for genetic endowment. Attention to nutritional status (i.e., increased dietary calcium or calcium and/or vitamin D supplements) also may be required, particularly in elderly patients and those at risk of vitamin D deficiency. Smoking and excessive alcohol are significant risk factors and should be avoided. Although the administration of estrogen to women at menopause is a powerful intervention to preserve bone and protect against fracture, the detrimental effects of hormone-replacement therapy (HRT) have mandated a major reexamination on treatment options (see later and Chapter 40).

Pharmacological agents used to manage osteoporosis act by decreasing the rate of bone resorption and thereby slowing the rate of bone loss (antiresorptive therapy) or by promoting bone formation (anabolic therapy). Because bone remodeling is a coupled process, antiresorptive drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in BMD. They nonetheless reduce fracture risk, particularly in the spine but also in the hip (for alendronate and risedronate). Increases in BMD during the first years of antiresorptive therapy represent a constriction of the remodeling space to a new steady-state level, after which BMD reaches a plateau (Figure 44–13). One consequence of this phenomenon is that therapeutic trials in osteoporosis must be of sufficient duration (i.e., at least 2 years) to determine whether an increase in BMD represents anything more than a simple reduction in remodeling space.

Pharmacological treatment of osteoporosis is aimed at restoring bone strength and preventing fractures. The long-standing centerpiece of this approach has been antiresorptive drugs such as the bisphosphonates, estrogen, or the selective estrogen receptor modulator (SERM) raloxifene, and, to some extent, calcitonin. These drugs inhibit osteoclast-mediated bone loss, thereby reducing bone turnover.
Until recently, antiresorptive drugs were the only agents approved in the U.S. for treating osteoporosis. The increase in bone density that they produce is variable and depends on the site and the particular drug; generally, the increase is <10% after 3 years (Figure 44–12). This situation changed in 2002 when the FDA approved the biologically active PTH fragment PTH(1–34) (teriparatide, FORTEO) for use in treating postmenopausal women with osteoporosis and to increase bone mass in men with primary or hypogonadal osteoporosis. For a review and proposed guidelines for teriparatide/PTH use, see Hodsmans et al. (2005). This agent should be used only after consideration of the risks (potential cause of osteosarcoma) and benefits in patients refractory to bisphosphonates or at serious risk of fracture. Therapeutic approaches likely will evolve considerably as newer treatment paradigms are developed and combinations of antiresorptive agents and PTH are introduced, and as the molecular physiology of osteoblast and osteoclast function is elucidated (Grey et al., 2005).

**Antiresorptive Agents. Bisphosphonates.** Bisphosphonates are the most frequently used drugs for the prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates alendronate and risedronate have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization.

Alendronate (FOSAMAX), risedronate (ACTONEL), and ibandronate (BONIVA) are approved for prevention and treatment of osteoporosis and for the treatment of glucocorticoid-associated osteoporosis. Multiple appropriate formulations are available. Studies of daily treatment with alendronate established its efficacy to increase bone mineral density, decrease bone turnover, and reduce the risk of vertebral fracture among women with osteoporosis (Bone et al., 2004; Liberman et al., 1995; Tonino et al., 2000; Tucci et al., 1996). Similar results were obtained with risedronate (Delmas et al., 2008). The results of 10-year daily treatment with 10 mg of alendronate (with 500 mg of supplemental calcium) reported a 14% increase of lumbar spine BMD, with smaller increments at the trochanter, total hip, and femoral neck (Bone et al., 2004). On reduction and discontinuation of treatment, BMD at the lumbar spine was maintained. Although significant decreases of BMD occurred at the total hip, femoral neck, and forearm, BMD at the lumbar spine, trochanter, total hip, and total body remained significantly above baseline values at year 10.

For patients in whom oral bisphosphonates cause severe esophageal distress despite countermeasures, intravenous zoledronate (RECLAST or ibandronate offer skeletal protection without causing adverse GI effects. For treatment of osteoporosis, ibandronate (3 mg) is given intravenously every 3 months; zoledronate is administered as 5 mg once yearly. Zoledronate is the first bisphosphonate to be approved from once-yearly intravenous treatment of osteoporosis. Intravenous ibandronate significantly increased BMD of the lumbar spine. No fracture prevention data for intravenous ibandronate are available. Zoledronate reduces both vertebral and nonvertebral fractures (Black et al., 2007). Optimal duration of treatment and long-term safety remain to be established. A 4-mg formulation (ZOMETA) is available for intravenous treatment of hypercalcemia of malignancy, multiple myeloma, or bone metastasis resulting from solid tumors.

**Denosumab.** As described earlier, RANKL binds to its cognate receptor RANK on the surface of precursor and mature osteoclasts, and stimulates these cells to mature and resorb bone. OPG, which competes with RANK for binding to RANKL, is the physiological inhibitor of RANKL. Denosumab is an investigational human monoclonal antibody that binds with high affinity to RANKL, mimicking the effect of OPG, and thereby reducing the binding of RANKL to RANK. Denosumab blocks osteoclast formation and activation. It increases BMD and decreases bone turnover markers when given subcutaneously once every 6 months. Denosumab, administered subcutaneously at 60 mg doses every 6 months, resulted in 68%, 41%, and 20% reductions in vertebral, hip and nonvertebral fractures, respectively, in a phase III clinical trial (Cummings et al., 2008). In the 3-year Fracture Reduction Evaluation with Denosumab and Osteoporosis Every Six Months (FREEDOM) Trial, denosumab significantly reduced morphometric vertebral fractures, and decreased hip and nonvertebral fractures and changes in BMD and bone turnover markers (Cummings et al., 2008). This novel therapy may soon gain FDA approval.

**Selective Estradiol Receptor Modulators (SERMs).** Considerable work has been undertaken to develop estrogenic compounds with tissue-selective activities. One of these, raloxifene (EVISTA), acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an anti-estrogen on the breast (Chapter 40). In postmenopausal women, raloxifene stabilizes and modestly increases BMD and has been shown to reduce the risk of vertebral compression fracture (Ettinger et al., 1999). Raloxifene is approved for both the prevention and treatment of osteoporosis. With the decreased use of estrogen for treating osteoporosis, the SERM raloxifene would seem to be an ideal alternative to HRT because raloxifene reduces the risk of vertebral fractures (albeit without a positive effect on nonvertebral fractures), breast
cancer, and coronary events (coronary death, nonfatal myocardial infarction, and hospitalized acute coronary syndromes other than myocardial infarction) (Clemett and Spencer, 2000). The major drawback of raloxifene is that it can worsen vasomotor symptoms.

**Estrogen.** There is an unambiguous relationship between estrogen deficiency and osteoporosis. Postmenopausal status or estrogen deficiency at any age significantly increases a patient’s risk for osteoporosis and fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (Chapter 40). The outcome of the Women’s Health Initiative (WHI) studies, however, strikingly altered the view of the therapeutic use of HRT for long-term prevention or treatment of osteoporosis. Significantly increased risks of heart disease and breast cancer were found (Anderson et al., 2004; Cauley et al., 2003). The consensus among experts now is to reserve HRT only for the short-term relief of vasomotor symptoms associated with menopause. HRT should be limited to osteoporosis prevention in women with significant ongoing vasomotor symptoms who are not at an increased risk for cardiovascular disease. An annual individualized risk-benefit reassessment should be performed on these patients.

**Calcium.** The physiological roles of Ca$^{2+}$ and its use in the treatment of hypocalcemic disorders were discussed earlier. The rationale for using supplemental calcium to protect bone varies with time of life.

For preteens and adolescents, adequate substrate calcium is required for bone accretion. Controlled trials indicate that supplemental calcium promotes adolescent bone acquisition (Johnston et al., 1992), but its impact on peak bone mass is not known. Higher calcium intake during the third decade of life is positively related to the final phase of bone acquisition (Recker et al., 1992). There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. Although little effect of calcium on trabecular bone has been reported, reduction in cortical bone loss with calcium supplementation has been observed (Elders et al., 1994), even in populations with high dietary calcium intake. In elderly subjects, supplemental calcium suppresses bone turnover, improves BMD. Although some studies found a concomitant decrease in the incidence of fracture (Dawson-Hughes et al., 1997), three randomized trials found that it did not reduce fracture rate in older women (Jackson et al., 2006).

Patients who are unable or unwilling to increase calcium by dietary means alone may choose from many palatable, low-cost calcium preparations. As noted previously, numerous oral calcium preparations are available. The most frequently prescribed is carbonate, which should be taken with meals to facilitate dissolution and absorption. Traditional dosing of calcium is ~1000 mg/day, nearly the amount present in a quart of milk. Adults >50 years of age need 1200 mg of calcium daily. More may be necessary to overcome endogenous intestinal calcium losses, but daily intakes of ≥2000 mg frequently are reported to be constipating.

**Vitamin D and Its Analogs.** Modest supplementation with vitamin D (400-800 IU/day) may improve intestinal Ca$^{2+}$ absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. A prospective study found that neither dietary calcium nor vitamin D intake was of major importance for the primary prevention of osteoporotic fractures in women (Michaelsson et al., 2003). However, supplemental vitamin D in combination with calcium reduced fracture incidence in multiple trials (Jackson et al., 2006). Several meta-analyses reported reduction in the rate of fractures when vitamin D and calcium were taken together. Because women commonly consume less than the recommended intake of vitamin D, use of supplemental vitamin D or increased consumption of such vitamin D–rich foods as dark fish may be prudent.

The use of calcitriol to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Calcitriol and the polar vitamin D metabolite 1α-hydroxycholecalciferol are used frequently in Japan and other countries, but experience in the U.S. has been mixed. Higher doses of calcitriol appear to be more likely to improve BMD, but at the risk of hypercalcemia; therefore, close scrutiny of patients and dose modification are required. Restriction of dietary calcium may reduce toxicity during calcitriol therapy (Gallagher and Goldgar, 1990). A low incidence of hypercalcemic and hypercalcemic complications of therapy in Japan may reflect relatively poor calcium intakes in that country.

**Calcitonin.** Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis; the largest increases occurred in patients with high intrinsic rates of bone turnover. One study showed that calcitonin nasal spray (200 units/day) reduced the incidence of vertebral compression fractures by ~40% in osteoporotic women (Chesnut et al., 2000).

**Thiazide Diuretics.** Although not strictly antiresorptive, thiazides reduce urinary Ca$^{2+}$ excretion and constrain bone loss in patients with hypercalcuria. Whether they will prove to be useful in patients who are not hypercalcemic is not clear, but data suggest that they reduce hip fracture risk. No sustained effect is observed (Schoofs et al., 2003). Hydrochlorothiazide, 25 mg once or twice daily, may reduce urinary Ca$^{2+}$ excretion substantially. Effective doses of thiazides for reducing urinary Ca$^{2+}$ excretion generally are lower than those necessary for blood pressure control. For a more detailed discussion of thiazide diuretics, see Chapter 25.

**Anabolic Agents. Teriparatide.** Teriparatide (FORTEO) is the only agent currently available that increases new bone formation. It is FDA-approved for treatment of osteoporosis for up to 2 years in both men and postmenopausal women at high risk for fractures. Teriparatide significantly decreased the incidence of vertebral (4.5% vs. 14%) and nonvertebral fractures (3% vs. 6%) compared to placebo in a prospective, randomized control study (FPT) (Neer et al., 2001). Teriparatide increases predominantly trabecular bone at the lumbar spine and femoral neck; it has less significant effects at cortical sites. Although initial studies showed dose-dependent actions, and side effects, because of concern (and black box label warning), teriparatide is approved at the 20 μg dose, administered once daily by subcutaneous injection in the thigh or abdominal wall. The most common adverse effects associated with teriparatide include injection-site pain, nausea, headaches, leg cramps, and dizziness.

**Combination Therapies**

**Osteoporosis.** Because teriparatide stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted that therapy combining the two would enhance the effect on BMD more than treatment with either one alone. However, addition of
alendronate to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men (Cosman, 2008). Sequential treatment with PTH(1-84) followed by alendronate increased vertebral BMD to a greater degree than alendronate or estrogen alone (Rittmaster et al., 2000). Recent work underscores the beneficial action of alendronate in consolidating the gains in lumbar spine BMD achieved by antecedent teriparatide treatment in men.

The fracture outcome 30 months after cessation of teriparatide therapy was studied in a cohort of patients included in the FPT. Approximately 50% of each group (teriparatide or control) were treated with a bisphosphonate for some period of time during the 30-month period. Patients treated with bisphosphonates after discontinuation of teriparatide showed continued increments in BMD, whereas those who received no treatment had declines (Prince et al., 2005).

**Paget’s Disease.** Although most patients with Paget’s disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and calcitonin decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective. When etidronate is given at higher doses (10-20 mg/kg per day) or continuously for >6 months, there is a substantial risk for osteomalacia. At lower doses (5-7.5 mg/kg per day), focal osteomalacia has been observed occasionally. Defective mineralization has not been observed with other bisphosphonates or with calcitonin.

Choice of optimal therapy for Paget’s disease varies among patients. Bisphosphonates are the standard therapy. Intravenous pamidronate induces long-term remission following a single infusion. Zoledronate seems to exhibit greater response rates and a longer median duration of complete response (Major et al., 2001). Compared with calcitonin, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects. Resistance to calcitonin develops in most patients. However, calcitonin is highly reliable and may have a distinct skeletal analogesic property. Mithramycin (plicamycin) has been used in difficult cases of Paget’s disease that do not respond to bisphosphonates or calcitonin. Therapeutic utility of this agent is limited by a high potential for hemorrhagic and other toxicities, and it is not generally recommended.

**FLUORIDE**

*Fluoride* is discussed because of its toxic properties and its effect on dentition and bone.

**Absorption, Distribution, and Excretion.** Human beings obtain fluoride predominantly from the ingestion of plants and water, with most absorption taking place in the intestine. The degree of fluoride absorption correlates with its water solubility. Relatively soluble compounds, such as sodium fluoride, are absorbed almost completely, whereas relatively insoluble compounds, such as cryolite (Na₃AlF₆) and the fluoride found in bone meal (fluoroapatite) are absorbed poorly. A second route of absorption is through the lungs, and inhalation of fluoride present in dusts and gases constitutes the major route of industrial exposure.

Fluoride is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone.

The kidneys are the major site of fluoride excretion. Small amounts of fluoride also appear in sweat, milk, and intestinal secretions; in a very hot environment, sweat can account for nearly 50% of total fluoride excretion.

**Pharmacological Actions and Uses.** Because it is concentrated in the bone, the radionuclide ¹⁸F has been used in skeletal imaging. Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts; if true, this may account for the poorly mineralized and mechanically defective bone seen in some studies. In doses of 30-60 mg/day, fluoride increases trabecular bone mineral density in many, but not all, patients. In one controlled trial, fluoride increased lumbar spine density (cancellous bone) but decreased cortical bone mineral density; these changes were associated with a significant increase in peripheral fractures and stress fractures (Riggs et al., 1990). In one study, sustained-release fluoride, which provided lower blood fluoride levels, increased bone mineral density and decreased fractures (Pak et al., 1994). Intermittent courses of slow-release fluoride also have been evaluated. When the total fluoride dose was kept constant (Balena et al., 1998), there was no difference in outcome between continuous and intermittent fluoride treatment; notably, both regimens increased cancellous and trabecular thickness to the same extent. Unfortunately, increased bone mass is not synonymous with increased bone strength (Riggs et al., 1990). Thus, the apparent effects of fluoride in osteoporosis are slight compared with those achieved with PTH or other agents.

Other pharmacological actions of fluoride can be classified as toxic. Fluoride inhibits several enzyme systems and diminishes tissue respiration and anaerobic glycolysis.

**Acute Poisoning.** Acute fluoride poisoning usually results from accidental ingestion of fluoride-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of fluoride on the intestinal mucosa. Systemic symptoms are varied and severe: increased irritability of the central nervous system consistent with the Ca²⁺-binding effect of fluoride and the resulting hypocalcemia; hypotension, presumably owing to central vasomotor depression as well as direct cardiotoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of sodium fluoride for humans is ~5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with lime water (0.15% calcium hydroxide solution) or other Ca²⁺ salts to precipitate the fluoride. Calcium gluconate is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

**Chronic Poisoning.** In humans, the major manifestations of chronic ingestion of excessive fluoride are osteosclerosis and mottled
Since its inception, regulation of the fluoride concentration of community water supplies periodically has encountered vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly between communities with fluoridated and nonfluoridated water (Richmond, 1985).

**CLINICAL SUMMARY**

Increasing evidence supports the concept that regular physical activity, adequate calcium intake, and lifestyle changes have a positive impact on bone remodeling, constrain bone loss, and reduce fracture risk. Antiresorptive agents such as bisphosphonates, estrogen, selective estrogen response modulators (SERMs), and calcium slow bone resorption. Recombinant human PTH is available for the treatment of osteoporosis and provides significant intervention for restoring normal bone mass.

Cinacalcet, a drug that acts directly on the parathyroid calcium-sensing receptor, provides a novel approach to decreasing PTH secretion in secondary hyperparathyroidism and parathyroid carcinoma. Improved assays for measuring biologically active and inactive forms of PTH may facilitate the diagnosis and treatment of diseases associated with PTH resistance.

Estrogen-replacement therapy, once a mainstay treatment for osteoporosis in women, has been curtailed by the findings of the Women’s Health Initiative: Despite estrogen’s beneficial effects on bone and fracture risk, alone or in combination with progestin, estrogen promotes an array of serious adverse cardiovascular consequences. The FDA now recommends that estrogen be reserved for women at significant risk of osteoporosis who cannot take other medications.

The acid-peptic diseases are those disorders in which gastric acid and pepsin are necessary, but usually not sufficient, pathogenic factors. Although inherently caustic, acid and pepsin in the stomach normally do not produce damage or symptoms because of intrinsic defense mechanisms. Barriers to the reflux of gastric contents into the esophagus comprise the primary esophageal defense. If these protective barriers fail and reflux occurs, dyspepsia and/or erosive esophagitis may result. Therapies are directed at decreasing gastric acidity, enhancing the lower esophageal sphincter, or stimulating esophageal motility (Chapter 46). The stomach is protected by a number of factors, collectively referred to as “mucosal defense,” many of which are stimulated by the local generation of prostaglandins and NO (Wallace, 2008). If these defenses are disrupted, a gastric or duodenal ulcer may form. The treatment and prevention of these acid-related disorders are accomplished by decreasing gastric acidity and enhancing mucosal defense. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases has stimulated new approaches to prevention and therapy.

**PHYSIOLOGY OF GASTRIC SECRETION**

Gastric acid secretion is a complex, continuous process in which multiple central and peripheral factors contribute to a common end point: the secretion of H+ by parietal cells. Neuronal (acetylcholine, ACh), paracrine (histamine), and endocrine (gastrin) factors all regulate acid secretion (Figure 45–1). Their specific receptors (M₃, H₂, and CCK₂, respectively) are on the basolateral membrane of parietal cells in the body and fundus of the stomach. Some of these receptors are also present on enterochromaffin-like cells (ECL), where they regulate the release of histamine. The H₂ receptor is a GPCR (Chapters 3 and 32) that activates the Gₛ–adenyl cyclase–cyclic AMP–PKA pathway. ACh and gastrin signal through GPCRs that couple to the Gₛ–PLC–IP₃–Ca²⁺ pathway in parietal cells. In parietal cells, the cyclic AMP and the Ca²⁺-dependent pathways activate H⁺, K⁺-ATPase (the proton pump), which exchanges hydrogen and potassium ions across the parietal cell membrane. This pump generates the largest ion gradient known in vertebrates, with an intracellular pH of ~7.3 and an intracanalicular pH of ~0.8.

The most important structures for CNS stimulation of gastric acid secretion are the dorsal motor nucleus of the vagal nerve, the hypothalamus, and the solitary tract nucleus. Efferent fibers originating in the dorsal motor nuclei descend to the stomach via the vagus nerve and synapse with ganglion cells of the enteric nervous system. ACh release from postganglionic vagal fibers directly stimulates gastric acid secretion through muscarinic M₃ receptors on the basolateral membrane of parietal cells. The CNS predominantly modulates the activity of the enteric nervous system via ACh, stimulating gastric acid secretion in response to the sight, smell, taste, or anticipation of food (the “cephalic” phase of acid secretion). ACh also indirectly affects parietal cells by increasing the release of histamine from the ECL cells in the fundus of the stomach and of gastrin from G cells in the gastric antrum.

ECL cells, the source of gastric histamine, usually are in close proximity to parietal cells. Histamine acts as a paracrine mediator, diffusing from its site of release to nearby parietal cells, where it activates H₂ receptors. The critical role of histamine in gastric acid secretion is dramatically demonstrated by the efficacy of H₂ receptor antagonists in decreasing gastric acid secretion.

Gastrin, which is produced by antral G cells, is the most potent inducer of acid secretion. Multiple pathways stimulate gastrin release, including CNS activation, local distention, and chemical
components of the gastric contents. Gastrin stimulates acid secretion indirectly by inducing the release of histamine by ECL cells; a direct effect on parietal cells also plays a lesser role.

Somatostatin (SST), which is produced by antral D cells, inhibits gastric acid secretion. Acidification of the gastric luminal pH to <3 stimulates SST release, which in turn suppresses gastrin release in a negative feedback loop. SST-producing cells are decreased in patients with H. pylori infection, and the consequent reduction of SST’s inhibitory effect may contribute to excess gastrin production.

**Gastric Defenses Against Acid.** The extremely high concentration of H⁺ in the gastric lumen requires robust defense mechanisms to protect the esophagus and the stomach. The primary esophageal defense is the lower esophageal sphincter, which prevents reflux of acidic gastric contents into the esophagus. The stomach protects itself from acid damage by a number of mechanisms that require adequate mucosal blood flow, perhaps because of the high metabolic activity and oxygen requirements of the gastric mucosa. One key defense is the secretion of a mucus layer that helps to protect gastric epithelial cells by trapping secreted bicarbonate at the cell surface. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by prostaglandins E₂ and I₂, which also directly inhibit gastric acid secretion by parietal cells. Thus, drugs that inhibit prostaglandin formation (e.g., NSAIDs, ethanol) decrease mucus secretion and predispose to the development of acid-peptic disease.

Figure 45–1 outlines the rationale and pharmacological basis for the therapy of acid-peptic diseases. The proton pump inhibitors are used most commonly, followed by the histamine H₂ receptor antagonists.
**PROTON PUMP INHIBITORS**

**Chemistry; Mechanism of Action; Pharmacology.** The most potent suppressors of gastric acid secretion are inhibitors of the gastric H⁺, K⁺-ATPase (proton pump) (Figure 45–2). In typical doses, these drugs diminish the daily production of acid (basal and stimulated) by 80–95%. Six proton pump inhibitors are available for clinical use: omeprazole (PRILOSEC, others) and its S-isomer, esomeprazole (NEXIUM), lansoprazole (PREVACID) and its R-enantiomer, dexlansoprazole (KAPIDEX), rabeprazole (ACIPHEX), and pantoprazole (PROTONIX, others). These drugs have different substitutions on their pyridine and/or benzimidazole groups but are remarkably similar in their pharmacological properties (Appendix II). Omeprazole is a racemic mixture of R- and S-isomers; the S-isomer, esomeprazole (S-omeprazole), is eliminated less rapidly than R-omeprazole, which theoretically provides a therapeutic advantage because of the increased t₁/₂. Despite claims to the contrary, all proton pump inhibitors have equivalent efficacy at comparable doses.

Proton pump inhibitors (PPIs) are prodrugs that require activation in an acid environment. After absorption into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracyclic sulfenamide (Figure 45–2), trapping the drug so that it cannot diffuse back across the canalicular membrane. The activated form then binds covalently with sulfhydryl groups of cysteines in the H⁺, K⁺-ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump molecules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24- to 48-hour) suppression of acid secretion, despite the much shorter plasma half-lives (0.5-2 hours) of the parent compounds. Because they block the final step in acid production, the proton pump inhibitors are effective in acid suppression regardless of other stimulating factors.

To prevent degradation of proton pump inhibitors by acid in the gastric lumen, oral dosage forms are supplied in different formulations:

- enteric-coated drugs contained inside gelatin capsules (omeprazole, dexlansoprazole, esomeprazole, and lansoprazole)

![Figure 45–2. Proton pump inhibitors. A. Inhibitors of gastric H⁺, K⁺-ATPase (proton pump). B. Conversion of omeprazole to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulfhydryl groups in the proton pump, thereby irreversibly inhibiting its activity. The other three proton pump inhibitors undergo analogous conversions.](image-url)
• enteric-coated granules supplied as a powder for suspension (lansoprazole)
• enteric-coated tablets (pantoprazole, rabeprazole, and omeprazole)
• powdered omeprazole combined with sodium bicarbonate (ZERID) contained in capsules and formulated for oral suspension

The delayed-release and enteric-coated tablets dissolve only at alkaline pH, whereas admixture of omeprazole with sodium bicarbonate simply neutralizes stomach acid; both strategies substantially improve the oral bioavailability of these acid-labile drugs. Until recently, the requirement for enteric coating posed a challenge to the administration of proton pump inhibitors in patients for whom the oral route of administration is not available (Freston et al., 2003). These patients and those requiring immediate acid suppression now can be treated parenterally with esomeprazole, pantoprazole, or lan-
soprazole, which are approved for intravenous administration in the U.S. A single intravenous bolus of 80 mg of pantoprazole inhibits acid production by 80-90% within an hour, and this inhibition persists for up to 21 hours, permitting once-daily dosing to achieve the desired degree of hypochlorhydria. The FDA-approved dose of intravenous pantoprazole for gastroesophageal reflux disease is 40 mg daily for up to 10 days. Higher doses (e.g., 160-240 mg in divided doses) are used to manage hypersecretory conditions such as the Zollinger-Ellison syndrome.

Pharmacokinetics. Because an acidic pH in the parietal cell acid canaliculi is required for drug activation and food stimulates acid production, these drugs ideally should be given ~30 minutes before meals. Concurrent administration of food may reduce somewhat the rate of absorption of proton pump inhibitors, but this effect is not thought to be clinically significant. Concomitant use of other drugs that inhibit acid secretion, such as H2 receptor antagonists, might be predicted to lessen the effectiveness of the proton pump inhibitors, but the clinical relevance of this potential interaction is unknown.

Once in the small bowel, proton pump inhibitors are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Several variants of CYP2C19 have been identified. Asians are more likely than whites or African Americans to have the CYP2C19 genotype that correlates with slow metabolism of proton pump inhibitors (23% vs. 3%, respectively), which has been suggested to contribute to heightened efficacy and/or toxicity in this ethnic group (Dickson and Stuart, 2003). Although the CYP2C19 genotype is correlated with the magnitude of gastric acid suppression by proton pump inhibitors in patients with gastroesophageal reflux disease, there is no evidence that the CYP2C19 genotype predicts clinical efficacy of these drugs (Chong and Ensom, 2003).

Because not all pumps or all parietal cells are active simultane-
ously, maximal suppression of acid secretion requires several doses of the proton pump inhibitors. For example, it may take 2-5 days of therapy with once-daily dosing to achieve the 70% inhibition of proton pumps that is seen at steady state (Wang and Hunt, 2008). More frequent initial dosing (e.g., twice daily) will reduce the time to achieve full inhibition but is not proven to improve patient outcome. Because the proton pump inhibition is irreversible, acid secretion will be suppressed for 24-48 hours, or more, until new proton pumps are synthesized and incorporated into the luminal membrane of parietal cells.

Chronic renal failure does not lead to drug accumulation with once-a-day dosing of the proton pump inhibitors. Hepatic disease substantially reduces the clearance of esomeprazole and lansoprazole. Thus, in patients with severe hepatic disease, dose reduction is recommended for esomeprazole and should be considered for lansoprazole.

Adverse Effects and Drug Interactions. Proton pump inhibitors generally cause remarkably few adverse effects. The most common side effects are nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, headaches, and skin rashes also have been reported. As noted earlier, proton pump inhibitors are metabolized by hepatic CYPs and therefore may interfere with the elimination of other drugs cleared by this route. Proton pump inhibitors have been observed to interact with warfarin (esomepra-
zole, lansoprazole, omeprazole, and rabeprazole), diazepam (esomeprazole and omeprazole), and cyclosporine (omeprazole and rabeprazole). Among the proton pump inhibitors, only omeprazole inhibits CYP2C19 (thereby decreasing the clearance of disulfiram, phenytoin, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of imipramine, several antipsy-
chotic drugs, tacrine, and theophylline). There is emerging evidence that omeprazole can interact adversely with the anticoagulant agent, clopidogrel, at the level of CYP2C19, for which both are substrates; thus, omeprazole can inhibit conversion of clopidogrel to the active anticoagulating form. Pantoprazole is less likely to result in this interaction (Ferreiro and Angiolillo, 2009; Norgard et al., 2009); concurrent use of clopidogrellarrv and PPIs (mainly pantoprazole) significantly reduced GI bleeding without increasing adverse cardiac events (Ray et al., 2010). For the pharmacological issues involved in the concurrent use of dual antiplatelet therapy and proton pump inhibitors, see Chapter 30, “Regulation of Blood Coagulation.”

Chronic treatment with omeprazole decreases the absorption of vitamin B12, but the clinical relevance of this effect is not clear. Loss of gastric acidity also may affect the bioavailability of such drugs as ketoconazole, ampicillin esters, and iron salts. Chronic use of proton pump inhibitors has been reported to be associated with an increased risk of bone fracture and with increased susceptibility to certain infec-
tions (e.g., hospital-acquired pneumonia, community-acquired Clostridium difficile) (Côté and Howden, 2008). Hypergastrinemia is more frequent and more severe with proton pump inhibitors than with H2 receptor antagonists, and gastrin levels of >500 ng/L occur in ~5-10% of users with chronic omeprazole administration. This hyper-
astrinemia may predispose to rebound hypersecretion of gastric acid upon discontinuation of therapy and also may promote the growth of gastrointestinal (GI) tumors. In rats, long-term administration of proton pump inhibitors causes hyperplasia of enterochromaffin-like cells and the development of gastric carcinoid tumors. Although the gastrin levels observed in rats are ~10-fold higher than those seen in human beings, this finding has raised concerns about the possibility of similar complications of proton pump inhibitors in humans, for which there is no unequivocal evidence.

Therapeutic Uses. Prescription proton pump inhibitors are used to promote healing of gastric and duodenal ulcers and to treat gastroesophageal reflux disease (GERD), including erosive esophagitis, which is either complicated or unresponsive to treatment with H2 receptor antagonists. Over-the-counter omeprazole is approved for the self-treatment of heartburn. Proton pump inhibitors also are the
mainstay in the treatment of pathological hypersecretory conditions, including the Zollinger-Ellison syndrome. Lansoprazole and esomeprazole are FDA approved for treatment and prevention of recurrence of nonsteroidal anti-inflammatory drug (NSAID)-associated gastric ulcers in patients who continue NSAID use. It is not clear if proton pump inhibitors affect the susceptibility to NSAID-induced damage and bleeding in the small and large intestine. In addition, all proton pump inhibitors are approved for reducing the risk of duodenal ulcer recurrence associated with *H. pylori* infections. Therapeutic applications of proton pump inhibitors are further discussed later under “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

**Use in Children.** In children, omeprazole is safe and effective for treatment of erosive esophagitis and GERD. Younger patients generally have increased metabolic capacity, which may explain the need for higher dosages of omeprazole per kilogram in children compared with adults.

### H₂ RECEPTOR ANTAGONISTS

The description of selective histamine H₂ receptor blockade was a landmark in the treatment of acid-peptic disease (Black, 1993). Before the availability of the H₂ receptor antagonists, the standard of care was simply acid neutralization in the stomach lumen, generally with inadequate results. The long history of safety and efficacy with the H₂ receptor antagonists eventually led to their availability without a prescription. Increasingly, however, proton pump inhibitors are replacing the H₂ receptor antagonists in clinical practice.

**Chemistry; Mechanism of Action; Pharmacology.** The H₂ receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H₂ receptors on the basolateral membrane of parietal cells. Four different H₂ receptor antagonists, which differ mainly in their pharmacokinetics (Appendix II) and propensity to cause drug interactions, are available in the U.S. (Figure 45–3): cimetidine (TAGAMET, others), ranitidine (ZANTAC, others), famotidine (PEPCID, others), and nizatidine (AXID, others). These drugs are less potent than proton pump inhibitors but still suppress 24-hour gastric acid secretion by ~70%. The H₂ receptor antagonists predominantly inhibit basal acid secretion, which accounts for their efficacy in suppressing nocturnal acid secretion. Because the most important determinant of duodenal ulcer healing is the level of nocturnal acidity, evening dosing of H₂-receptor antagonists is adequate therapy in most instances. Ranitidine and nizatidine also may stimulate GI motility, but the clinical importance of this effect is unknown.

![Figure 45–3. Histamine and H₂ receptor antagonists.](image)

All four H₂ receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of cimetidine, ranitidine, and famotidine also are available. When the oral or nasogastric routes are not an option, these drugs can be given in intermittent intravenous boluses or by continuous intravenous infusion (Table 45–1). The latter provides better control of gastric pH but is not proven to be more effective in preventing significant bleeding in critically ill patients.

**Pharmacokinetics.** The H₂ receptor antagonists are rapidly absorbed after oral administration, with peak serum concentrations

</table>
within 1-3 hours. Absorption may be enhanced by food or decreased by antacids, but these effects probably are unimportant clinically. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4-5 hours (cimetidine), 6-8 hours (ranitidine), or 10-12 hours (famotidine). Unlike proton pump inhibitors, only a small percentage of H₂ receptor antagonists are protein bound. Small amounts (from <10% to ~35%) of these drugs undergo metabolism in the liver, but liver disease per se is not an indication for dose adjustment. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce doses of H₂ receptor antagonists in patients with decreased creatinine clearance. Neither hemodialysis nor peritoneal dialysis clears significant amounts of the drugs.

**Adverse Reactions and Drug Interactions.** Like the proton pump inhibitors, the H₂ receptor antagonists generally are well tolerated, with a low (<3%) incidence of adverse effects. Side effects usually are minor and include diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less common side effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration of the drugs or in elderly subjects. Long-term use of cimetidine at high doses—seldom used clinically today—decreases testosterone binding to the androgen receptor and inhibits a CYP that hydroxylates estradiol. Clinically, these effects can cause galactorrhea in women and gynecomastia, reduced sperm count, and impotence in men. Several reports have associated H₂ receptor antagonists with various blood dyscrasias, including thrombocytopenia. H₂ receptor antagonists cross the placenta and are excreted in breast milk. Although no major teratogenic risk has been associated with these agents, caution nevertheless is warranted when they are used in pregnancy.

All agents that inhibit gastric acid secretion may alter the rate of absorption and subsequent bioavailability of the H₂ receptor antagonists (see “Antacids” section). Drug interactions with H₂ receptor antagonists occur mainly with cimetidine, and its use has decreased markedly. Cimetidine inhibits CYPs (e.g., CYP1A2, CYP2C9, and CYP2D6), and thereby can increase the levels of a variety of drugs that are substrates for these enzymes. Ranitidine also interacts with hepatic CYPs, but with an affinity of only 10% of that of cimetidine; thus, ranitidine interferes only minimally with hepatic metabolisms of other drugs. Famotidine and nizatidine are even safer in this regard, with no significant drug interactions mediated by inhibiting hepatic CYPs. Slight increases in blood-alcohol concentration may result from concomitant use of H₂ receptor antagonists, but this is unlikely to be clinically significant.

**Therapeutic Uses.** The major therapeutic indications for H₂-receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated GERD, and to prevent the occurrence of stress ulcers. More information about the therapeutic applications of H₂ receptor antagonists is provided in the section “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

**TOLERANCE AND REBOUND WITH ACID-SUPPRESSING MEDICATIONS**

Tolerance to the acid-suppressing effects of H₂ receptor antagonists is well described and may account for a diminished therapeutic effect with continued drug administration (Sandevik et al., 1997). Tolerance can develop within 3 days of starting treatment and may be resistant to increased doses of the medications. Diminished sensitivity to these drugs may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells. Proton pump inhibitors, despite even greater elevations of endogenous gastrin, do not cause this phenomenon, probably because their site of action is distal to the action of histamine on acid release. However, rebound increases in gastric acidity can occur when either of these drug classes is discontinued, possibly reflecting changes in function and justifying a gradual drug taper or the substitution of alternatives (e.g., antacids) in at-risk patients.

**AGENTS THAT ENHANCE MUCOSAL DEFENSE**

**Prostaglandin Analogs: Misoprostol**

**Chemistry; Mechanism of Action; Pharmacology.** Prostaglandin E₂ (PGE₂) and prostacyclin (PGI₂) are the major prostaglandins synthesized by the gastric mucosa. Contrary to their cyclic AMP-elevating effects on many cells via EP₃ and EP₄ receptors, these prostanoids bind to the EP₂ receptor on parietal cells (Chapters 33 and 34) and stimulate the Gₛ pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE₂ also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Although smaller doses than those required for acid suppression can protect the gastric mucosa in laboratory animals, this has not been convincingly demonstrated in humans; acid suppression appears to be the most important effect clinically (Wolfe and Sachs, 2000).

Because NSAIDs diminish prostaglandin formation by inhibiting cyclooxygenase, synthetic prostaglandin analogs offer a logical approach to reducing NSAID-induced mucosal damage. Misoprostol (15-deoxy-16-hydroxy-16-methyl-PGE₁; CYTOTEC, others) is a synthetic analog of PGE₁. Structural modifications include an additional methyl ester group at C₁ that increases potency and duration of antisecretory effect, and transfer of a hydroxyl group from C₁₅ to C₁₆ and addition of a methyl group that increases oral bioactivity, duration of antisecretory action, and safety. The degree of inhibition of gastric acid secretion by misoprostol is directly related to dose; oral doses of 100-200 μg significantly inhibit basal acid secretion (up to 85-95% inhibition) or food-stimulated acid secretion (up to 75-85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 μg four times a day.
Pharmacokinetics. Misoprostol is rapidly absorbed after oral administration and then is rapidly and extensively de-esterified to form misoprostol acid, the principal and active metabolite of the drug. Some of this conversion may occur in the parietal cells. A single dose inhibits acid production within 30 minutes; the therapeutic effect peaks at 60-90 minutes and lasts for up to 3 hours. Food and antacids decrease the rate of misoprostol absorption, resulting in delayed and decreased peak plasma concentrations of the active metabolite. The free acid is excreted mainly in the urine, with an elimination t1/2 of 20-40 minutes.

Adverse Effects. Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take misoprostol. Apparently dose related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe or protracted cases may necessitate drug discontinuation. Misoprostol can cause clinical exacerbations of inflammatory bowel disease (Chapter 47) and should be avoided in patients with this disorder. Misoprostol is contraindicated during pregnancy because it can increase uterine contractility.

Therapeutic Use. Misoprostol is FDA-approved to prevent NSAID-induced mucosal injury. However, it rarely is used because of its adverse effects and the inconvenience of four-times-daily dosing.

SUCRALFATE

Chemistry; Mechanism of Action; Pharmacology. In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. Sucralfate (CARAFATE, others) consists of the octasulfate of sucrose to which Al(OH)₃ has been added. In an acid environment (pH <4), sucralfate undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 hours after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, sucralfate may have additional cytoprotective effects, including stimulation of local production of prostaglandins and epidermal growth factor. Sucralfate also binds bile salts; thus some clinicians use sucralfate to treat individuals with the syndromes of biliary esophagitis or gastritis (the existence of which is controversial).

Therapeutic Uses. The use of sucralfate to treat peptic acid disease has diminished in recent years. Nevertheless, because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients, sucralfate may offer an advantage over proton pump inhibitors and H₂ receptor antagonists for the prophylaxis of stress ulcers. Due to its unique mechanism of action, sucralfate also has been used in several other conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation and aphthous ulcers) and bile reflux gastropathy. Administered by rectal enema, sucralfate also has been used for radiation proctitis and solitary rectal ulcers. Because it is activated by acid, sucralfate should be taken on an empty stomach 1 hour before meals. The use of antacids within 30 minutes of a dose of sucralfate should be avoided. The usual dose of sucralfate is 1 g four times daily (for active duodenal ulcer) or 1 g twice daily (for maintenance therapy).

Adverse Effects. The most common side effect of sucralfate is constipation (~2%). Because some aluminum can be absorbed, sucralfate should be avoided in patients with renal failure who are at risk for aluminum overload. Likewise, aluminum-containing antacids should not be combined with sucralfate in these patients. Sucralfate forms a viscous layer in the stomach that may inhibit absorption of other drugs, including phenytoin, digoxin, cimetine, ketoconazole, and fluoroquinolone antibiotics. Sucralfate therefore should be taken at least 2 hours after the administration of other drugs. The “sticky” nature of the viscous gel produced by sucralfate in the stomach also may be responsible for the development of bezoars in some patients, particularly in those with underlying gastroparesis.

ANTACIDS

Although hallowed by tradition, the antacids largely have been replaced by more effective and convenient drugs. Nevertheless, they continue to be used by patients for a variety of indications, and some knowledge of their pharmacology is important for the medical professional (Table 45–2 compares some commonly used antacid preparations).

Many factors, including palatability, determine the effectiveness and choice of antacid. Although sodium bicarbonate effectively neutralizes acid, it is very water soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. Depending on particle size and crystal structure, CaCO₃ rapidly and effectively neutralizes gastric H⁺, but the release of CO₂ from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration.

Combinations of Mg²⁺ (rapidly reacting) and Al³⁺ (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. Magaldrate is a hydroxyxymagnesium aluminate complex that is converted rapidly in gastric acid to Mg(OH)₂ and Al(OH)₃, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of magnesium and aluminum theoretically counteract the adverse effects of each other on the bowel (Al³⁺ can relax gastric smooth muscle, producing delayed gastric emptying and constipation; Mg²⁺ exerts the opposite effects), such balance is not always achieved in practice.

Simethicone, a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations, particularly those with aspirin, that are marketed for “acid indigestion” are irrational choices, are potentially unsafe in patients predisposed to gastroduodenal ulcers, and should not be used.
The relative effectiveness of antacid preparations is expressed as milliequivalents of acid-neutralizing capacity (defined as the quantity of 1N HCl, expressed in milliequivalents, that can be brought to pH 3.5 within 15 minutes); according to FDA requirements, antacids must have a neutralizing capacity of at least 5 mEq per dose. Due to discrepancies between in vitro and in vivo neutralizing capacities, antacid doses in practice are titrated simply to relieve symptoms. For uncomplicated ulcers, antacids are given orally 1 and 3 hours after meals and at bedtime. This regimen, providing ~120 mEq of a Mg-Al combination per dose, may be almost as effective as conventional dosing with an H2 receptor antagonist. For severe symptoms or uncontrolled reflux, antacids can be given as often as every 30-60 minutes. In general, antacids should be administered in suspension form because this probably has a greater neutralizing capacity than powder or tablet dosage forms. If tablets are used, they should be thoroughly chewed for maximum effect.

Antacids are cleared from the empty stomach in ~30 minutes. However, the presence of food is sufficient to elevate gastric pH to ~5 for ~1 hour and to prolong the neutralizing effects of antacids for ~2-3 hours. Antacids are cleared from the empty stomach in ~30 minutes. However, the presence of food is sufficient to elevate gastric pH to ~5 for ~1 hour and to prolong the neutralizing effects of antacids for ~2-3 hours.

Antacids vary in the extent to which they are absorbed, and hence in their systemic effects. In general, most antacids can elevate urinary pH by ~1 pH unit. Antacids that contain Al3+, Ca2+, or Mg2+ are absorbed less completely than are those that contain NaHCO3. With normal renal function, the modest accumulations of Al3+ and Mg2+ do not pose a problem; with renal insufficiency, however, absorbed Al3+ can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca2+ is absorbed, causing a transient hypercalcemia. Although this is not a problem in normal patients, the hypercalcemia from as little as 3-4 g of CaCO3 per day can be problematic in patients with uremia. In the past, when large doses of NaHCO3 and CaCO3 were administered commonly with milk or cream for the management of peptic ulcer, the milk-alkali syndrome (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca2+ (five to forty 500-mg tablets per day of calcium carbonate) taken with milk. Patients may be asymptomatic or may present with the insidious onset of hypercalcemia, reduced secretion of parathyroid hormone, retention of phosphate, precipitation of Ca2+ salts in the kidney, and renal insufficiency.

By altering gastric and urinary pH, antacids may affect a number of drugs (e.g., thyroid hormones, allopurinol, and imidazole antifungals, by altering rates of dissolution and absorption, bioavailability, and renal elimination). Al3+ and Mg2+ antacids also are notable for their propensity to chelate other drugs present in the GI tract, forming insoluble complexes that pass through the GI tract without absorption. Thus it generally is prudent to avoid concurrent administration of antacids and drugs intended for systemic absorption. Most interactions can be avoided by taking antacids 2 hours before or after ingestion of other drugs.

Other Acid Suppressants and Cytoprotectants

The M1 muscarinic receptor antagonists pirenzepine and telenzepine (Chapter 9) can reduce basal acid production by 40-50% and long have been used to treat patients with peptic ulcer disease in countries other than the U.S. The ACh receptor on the parietal cell itself is of the M1 subtype, and these drugs are believed to suppress neural stimulation of acid production via actions on M1 receptors of intramural ganglia (Figure 45–1). Because of their relatively poor efficacy, significant and undesirable anticholinergic side effects, and risk of blood disorders (pirenzepine), they rarely are used today.

*a* Contents, milligrams per tablet or per 5 ml.

*b* Acid neutralizing capacity, milliequivalents per tablet or per 5 ml.

The U.S. marketplace for antacids is fluid. The current trend of “reusing” well-known brand names to introduce new products that contain an active ingredient different from expected is a source of confusion that can present a danger to patients. Medication safety experts encourage clinical practitioners to refer to the active ingredient(s) in conjunction with the proprietary (brand) name when selecting OTC products.
In the hope of providing more rapid onset of action and sustained acid suppression, reversible inhibitors of the gastric H⁺, K⁺-ATPase (e.g., the pyrrolopyridazine derivative AKU517) are being developed for clinical use. Antagonists of the CCK2 gastrin receptor on parietal cells also are under study. The precise role that these agents will play in the therapy of acid-peptic disorders in the future is yet to be determined.

Rebamipide (2-(4-chlorobenzoylamino)-3-[2(1H)-quinolinone-4-yl]-propionic acid) is used for ulcer therapy in parts of Asia. It appears to exert a cytoprotective effect both by increasing prostaglandin generation in gastric mucosa and by scavenging reactive oxygen species. Ecabet (GASTROM; 12-sulfodehydroabietic acid monosodium), which appears to increase the formation of PGE₂ and PGI₂, also is used for ulcer therapy, mostly in Japan. Carbenoxolone, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Its exact mechanism of action is not clear, but it may alter the composition and quantity of mucin. Unfortunately, carbenoxolone inhibits the type I isozyme of 11β-hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (Chapter 42).

Bismuth compounds (Chapter 46) may be as effective as cimetidine in patients with peptic ulcers and are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucin and bicarbonate production, and have significant antibacterial effects. Bismuth compounds are an important component of many anti-*Helicobacter* regimens; however, given the availability of more effective drugs, bismuth compounds seldom are used alone as cytoprotective agents.

**SPECIFIC ACID-PePTIC DISORDERS AND THERAPEUTIC STRATEGIES**

The success of acid-suppressing agents in a variety of conditions is critically dependent on their ability to keep intragastric pH above a certain target, generally pH 3-5; this target varies to some extent with the disease being treated (Figure 45–4).

**Gastroesophageal Reflux Disease**

In the U.S., it is estimated that one in five adults has symptoms of heartburn or gastroesophageal regurgitation at least once a week. Although most cases follow a relatively benign course, these symptoms, often referred to as “gastroesophageal reflux disease” (GERD), can be associated with severe erosive esophagitis; stricture formation and Barrett’s metaplasia (replacement of squamous by intestinal columnar epithelium), in turn, is associated with a small but significant risk of adenocarcinoma. Most of the symptoms of GERD reflect injurious effects of the refluxed acid-peptic content on the esophageal epithelium, providing the rationale for suppression of gastric acid. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis. Proton pump inhibitors clearly are more effective than H₂ receptor antagonists in achieving these goals. Healing rates after 4 weeks and 8 weeks of therapy with proton pump inhibitors are ~80% and 90%, respectively; the corresponding healing rates with H₂ receptor antagonists are 50% and 75%, respectively. Indeed, proton pump inhibitors are so effective that their empirical use is advocated as a therapeutic trial in patients in whom GERD is suspected to play a role in the pathogenesis of symptoms.

Because of the wide clinical spectrum associated with GERD, the therapeutic approach is best tailored to the level of severity in the individual patient (Figure 45–5). In general, the optimal dose for each patient is determined based on symptom control, and routine measurement of esophageal pH to guide dosing is not recommended. Strictures associated with GERD also respond better to proton pump inhibitors than to H₂ receptor antagonists; indeed, the use of proton pump inhibitors reduces the requirement for esophageal dilation. Unfortunately, one of the other complications of GERD, Barrett’s esophagus, appears to be more refractory to therapy because neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia or to decrease the incidence of tumors.

Regimens for the treatment of GERD with proton pump inhibitors and histamine H₂ receptor antagonists are listed in Table 45–3. Although some patients with mild GERD symptoms may be managed by nocturnal doses of H₂ receptor antagonists,
twice-daily dosing usually is required. Antacids are recommended only for the patient with mild, infrequent episodes of heartburn. In general, prokinetic agents (Chapter 46) are not particularly useful for GERD, either alone or in combination with acid-suppressant medications.

GERD is a chronic disorder that requires long-term therapy. Some experts advocate “stepdown” approaches that attempt to maintain symptomatic remission by either decreasing the dose of the proton pump inhibitor or switching to an H2 receptor antagonist. Other experts have advocated intermittent, “on-demand” therapy with proton pump inhibitors for symptomatic relief in patients who have responded initially but continue to have symptoms. However, many patients will maintain their requirement for proton pump inhibitors, and several studies suggest that these drugs are better than H2 receptor antagonists for maintaining remission in GERD.

Severe Symptoms and Nocturnal Acid Breakthrough. In patients with severe symptoms or extraintestinal manifestations of GERD, twice-daily dosing with a proton pump inhibitor may be needed. However, it is difficult if not impossible to render patients achlorhydric—even on twice-daily doses of proton pump inhibitors—and two-thirds or more of subjects will continue to make acid, particularly at night. This phenomenon, called nocturnal acid breakthrough, has been invoked as a cause of refractory symptoms in some patients with GERD. However, decreases in gastric pH at night while on therapy generally are not associated with acid reflux into the esophagus, and the rationale for suppressing nocturnal acid secretion (even if feasible) remains to be established. Nevertheless, patients with continuing symptoms on twice-daily proton pump inhibitors are often treated by adding an H2 receptor antagonist at night. Although this can further suppress acid production, the effect is short lived, probably due to the development of tolerance, as described earlier (Fackler et al., 2002).

**Therapy for Extraintestinal Manifestations of GERD.** With varying levels of evidence, acid reflux has been implicated in a variety of atypical symptoms, including noncardiac chest pain, asthma, laryngitis, chronic cough, and other ear, nose, and throat conditions. Proton pump inhibitors have been used with some success in certain patients with these disorders, generally in higher doses and for longer periods of time than those used for patients with more classic symptoms of GERD.
GERD and Pregnancy. Heartburn is estimated to occur in 30-50% of pregnancies, with an incidence approaching 80% in some populations (Richter, 2003). In the vast majority of cases, GERD ends soon after delivery and thus does not represent an exacerbation of a preexisting condition. Nevertheless, because of its high prevalence and the fact that it can contribute to the nausea of pregnancy, treatment often is required. Treatment choice in this setting is complicated by the paucity of data for the most commonly used drugs. In general, most drugs used to treat GERD fall in FDA Category B, with the exception of omeprazole (FDA Category C).

Mild cases of GERD during pregnancy should be treated conservatively; antacids or sucralfate are considered the first-line drugs. If symptoms persist, H₂ receptor antagonists can be used, with ranitidine having the most established track record in this setting. PPIs are reserved for women with intractable symptoms or complicated reflux disease. In these situations, lansoprazole is considered the preferred choice among the proton pump inhibitors, based on animal data and available experience in pregnant women.

PEPTIC ULCER DISEASE

The pathophysiology of peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, prostaglandin, NO, and other peptides and growth factors) and injurious factors (acid and pepsin). On average, patients with duodenal ulcers produce more acid than do control subjects, particularly at night (basal secretion). Although patients with gastric ulcers have normal or even diminished acid production, ulcers rarely if ever occur in the complete absence of acid. Presumably, a weakened mucosal defense and reduced bicarbonate production contribute to the injury from the relatively lower levels of acid in these patients. *H. pylori* and exogenous agents such as NSAIDs interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with *H. pylori* infection of the stomach. This infection may lead to impaired production of somatostatin by D cells and, in time, decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate production.

NSAIDs also are very frequently associated with peptic ulcers and bleeding. Topical injury by the luminal presence of the drug appears to play a minor role in the pathogenesis of these ulcers, as evidenced by the fact that ulcers can occur with very low doses of aspirin (10 mg) or with parenteral administration of NSAIDs (Wallace, 2008). The effects of these drugs are instead mediated systemically; the critical element is suppression of mucosal prostaglandin synthesis (particularly PGE₂ and PGI₂). Most of the mucosal prostaglandin synthesis occurs via the constitutively expressed cyclooxygenase-1 (COX-1), but COX-2, which can be very rapidly induced, also contributes significantly to the generation of mucosal-protective prostaglandins. Thus suppression of COX-1 and COX-2 by NSAIDs contributes to the induction of mucosal injury. COX-2-derived prostaglandins are particularly important in repair of mucosal injury (Wallace, 2008).

Table 45–4 summarizes current recommendations for drug therapy of gastroduodenal ulcers. Proton pump inhibitors relieve symptoms of duodenal ulcers and promote healing more rapidly than do H₂ receptor antagonists, although both classes of drugs are very effective in this setting. Peptic ulcer represents a chronic disease, and recurrence within 1 year is expected in the majority of patients who do not receive prophylactic acid suppression. With the appreciation

| Table 45–4 |
| Recommendations for Treatment of Gastroduodenal Ulcers |
| DRUG | ACTIVE ULCER | MAINTENANCE THERAPY |
| **H₂ Receptor Antagonists** | | |
| Cimetidine | 800 mg at bedtime/400 mg twice daily | 400 mg at bedtime |
| Famotidine | 40 mg at bedtime | 20 mg at bedtime |
| Nizatidine/ranitidine | 300 mg after evening meal or at bedtime/150 mg twice daily | 150 mg at bedtime |
| **Proton Pump Inhibitors** | | |
| Lansoprazole | 15 mg (DU; NSAID risk reduction) daily | |
| | 30 mg (GU including NSAID-associated) daily | |
| Omeprazole | 20 mg daily | |
| Rabeprazole | 20 mg daily | |
| **Prostaglandin Analog** | | |
| Misoprostol | 200 μg four times daily (NSAID-associated ulcer prevention)* | |

DU, duodenal ulcer; GU, gastric ulcer.

*Only misoprostol 800 μg/day has been directly shown to reduce the risk of ulcer complications such as perforation, hemorrhage, or obstruction (Rostom et al., 2009).
that \textit{H. pylori} plays a major etiopathogenic role in the majority of peptic ulcers, prevention of relapse is focused on eliminating this organism from the stomach. Chronic acid suppression, once the mainstay of ulcer prevention, now is used mainly in patients who are \textit{H. pylori}–negative or, in some cases, for maximum prevention of recurrence in patients who have had life-threatening complications.

Intravenous pantoprazole or lansoprazole clearly is the preferred therapy in patients with acute bleeding ulcers. The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

\textbf{Treatment of \textit{Helicobacter pylori} Infection.} \textit{H. pylori}, a gram-negative rod, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma (Suerbaum and Michetti, 2002). Because of the critical role of \textit{H. pylori} in the pathogenesis of peptic ulcers, to eradicate this infection is standard care in patients with gastric or duodenal ulcers. Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of \textit{H. pylori} also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment.

Many regimens for \textit{H. pylori} eradication have been proposed. Evidence-based literature review suggests that the ideal regimen in this setting should achieve a cure rate of at least 80\%. Five important considerations influence the selection of an eradication regimen (Chey and Wong, 2007; Graham, 2000) (Table 45–5). First, single-antibiotic regimens are ineffective in eradicating \textit{H. pylori} infection and lead to microbial resistance. Combination therapy with two or three antibiotics (plus acid-suppressive therapy) is associated with the highest rate of \textit{H. pylori} eradication. Second, a proton pump inhibitor or \textit{H}$_2$ receptor antagonist significantly enhances the effectiveness of \textit{H. pylori} antibiotic regimens containing amoxicillin or clarithromycin. Third, a regimen of 10–14 days of treatment appears to be better than shorter treatment regimens; in the U.S., a 14-day course of therapy generally is preferred. Fourth, poor patient compliance is linked to the medication-related side effects experienced by as many as half of patients taking triple-agent regimens, and to the inconvenience of three- or four-drug regimens administered several times per day. Packaging that combines the daily doses into one convenient unit is available and may improve patient compliance (Table 45–5). Finally, the emergence of resistance to clarithromycin and metronidazole increasingly is recognized as an important factor in the failure to eradicate \textit{H. pylori}. Clarithromycin resistance is related to mutations that prevent binding of the antibiotic to the ribosomes of the pathogen and is an all-or-none phenomenon. In contrast, metronidazole resistance is relative rather than absolute and may involve several adaptations by the bacteria. In the presence of \textit{in vitro} evidence of resistance to metronidazole, amoxicillin should be used instead. In areas with a high frequency of resistance to clarithromycin and metronidazole, a 14-day quadruple-drug regimen (three antibiotics combined with a proton pump inhibitor) generally is effective therapy.

\textbf{NSAID-Related Ulcers.} Chronic NSAID users have a 2–4\% risk of developing a symptomatic ulcer, GI bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if at all possible. If continued therapy is needed, selective COX-2 inhibitors may be considered, although this does not eliminate the risk of subsequent ulcer formation and the possible association of these drugs with adverse cardiovascular events mandates caution (Chapter 34). Moreover, any GI benefit of selective COX-2 inhibitors is lost if the patient is also taking low-dose aspirin. Healing of ulcers despite continued NSAID use is possible with the use

\begin{table}[h]

of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens (e.g., ≥8 weeks). Again, proton pump inhibitors are superior to H₂ receptor antagonists and misoprostol in promoting the healing of active ulcers (healing rates of 80-90% for proton pump inhibitors vs. 60-75% for the H₂ receptor antagonists), and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration (Lanas and Hunt, 2006; Rostom et al., 2009).

**Stress-Related Ulcers.** Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care. The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H₂ receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of proton pump inhibitors are available, it is likely that they will prove to be equally beneficial. However, there is some concern over the risk of pneumonia secondary to gastric colonization by bacteria in an alkaline milieu. In this setting, sucralfate appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia. This approach also appears to provide reasonable prophylaxis against bleeding, but it is less convenient (Cook et al., 1998).

**Zollinger-Ellison Syndrome.** Patients with this syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid, sometimes in the setting of multiple endocrine neoplasia, type I. This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchlorhydria. Proton pump inhibitors clearly are the drugs of choice, usually given at twice the routine dosage for peptic ulcers with the therapeutic goal of reducing acid secretion to 1-10 mmol/hour.

**Nonulcer Dyspepsia.** This term refers to ulcer-like symptoms in patients who lack overt gastroduodenal ulceration. It may be associated with gastritis (with or without *H. pylori*) or with NSAID use, but the pathogenesis of this syndrome remains controversial. Although empirical treatment with acid-suppressive agents is used routinely in patients with nonulcer dyspepsia, there is no convincing evidence of their benefit in controlled trials.

**CLINICAL SUMMARY**

The control of acid-peptic disease represents a major triumph for modern pharmacology. Proton pump inhibitors are considered superior for acid suppression in most clinically significant acid-peptic diseases, including gastroesophageal reflux disease, peptic ulcers, and NSAID-induced ulcers. Proton pump inhibitors also are employed in combination with antibiotics to eradicate infection with *H. pylori* and thereby play a role in preventing recurrent peptic ulcers. These agents largely have replaced the use of misoprostol and sucralfate, although the latter still is a low-cost alternative for prophylaxis against stress ulcers. The delay in maximal inhibition of acid secretion with the proton pump inhibitors (3-5 days) makes them less suited for use on an as-needed basis for symptom relief. In this setting, H₂ receptor antagonists, although less effective than proton pump inhibitors in suppressing acid secretion, have a more rapid onset of action that makes them useful for patient-directed management of mild or infrequent symptoms.

**BIBLIOGRAPHY**

INTRODUCTION TO GASTROINTESTINAL MOTILITY

The gastrointestinal (GI) tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle and epithelium themselves, as well as local nerves of the enteric nervous system (ENS), the autonomic nervous system (ANS), and circulating hormones (De Giorgio et al., 2007; Furness, 2006; Grundy et al., 2006; Wood, 2008). Of these, perhaps the most important regulator of physiological gut function is the ENS (Figure 46–1). The ENS is an extensive collection of nerves that constitutes the third division of the ANS. It is the only part of the ANS truly capable of autonomous function if separated from the central nervous system (CNS). The ENS lies within the wall of the GI tract organized into two connected networks of neurons and nerve fibers: the myenteric (Auerbach’s) plexus, found between the circular and longitudinal muscle layers, and the submucosal (Meissner’s) plexus, located in the submucosa. The former is largely responsible for motor control, whereas the latter regulates secretion, fluid transport, and blood flow. The ENS and the ANS are also involved in host defense and innervate organs and cells of the immune system (Rhee et al., 2009).

Generation and Regulation of GI Activity

The ENS is responsible for the largely autonomous nature of most GI activity. This activity is organized into relatively distinct programs that respond to input from the local environment of the gut, as well as the ANS-CNS. Each program consists of a series of complex, but coordinated, patterns of secretion and movement that show regional and temporal variation. The fasting program of the gut is called the MMC (migrating myoelectric complex when referring to electrical activity and migrating motor complex when referring to the accompanying contractions) and consists of a series of four phasic activities. The most characteristic, phase III, consists of clusters of rhythmic contractions that occupy short segments of the intestine for a period of 6-10 minutes before proceeding caudally (toward the anus). Phase II of the MMC is associated with the release of the peptide hormone motilin. Agonists of motilin stimulate motility in the proximal gut and are used clinically (Sanger, 2008). One whole MMC cycle (i.e., all four phases) takes ~80-110 minutes. The migrating motor complex occurs in the fasting state, during which it helps sweep debris caudal in the gut and serves to limit the overgrowth of luminal bacteria. The migrating motor complex cycles continually in animals that feed constantly but is interrupted by another pattern of contractions—the fed program—in intermittently feeding animals such as humans. The fed program consists of high-frequency (12-15 per minute) contractions that are either propagated for short segments (propulsive) or are irregular and not propagated (mixing).

Reflex circuits within the ENS underlie the stereotyped behaviors of the gut, such as peristalsis. Physiologically, peristalsis is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the ascending excitatory reflex results in contraction of the circular muscle on the oral side of the bolus, whereas the descending inhibitory reflex results in relaxation on the anal side. The net pressure gradient moves the bolus caudally. Reflex circuits within the ENS underlie the stereotyped behaviors of the gut, such as peristalsis. Physiologically, peristalsis is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the ascending excitatory reflex results in contraction of the circular muscle on the oral side of the bolus, whereas the descending inhibitory reflex results in relaxation on the anal side. The net pressure gradient moves the bolus caudally. Three neural elements, responsible for sensory, relay, and effector functions, are required to produce these reflexes. Luminal factors stimulate sensory elements in the mucosa, leading to a coordinated pattern of
muscle activity that is directly controlled by the motor neurons of the myenteric plexus to provide the effector component of the peristaltic reflex. Motor neurons receive input from ascending and descending interneurons (which constitute the relay and programming systems) that are of two broad types, excitatory and inhibitory. The primary neurotransmitter of the excitatory motor neurons is acetylcholine (ACh), although tachykinins, co-released by these neurons, also play a role. The principal neurotransmitter in the inhibitory motor neurons appears to be NO, although important contributions may also be made by ATP, vasoactive intestinal peptide, and pituitary adenylyl cyclase–activating peptide (PACAP), all of which are variably coexpressed with NO synthase. Substantial progress has been made in elucidating the mucosal sensor for initiating peristalsis and other reflexes. Enterochromaffin cells, scattered throughout the epithelium of the intestine, release serotonin (5-HT) to initiate many gut reflexes (Gershon and Tack, 2007) by acting locally on enteric neurons. Excessive release of 5-HT from the gut wall (e.g., by chemotherapeutic agents) leads to vomiting by actions of 5-HT on vagal nerve endings in the proximal small intestine. Compounds targeting the 5-HT system are important modulators of motility, secretion, and emesis.

This view of nerve–muscle interaction within the GI tract is in many ways oversimplified, and other cell types are important. One of these is the interstitial cell of Cajal, distributed within the gut wall and responsible for setting the electrical rhythm, and hence the pace of contractions, in various regions of the gut. These cells also translate or modulate excitatory and inhibitory neuronal communication to the smooth muscle (Ward et al., 2004).

Excitation-Contraction Coupling in GI Smooth Muscle
Control of tension in GI smooth muscle is in large part dependent on the intracellular Ca2+ concentration. In general, there are two types of excitation-contraction coupling. Ionotropic receptors can mediate changes in membrane potential, which in turn activate voltage-dependent Ca2+ channels to trigger an influx of Ca2+ (electro-mechanical coupling); metabotropic receptors activate various signal transduction pathways to release Ca2+ from intracellular stores (pharmaco-mechanical coupling). Inhibitory receptors also exist on smooth muscle and generally act via PKA and PKG, whose kinase activities can lead to hyperpolarization, decreased cytosolic [Ca2+], and reduced interaction of actin and myosin. As an example, NO may induce relaxation via activation of guanylyl cyclase-cyclic GMP pathway, and the opening of several types of K+ channels.

OVERVIEW OF FUNCTIONAL AND MOTILITY DISORDERS OF THE BOWEL
GI motility disorders are a complex and heterogeneous group of syndromes whose pathophysiology is not completely understood. Typical motility disorders include
achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), myopathic and neuropathic forms of intestinal dysmotility, and others. These disorders can be congenital, idiopathic, or secondary to systemic diseases (e.g., diabetes mellitus or scleroderma). This term also has traditionally (and perhaps inaccurately) included disorders—such as irritable bowel syndrome (IBS) and noncardiac chest pain—in which disturbances in pain processing or sensory function may be more important than any associated motor patterns. For most of these disorders, treatment remains empirical and symptom based, reflecting our ignorance of the specific derangements in pathophysiology involved.

**PROKINETIC AGENTS AND OTHER STIMULANTS OF GI CONTRACTILITY**

Activation of muscarinic receptors with the older cholinomimetic agents (Chapter 9) or AChE inhibitors (Chapter 10), is not a very effective strategy for treating GI motility disorders because these agents enhance contractions in a relatively uncoordinated fashion that produces little or no net propulsive activity. The use of cholinergic agents is discussed in the previous edition of this book.

By contrast, prokinetic agents are medications that enhance coordinated GI motility and transit of material in the GI tract. Although ACh, when released from primary motor neurons in the myenteric plexus, is the principal immediate mediator of muscle contractility, most of the clinically useful prokinetic agents act “upstream” of ACh, at receptor sites on the motor neuron itself, or even more indirectly, on neurons or non-neuronal cells one or two orders removed from it. Although pharmacologically and chemically diverse, these agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility. Coordination of activity among the segments of the gut, necessary for propulsion of luminal contents, therefore is maintained.

Agents useful clinically in altering GI motility are considered next.

**Dopamine Receptor Antagonists**

Dopamine (DA) is present in significant amounts in the GI tract and has several inhibitory effects on motility, including reduction of lower esophageal sphincter and intragastric pressures. These effects, which apparently result from suppression of ACh release from myenteric motor neurons, are mediated by D2 dopaminergic receptors. By antagonizing the inhibitory effect of dopamine on myenteric motor neurons, DA receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of DA receptors in the chemoreceptor trigger zone. Examples of such agents are metoclopramide and domperidone.

**Metoclopramide. Chemistry, Mechanism of Action, and Pharmacological Properties.** Metoclopramide (Reglan, others) and other substituted benzamides are derivatives of para-aminobenzoic acid and are structurally related to procainamide.

The mechanisms of action of metoclopramide are complex and involve 5-HT4 receptor agonism, vagal and central 5-HT3 antagonism, and possible sensitization of muscarinic receptors on smooth muscle, in addition to DA receptor antagonism. Metoclopramide is one of the oldest true prokinetic agents; its administration results in coordinated contractions that enhance transit. Its effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. Despite having in vitro effects on the contractility of colonic smooth muscle, metoclopramide has no clinically significant effects on large-bowel motility.

**Pharmacokinetics.** Metoclopramide is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a t1/2 of 4-6 hours. Peak concentrations occur within 1 hour after a single oral dose; the duration of action is 1-2 hours.

**Therapeutic Use.** Metoclopramide has been used in patients with gastroesophageal reflux disease to produce symptomatic relief of, but not healing of, associated esophagitis. It clearly is less effective than modern acid-suppressive medications, such as proton pump inhibitors or histamine H2 receptor antagonists, and now rarely is used in this setting. Metoclopramide is indicated more often in symptomatic patients with gastroparesis, in whom it may cause mild to modest improvements of gastric emptying (Tonini et al., 2004). Metoclopramide injection is used as an adjunctive measure in medical or diagnostic procedures such as intestinal intubation or contrast radiography of the GI tract. Although it has been used in patients with postoperative ileus, its ability to improve transit in disorders of small-bowel motility appears to be limited. In general, its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes. Metoclopramide has also been used in the treatment of persistent hiccups, but its efficacy in this condition is equivocal at best.
Metoclopramide is available in oral dosage forms (tablets and solution) and as a parenteral preparation for intravenous or intramuscular use. The usual initial oral dose range is 10 mg, 30 minutes before each meal and at bedtime. The onset of action is within 30-60 minutes after an oral dose. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10-15 minutes) or intravenously (onset of action 1-3 minutes). For prevention of chemotherapy-induced emesis, metoclopramide can be given as an infusion of 1-2 mg/kg administered over at least 15 minutes, beginning 30 minutes before the chemotherapy is begun and repeated as needed every 2 hours for two doses, then every 3 hours for three doses.

**Adverse Effects.** The major side effects of metoclopramide include extrapyramidal effects, such as those seen with the phenothiazines (Chapter 16). Dystonias, usually occurring acutely after intravenous administration, and parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and are reversible upon discontinuation of metoclopramide. Tardive dyskinesia also can occur with chronic treatment (months to years) and may be irreversible. Extrapyramidal effects appear to occur more commonly in children and young adults and at higher doses. Like other DA antagonists, metoclopramide also can cause galactorrhea by blocking the inhibitory effect of dopamine on prolactin release, but this adverse effect is relatively infrequent in clinical practice. Methemoglobinemia has been reported occasionally in premature and full-term neonates receiving metoclopramide.

**Domperidone; D₂ Receptor Antagonists**

In contrast to metoclopramide, domperidone predominantly antagonizes the D₂ receptor without major involvement of other receptors. It is not available for use in the U.S. but has been used elsewhere ( MOTILUM, others) and has modest prokinetic activity in doses of 10-20 mg three times a day. Although it does not readily cross the blood-brain barrier to cause extrapyramidal side effects, domperidone exerts effects in the parts of the CNS that lack this barrier, such as those regulating emesis, temperature, and prolactin release. As is the case with metoclopramide, domperidone does not appear to have any significant effects on lower GI motility. Other D₂ receptor antagonists being explored as prokinetic agents include levosulpiride, the levovenantiomer of sulpiride.

**Serotonin Receptor Agonists**

5-HT plays an important role in the normal motor and secretory function of the gut (Gershon and Tack, 2007) (Chapter 13). Indeed, >90% of the total 5-HT in the body exists in the GI tract. The enterochromaffin cell, a specialized cell found in the epithelium lining the mucosa of the gut, produces most of this 5-HT and rapidly releases 5-HT in response to chemical and mechanical stimulation (e.g., food boluses; noxious agents such as cisplatin; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5-HT triggers the peristaltic reflex (Figure 46–1) by stimulating intrinsic sensory neurons in the myenteric plexus (via 5-HT₁₅ and 5-HT₄ receptors), as well as extrinsic vagal and spinal sensory neurons (via 5-HT₃ receptors). Additionally, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes resulting in epithelial secretion. 5-HT receptors also are found on other neurons in the enteric nervous system, where they can be either stimulatory (5-HT₁₃ and 5-HT₆) or inhibitory (5-HT₁₅). In addition, serotonin also stimulates the release of other neurotransmitters, depending on the receptor subtype. Thus, 5-HT₁₃ stimulation of the gastric fundus results in release of NO and reduces smooth muscle tone. 5-HT₄ stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both 5-HT₁₃ and 5-HT₄ receptors facilitate interneuronal signaling. Developmentally, 5-HT acts as a neurotrophic factor for enteric neurons via the 5-HT₂B and 5-HT₄ receptors.

Reuptake of serotonin by enteric neurons and epithelium is mediated by the same transporter (SERT; Chapters 5 and 13) as 5-HT reuptake by serotonergic neurons in the CNS. This reuptake therefore also is blocked by selective serotonin reuptake inhibitors (SSRIs, Chapter 15), which explains the common side effect of diarrhea that accompanies the use of these agents. Modulation of the multiple, complex, and sometimes opposing effects of 5-HT on gut motor function has become a major target for drug development.

The availability of serotonergic prokinetic drugs has in recent years been restricted because of serious adverse cardiac events. Tegaserod maleate (ZELNORM) was discontinued in 2007 and cisapride is available only via a restricted investigational drug protocol. A novel 5-HT₄ agonist, prucalopride (RESOLOR), is approved for use in Europe for symptomatic treatment of chronic constipation in women in whom laxatives fail to provide adequate relief.

**Cisapride.** Cisapride (PROPLIS) is a substituted piperidinyl benzamide (Figure 46–2) that appears to stimulate 5-HT₄ receptors and increase adenylyl cyclase activity within neurons. It also has weak 5-HT₃ antagonistic properties and may directly stimulate smooth muscle. Cisapride was a commonly used prokinetic agent, particularly for gastroesophageal reflux disease and gastroparesis. However, it no longer is generally available in the U.S. because of its potential to induce serious and occasionally fatal cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. These arrhythmias result from a prolonged QT interval through an interaction with pore-forming subunits of the HERG K⁺ channel. HERG K⁺ channels conduct the rapid delayed rectifier K⁺ current that is important for normal repolarization of the ventricle (Chapter 29). Cisapride-induced ventricular arrhythmias occur most
often when the drug is combined with other drugs that inhibit CYP3A4 (Chapter 6); such combinations inhibit the metabolism of cisapride and lead to high plasma concentrations of the drug. Due to its association with ventricular arrhythmias, cisapride is contraindicated in patients with a history of prolonged QT interval, renal failure, ventricular arrhythmias, ischemic heart disease, congestive heart failure, respiratory failure, uncorrected electrolyte abnormalities (e.g., hypokalemia and hypomagnesemia), or concomitant medications known to prolong the QT interval. At this time, cisapride is available only through an investigational, limited-access program for patients with GERD, gastroparesis, pseudo-obstruction, refractory severe chronic constipation, and neonatal enteral feeding intolerance who have failed all standard therapeutic modalities and who have undergone a thorough diagnostic evaluation, including an ECG.

**Prucalopride** (Resolor; Figure 46–2) is a benzofuran derivative and a specific 5-HT₄-receptor agonist that facilitates cholinergic neurotransmission. It acts throughout the length of the intestine, increasing oral-cecal transit and colonic transit without affecting gastric emptying in healthy volunteers. In patients with chronic idiopathic constipation, prucalopride was able to improve colonic transit and stool frequency. Given in doses of 2 and 4 mg orally, once daily, there were significant normalization of bowel habits including increased stool frequency and consistency (Gale, 2009). This drug recently gained approval in Europe for use in women with chronic constipation in whom laxatives fail to provide adequate relief.

**Motilides**

**Macrolides and Erythromycin.** Motilin, a 22–amino acid peptide hormone found in the GI M cells and in some enterochromaffin cells of the upper small bowel, is a potent contractile agent of the upper GI tract. Motilin levels fluctuate in association with the migrating motor complex and appear to be responsible for the amplification, if not the actual induction, of phase III activity. In addition, motilin receptors are found on smooth muscle cells and enteric neurons.

The effects of motilin can be mimicked by erythromycin, a discovery that arose from the frequent occurrence of GI side effects with the use of this antibiotic. This property is shared to varying extents by other macrolide antibiotics (Chapter 55), including oleandomycin, azithromycin, and clarithromycin. In addition to its motilin-like effects, which are most pronounced at higher doses (250-500 mg), erythromycin at lower doses (e.g., 40-80 mg) also may act by other poorly defined mechanisms that may involve cholinergic facilitation.

Erythromycin induces phase III migrating motor complex activity in dogs and increases smooth muscle contractility. It has multiple effects on upper GI motility, increasing lower esophageal pressure and stimulating gastric and small-bowel contractility. By contrast, it has little or no effect on colonic motility. At doses higher than 3 mg/kg, it can produce a spastic type of contraction in the small bowel, resulting in cramps, impairment of transit, and vomiting.

**Therapeutic Use.** The best established use of erythromycin as a prokinetic agent is in patients with diabetic gastroparesis, where it can improve gastric emptying in the short term. Erythromycin-stimulated gastric contractions can be intense and result in “dumping” of relatively...
undigested food into the small bowel. This potential disadvantage can be exploited clinically to clear the stomach of undigestible residue such as plastic tubes or bezoars. Anecdotally, erythromycin also has been of benefit in patients with small-bowel dysmotility such as that seen in scleroderma, ileus, or pseudo-obstruction. Rapid development of tolerance to erythromycin, possibly by downregulation of the motilin receptor, and undesirable (in this context) antibiotic effects have limited the use of this drug as a prokinetic agent. Several non-antibiotic synthetic analogs of erythromycin and peptide analogs of motilin have been developed; to date, the clinical results have been disappointing.

A standard dose of erythromycin for gastric stimulation is 3 mg/kg intravenously or 200-250 mg orally every 8 hours. For small-bowel stimulation, a smaller dose (e.g., 40 mg intravenously) may be more useful, as higher doses may actually retard motility of this organ. Concerns about toxicity, pseudomembranous colitis, and the induction of resistant strains of bacteria, among other things, limit the use of erythromycin to acute situations or in circumstances where patients are resistant to other medications.

**Motilin Receptor Agonists.** A number of these drugs have been developed for the treatment of diabetic gastroparesis. Currently, mitomcinal (GM-611), a macrolide nonantibiotic, shows promise for the treatment of gastroparesis (Gale, 2009).

**Miscellaneous Agents for Stimulating Motility**

The GI hormone cholecystokinin (CCK) is released from the intestine in response to meals and delays gastric emptying, causes contraction of the gallbladder, stimulates pancreatic enzyme secretion, increases intestinal motility, promotes satiety, and has a host of other actions. The C-terminal octapeptide of CCK, sinalcalide (KINEVAC), is useful for stimulating the gallbladder and/or pancreas and may also be used for accelerating barium transit through the small bowel for diagnostic testing of these organs. This drug is administered intravenously 0.02-0.04 \( \mu \text{g/kg} \) over 30-60 seconds or up to 30-45 minutes depending on the test. Administration of this agent is frequently accompanied by nausea and abdominal pain, and much less frequently dizziness. Concerns that should be noted using this agent are related to the expulsion of small gallstones into the common bile duct or cystic duct. Dexloxiglumide is a CCK\(_1\) (or CCK-A)–receptor antagonist that can improve gastric emptying and was investigated as a treatment for gastroparesis and for constipation–dominant IBS, but may also have uses in feeding intolerance in critically ill individuals. Clonidine also has been reported to be of benefit in patients with gastroparesis. Octreotide acetate (SANDOSTATIN, others), a somatostatin analogue, also is used in some patients with intestinal dysmotility.

In some disorders of motility, effective treatment does not necessarily require a “neuroenteric” approach. One such example is gastroesophageal reflux disease. Acid reflux is associated with transient lower esophageal sphincter relaxations that occur in the absence of a swallow. Because the damage to the esophagus ultimately is inflicted by acid, the most effective therapy for gastroesophageal reflux disease still is the suppression of acid production by the stomach (Chapter 45). Neither metoclopramide nor cisapride by itself is particularly effective in gastroesophageal reflux disease. However, a new approach under investigation relies on suppression of the transient lower esophageal sphincter relaxations, as achieved by CCK\(_1\)–receptor antagonists (such as dexloxiglumide), GABA agonists (such as baclofen), and inhibitors of NO synthesis.

**Agents that Suppress Motility**

Smooth muscle relaxants such as organic nitrates and Ca\(^{2+}\)-channel antagonists (Chapters 27 and 28) often produce temporary, if partial, relief of symptoms in motility disorders such as achalasia, in which the lower esophageal sphincter fails to relax, resulting in a functional obstruction to the passage of food and severe difficulty in swallowing. A more recent approach relies on the use of preparations of botulinum toxin (BOTOX, DYSPORT, MYOBLOC), injected directly into the lower esophageal sphincter via an endoscope, in doses of 80-100 units (Zhao and Pasricha, 2003). This potent agent inhibits ACh release from nerve endings (Chapter 11) and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance. However, its effects dissipate over a period of several months, requiring repeated injections; there is also some potential for post-administration “spread” of the toxin that can result in life-threatening consequences. Botulinum toxin preparations likely will be more widely used especially in the elderly and in those with other risks for pneumatic dilation. Other GI conditions in which botulinum toxin A has been used include gastroparesis, sphincter of Oddi dysfunction, and anal fissures, although currently there are not strong trial data to support its efficacy.

**LAXATIVES, CATHARTICS, AND THERAPY FOR CONSTIPATION**

**Overview of GI Water and Electrolyte Flux.** Fluid content is the principal determinant of stool volume and consistency; water normally accounts for 70-85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion and secretion of water and electrolytes) and output (absorption) along the length of the GI tract. The daily challenge for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind a manageable pool of fluid for proper expulsion of waste material via the process of defecation. Normally ~8-9 L of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 46–3). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only ~1-1.5 L crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving ~100 mL of fecal water daily.

Under normal circumstances, these quantities are well within the range of the total absorptive capacity of the small bowel (~16 L) and colon (4-5 L). Neurohumoral mechanisms, pathogens, and drugs can alter these processes, resulting in changes in either secretion or absorption of fluid by the intestinal epithelium. Altered motility also contributes in a general way to this process, as the extent of absorption parallels transit time. With decreased motility and excess fluid removal,
feces can become inspissated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea occurs.

**Constipation: General Principles of Pathophysiology and Treatment.** Scientific definitions rely mostly on stool number; most surveys have found the normal stool frequency on a Western diet to be at least three times a week. However, patients use the term constipation not only for decreased frequency, but also for difficulty in initiation or passage, passage of firm or small-volume feces, or a feeling of incomplete evacuation. By questionnaire, 25% of the population of the U.S., more commonly women and elderly people, complain of constipation. A survey of bowel habits of adults in the U.S. showed that 18% of respondents used laxatives at least once a month, but nearly one-third of users did not have constipation. Approximately 2.5 million physician visits per year are attributed to constipation. Constipation has many reversible or secondary causes, including lack of dietary fiber, drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation have normal colonic transit. These patients either have IBS or define constipation in terms other than stool frequency (e.g., changes in consistency, excessive straining, or a feeling of incomplete evacuation). In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility or, less commonly, as an isolated disorder of defection or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the rectoanal region. Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions. Mixing in the colon is accomplished in a way similar to that in the small bowel: by short- or long-duration, stationary (nonpropulsive) contractions. Propulsive contractions in the colon include giant migrating contractions, also known as colonic mass actions or mass movements, which propagate caudally over extended lengths in the colon and evoke mass transfer of feces from the right to the left colon once or twice a day. Disturbances in motility therefore may have complex effects on bowel movements. “Decreased motility” of the mass action type and “increased motility” of the nonpropulsive type may lead to constipation. In any given patient, the predominant factor often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and is based, in most cases, on nonspecific principles.

In many cases, constipation can be corrected by adherence to a fiber-rich (20-35 g daily) diet, adequate fluid intake, appropriate bowel habits and training, and avoidance of constipating drugs. However, the association between constipation and either fluid intake or exercise has not withstood scientific scrutiny. Constipation related to medications can be corrected by use of alternative drugs where possible, or adjustment of dosage. If non-pharmacological measures alone are inadequate or unrealistic (e.g., because of elderly age or infirmity), they may be supplemented with bulk-forming agents or osmotic laxatives. When stimulant laxatives are used, they should be administered at the lowest effective dosage and for the shortest period of time to avoid abuse. In addition to perpetuating dependence on drugs, the laxative habit may lead to excessive loss of water and electrolytes; secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported.

In addition to treating constipation, laxatives frequently are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable.
The terms laxatives, cathartics, purgatives, aperients, and evacuants often are used interchangeably. There is a distinction, however, between laxation (the evacuation of formed fecal material from the rectum) and catharsis (the evacuation of unformed, usually watery fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are actually cathartics that act as laxatives at low doses.

Laxatives generally act in one of the following ways: (1) enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms; (2) decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport; or (3) altering motility by either inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions. Based on their actions, laxatives can be classified as shown in Table 46–1; their known effects on motility and secretion are listed in Table 46–2. However, studies indicate considerable overlap among these traditional categories. A variety of laxatives, both osmotic agents and stimulants, increase the activity of NO synthase and the biosynthesis of platelet-activating factor in the gut. Platelet-activating factor is a phospholipid proinflammatory mediator that stimulates colonic secretion and GI motility (Izzo et al., 1998). NO also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, and bisacodyl (but not senna), as well as magnesium sulfate.

An alternate way to classify laxatives is by the pattern of effects produced by the usual clinical dosage (Table 46–3).

### Dietary Fiber and Supplements

Under normal circumstances, the bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber is defined as that part of food that resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying quantities.

### Table 46–1

**Classification of Laxatives**

1. **Luminally active agents**
   - Hydrophilic colloids; bulk-forming agents (bran, psyllium, etc.)
   - Osmotic agents (non-absorbable inorganic salts or sugars)
   - Stool-wetting agents (surfactants) and emollients (docusate, mineral oil)
2. **Nonspecific stimulants or irritants (with effects on fluid secretion and motility)**
   - Diphenylmethanes (bisacodyl)
   - Anthraquinones (senna and cascara)
   - Castor oil
3. **Prokinetic agents (acting primarily on motility)**
   - 5-HT₄ receptor agonists
   - Dopamine receptor antagonists
   - Motilides (erythromycin)

degrees, depending on its chemical nature and water solubility. Fermentation of fiber has two important effects:

- it produces short-chain fatty acids that are trophic for colonic epithelium
- it increases bacterial mass

Although fermentation of fiber generally decreases stool water, short-chain fatty acids also may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. However, fiber that is not fermented can attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 46–4). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Bran, the residue left when flour is made from cereal grains, contains >40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight. Fruits and vegetables contain more pectins and hemicelluloses, which are more readily fermentable and produce less effect on stool transit. Psyllium husk, derived from the seed of the plantago herb (Plantago ovata; known as ispaghula or isabgol in many parts of the world), is a component of many commercial products for constipation (METAMUCIL, others). Psyllium husk contains a hydrophilic mucilloid that undergoes significant fermentation in the colon, leading to an increase in colonic bacterial mass. The usual dose is 2.5-4 g (1-3 teaspoonfuls in 250 mL of fruit juice), titrated upward until the desired goal is reached. A variety of semisynthetic celluloses—e.g., methylcellulose (CITRUCEL, others) and the hydrophilic resin calcium polycarbophil (FIBERCON, FIBERALL, others), a polymer of acrylic acid resin—also are available. These poorly fermentable compounds absorb water and increase fecal bulk. Malt soup extract (MALSTSUPEX, others), an extract of malt from barley grains that contains small amounts of polymeric carbohydrates, proteins, electrolytes, and vitamins, is another orally administered bulk-forming agent.

Fiber is contraindicated in patients with obstructive symptoms and in those with megacolon or megarectum. Fecal impaction should be treated before initiating fiber supplementation. Bloating is the most common side effect of soluble fiber products (perhaps due to colonic fermentation), but it usually decreases with time. Calcium polycarbophil preparations release Ca\(^{2+}\) in the GI tract and thus should be avoided by patients who must restrict their intake of calcium or who are taking tetracycline. Sugar-free bulk laxatives may contain aspartame and are contraindicated in patients with phenylketonuria. Allergic reactions to psyllium have been reported.

### Osmotically Active Agents

#### Saline Laxatives

Laxatives containing magnesium cations or phosphate anions commonly are called saline laxatives: magnesium sulfate, magnesium hydroxide, magnesium citrate, sodium phosphate. Their cathartic action is believed to result from osmotically mediated water retention, which then stimulates peristalsis. Other mechanisms may contribute to their effects, including the production of inflammatory mediators. Magnesium-containing laxatives may stimulate the release of cholecystokinin, which leads to intraluminal fluid and electrolyte accumulation and to increased intestinal motility. It is estimated that for every additional mEq of Mg\(^{2+}\) in the intestinal lumen, fecal weight increases by ~7 g. The usual dose of magnesium salts contains 40-120 mEq of Mg\(^{2+}\) and produces 300-600 mL of stool within 6 hours. The intensely bitter taste of some

*Employed in high dosage for rapid cathartic effect and in lower dosage for laxative effect.*
preparations may induce nausea and can be masked with citrus juices.

Phosphate salts are better absorbed than magnesium-based agents and therefore need to be given in larger doses to induce catharsis. The most frequently employed preparations of sodium phosphate are an oral solution (FLEET PHOSPHO-SODA) and tablets (VISICOL, OSMOPREP). Over-the-counter oral sodium phosphate products for bowel cleansing were withdrawn from the market in 2008 following the determination by the FDA that only prescription medications should be available for this purpose. To reduce the likelihood of acute phosphate nephropathy, oral phosphates should be avoided in patients at risk (the elderly, patients with known bowel pathology or renal dysfunction, and patients on angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], and nonsteroidal anti-inflammatory drugs [NSAIDs]) and the two-dose regimens should be split evenly with the first dose taken the evening before the exam and the second starting 3-5 hours before the exam. Adequate fluid intake (1-3 L) is essential for any oral sodium phosphate regimen used for colonic preparation.

Magnesium- and phosphate-containing preparations must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities, and in patients on diuretic therapy. Patients taking >45 mL of oral sodium phosphate as a prescribed bowel preparation may experience electrolyte shifts that pose a risk for the development of symptomatic dehydration, renal failure, metabolic acidosis, tetany from hypocalcemia, and even death in vulnerable populations.

**Nondigestible Sugars and Alcohols.** Lactulose (CEPHULAC, CHRONULAC, others) is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity. This and other non-absorbable sugars such as sorbitol and mannitol are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and vincristine, of constipation in the elderly, and of idiopathic chronic constipation.

They are available as 70% solutions, which are given in doses of 15-30 mL at night, with increases as needed up to 60 mL per day in divided doses. Effects may not be seen for 24-48 hours after dosing is begun. Abdominal discomfort or distention and flatulence are relatively common in the first few days of treatment but usually subside with continued administration. A few patients dislike the sweet taste of the preparations; dilution with water or administering the preparation with fruit juice can mask the taste.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver disease have an impaired capacity to detoxify ammonia coming from the colon, where it is produced by bacterial metabolism of fecal urea. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in “trapping” of the ammonia by its conversion to the polar ammonium ion. Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal in this condition is to give sufficient amounts of lactulose (usually 20-30 g, three to four times per day) to produce two to three soft stools a day with a pH of 5-5.5.

**Polyethylene Glycol–Electrolyte Solutions.** Long-chain polyethylene glycols (PEGs; molecular weight ~3350 Da) are poorly absorbed, and PEG solutions are retained in the lumen by virtue of their high osmotic nature. When used in high volume, aqueous solutions of PEGs with electrolytes (COLYTE, GOLYTELY, others) produce an effective catharsis and have replaced oral sodium phosphates as the most widely used preparations for colonic cleansing prior to radiological, surgical, and endoscopic procedures. Usually 240 mL of this solution is taken every 10 minutes until 4 L is consumed or the rectal

effluent is clear. To avoid net transfer of ions across the intestinal wall, these preparations contain an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride. The osmotic activity of the PEG molecules retains the added water and the electrolyte concentration assures little or no net ionic shifts.

PEGs (without electrolytes) are also increasingly being used in smaller doses (250-500 mL daily) for the treatment of constipation in difficult cases. A powder form of polyethylene glycol 3350 (MIRALAX, others) is now available for the short-term treatment (≤2 weeks) of occasional constipation, although the agent has been prescribed safely for longer periods in clinical practice. The usual dose is 17 g of powder per day in 8 ounces of water. This preparation does not contain electrolytes, so larger volumes may represent a risk for ionic shifts. As with other laxatives, prolonged, frequent, or excessive use may result in dependence or electrolyte imbalance.

**Stool-Wetting Agents and Emollients**

Docusate salts are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool and permitting easier defecation. However, these agents also stimulate intestinal fluid and electrolyte secretion (possibly by increasing mucosal cyclic AMP) and alter intestinal mucosal permeability. Docusate sodium (diocetyl sodium sulfosuccinate; COLACE, DOXINATE, others) and docusate calcium (diocetyl calcium sulfosuccinate; SURF-LAX, others), are available in several dosage forms. Despite their widespread use, these agents have marginal, if any, efficacy in most cases of constipation.

Mineral oil is a mixture of aliphatic hydrocarbons obtained from petrolatum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2-3 days, it penetrates and softens the stool and may interfere with resorption of water. The side effects of mineral oil preclude its regular use and include interference with absorption of fat-soluble substances (such as vitamins), elicitation of foreign-body reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur, so “heavy” mineral oil should not be taken at bedtime and “light” (topical) mineral oil should never be administered orally.

**Stimulant (Irritant) Laxatives**

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle. These agents probably induce a limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility. Proposed mechanisms include activation of prostaglandin–cyclic AMP and NO–cyclic GMP pathways, platelet-activating factor production (see earlier), and inhibition of Na+, K+-ATPase. Included in this group are diphenylmethane derivatives, anthraquinones, and ricinoleic acid.

**Diphenylmethane Derivatives.** Bisacodyl (DULCOLAX, CORRECTOL, others) is the only diphenylmethane derivative available in the U.S. It is marketed as enteric-coated and regular tablets and as a suppository for rectal administration.

The usual oral daily dose of bisacodyl is 10-15 mg for adults and 5-10 mg for children ages 6-12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, and so the laxative effects after an oral dose usually are not produced in <6 hours; taken at bedtime, it will produce its effect the next morning. Suppositories work much more rapidly, within 30-60 minutes. Due to the possibility of developing an atomic nonfunctioning colon, bisacodyl should not be used for >10 consecutive days.

Bisacodyl is mainly excreted in the stool; ~5% is absorbed and excreted in the urine as a glucuronide. Overdosage can lead to catharsis and fluid and electrolyte deficits. The diphenylmethanes can damage the mucosa and initiate an inflammatory response in the small bowel and colon. To avoid drug activation in the stomach with consequent gastric irritation and cramping, patients should swallow tablets without chewing or crushing and avoid milk or antacid medications within 1 hour of the ingestion of bisacodyl.

Phenolphthalein, once among the most popular components of laxatives, has been withdrawn from the market in the U.S. because of potential carcinogenicity. Oxyphenisatin, another older drug, was withdrawn due to hepatotoxicity. Sodium picosulfate (LUBRILAX, SUR-LAX) is a diphenylmethane derivative widely available outside of the U.S. It is hydrolyzed by colonic bacteria to its active form, and hence acts locally only in the colon. Effective doses of the diphenylmethane derivatives vary as much as 4- to 8-fold in individual patients. Consequently, recommended doses may be ineffective in some patients but may produce cramps and excessive fluid secretion in others.

**Anthraquinone Laxatives.** These derivatives of plants such as aloe, cascara, and senna share a tricyclic anthracene nucleus modified with hydroxyl, methyl, or carboxyl groups to form monoanthrones, such as rhein and frangula. Monoanthrones are irritating to the oral mucosa; however, the process of aging or drying converts them to more innocuous dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms.

Senna (SENOKOT, EX-LAX, others) is obtained from the dried leaflets on pods of *Cassia acutifolia* or *Cassia angustifolia* and contains the rhein dianthrone glycosides sennoside A and B. *Cascara sagrada* is obtained from the bark of the buckthorn tree and contains the glycosides barbaloin and chrysaloin. Barbaloin is also found in aloe. The rhubarb plant also produces anthraquinone compounds that
have been used as laxatives. Anthraquinones can also be synthesized; however, the synthetic monoanthrone danthon was withdrawn from the U.S. market because of concerns over possible carcinogenicity. In addition, all aloe and cascara sagrada products sold as laxatives have been categorized by FDA as not generally recognized as safe and effective for over-the-counter use because of a lack of scientific information about potential carcinogenicity.

Although these ingredients may still be sold over-the-counter in the U.S., legally they cannot be labeled for use as laxatives. This judgment is medically prudent but may provoke a longing for times past in Joyceans, who recall that cascara sagrada, the sacred bark, worked well for Leopold Bloom, in Dublin, on June 16, 1904:

_Midway, his last resistance yielding, he allowed his bowels to ease themselves quietly as he read, reading still patiently that slight constipation of yesterday quite gone. Hope its not too big to bring on piles again. No, just right. So. Ah! Costive one tabloid of cascara sagrada. Life might be so._ (Joyce, 1922)

Anthraquinone laxatives can produce giant migrating colonic contractions and induce water and electrolyte secretion. They are poorly absorbed in the small bowel, but because they require activation in the colon, the laxative effect is not noted until 6-12 hours after ingestion. Active compounds are absorbed to a variable degree from the colon and excreted in the bile, saliva, milk, and urine.

The adverse consequences of long-term use of these agents have limited their use. A melanotic pigmentation of the colonic mucosa (melanosisis coli) has been observed in patients using anthraquinone laxatives for long periods (at least 4-9 months). Histologically, this is caused by the presence of pigment-laden macrophages within the lamina propria. The condition is benign and reversible on discontinuation of the laxative. These agents also have been associated with the development of “cathartic colon,” which can be seen in patients (typically women) who have a long-standing history (typically years) of laxative abuse. Regardless of whether a definitive causal relationship can be demonstrated between the use of these agents and colonic pathology, it is clear that they should not be recommended for chronic or long-term use.

**Castor Oil.** A bane of childhood since the time of the ancient Egyptians, castor oil (purge, neosold, others) is derived from the bean of the castor plant, *Ricinus communis*. The castor bean is the source of an extremely toxic protein, ricin, as well as the oil (chiefly of the triglyceride of ricinoleic acid). The triglyceride is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, ricinoleic acid, which acts primarily in the small intestine to stimulate secretion of fluid and electrolytes and speed intestinal transit. When taken on an empty stomach, as little as 4 mL of castor oil may produce a laxative effect within 1-3 hours; however, the usual dose for a cathartic effect is 15-60 mL for adults. Because of its unpleasant taste and its potential toxic effects on intestinal epithelium and enteric neurons, castor oil is seldom recommended now.

**Prokinetic and Other Agents for Constipation**

Although several of the agents already described stimulate motility, they do so in nonspecific or indirect ways. By contrast, the term _prokinetic_ generally is reserved for agents that enhance GI transit via interaction with specific receptors involved in the regulation of motility.

Newer agents, such as the potent 5-HT<sub>4</sub>-receptor agonist prucalopride, may be useful for the treatment of chronic constipation. Another potentially useful agent is misoprostol, a synthetic prostaglandin analog primarily used for protection against gastric ulcers resulting from the use of NSAIDs (Chapters 34 and 45). Prostaglandins can stimulate colonic contractions, particularly in the descending colon, and this may account for the diarrhea that limits the usefulness of misoprostol as a gastroprotectant. However, this property may be utilized for therapeutic gain in patients with intractable constipation. Colchicine, a microtubule formation inhibitor used for gout (Chapter 34), also has been shown to be effective in constipation (mechanism unknown), but its toxicity has limited widespread use. A novel biological agent, neurotrophin-3 (NT-3), recently was shown to be effective in improving frequency and stool consistency and decreasing straining, again by an unknown mechanism of action.

A new development in the treatment of constipation is the introduction of drugs that enhance fluid secretion by acting locally on ion channels in the colonic epithelium, to promote secretion. Lubiprostone (AMITIZA) is a prostanoid activator of Cl<sup>-</sup> channels. The drug appears to bind to EP<sub>4</sub> receptors linked to activation of adenyl cyclase, leading to enhanced apical Cl<sup>-</sup> conductance; the identity of the Cl<sup>-</sup> channel(s) involved is not certain, possibly CFTR and CIC-2. Lubiprostone was recently introduced for treatment of chronic constipation in adults and irritable bowel syndrome with constipation (IBS-C) in adult women. The drug promotes the secretion of a chloride-rich fluid and so improves stool consistency and promotes increased frequency by reflexly activating motility. A dose of 8 μg twice daily was found to be effective in IBS-C, though higher doses (24 μg twice daily) is given for chronic constipation. The drug is poorly bioavailable, acting only in the lumen of the bowel. Side effects of lubiprostone include nausea, headache, diarrhea, allergic reactions, and dyspnea.

Another class of secretory agent is represented by linaclotide, a 14-amino acid peptide agonist of guanylate cyclase C that stimulates secretion and motility. This compound shows promise in the treatment of IBS-C and chronic constipation, and it appears to have few serious side effects (Gale, 2009). Recent work in rodents suggests it may also be antinociceptive, reducing
visceral pain (Eutamene et al., 2009), a major factor in IBS-C.

**Opioid-Induced Constipation**

Opioids are the main class of analgesics in the treatment and palliation of cancer, as well as other chronic pain states. Opioids cause severe constipation, which significantly limits their acceptability and reduces quality of life considerably. Laxatives and dietary strategies are frequently ineffective in the management of opioid-induced constipation. A promising strategy is the prevention of opioid-induced constipation with peripherally acting μ opioid receptor antagonists that specifically target the underlying reason for this condition, without limiting centrally produced analgesia. Methylnaltrexone (RELISTOR) was approved for the treatment of opioid-induced constipation by the FDA in 2008. Approval was based on multicenter trials demonstrating good efficacy in initiating bowel movements after injection of the drug in end-stage cancer patients in a hospice setting. When methylnaltrexone (0.15-0.3 mg/kg) was administered repeatedly every other day for 2 weeks, bowel movements occurred in 50% of the patients, compared with 8–15% of patients receiving placebo (Holzer, 2009). Another μ opioid antagonist, alvimopan (ENTEREG, 0.5-1 mg twice daily for 6 weeks) has also been tested in this setting where it increased spontaneous bowel movements and improved other symptoms of opioid-induced constipation without compromising analgesia (Holzer, 2009). Opioid-induced constipation represents an off-label use for alvimopan.

**Post-operative Ileus**

Post-operative ileus refers to the intolerance to oral intake and non-mechanical obstruction of the bowel that occurs after abdominal and non-abdominal surgery. It generally lasts 1-3 days after surgery with some variation along the length of the bowel. The pathogenesis is complex and is a combination of activation of neural inhibitory reflexes involving enteric μ opioid receptors and the activation of local inflammatory mechanisms that reduce smooth muscle contractility. The condition is exacerbated by opioids, which are the mainstay of post-operative analgesia. The extent to which endogenous opioids are involved in post-operative ileus remains to be determined. Prolonged post-operative ileus is hard to treat, and therefore considerable efforts are made to prevent its occurrence, including use of epidural anesthetics, minimally invasive surgeries, and reduced narcotic administration. Prokinetic agents typically do not have much effect in this condition, but recently, two new therapeutic agents have been introduced that have benefit in reducing GI recovery time after surgery. Alvimopan (ENTEREG) is an orally active peripherally restricted μ opioid receptor antagonist that is FDA approved for limited indications following surgery (12 mg prior to surgery and then once daily for up to 7 days or until discharge; not to exceed 15 doses total). Methylnaltrexone (RELISTOR) is another peripherally restricted μ opioid receptor antagonist that lacks anti-analgesic actions. Methylnaltrexone reportedly enhanced GI transit but did not reduce time to discharge compared to standard approaches (Holzer, 2009). It is FDA approved for the treatment of opioid-induced constipation in patients receiving palliative care when laxative therapy is insufficient.

Dexpanthenol (ILOPAN, others) is the alcohol of pantothenic acid (vitamin B₃). The drug is a congener of pantothenic acid, a precursor of coenzyme A, which serves as a cofactor in the synthesis of ACh by choline acetyl transferase. It is proposed to act by enhancing ACh synthesis. ACh is the major excitatory transmitter of the gut. Dexpanthenol is used as an injection immediately postoperatively after major abdominal surgery to minimize the occurrence of paralytic ileus. It is given by intramuscular injection (200-500 mg) immediately and then 2 hours later and every 6 hours after that until the situation has resolved. It may cause mild hypotension and shortness of breath as well as local irritation.

**Enemas and Suppositories**

Enemas commonly are employed, either by themselves or as adjuncts to bowel preparation regimens, to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this. Specialized enemas contain additional substances that are either osmotically active or irritant; however, their safety and efficacy have not been studied in a rigorous manner. Repeated enemas with tap water or other hypotonic solutions can cause hyponatremia; repeated enemas with sodium phosphate–containing solution can cause hypocalcemia. Phosphate-containing enemas also are known to alter the appearance of rectal mucosa and contribute to acute phosphate nephropathy in susceptible patients.

Glycerin is a trihydroxy alcohol that is absorbed orally but acts as a hygroscopic agent and lubricant when given rectally. The resultant water retention stimulates peristalsis and usually produces a bowel movement in less than an hour. Glycerin is for rectal use only and is given in a single daily dose as a 2- or 3-g rectal suppository or as 5-15 mL of an 80% solution in enema form. Rectal glycerin may cause local discomfort, burning, or hyperemia and (minimal) bleeding. Some glycerin suppositories contain sodium stearate, which can cause local irritation.

Another agent for occasional constipation makes use of rectal distention to initiate laxation. CEO-TWO suppositories contain...
sodium bicarbonate and potassium bitartrate. When administered rectally, the suppository produces CO₂, which initiates a bowel movement in 5-30 minutes.

**ANTI-DIARRHEAL AGENTS**

**Diarrhea: General Principles and Approach to Treatment.** Diarrhea (Greek and Latin: *dia*, through, and *rheein*, to flow or run) does not require any definition to people who suffer from “the too rapid evacuation of too fluid stools.” Scientists usually define diarrhea as excessive fluid weight, with 200 g per day representing the upper limit of normal stool water weight for healthy adults in the Western world. Because stool weight is largely determined by stool water, most cases of diarrhea result from disorders of intestinal water and electrolyte transport.

An appreciation and knowledge of the underlying causative processes in diarrhea facilitates effective treatment. From a mechanistic perspective, diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen); excessive secretion of electrolytes and water into the intestinal lumen; exudation of protein and fluid from the mucosa; and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a benign, self-limited illness requiring no treatment or evaluation. In severe cases, dehydration and electrolyte imbalances are the principal risk, particularly in infants, children, and frail elderly patients. Oral rehydration therapy therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This is of particular importance in developing countries, where the use of such therapy saves many thousands of lives per year. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute diarrhea. Sodium and chloride absorption is linked to glucose uptake by the enterocyte; this is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea in adults should be reserved for patients with significant or persistent symptoms. Nonspecific anti-diarrheal agents typically do not address the underlying pathophysiology responsible for the diarrhea; their principal utility is to provide symptomatic relief in mild cases of acute diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided as much as possible in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms; they also may induce local complications such as toxic megacolon.

**Bulk-Forming and Hydroscopic Agents.** Hydrophilic and poorly fermentable colloids or polymers such as *carboxymethylcellulose* and calcium polycarboxophil absorb water and increase stool bulk (calcium polycarboxophil absorbs 60 times its weight in water). They usually are used for constipation but are sometimes useful in acute episodic diarrhea and in mild chronic diarrheas in patients suffering with IBS. The mechanism of this effect is not clear, but they may work as gels to modify stool texture and viscosity and to produce a perception of decreased stool fluidity. Some of these agents also may bind bacterial toxins and bile salts. Clays such as kaolin (a hydrated aluminum silicate) and other silicates such as attapulgite (magnesium aluminum disilicate; DIASORB, others) bind water avidly (attapulgite absorbs eight times its weight in water) and also may bind enterotoxins. However, binding is not selective and may involve other drugs and nutrients; hence these agents are best avoided within 2-3 hours of taking other medications. A mixture of kaolin and pectin (a plant polysaccharide) is a popular over-the-counter remedy (KAOPECTOLIN, others) and may provide useful symptomatic relief of mild diarrhea.

**Bile Acid Sequestrants.** Cholestyramine, colestipol, and colesevalam effectively bind bile acids and some bacterial toxins. Cholestyramine is useful in the treatment of bile salt–induced diarrhea, as in patients with resection of the distal ileum. In these patients, there is partial interruption of the normal enterohepatic circulation of bile salts, resulting in excessive concentrations reaching the colon and stimulating water and electrolyte secretion. Patients with extensive ileal resection (usually >100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of cholestyramine aggravates the diarrhea. The drug also has had an historic role in treating mild antibiotic-associated diarrhea and mild colitis due to *Clostridium difficile*. However, its use in infectious diarrheas generally is discouraged because it may decrease clearance of the pathogen from the bowel.
In patients suspected of having bile salt–induced diarrhea, a trial of cholestyramine (QUESTRAN, QUESTRAN LIGHT, others) can be given at a dose of 4 g of the dried resin (four times a day). If successful, the dose may be titrated down to achieve the desired stool frequency.

Cholestyramine resin also is helpful for the relief of pruritus associated with partial biliary obstruction and in conditions such as primary biliary cirrhosis. In such conditions, excessive bile acids are thought to be deposited in the skin and cause irritation. Cholestyramine increases fecal excretion of bile acids and reduces circulating and eventually systemic levels with relief of pruritus in ~1-3 weeks.

**Bismuth.** Bismuth compounds have been used to treat a variety of GI diseases and symptoms for centuries, although their mechanism of action remains poorly understood. PEPTO-BISMOL (or generic formulations of bismuth subsalicylate) is an over-the-counter preparation estimated to be used by 60% of American households. It is a crystal complex consisting of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the bismuth subsalicylate reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid. Although 99% of the bismuth passes unaltered and unabsorbed into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, the product carries the same labeled warning regarding Reye’s syndrome as other salicylates, and patients taking other forms of salicylates should be made aware of the overlap in adverse effect.

Bismuth is thought to have anti-secretory, anti-inflammatory, and antimicrobial effects. Nausea and abdominal cramps also are relieved by bismuth. The clay in PEPTO-BISMOL and generic formulations also may have some additional benefits in diarrhea, but this is not clear. Bismuth subsalicylate has been used extensively for the prevention and treatment of traveler’s diarrhea, but it also is effective in other forms of episodic diarrhea and in acute gastroenteritis. Today, the most common antibacterial use of this agent is in the treatment of Helicobacter pylori (Chapter 45). A recommended dose of the bismuth subsalicylate (30 mL of regular strength liquid or two tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 30-60 minutes, as needed, up to eight times a day. Bismuth products have a long track record of safety at recommended doses, although impaction may occur in infants and debilitated patients. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the GI tract.

**Probiotics.** The GI tract contains a vast commensal microflora that is necessary for health. Alterations in the balance or composition of the microflora are responsible for antibiotic-associated diarrhea, and possibly other disease conditions. The administration of nonpathogenic bacteria to recolonize the gut is an area of intense investigation (Sartor, 2005). Probiotic preparations containing a variety of bacterial strains have shown some degree of benefit in acute diarrheal conditions, antibiotic-associated diarrhea, and infectious diarrhea, but most clinical studies have been small and conclusions are therefore limited. Because these agents are generally safe, their use continues despite mainly anecdotal evidence of efficacy.

### Anti-Motility and Anti-Secretory Agents

**Opioids.** Opioids continue to be widely used in the treatment of diarrhea. They act by several different mechanisms, mediated principally through either μ- or δ-opioid receptors on enteric nerves, epithelial cells, and muscle (Chapter 18). These mechanisms include effects on intestinal motility (μ receptors), intestinal secretion (δ receptors), or absorption (μ and δ receptors). Commonly used anti-diarrheals such as diphenoxylate, difenoxin, and loperamide act principally via peripheral μ opioid receptors and are preferred over opioids that penetrate the CNS.

**Loperamide.** Loperamide (IMODIUM, IMODIUM A-D, others), a piperidine butyramide derivative with μ receptor activity, is an orally active anti-diarrheal agent. The drug is 40-50 times more potent than morphine as an anti-diarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. Loperamide also increases anal sphincter tone, an effect that may be of therapeutic value in some patients who suffer from anal incontinence. In addition, loperamide has anti-secretory activity against cholera toxin and some forms of *Escherichia coli* toxin, presumably by acting on G_{i}-linked receptors and countering the increase in cellular cyclic AMP generated in response to the toxins.

Because of its effectiveness and safety, loperamide is marketed for over-the-counter distribution and is available in capsule, solution, and chewable tablet forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3-5 hours. It has a t\textsubscript{1/2} of ~11 hours and undergoes extensive hepatic metabolism. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg per day. If clinical improvement in acute diarrhea does not occur within 48 hours, loperamide should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2-5 years, 4 mg for ages 6-8 years, and 6 mg for ages 8-12 years. Loperamide is not recommended for use in children <2 years of age.

Loperamide has been shown to be effective against traveler’s diarrhea, used either alone or in combination with antimicrobial agents (trimethoprim, trimethoprim-sulfamethoxazole, or a fluoroquinolone). Loperamide also has been used as adjunct treatment in almost all forms of chronic diarrheal disease, with few adverse effects. Loperamide lacks significant abuse potential and is more effective in treating diarrhea than diphenoxylate. Overdosage, however, can result in CNS depression (especially in children) and paralysis ileus. In patients with active inflammatory bowel disease involving the colon (Chapter 47), loperamide should be used with great caution, if at all, to prevent development of toxic megacolon.
Diphenoxylate and Difenoxin. Diphenoxylate and its active metabolite difenoxin (diphenoxylate acid) are piperidine derivatives that are related structurally to meperidine. As anti-diarrheal agents, diphenoxylate and difenoxin are somewhat more potent than morphine.

Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1-2 hours. Diphenoxylate is rapidly deesterified to difenoxin, which is eliminated with a t1/2 of ~12 hours. Both drugs can produce CNS effects when used in higher doses (40-60 mg per day) and thus have a potential for abuse and/or addiction. They are available in preparations containing small doses of atropine (considered subtherapeutic) to discourage abuse and deliberate overdose: 25 μg of atropine sulfate per tablet with either 2.5 mg diphenoxylate hydrochloride (LOMOTIL) or 1 mg of difenoxin hydrochloride (MOTOPEN). The usual dosage is two tablets initially, then one tablet every 3-4 hours, not to exceed eight tablets per day. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the atropine (dry mouth, blurred vision, etc.) (Chapter 9).

Other opioids used for diarrhea include codeine (in doses of 30 mg given three or four times daily) and opium-containing compounds. Paregoric (camphorated opium tincture) contains the equivalent of 2 mg of morphine per 5 mL (0.4 mg/mL); deodorized tincture of opium, which is 25 times stronger, contains the equivalent of 50 mg of morphine per 5 mL (10 mg/mL). The two tinctures sometimes are confused in prescribing and dispensing, resulting in dangerous overdoses. The anti-diarrheal dose of opium tincture for adults is 0.6 mL (equivalent to 6 mg morphine) four times daily; the adult dose of paregoric is 5-10 mL (equivalent to 2-4 mg morphine) one to four times daily. Paregoric is used in children at a dose of 0.25-0.5 mL/kg (equivalent to 0.1-0.2 mg morphine/kg) one to four times daily.

Enkephalins are endogenous opioids that are important enteric neurotransmitters. Enkephalins inhibit intestinal secretion without affecting motility. Racecadotril (acetorphan), a dipeptide inhibitor of enkephalase, reinforces the effects of endogenous enkephalins on the δ-opioid receptor to produce an anti-diarrheal effect.

α, Adrenergic Receptor Agonists. α, Adrenergic receptor agonists such as clonidine can interact with specific receptors on enteric neurons and enterocytes, thereby stimulating absorption and inhibiting secretion of fluid and electrolytes and increasing intestinal transit time. These agents may have a special role in diabetics with chronic diarrhea, in whom autonomic neuropathy can lead to loss of norepinephrin innervation. Oral clonidine (beginning at 0.1 mg twice a day) has been used in these patients; the use of a topical preparation (e.g., CATAPRES TTS, two patches a week) may result in more steady plasma levels of the drug. Clonidine also may be useful in patients with diarrhea caused by opiate withdrawal. Side effects such as hypotension, depression, and perceived fatigue may be dose limiting in susceptible patients.

Octreotide and Somatostatin. Octreotide (SANDOSTATIN, others) (Chapter 43) is an octapeptide analog of somatostatin (SST) that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the GI tract. Its mechanism of action appears to involve inhibition of hormone secretion, including 5-HT and various other GI peptides (e.g., gastrin, vasoactive intestinal polypeptide (VIP), insulin, secretin, etc.). Octreotide has been used off label, with varying success, in other forms of secretory diarrhea such as chemotherapy-induced diarrhea, diarrhea associated with human immunodeficiency virus (HIV), and diabetes-associated diarrhea. Its greatest utility, however, may be in the “dumping syndrome” seen in some patients after gastric surgery and pyloroplasty. In this condition, octreotide inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects.

Octreotide has a t1/2 of 1-2 hours and is administered either subcutaneously or intravenously as a bolus dose. Standard initial therapy with octreotide is 50-100 μg, given subcutaneously two or three times a day, with titration to a maximum dose of 500 μg three times a day based on clinical and biochemical responses. A long-acting preparation of octreotide acetate enclosed in biodegradable microspheres (SANDOSTATIN LAR DEPOT) is available for use in the treatment of diarrheas associated with carcinoid tumors and VIP–secreting tumors, as well as in the treatment of acromegaly (Chapter 44). This preparation is injected intramuscularly once per month in a dose of 20 or 30 mg. Side effects of octreotide depend on the duration of therapy. Short-term therapy leads to transient nausea, bloating, or pain at sites of injection. Long-term therapy can lead to gallstone formation and hypo- or hyperglycemia. Another long-acting SST analog, lanreotide (SOMATULIN, others), is available in Europe but not in the U.S.; another, vapreotide, is under development. SST (STILAMIN) also is available in Europe.

Variceal Bleeding. Vasoactive agents have been used to control variceal bleeding. Traditionally, vasopressin has been used (Chapter 26), but its significant side effects—such as myocardial ischemia, peripheral vascular disease, and the release of plasminogen activator and factor VIII—have led to its decline. SST and octreotide are effective in reducing hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. Octreotide also may act through the autonomic nervous system. These agents can control bleeding acutely and decrease bleeding-related mortality, with an efficacy comparable to endoscopic therapy or balloon tamponade. The major advantage of somatostatin and octreotide over vasopressin is their safety. Because of its short t1/2 (1-2 minutes), SST can be given only by intravenous infusion (a 250 μg bolus dose followed by 250 μg hourly for 5 days). Higher doses (up to 500 μg/hour) are more efficacious and can be used for patients who continue to bleed on the lower dose (Moitinho
et al., 2001). For patients with variceal bleeding, therapy with octreotide usually is initiated while the patient is awaiting endoscopy.

**Intestinal Dysmotility.** Octreotide has complex and apparently conflicting effects on GI motility, including inhibition of antral motor activity and colonic tone. However, octreotide also can rapidly induce phase III activity of the migrating motor complex in the small bowel to produce longer and faster contractions than those occurring spontaneously. Its use has been shown to result in improvement in selected patients with scleroderma and small-bowel dysfunction.

**Pancreatitis.** Both SST and octreotide inhibit pancreatic secretion and have been used for the prophylaxis and treatment of acute pancreatitis. The rationale for their use is to “put the pancreas to rest” so as to not aggravate inflammation by the continuing production of proteolytic enzymes, to reduce intraductal pressures, and to ameliorate pain. Octreotide probably is less effective than SST in this regard because it may cause an increase in sphincter of Oddi pressure and perhaps also have a deleterious effect on pancreatic blood flow. Although some studies have suggested that these agents improve mortality in patients with acute pancreatitis, definitive data are lacking.

**Other Agents**

Calcium channel blockers such as verapamil and nifedipine (Chapters 25 and 27) reduce motility and may promote intestinal electrolyte and water absorption. Constipation, in fact, is a significant side effect of these drugs. However, because of their systemic effects and the availability of other agents, they seldom if ever are used for diarrheal illnesses.

Berberine is a plant alkaloid that has been used for millennia in traditional Indian and Chinese medicine. It is produced by several genera of the families Ranunculaceae and Berberidaceae (e.g., Berberis, Mahonia, and Coptis) and has complex pharmacological actions that include antimicrobial actions, stimulation of bile flow, inhibition of ventricular tachyarrhythmias, and possible antineoplastic activity. It is used most commonly in bacterial diarrhea and cholera, but is also apparently effective against intestinal parasites. The anti-diarrheal effects in part may be related to its ability to inhibit smooth muscle contraction and delay intestinal transit by antagonizing the effects of ACh (by competitive and noncompetitive mechanisms) and blocking the entry of Ca\(^{2+}\) into cells. In addition, it inhibits intestinal secretion.

Chloride channel blockers are effective anti-secretory agents *in vitro* but are too toxic for human use and have not proven to be effective anti-diarrheal agents *in vivo*. Calmodulin inhibitors, which include chlorpromazine, also are anti-secretory. Zaldaride maleate, an investigational drug in this class, may be effective in traveler’s diarrhea by reducing secretion without affecting intestinal motility.

**IRRITABLE BOWEL SYNDROME (IBS)**

IBS, a condition that affects up to 15% of the population in the U.S., is perhaps one of the more challenging nonfatal illnesses seen by gastroenterologists (Mertz, 2003). Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal pain associated with altered bowel movements. The pathophysiology of this condition is not clear; it appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders. The disturbances in bowel function, which can be either constipation or diarrhea or both at different times, have led to the classical interpretation of IBS as being a “motility disorder,” but motor disturbances cannot explain the entire clinical picture. Recently, more emphasis has been devoted to the pathogenesis of pain in these patients, and there now is considerable evidence to suggest a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological stimuli in this syndrome. The etiopathogenesis of this visceral hypersensitivity probably is multifactorial; a popular hypothesis is that transient visceral injury in genetically predisposed individuals leads to longstanding sensitization of the neural pain circuit despite complete resolution of the initiating event. Increasingly, this concept is being extended to other so-called functional disorders of the gut characterized by unexplained pain, including noncardiac chest pain and nonulcer dyspepsia. These disorders, also considered for many years to arise from motor disturbances, may in fact represent part of a spectrum of a new syndrome of “visceral hyperalgesia.”

Many patients can be managed satisfactorily with a strong patient-physician relationship, simple counseling, and adjunctive measures, including dietary restrictions and fiber supplementation; overt psychological abnormalities should be treated appropriately. Despite these measures, a significant proportion of patients remain plagued by severe symptoms, and drug therapy is attempted almost invariably. However, there are very few effective pharmacological options for these patients, a situation that in part reflects our limited understanding of the pathogenesis of this syndrome.

The pharmacological approach to IBS reflects its multifaceted nature. Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific. Patients with mild symptoms often are started on fiber supplements; this approach may work for constipation and diarrhea (by binding water). Patients with episodic, discrete pain episodes often are treated with agents that may reduce smooth muscle contractility in the gut. These so-called antispasmodics include anticholinergic agents, Ca\(^{2+}\) channel antagonists, and peripheral opioid receptor antagonists. The use of most such drugs is hallowed by years of tradition but seldom has been subjected to critical assessment; however, these drugs may be modestly effective in a subset of patients and are useful adjuncts.

In recent years, an increasing emphasis is being placed on the pharmacological treatment of visceral sensitivity. Although the biological basis of visceral hyperalgesia in IBS patients is not known, a possible role for serotonin has been suggested based on its known
involvement in sensitization of nociceptor neurons in inflammatory conditions. This has led to the development of specific receptor modulators, such as the 5-HT3 antagonist alosetron (Figure 46–2). Buspirone and sumatriptan are 5-HT1 receptor agonists (Chapter 13) that can reduce gastric and colonic sensitivity to distention and are being evaluated in clinical trials.

The most effective class of agents in this regard has been the tricyclic anti-depressants (Chapter 15), which can have neuromodulatory and analgesic properties independent of their anti-depressant effect. Tricyclic anti-depressants have a proven track record in the management of chronic “functional” visceral pain. Effective analgesic doses of these drugs (e.g., 25–75 mg per day of nortryptiline) are significantly lower than those required to treat depression. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns, which can be considered desirable effects in this group of patients. Selective serotonin reuptake inhibitors have fewer side effects and have been advocated particularly for patients with functional constipation because they can increase bowel movements and even cause diarrhea. However, they probably are not as effective as tricyclic anti-depressants in the management of visceral pain.

α2 Adrenergic agonists, such as clonidine (Chapter 12), also can increase visceral compliance and reduce distention-induced pain. The SST analog octreotide has selective inhibitory effects on peripheral afferent nerves projecting from the gut to the spinal cord in healthy human beings and has been shown to blunt the perception of rectal distention in patients with IBS. Fedotozine, an investigational opioid that appears to be a peripherally active, selective κ receptor antagonist, produces marginal improvement in symptoms in patients with IBS and functional dyspepsia. The lack of CNS effects is an advantage in such patients in whom chronic medication use is anticipated. Other agents of unproven value include leuprolide, a gonadotropin-releasing hormone analog (Chapter 42).

Alosetron and Other 5-HT3 Antagonists

The 5-HT3 receptor participates in several important processes in the gut, including sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. Some of these effects in experimental models are potentially conflicting, with release of excitatory and inhibitory neurotransmitters. However, the clinical effect of 5-HT3 antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. In general, therefore, these antagonists produce the opposite effects seen with 5-HT3 agonists. Although they also may blunt visceral sensation, a direct effect on spinal afferents has not been fully established. Alosetron (Lotronex) was the first agent in this class specifically approved for the treatment of diarrhea-predominant IBS in women. Alosetron is a much more potent antagonist of the 5-HT3 receptor than ondansetron and causes significant (although modest) improvements in abdominal pain as well as stool frequency, consistency, and urgency in these patients. Shortly after its initial release, alosetron was withdrawn from the U.S. market because of an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. The mechanism of this effect is not fully established but may result from the drug’s ability to suppress intestinal relaxation, thereby causing severe spasm in segments of the colon in susceptible individuals. It is not clear whether this is a nonspecific effect or involves serotoninergic mechanisms. Nevertheless, the FDA has reapproved this drug for diarrhea-predominant IBS under a limited distribution system. However, concerns about the consequences of prescribing this drug are important, and the manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent protocol before dispensing.

Alosetron is rapidly absorbed from the GI tract; its duration of action (~10 hours) is longer than expected from its t1/2 of 1.5 hours. It is metabolized by hepatic CYPs. The drug should be started at 1 mg per day for the first 4 weeks and advanced to a maximum of 1 mg twice daily if an adequate response is not achieved.

Other 5-HT3 antagonists currently available in the U.S. are approved for nausea and vomiting (see later in this chapter and Chapter 13).

**ANTI-SpasMODICS AND OTHER AGENTS**

**Anticholinergic agents** (“spasmolytics” or “anti-spasmodics”) often are used in patients with IBS. The most common agents of this class available in the U.S. are nonspecific antagonists of the muscarinic receptor (Chapter 9) and include the tertiary amines dicyclomine (Bentyl, others) and hyoscyamine (Levsin, others) and the quaternary ammonium compounds glycopyrrolate (Robinul, others) and methscopolamine (Pamine, others). The advantage of the latter two compounds is that they have a limited propensity to cross the blood-brain barrier and hence a lower risk for neurological side effects such as lightheadedness, drowsiness, or nervousness. These agents typically are given either on an as-needed basis (with the onset of pain) or before meals to prevent the pain and fecal urgency that predictably occur in some patients with IBS (with presumed exaggerated gastrocolic reflex).

Dicyclomine is given in doses of 20 mg orally every 6 hours initially and increased to 40 mg every 6 hours unless limited by side effects. Doses <160 mg/day are not usually effective and should be discontinued after a 2-week trial period. Hyoscyamine is available as immediate-release oral capsules, tablets, elixir, drops, and a nonaerosol spray (all administered as 0.125–0.25 mg every 4 hours as needed), and extended-release forms for oral use (0.25–0.375 mg every 12 hours as needed). An injectable is available for subcutaneous, intravenous, or intramuscular administration. Regardless of the formulation, the adult dose of hyoscyamine usually should not exceed 1.5 mg in 24 hours. Glycopyrrolate is available as immediate-release tablets; the dose is 1–2 mg two or three times daily, not to exceed 8 mg/day. Methscopolamine is provided as 2.5-mg and 5-mg tablets; the dose is 2.5 mg a half hour before meals and 2.5–5 mg at bedtime.

**Other Drugs.** Cimetropium, an antimuscarinic compound that reportedly is effective in patients with IBS, is not available in the U.S. Otilonium bromide is a quaternary ammonium salt with antimuscarinic effects that also appears to block Ca2+ channels and neurokinin
ANTISEROTONIN RECEPTOR ANTAGONISTS

Serotonin (5-HT3) receptors are the predominant receptor subtype involved in nausea and vomiting (Figure 46–4), and an understanding of their nature has allowed a rational approach to the pharmacological treatment of nausea and vomiting (Hornby, 2001; Scuderi, 2003).

Anti-emetics generally are classified according to the predominant receptor on which they are proposed to act (Table 46–5). However, considerable overlap among these mechanisms exists, particularly for the older agents (Table 46–6). For treatment and prevention of the nausea and emesis associated with cancer chemotherapy, several anti-emetic agents from different pharmacological classes may be used in combination (Table 46–7). The individual classes of agents are presented next.

5-HT3 Receptor Antagonists

Chemistry, Pharmacological Effects, and Mechanism of Action. Ondansetron (ZOFran, others) is the prototypical drug in this class. Since their introduction in the early 1990s, the 5-HT3 receptor antagonists have become the most widely used drugs for chemotherapy-induced emesis. Other agents in this class include granisetron (KYTRIL, others), dolasetron (ANZEMET), palonosetron (ALOXI), and tropisetron (available in some countries but not in the U.S.). The differences among these agents are related mainly to their chemical structures, 5-HT3 receptor affinities, and pharmacokinetic profiles (Table 46–8). Alosetron was discussed separately earlier.

There is evidence that effects at peripheral and central sites contribute to the efficacy of these agents. 5-HT3 receptors are present in several critical sites involved in emesis, including vagal afferents, the STN (which receives signals from vagal afferents), and the area postrema itself (Figure 46–4). Serotonin is released by the enterochromaffin cells of the small intestine in response to chemotherapeutic agents and may stimulate vagal afferents (via 5-HT3 receptors) to initiate the vomiting reflex. Experimentally, vagotomy has been shown to prevent cisplatin-induced emesis. However, the highest concentrations of 5-HT3 receptors in the CNS are found in the STN and CTZ, and antagonists of 5-HT3 receptors also may suppress nausea and vomiting by acting at these sites.

Pharmacokinetics. The anti-emetic effects of these drugs persist long after they disappear from the circulation, suggesting their continuing interaction at the receptor level. In fact, all of these drugs can be administered effectively just once a day.

These agents are absorbed well from the GI tract. Ondansetron is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. Although ondansetron clearance also is reduced in elderly patients, no adjustment in dosage for age is recommended. Granisetron also is metabolized predominantly by the liver, a process that appears to involve

**ANTI-NAUSEANTS AND ANTI-EMETIC AGENTS**

**Nausea and Vomiting**

The act of emesis and the sensation of nausea that accompanies it generally are viewed as protective reflexes that serve to rid the stomach and intestine of toxic substances and prevent their further ingestion. Vomiting is a complex process that consists of a pre-ejection phase (gastric relaxation and retroperistalsis), retching (rhythmic action of respiratory muscles preceding vomiting and consisting of contraction of abdominal and intercostal muscles and diaphragm against a closed glottis), and ejection (intense contraction of the abdominal muscles and relaxation of the upper esophageal sphincter). This is accompanied by multiple autonomic phenomena including salivation, shivering, and vasomotor changes. During prolonged episodes, marked behavioral changes including lethargy, depression, and withdrawal may occur. The process appears to be coordinated by a central emesis center in the lateral reticular formation of the midbrainstem adjacent to both the chemoreceptor trigger zone (CTZ) in the area postrema (AP) at the bottom of the fourth ventricle and the solitary tract nucleus (STN). The lack of a blood-brain barrier allows the CTZ to monitor blood and cerebrospinal fluid constantly for toxic substances and to relay information to the emesis center to trigger nausea and vomiting. The emesis center also receives information from the gut, principally by the vagus nerve (via the STN) but also by splanchnic afferents via the spinal cord. Two other important inputs to the emesis center come from the cerebral cortex (particularly in anticipatory nausea or vomiting) and the vestibular apparatus (in motion sickness). In turn, the center sends out efferents to the nuclei responsible for respiratory, salivary, and vasomotor activity, as well as to striated and smooth muscle involved in the act. The CTZ has high concentrations of receptors for serotonin (5-HT3), dopamine (D3), and opioids; the STN is rich in receptors for enkephalin, histamine, and ACh, and also contains 5-HT3 receptors. A variety of these neurotransmitters are involved in nausea and vomiting (Figure 46–4), and an understanding of their nature has allowed a rational approach to the pharmacological treatment of nausea and vomiting (Hornby, 2001; Scuderi, 2003).

Anti-emetics generally are classified according to the predominant receptor on which they are proposed to act (Table 46–5). However, considerable overlap among these mechanisms exists, particularly for the older agents (Table 46–6). For treatment and prevention of the nausea and emesis associated with cancer chemotherapy, several anti-emetic agents from different pharmacological classes may be used in combination (Table 46–7). The individual classes of agents are presented next.

5-HT3 Receptor Antagonists

Chemistry, Pharmacological Effects, and Mechanism of Action. Ondansetron (ZOFran, others) is the prototypical drug in this class. Since their introduction in the early 1990s, the 5-HT3 receptor antagonists have become the most widely used drugs for chemotherapy-induced emesis. Other agents in this class include granisetron (KYTRIL, others), dolasetron (ANZEMET), palonosetron (ALOXI), and tropisetron (available in some countries but not in the U.S.). The differences among these agents are related mainly to their chemical structures, 5-HT3 receptor affinities, and pharmacokinetic profiles (Table 46–8). Alosetron was discussed separately earlier.

There is evidence that effects at peripheral and central sites contribute to the efficacy of these agents. 5-HT3 receptors are present in several critical sites involved in emesis, including vagal afferents, the STN (which receives signals from vagal afferents), and the area postrema itself (Figure 46–4). Serotonin is released by the enterochromaffin cells of the small intestine in response to chemotherapeutic agents and may stimulate vagal afferents (via 5-HT3 receptors) to initiate the vomiting reflex. Experimentally, vagotomy has been shown to prevent cisplatin-induced emesis. However, the highest concentrations of 5-HT3 receptors in the CNS are found in the STN and CTZ, and antagonists of 5-HT3 receptors also may suppress nausea and vomiting by acting at these sites.

Pharmacokinetics. The anti-emetic effects of these drugs persist long after they disappear from the circulation, suggesting their continuing interaction at the receptor level. In fact, all of these drugs can be administered effectively just once a day.

These agents are absorbed well from the GI tract. Ondansetron is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. Although ondansetron clearance also is reduced in elderly patients, no adjustment in dosage for age is recommended. Granisetron also is metabolized predominantly by the liver, a process that appears to involve
Figure 46–4. Pharmacologist's view of emetic stimuli. Myriad signaling pathways lead from the periphery to the emetic center. Stimulants of these pathways are noted in italics. These pathways involve specific neurotransmitters and their receptors (bold type). Receptors are shown for dopamine (D₂), acetylcholine (muscarinic, M), histamine (H₁), cannabinoids (CB₁), substance P (NK₁), and 5-hydroxytryptamine (5-HT₃). Some of these receptors also may mediate signaling in the emetic center.

⁴The most effective agents for chemotherapy-induced nausea and vomiting are the 5-HT₃ antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy as well as reduce the incidence of side effects.

⁵Also has some peripheral activity at 5-HT₃ receptors.

⁶Also has some antihistaminic and anticholinergic activity.
the CYP3A family, as it is inhibited by ketoconazole. Dolasetron is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver while about one-third of it is excreted unchanged in the urine. Palonosetron is metabolized principally by CYP2D6 and excreted in the urine as the metabolized and the unchanged forms in about equal proportions.

**Therapeutic Use.** These agents are most effective in treating chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation, where all three agents appear to be equally efficacious. They also are effective against hyperemesis of pregnancy, and to a lesser degree, postoperative nausea, but not against motion sickness. Unlike other agents in this class, palonosetron also may be helpful in delayed emesis, perhaps a reflection of its long $t_{1/2}$.

These agents are available as tablets, oral solution, and intravenous preparations for injection. For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (Table 46–8) infused over 15 minutes, beginning 30 minutes before chemotherapy, or in 2-3 divided doses, with the first usually given 30 minutes before and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly (ondansetron only) or orally. Granisetron is available as a transdermal formulation that is applied 24-48 hours before chemotherapy and worn for up to 7 days.

**Adverse Effects.** In general, these drugs are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and lightheadedness. As a class, these agents have been shown experimentally to induce minor electrocardiographic changes, but these are not expected to be clinically significant in most cases.

**Dopamine-Receptor Antagonists**

Phenothiazines such as prochlorperazine, thiethylperazine (discontinued in the U.S.), and chlorpromazine (Chapter 16) are among the most commonly used “general-purpose” anti-nauseants and antiemetics. Their effects in this regard are complex, but their principal mechanism of action is $D_2$ receptor antagonism at the CTZ. Compared with metoclopramide or ondansetron, these drugs do not appear to be as uniformly effective in cancer chemotherapy–induced emesis. But they also possess antihistaminic and anticholinergic activities, which are of value in other forms of nausea, such as motion sickness.

For details, see Scuderi, 2003. Plus signs indicate some (+) to considerable (++++) interaction. (–) indicates no effect.
Antihistamines

Histamine H₁ antagonists are primarily useful for motion sickness and postoperative emesis. They act on vestibular afferents and within the brainstem. Cyclizine, hydroxyzine, promethazine, and diphenhydramine are examples of this class of agents. Cyclizine has additional anticholinergic effects that may be useful for patients with abdominal cancer. For a detailed discussion of these drugs, see Chapter 32.

Anticholinergic Agents

The most commonly used muscarinic receptor antagonist is scopolamine (hyoscine), which can be injected as the hydrobromide, but usually is administered as the free base in the form of a transdermal patch (TRANSERM-SCOP). Its principal utility is in the prevention and treatment of motion sickness, although it has been shown to have some activity in postoperative nausea and vomiting tool. In general, anticholinergic agents have no role in chemotherapy-induced nausea. For a detailed discussion of these drugs, see Chapter 9.

Substance P Receptor Antagonists

The nausea and vomiting associated with cisplatin (Chapter 61) have two components: an acute phase that universally is experienced (within 24 hours after chemotherapy) and a delayed phase that affects only some patients (on days 2-5). 5-HT₃ receptor antagonists are not very effective against delayed emesis. Antagonists of the NK₁ receptors for substance P, such as aprepitant (and its parenteral formulation, fosaprepitant; EMEND), have anti-emetic effects in delayed nausea and improve the efficacy of standard anti-emetic regimens in patients receiving multiple cycles of chemotherapy.

After absorption, aprepitant is bound extensively to plasma proteins (>95%); it is metabolized avidly, primarily by hepatic CYP3A4, and is excreted in the stools; its t₁/₂ is 9-13 hours. Aprepitant has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including dexamethasone, methylprednisolone (whose dose may need to be reduced by 50%), and warfarin. Aprepitant is contraindicated in patients on cisapride or pimozide, in whom life-threatening QT prolongation has been reported.

Aprepitant is supplied in 40-, 80- and 125-mg capsules and is administered for 3 days in conjunction with highly emetogenic chemotherapy, along with a 5-HT₃ antagonist and a corticosteroid. The recommended adult dosage of aprepitant is 125 mg administered 1 hour before chemotherapy on day 1, followed by 80 mg once daily in the morning on days 2 and 3 of the treatment regimen.

Cannabinoids

Dronabinol (Δ-9-tetrahydrocannabinol; marinol) is a naturally occurring cannabinoid that can be synthesized chemically or

extracted from the marijuana plant, *Cannabis sativa*. The exact mechanism of the anti-emetic action of dronabinol is not known but probably relates to stimulation of the CB₁ subtype of cannabinoid receptors on neurons in and around the vomiting center in the brainstem (Van Sickle et al., 2001).

**Pharmacokinetics.** Dronabinol is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2-4 hours. It undergoes extensive first-pass metabolism with limited systemic bioavailability after single doses (only 10-20%). Active and inactive metabolites are formed in the liver; the principal active metabolite is 11-OH-delta-9-tetrahydrocannabinol. These metabolites are excreted primarily via the biliary-fecal route, with only 10-15% excreted in the urine. Both dronabinol and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of dronabinol can result in detectable levels of metabolites for several weeks.

**Therapeutic Use.** Dronabinol is a useful prophylactic agent in patients receiving cancer chemotherapy when other anti-emetic medications are not effective. It can stimulate appetite and has been used in patients with acquired immunodeficiency syndrome (AIDS) and anorexia. As an anti-emetic agent, it is administered at an initial dose of 5 mg/m² given 1-3 hours before chemotherapy and then every 2-4 hours afterward for a total of four to six doses. If this is not adequate, incremental increases can be made up to a maximum of 15 mg/m² per dose. For other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to a maximum of 20 mg per day.

**Adverse Effects.** Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity. This can lead to palpitations, tachycardia, vasodilation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like “highs” (e.g., euphoria, somnolence, detachment, dizziness, anxiety, nervousness, panic, etc.) can occur, as can more disturbing effects such as paranoid reactions and thinking abnormalities. After abrupt withdrawal of dronabinol, an abstinence syndrome (irritability, insomnia, and restlessness) can occur. Because of its high affinity for plasma proteins, dronabinol can displace other plasma protein-bound drugs, whose doses may have to be adjusted as a consequence. Dronabinol should be prescribed with great caution to persons with a history of substance abuse (alcohol, drugs) because it also may be abused by these patients.

*Nabilone* (CESAMET) is a synthetic cannabinoid with a mode of action similar to that of dronabinol.

**Pharmacokinetics.** Nabilone, like dronabinol, is a highly lipid-soluble compound that is rapidly absorbed after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 hours. The t₁/₂ is ~2 hours for the parent compound and 35 hours for metabolites. The metabolites are excreted primarily via the biliary-fecal route (60%), with only ~25% excreted in the urine.

**Therapeutic Use.** Nabilone is a useful prophylactic agent in patients receiving cancer chemotherapy when other anti-emetic medications are not effective. A dose (1-2 mg) can be given the night before chemotherapy; usual dosing starts 1-3 hours before treatment and then every 8-12 hours during the course of chemotherapy and for 2 days following its cessation.

**Adverse Effects.** The adverse effects are largely the same as for dronabinol, with significant CNS actions in >10% of patients. Cardiovascular, GI, and other side effects are also common and together with the CNS actions limit the usefulness of this agent.

### Glucocorticoids and Anti-Inflammatory Agents

Glucocorticoids such as dexamethasone can be useful adjuncts (Table 46–7) in the treatment of nausea in patients with widespread cancer, possibly by suppressing peritumoral inflammation and prostaglandin production. A similar mechanism has been invoked to explain beneficial effects of NSAIDs in the nausea and vomiting induced by systemic irradiation. For a detailed discussion of these drugs, see Chapters 34 and 42.

### Benzodiazepines

Benzodiazepines, such as lorazepam and alprazolam, by themselves are not very effective anti-emetics, but their sedative, amnesic, and anti-anxiety effects can be helpful in reducing the anticipatory...
component of nausea and vomiting in patients. For a detailed discussion of these drugs, see Chapter 17.

**Phosphorated Carbohydrate Solutions**

Aqueous solutions of glucose, fructose, and phosphoric acid (EMETROL, NAUSETROL) are available over the counter to relieve nausea. Their mechanism of action is not well established. They may be safely taken for a short period (1 hour with a dose every 15 minutes).

**AGENTS USED FOR MISCELLANEOUS GI DISORDERS**

**Chronic Pancreatitis and Steatorrhea**

**Pancreatic Enzymes.** Chronic pancreatitis is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). Because there is no cure for chronic pancreatitis, the goals of pharmacological therapy are prevention of malabsorption and palliation of pain. The cornerstone of therapy for malabsorption is the use of pancreatic enzymes. Although also used for pain, these agents are much less effective for this symptom.

**Enzyme Formulations.** In the past, two preparations (and many brands thereof) of pancreatic enzymes were available for replacement therapy, pancreatin and pancrelips. As of 2009, only pancrelipase (CREON, ZENPEP) is licensed for sale in the U.S. Pancreatic enzymes are typically prescribed on the basis of the lipase content. Pancrelipase products contain various amounts of lipase, protease, and amylase and thus may not be interchangeable. Excess lipase administration has been implicated in the development of fibrosing colonopathy and adherence to published dosing guidelines is thought to minimize this risk (Borowitz et al., 2002).

**Replacement Therapy for Malabsorption.** Fat malabsorption (steatorrhea) and protein malabsorption occur when the pancreas loses >90% of its ability to produce digestive enzymes. The resultant diarrhea and malabsorption can be managed reasonably well if 30,000 USP units of pancreatic lipase are delivered to the duodenum during a 4-hour period with and after meals; this represents ~10% of the normal pancreatic output. Alternatively, one can titrate the dosage to the fat content of the diet, with ~8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes contain up to 20,000 units of lipase and 76,000 units of protease, and the typical dose of pancrelipase is one to three capsules or tablets with or just before meals and snacks, adjusted until a satisfactory symptomatic response is obtained. The loss of pancreatic amylase does not present a problem because of other sources of this enzyme (e.g., salivary glands). The commercially available products are formulated as delayed-release capsules to overcome the need to control gastric acid pharmacologically.

**Enzymes for Pain.** Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative feedback inhibition of the pancreas by the presence of duodenal proteases. The release of cholecystokinin (CCK), the principal secretagogue for pancreatic enzymes, is triggered by CCK-releasing monitor peptide in the duodenum, which normally is denatured by pancreatic trypsin. In chronic pancreatitis, trypsin insufficiency leads to persistent activation of this peptide and an increased release of CCK, which is thought to cause pancreatic pain because of continuous stimulation of pancreatic enzyme output and increased intraductal pressure. Delivery of active proteases to the duodenum (which can be done reliably only with uncoated preparations) therefore is important for the interruption of this loop. Although enzymatic therapy has become firmly entrenched for the treatment of painful pancreatitis, the evidence supporting this practice is equivocal at best.

In general, pancreatic enzyme preparations are tolerated extremely well by patients. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported.

**Medium-chain triglycerides.** Medium-chain triglycerides (MCTs) may provide an additional source of calories in patients with weight loss and a poor response to diet and pancreatic enzyme therapy. MCTs are readily degraded by gastric and pancreatic lipase, and they do not require bile for digestion. In addition, they can be directly absorbed in the intestine. Oral administration of an enteral formula such as PEPTAMEN, which is enriched in MCTs and hydrolyzed peptides, may be of benefit.

**Octreotide.** Octreotide (Chapter 38) also has been used, with questionable efficacy, to decrease refractory abdominal pain in patients with chronic pancreatitis.

**Enzyme Deficiencies**

Congenital or acquired deficiencies in digestive enzymes may lead to malabsorption and diarrhea as well as other GI symptoms. Most commonly seen are lactose intolerance, which occurs in the West (10-20%) but in some Asian populations may exceed 90%. Clinically, diarrhea, pain and flatulence occur. Treatment consists of reducing dietary intake of lactose, primarily by reducing consumption of milk and dairy products. Enzyme replacements are over the counter and can be added to meals. They are bacterial or yeast-derived β-galactosidases, with varying efficacy (LACTAID, LACTRASE, DAIYREASE, others). Because of considerable individual variation and the uncertain degree of efficacy of these preparations, patients must establish an effective dosing regime empirically. Because of the essential requirements to maintain protein, calcium, and vitamin D intake, these must be supplemented or alternative sources provided in the diet if dairy products are limited.

Congenital sucrase-isomaltase deficiency is less common. The symptoms include diarrhea, abdominal pain, and weight loss. This is a congenital disease and may be diagnosed in children who are failing to thrive and are susceptible to repeated infections. Treatment with enzyme replacement therapy is effective. Sacrosidase (SUCRAID) taken with meals reduces or attenuates symptoms in most cases. Elimination of sugars and carbohydrates from the diet is not practical.

**BILE ACIDS**

Bile acids and their conjugates are essential components of bile that are synthesized from cholesterol in the liver. The major bile acids in human adults are depicted in Figure 46–5. Bile acids induce bile flow,
feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the dispersion and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine (mainly in the terminal ileum), returned to the liver, and then again secreted in bile (enterohepatic circulation). Cholic acid, chenodeoxycholic acid, and deoxycholic acid constitute 95% of bile acids; lithocholic acid and ursodeoxycholic acid are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called bile salts. Colonic bacteria convert primary bile acids (cholic and chenodeoxycholic acid) to secondary acids (mainly deoxycholic and lithocholic acid) by sequential deconjugation and dehydroxylation. These secondary bile acids also are absorbed in the colon and join the primary acids in the enterohepatic pool.

Dried bile from the Himalayan bear (Yutan) has been used for centuries in China to treat liver disease. Ursodeoxycholic acid (UDCA; ursodiol, ACTIGALL, others) (Figure 46–5) is a hydrophilic, dehydroxylated bile acid that is formed by epimerization of the bile acid chenodeoxycholic acid (CDCA; chenodiol) in the gut by intestinal bacteria; it comprises ~1-3% of the total bile acid pool in human beings but is present at much higher concentrations in bears. When administered orally, litholytic bile acids such as chenodiol and ursodiol can alter relative concentrations of bile acids, decrease biliary lipid secretion, and reduce the cholesterol content of the bile so that it is less lithogenic. Ursodiol also may have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases.

Bile acids were first used therapeutically for gallstone dissolution; use for this indication requires a functional gallbladder because the modified bile must enter the gallbladder to interact with gallstones. To be amenable to dissolution, the gallstones must be composed of cholesterol monohydrate crystals and generally must be <15 mm in diameter to provide a favorable ratio of surface to size. For these reasons, the overall efficacy of litholytic bile acids in the treatment of gallstones has been disappointing (partial dissolution occurs in 40-60% of patients completing therapy and is complete in only 33-50% of these). Although a combination of chenodiol and ursodiol probably is better than either agent alone, ursodiol is preferred as a single agent because of its greater efficacy and less-frequent side effects (e.g., hepatotoxicity).

Primary biliary cirrhosis is a chronic, progressive, cholestatic liver disease of unknown etiology that typically affects middle-aged to elderly women. Ursodiol (administered at 13-15 mg/kg per day in two divided doses) reduces the concentration of primary bile acids and improves biochemical and histological features of primary biliary cirrhosis, especially in early disease. Patients with advanced primary biliary cirrhosis and complications such as ascites do not benefit from this treatment. Ursodiol also has been used in a variety of other cholestatic liver diseases, including primary sclerosing cholangitis, and in cystic fibrosis; in general, it is less effective in these conditions than in primary biliary cirrhosis.

### ANTI-FLATULENCE AGENTS

“Gas” is a common but relatively vague GI complaint, used in reference not only to flatulence and eructation but also bloating or fullness. Although few symptoms can be directly attributable to excessive intestinal gas, over-the-counter and herbal preparations that are touted as anti-flatulent are very popular. One of these is simethicone (MYLICON, GAS-X, others), a mixture of siloxane polymers stabilized with silicon dioxide.

Simethicone is an inert, non-toxic insoluble liquid. Because of its ability to collapse bubbles by forming a thin layer on their surface, it is an effective anti-foaming agent. Although it may be effective in diminishing gas volumes in the GI tract, it is not clear whether this accomplishes a therapeutic effect. Simethicone is available in chewable tablets, liquid-filled capsules, suspensions, and orally dissolving strips, either by itself or in combination with other over-the-counter medications including antacids and other digestants. The usual dosage in adults is 40-25 mg four times daily. Activated charcoal may also be used alone or in combination with simethicone, but has not been shown conclusively to have much benefit.

An alpha-galactosidase preparation (BEANO) is available over-the-counter to reduce gas from baked beans.

### CLINICAL SUMMARY

**GI Motility Disorders.** As a group, these are difficult disorders to treat because of a lack of effective therapeutic
options. For patients with gastroparesis, first-line therapy consists of metoclopramide, which accelerates gastric emptying and also has anti-emetic effects. Erythromycin, a motilin agonist, also has been employed, but is most effective for short-term use. For patients with small-bowel dysmotility, the choices are even more limited: Metoclopramide and erythromycin generally do not work; therapy with octreotide may benefit a subset of patients.

Constipation. Although many choices exist for this condition, most therapies are empirical and non-specific. Constipation often can be addressed by simple measures such as increasing fiber intake, avoiding constipating medications, and the judicious use of osmotic laxatives on an as-needed basis. For more persistent symptoms, a specific prokinetic 5-HT₄ receptor agonist or Cl⁻ channel agonist may be effective in some patients. Stimulant laxatives, although effective, should be avoided for long-term use. Patients with chronic constipation who do not respond to simple measures should undergo further testing to discover uncommon but specific disorders of colonic or anorectal motility.

Diarrhea. In most cases, an attempt should be made to find the underlying cause and to target it specifically. If no such cause is found, chronic diarrhea can be treated empirically, with the simplest approach being bulk-forming and hygroscopic agents, followed by opioids such as loperamide for diarrhea associated with inflammatory bowel disease or diphenoxylate/difenoxin can be used to manage acute exacerbations of chronic functional diarrhea.

Irritable Bowel Syndrome. IBS consists of abdominal pain and discomfort associated with diarrhea, constipation, or alternating bouts of diarrhea and constipation. This common syndrome requires a combination of pharmacological and behavioral approaches that include dietary modifications and psychological counseling. No one therapy will work for all patients and currently there are no therapies focused on IBS that treat both the pain and GI symptoms. Anti-spasmodics are useful by themselves in mild cases and as adjuncts in a regimen that includes tricyclic anti-depressants for more persistent pain.

Nausea and Vomiting. The development of the 5-HT₃ receptor antagonists has led to a major advances in the treatment of nausea and vomiting, especially in the post-chemotherapy and post-operative settings. Anticholinergics are most effective in motion sickness. Antihistamines and related drugs still are useful for empirical treatment of nausea from a variety of causes. Dronabinol or nabilone may be an effective agent for some refractory cases. The clinical utility of newer agents such as aprepitant in situations other than post-chemotherapy nausea will be tested in coming years.

Pharmacotherapy of Inflammatory Bowel Disease

John L. Wallace and Keith A. Sharkey

Inflammatory bowel disease (IBD) is a spectrum of chronic, idiopathic, inflammatory intestinal conditions. IBD causes significant gastrointestinal (GI) symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD also is associated with a variety of extraintestinal manifestations, including arthritis, ankylosing spondylitis, sclerosing cholangitis, uveitis, iritis, pyoderma gangrenosum, and erythema nodosum.

IBD conventionally is divided into two major subtypes: ulcerative colitis and Crohn’s disease. Ulcerative colitis is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (e.g., proctitis, left-sided colitis, or pancolitis). Crohn’s disease, by contrast, is characterized by transmural inflammation of any part of the GI tract but most commonly the area adjacent to the ileocecal valve. The inflammation in Crohn’s disease is not necessarily confluent, frequently leaving “skip areas” of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or, alternatively, fistula formation.

Medical therapy for IBD is problematic. Because no unique abnormality has been identified, current therapy for IBD seeks to dampen the generalized inflammatory response; however, no agent can reliably accomplish this, and the response of an individual patient to a given medicine may be limited and unpredictable. Based on this variable response, clinical trials generally employ standardized quantitative assessments of efficacy that take into account both clinical and laboratory parameters (e.g., the Crohn’s Disease Activity Index). The disease also exhibits marked fluctuations in activity—even in the absence of therapy—leading to a significant “placebo effect” in therapeutic trials.

Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating specific complications such as fistulas. Specific drugs may be better suited for one or the other of these aims (Table 47–1). For example, glucocorticoids remain the treatment of choice for moderate to severe flares but are inappropriate for long-term use because of side effects and their inability to maintain remission. Other immunosuppressive agents, such as azathioprine, that require several weeks to achieve their therapeutic effect, have a limited role in the acute setting but are preferred for long-term management.

For many years glucocorticoids, sulfasalazine and 5-aminosalicylic acid were the mainstays of pharmacotherapy for IBD. More recently, agents used in other immune/inflammatory conditions, such as azathioprine and cyclosporine, have been adapted for IBD therapy. Advances in the understanding of the inflammatory response and improved biotechnology have led to the development of biological agents that can target single steps in the immune cascade, a successful and widely accepted strategy. Drug delivery to the appropriate site(s) along the GI tract also has been a major challenge, and second-generation agents have improved drug delivery, increased efficacy, and decreased side effects.

**PATHOGENESIS OF INFLAMMATORY BOWEL DISEASE**

Crohn’s disease and ulcerative colitis are chronic idiopathic inflammatory disorders of the GI tract; a summary of proposed pathogenic events and potential sites of therapeutic intervention is shown in Figure 47–1.

ABBREVIATIONS: 6-MP, 6-mercaptopurine; AZA, azathioprine. (From Sands BE. Therapy of inflammatory bowel disease. Gastroenterology. 2000;118(2 Suppl 1): S68-S82. Table 1, Pg S71. With permission from Elsevier. Copyright © Elsevier.)
Although Crohn’s disease and ulcerative colitis share a number of GI and extraintestinal manifestations and can respond to a similar array of drugs, emerging evidence suggests that they result from fundamentally distinct pathogenetic mechanisms (Xavier and Podolsky, 2007). Histologically, the transmural lesions in Crohn’s disease exhibit marked infiltration of lymphocytes and macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in ulcerative colitis have lymphocytic and neutrophilic infiltrates. Within the diseased bowel in Crohn’s disease, the cytokine profile includes increased levels of interleukin (IL)-12, IL-23, interferon-γ, and tumor necrosis factor-α (TNFα), findings characteristic of T-helper 1 (TH1)–

**Figure 47–1. Proposed pathogenesis of inflammatory bowel disease and target sites for pharmacological intervention.** Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the epithelial barrier is impaired, bacterial antigens can gain access to antigen-presenting cells (APC) such as dendritic cells in the lamina propria. These cells then present the antigen(s) to CD4+ lymphocytes and also secrete cytokines such as interleukin (IL)-12 and IL-18, thereby inducing the differentiation of TH1 cells in Crohn’s disease (or, under the control of IL-4, type 2 helper T cells [TH2] in ulcerative colitis). The balance of pro-inflammatory and anti-inflammatory events is also governed by regulatory TH17 and TReg cells, both of which serve to limit immune and inflammatory responses in the GI tract. Transforming growth factor (TGF)β and IL-6 are important cytokines that drive the expansion of the regulatory T cell subsets. The TH1 cells produce a characteristic array of cytokines, including interferon (IFN)γ and TNFα, which in turn activate macrophages. Macrophages positively regulate TH1 cells by secreting additional cytokines, including IFNγ and TNFα. Recruitment of a variety of leukocytes is mediated by activation of resident immune cells including neutrophils. Cell adhesion molecules such as integrins are important in the infiltration of leukocytes and novel biological therapeutic strategies aimed at blocking leukocyte recruitment are effective at reducing inflammation. General immunosuppressants (e.g., glucocorticoids, thioguanine derivatives, methotrexate, and cyclosporine) affect multiple sites of inflammation. More site-specific intervention involve intestinal bacteria (antibiotics, prebiotics, and probiotics) and therapy directed at TNFα or IL-12 (see text for further details).
mediated inflammatory processes. In contrast, the inflammatory response in ulcerative colitis resembles aspects of that mediated by the TH2 pathway. Recently, this relatively simplistic classification has been revised in the light of the description of regulatory T cells and pro-inflammatory TH17 cells, a novel T-cell population that expresses IL-23 receptor as a surface marker and produces, among others, the pro-inflammatory cytokines IL-17, IL-21, IL-22, and IL-26. Several studies have demonstrated an important role of TH17 cells in intestinal inflammation, particularly in Crohn’s disease (Cho, 2008; Strober et al., 2007).

Important insights into pathogenesis have emerged from genetic analyses of Crohn’s disease. Mutations in the gene NOD2 (nucleotide-binding oligomerization domain-2; also called CARD15) are associated with both familial and sporadic Crohn’s disease in whites (Hugot et al., 2001; Ogura et al., 2001). NOD2 is expressed in monocytes, granulocytes, dendritic cells, Paneth cells, and epithelial cells. It is proposed to function as an intracellular sensor for bacterial infection by recognizing peptidoglycans, thereby playing an important role in the natural immunity to bacterial pathogens. Consistent with this model, other studies have identified bacterial antigens, including pseudomonal protein I2 (Dalwadi et al., 2001) and a flagellin protein (Lodes et al., 2004), as dominant superantigens that induce the TH1 response in Crohn’s disease (shown as bacterial products in Figure 47–1). More recently, genome-wide studies have revealed other genes associated with IBD, whose identification may lead to the development of novel therapeutics (Cho, 2008).

Thus, these converging experimental approaches are generating novel insights into the pathogenesis of Crohn’s disease that soon may translate into novel therapeutic approaches to IBD. The major therapeutic agents available for IBD are described next.

**MESALAMINE (5-ASA)-BASED THERAPY**

**Chemistry, Mechanism of Action, and Pharmacological Properties.** First-line therapy for mild to moderate ulcerative colitis generally involves mesalamine (5-aminosalicylic acid, or 5-ASA). The archetype for this class of medications is sulfasalazine (AZULFIDINE), which consists of 5-ASA linked to sulfapyridine by an azo bond (Figure 47–2). Although this drug was developed originally as therapy for rheumatoid arthritis, clinical trials serendipitously demonstrated a beneficial effect on the GI symptoms of subjects with concomitant ulcerative colitis. Sulfasalazine is a prime example of an oral drug that is delivered effectively to the distal GI tract. Given individually, either 5-ASA or sulfapyridine is absorbed in the upper GI tract; the azo linkage in sulfasalazine prevents absorption in the stomach and small intestine, and the individual components are not liberated for absorption until colonic bacteria cleave the bond. 5-ASA is now regarded as the therapeutic moiety, with little, if any, contribution by sulfapyridine.

Mesalamine is a salicylate, but its therapeutic effect does not appear to relate to cyclooxygenase inhibition; indeed, traditional nonsteroidal anti-inflammatory drugs and selective inhibitors of cyclooxygenase-2 (“coxibs”) may exacerbate IBD. Many potential sites of action have been demonstrated in vitro for either sulfasalazine or mesalamine: inhibition of the production of IL-1 and TNFα, inhibition of the lipoxygenase pathway, scavenging of free radicals and oxidants, and inhibition of NF-κB, a transcription factor pivotal to production of inflammatory mediators. Specific mechanisms of action of these drugs have not been identified.

Although not active therapeutically, sulfapyridine causes many of the adverse effects observed in patients taking sulfasalazine. To preserve the therapeutic effect of 5-ASA without the adverse effects of sulfapyridine, several second-generation 5-ASA compounds have been developed (Figures 47–2, 47–3, and 47–4). They are divided into two groups: prodrugs and coated drugs. Prodrugs contain the same azo bond as sulfasalazine but replace the linked sulfapyridine with either another 5-ASA (olsalazine, DIPENTUM) or an inert compound...
(balsalazide, COLAZIDE). Thus, these compounds act at sites along the GI tract similar to those of sulfasalazine. The alternative approaches employ either a delayed-release formulation (PENTASA) or a pH-sensitive coating (ASACOL; LIALDA/MEZA V ANT). Delayed-release mesalamine is released throughout the small intestine and colon, whereas pH-sensitive mesalamine is released in the terminal ileum and colon. These different distributions of drug delivery have potential therapeutic implications.

Oral sulfasalazine is effective in patients with mild or moderately active ulcerative colitis, with response rates in the range of 60-80% (Prantera et al., 1999). The usual dose is 4 g/day in four divided doses with food; to avoid adverse effects, the dose is increased gradually from an initial dose of 500 mg twice a day. Doses as high as 6 g/day can be used but cause an increased incidence of side effects. For patients with severe colitis, sulfasalazine is of less certain value, even though it is often added as an adjunct to systemic glucocorticoids. Regardless of disease severity, the drug plays a useful role in preventing relapses once remission has been achieved. In general, newer 5-ASA preparations have similar therapeutic efficacy in ulcerative colitis with fewer side effects. Because they largely bypass the small intestine, the second-generation 5-ASA prodrugs such as olsalazine and balsalazide do not have a significant effect in small-bowel Crohn’s disease.

Topical preparations of mesalamine suspended in a wax matrix suppository (ROWASA) or in a suspension enema (CANASA) are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical hydrocortisone in this setting, with response rates of 75-90%. Mesalamine enemas (4 g/60 mL) should be used at bedtime and retained for at least 8 hours; the suppository (500 mg) should be used two to three times a day with the objective of retaining it for at least 3 hours. Response to local therapy with mesalamine may occur within 3-21 days; however, the usual course of therapy is from 3-6 weeks. Once remission has occurred, lower doses are used for maintenance.

**Pharmacokinetics.** Approximately 20-30% of orally administered sulfasalazine is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (~10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg mesalamine for every gram of the parent compound. Thereafter, the individual components of sulfasalazine follow different metabolic pathways. Sulfapyridine, which is highly lipid soluble, is absorbed rapidly from the colon. It undergoes extensive hepatic metabolism, including acetylation and hydroxylation, conjugation with glucuronic acid, and excretion in the urine. The acetylation phenotype of the patient determines plasma levels of sulfapyridine and the probability of side effects;
rapid acetylators have lower systemic levels of the drug and fewer adverse effects. By contrast, only 25% of mesalamine is absorbed from the colon, and most of the drug is excreted in the stool. The small amount that is absorbed is acetylated in the intestinal mucosal wall and the liver and then excreted in the urine. Intraluminal concentrations of mesalamine therefore are very high (~1500 μg/mL or 10 mM in patients taking a typical dose of 3 g/day).

The pH-sensitive coatings (methyl-methacrylate methacrylic acid copolymer) of ASACOL (EUDAGRIT) and LIALDA/MEZAVANT limit gastric and small intestinal absorption of 5-ASA, as assessed by urinary, ileostomal, and fecal measurements of the various metabolites. The pharmacokinetics of PENTASA differ somewhat. The ethylcellulose-coated micro-granules are released in the upper GI tract as discrete prolonged-release units of mesalamine. Acetylated mesalamine can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, but some intact micro-granules also can be detected in the colon. Because it is released in the small bowel, a greater fraction of PENTASA is absorbed systemically compared with the other 5-ASA preparations.

Adverse Effects. Side effects of sulfasalazine occur in 10-45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose related, including headache, nausea, and fatigue. These reactions can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. Sulfasalazine reversibly decreases the number and motility of sperm but does not impair female fertility. Sulfasalazine inhibits intestinal folate absorption and is usually administered with folic acid.

The newer mesalamine formulations generally are well tolerated, and side effects are relatively infrequent and minor. Headache, dyspepsia, and skin rash are the most common. Diarrhea appears to be particularly common with olsalazine (occurring in 10-20% of patients); this may be related to its ability to stimulate chloride and fluid secretion in the small bowel. Nephrotoxicity, although rare, is a more serious concern. Mesalamine has been associated with interstitial nephritis; although its pathogenic role is controversial, renal function should be monitored in all patients receiving these drugs. Both sulfasalazine and its metabolites cross the placenta but have not been shown to harm the fetus. Although less well studied, the newer formulations appear to be safe in pregnancy. The risks to the fetus from the consequences of uncontrolled IBD in pregnant women are believed to outweigh the risks associated with the therapeutic use of these agents.

GLUCOCORTICOIDs

The effects of glucocorticoids on the inflammatory response are numerous and well documented (Chapters 38 and 42). Although glucocorticoids are universally recognized as effective in acute exacerbations, their use in either ulcerative colitis or Crohn’s disease involves considerable challenges and pitfalls, and they are indicated only for moderate to severe IBD.

The response to glucocorticoids in individual patients with IBD divides them into three general classes: responsive, dependent, and unresponsive. Glucocorticoid-responsive patients improve clinically, generally within 1-2 weeks and remain in remission as the steroids are tapered and then discontinued. Glucocorticoid-dependent patients also respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered. Glucocorticoid-unresponsive patients do not improve even with prolonged high-dose steroids. Approximately 40% of patients are glucocorticoid responsive, 30-40% have only a partial response or become glucocorticoid dependent, and 15-20% of patients do not respond to glucocorticoid therapy.

Glucocorticoids sometimes are used for prolonged periods to control symptoms in corticosteroid-dependent patients. However, the failure to respond to steroids with prolonged remission (i.e., a disease relapse) should prompt consideration of alternative therapies, including immunosuppressive agents and anti-TNFα therapies. Glucocorticoid are not effective in maintaining remission in either ulcerative colitis or Crohn’s disease (Steinhart et al., 2003); their significant side effects have led to increased emphasis on limiting the duration and cumulative dose of corticosteroids in IBD.

The approach to glucocorticoid therapy in IBD differs somewhat from that in diseases such as asthma or rheumatoid arthritis. Initial doses are 40-60 mg of prednisone or equivalent per day; higher doses generally are no more effective. The glucocorticoid dose in IBD is tapered over weeks to months. Even with these slow tapers, however, efforts should be made to minimize the duration of therapy. Glucocorticoids induce remission in most patients with either ulcerative colitis or Crohn’s disease (Faubion et al., 2001). Oral prednisone is the preferred agent for moderate to severe disease, and the typical dose is 40-60 mg once a day. Most patients improve substantially within 5 days of initiating treatment; others require treatment for several weeks before remission occurs. For more severe cases, glucocorticoids are given intravenously. Generally, methylprednisolone or hydrocortisone is used for intravenous therapy, although some experts believe that corticotropin (ACTH) is more effective in patients who have not previously received any steroids.

Topically acting agents (i.e., given by enema) have fewer adverse effects than systemic steroids but are also less effective in reducing remission. Glucocorticoid enemas are useful mainly in patients whose disease is limited to the rectum and left colon. Hydrocortisone is available as a retention enema (100 mg/60 mL), and the usual dose is one 60-mL enema per night for 2 or 3 weeks. When administered optimally, the drug can reach up to or beyond the descending colon. Patients with distal disease usually respond within 3-7 days. Absorption, although less than with oral preparations, is still substantial (up to 50-75%). Hydrocortisone also can be given once or twice daily as a 10% foam suspension (CORTIFOAM) that delivers 80 mg hydrocortisone per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty retaining fluid.

Budesonide (ENTOCORT ER) is an enteric-release form of a synthetic steroid that is used for ileoceleal Crohn’s disease
Thiopurine Derivatives

It is proposed to deliver adequate steroid therapy to a specific portion of inflamed gut while minimizing systemic side effects owing to extensive first-pass hepatic metabolism to inactive derivatives. Topical therapy (e.g., enemas and suppositories) also is effective in treating colitis limited to the left side of the colon. Although the topical potency of budesonide is 200 times higher than that of hydrocortisone, its oral systemic bioavailability is only 10%. In some studies, budesonide was associated with a lower incidence of systemic side effects than prednisone, although data also indicate that systemic steroids are more effective in patients with higher Crohn’s Disease Activity Index scores. Budesonide (9 mg/day for up to 8 weeks followed by 6 mg/day for maintenance of remission for up to 3 months) is effective in the acute management of mild-to-moderate exacerbations of Crohn’s disease, but its role in maintaining remission has not been fully delineated (Hofer, 2003).

A significant number of patients with IBD fails to respond adequately to glucocorticoids and are either steroid-resistant or steroid-dependent. The reasons for this failure are poorly understood but may involve complications such as fibrosis or strictures in Crohn’s disease, which will not respond to anti-inflammatory measures alone; local complications such as abscesses, in which case the use of glucocorticoids may lead to uncontrolled sepsis; and intercurrent infections with organisms such as cytomegalovirus and Clostridium difficile. Steroid failures also may be related to specific pharmacogenomic factors such as upregulation of the multidrug resistance (mdr) gene (Farrell et al., 2000) or altered levels of corticosteroid-binding globulin.

IMMUNOSUPPRESSIVE AGENTS

Several drugs developed initially for cancer chemotherapy or as immunosuppressive agents in organ transplants have been adapted for treatment of IBD. Although their initial use in IBD was based on their immunosuppressive effects, their specific mechanisms of action are unknown. Increasing clinical experience has defined specific roles for each of these agents as mainstays in the pharmacotherapy of IBD. However, their potential for serious adverse effects mandates a careful assessment of risks and benefits in each patient.

Thiopurine Derivatives

The cytotoxic thiopurine derivatives mercaptopurine (6-MP, PURLINETHOL) and azathioprine (IMMURAN) (Chapters 51 and 52) are used to treat patients with severe IBD or those who are steroid resistant or steroid dependent (Prefontaine et al., 2009). These thiopurines are prodrugs: azathioprine is converted to mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides that are the presumed active moiety (Figure 47–5).

These drugs generally are used interchangeably with appropriate dose adjustments, typically azathioprine (2-2.5 mg/kg) or mercaptopurine (1.5 mg/kg). As discussed later, the pathways by which they are metabolized are clinically relevant, and specific assays can be used to assess clinical response and to avoid side effects. Because of concerns about side effects, these drugs were used initially only in Crohn’s disease, which lacks a surgical curative option. They now are considered equally effective in Crohn’s disease and ulcerative colitis. These drugs effectively maintain remission in both diseases; they also may prevent (or, more typically, delay) recurrence of Crohn’s disease after surgical resection. Finally, they are used successfully to treat fistulas in Crohn’s disease. The clinical response to azathioprine or mercaptopurine may take weeks to months, such that other drugs with a more rapid onset of action (e.g., mesalamine, glucocorticoids, or infliximab) are preferred in the acute setting.

The decision to initiate immunosuppressive therapy depends on an accurate assessment of the risk/benefit ratio. In general, physicians who treat IBD believe that the long-term risks of azathioprine–mercaptopurine are lower than those of steroids. Thus these purines are used in glucocorticoid-unresponsive or glucocorticoid-dependent disease and in patients who have had recurrent flares of disease requiring repeated courses of steroids. Additionally, patients who have not responded adequately to mesalamine but are not acutely ill may benefit by conversion from glucocorticoids to immunosuppressive drugs. Immunosuppressives therefore may be viewed as steroid-sparing agents.

Adverse effects of azathioprine–mercaptopurine can be divided into three general categories: idiosyncratic, dose related, and possible. Although the therapeutic effects of azathioprine–mercaptopurine often are delayed, their adverse effects occur at any time after initiation of treatment and can affect up to 10% of patients. The most serious idiosyncratic reaction is pancreatitis, which affects ~5% of patients treated with these drugs. Fever, rash, and arthralgias are seen occasionally, whereas nausea and vomiting are somewhat more frequent. The major dose-related adverse effect is bone marrow suppression, and circulating blood counts should be monitored closely when therapy is initiated and at less frequent intervals during maintenance therapy (e.g., every 3 months). Elevations in

---

**Figure 47–5. Metabolism of azathioprine and 6-mercaptopurine.**

HGPRT, hypoxanthine–guanine phosphoribosyl transferase; TPMT, thiopurine methyltransferase; XO, xanthine oxidase. The activities of these enzymes vary among humans because genetic polymorphisms are expressed differentially, explaining responses and side effects when azathioprine–mercaptopurine therapy is employed (see text for details).
liver function tests also may be dose related. Although keeping drug levels in the appropriate range diminishes these adverse effects, they can occur even with therapeutic serum levels of 6-thioguanine nucleotides. The serious adverse effect of cholestatic hepatitis is relatively rare. Although the increased risk of infection is a significant concern with immunosuppressives, especially if pancytopenia occurs, infections are linked more closely to concomitant glucocorticoid therapy than to the immunosuppressives (Aberra et al., 2003).

Immunosuppressive regimens given in the setting of cancer chemotherapy or organ transplants have been associated with an increased incidence of malignancy, particularly non-Hodgkin’s lymphoma. Definitive conclusions about the causative roles of azathioprine–mercaptopurine in lymphomas are complicated by the possible increased incidence of lymphomas in IBD per se and by the relative rarity of these cancers. The increased risk, if any, must be relatively small.

Metabolism and Pharmacogenetics. Favorable responses to azathioprine–mercaptopurine are seen in up to two-thirds of patients. Recent insights into the metabolism of the thiopurine agents and appreciation of genetic polymorphisms in these pathways have provided new insights into variability in response rates and adverse effects. As shown in Figure 47–4, mercaptopurine has three metabolic fates:

- conversion by xanthine oxidase to 6-thiouric acid
- metabolism by thiopurine methyltransferase (TPMT) to 6-methyl-mercaptopurine (6-MMP)
- conversion by hypoxanthine–guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides and other metabolites

The relative activities of these different pathways may explain, in part, individual variations in efficacy and adverse effects of these immunosuppressives.

The plasma t½ of mercaptopurine is limited by its relatively rapid (i.e., within 1-2 hours) uptake into erythrocytes and other tissues. Following this uptake, differences in TPMT activity determine the drug’s fate. Approximately 80% of the U.S. population has what is considered “normal” metabolism, whereas 1 in 300 individuals has minimal TPMT activity. In the latter setting, mercaptopurine metabolism is shifted away from 6-methyl-mercaptopurine and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity; given a similar dose, these individuals will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, ~10% of the population is considered rapid metabolizers. In these individuals, mercaptopurine is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Given this variability, some experts evaluate an individual’s TPMT activity status prior to initiating treatment with thiopurines and also measure 6-thioguanine/6-MMP levels in individuals not responding to therapy. To avoid these complexities, treatment with 6-thioguanine was explored; unfortunately, 6-thioguanine is associated with a high incidence of an uncommon liver abnormality, hepatic nodular regeneration, and associated portal hypertension; 6-thioguanine therapy of IBD therefore has been abandoned.

Xanthine oxidase in the small intestine and liver converts mercaptopurine to thiouric acid, which is inactive as an immunosuppressant. Inhibition of xanthine oxidase by allopurinol diverts mercaptopurine to more active metabolites such as 6-thioguanine and increases both immunosuppressant and potential toxic effects. Thus, patients on mercaptopurine should be warned about potentially serious interactions with medications used to treat gout or hyperuricemia, and the dose should be decreased to 25% of the standard dose in subjects who are already taking allopurinol.

**Methotrexate**

*Methotrexate* was engineered to inhibit dihydrofolate reductase, thereby blocking DNA synthesis and causing cell death. First used in cancer treatment, methotrexate subsequently was recognized to have beneficial effects in autoimmune diseases such as rheumatoid arthritis and psoriasis (Chapter 62 discusses the use of methotrexate in dermatological disorders). The anti-inflammatory effects of methotrexate may involve mechanisms in addition to inhibition of dihydrofolate reductase.

As with azathioprine–mercaptopurine, methotrexate generally is reserved for patients whose IBD is either steroid-resistant or steroid-dependent. In Crohn’s disease, it both induces and maintains remission, generally with a more rapid response than that seen with mercaptopurine or azathioprine (Feagan et al., 1995). Its use in ulcerative colitis has not been thoroughly investigated. Therapy of IBD with methotrexate differs somewhat from its use in other autoimmune diseases. Most important, higher doses (e.g., 15-25 mg/week) are given parenterally. The increased efficacy with parenteral administration may reflect the unpredictable intestinal absorption at higher doses of methotrexate. For unknown reasons, the incidence of methotrexate-induced hepatic fibrosis in patients with IBD is lower than that seen in patients with psoriasis. Use of methotrexate for treatment of IBD has largely been supplanted by biological therapies (such as anti-TNFα antibodies).

**Cyclosporine**

The calcineurin inhibitor cyclosporine is a potent immunomodulator used most frequently after organ transplantation (Chapter 35). It is effective in specific clinical settings in IBD, but the high frequency of significant adverse effects limits its use as a first-line medication.

Cyclosporine is effective in patients with severe ulcerative colitis who have failed to respond adequately to glucocorticoid therapy. Between 50% and 80% of these severely ill patients...
improve significantly (generally within 7 days) in response to intravenous cyclosporine (2-4 mg/kg per day), sometimes avoiding emergent colectomy. Careful monitoring of cyclosporine levels is necessary to maintain a therapeutic level in whole blood between 300 and 400 ng/mL.

Oral cyclosporine is less effective as maintenance therapy in Crohn’s disease, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with neoral or generic (formulations of cyclosporine with increased oral bioavailability) may be more effective, but this has not been studied fully. The calcineurin inhibitors can be used to treat fistulizing complications of Crohn’s disease. A significant rapid response to intravenous cyclosporine has been observed; however, frequent relapses accompany oral cyclosporine therapy, and other medical strategies are required to maintain fistula closure. Thus, the calcineurin inhibitors generally are used to treat specific problems over a short term while providing a bridge to longer-term therapy (Sandborn, 1995).

Other immunomodulators that are being evaluated in IBD include the calcineurin inhibitor tacrolimus (FK 506, Prograf), mycophenolate mofetil and mycophenolate (cellcept, myfortic), inhibitors of inosine monophosphate dehydrogenase to which lymphocytes are especially susceptible (Chapter 35).

**BIOLOGICAL THERAPIES**

**Infliximab** (Remicade, CA2) is a chimeric immunoglobulin (25% mouse, 75% human) that binds to and neutralizes TNF-α. Although many, both pro- and anti-inflammatory cytokines, are generated in the inflamed gut in IBD (Figure 47-1), there is some rationale for targeting TNF-α because it is one of the principal cytokines mediating the Th1 immune response characteristic of Crohn’s disease (Targan et al., 1997).

Although infliximab was designed specifically to target TNF-α, it may have more complex actions. Infliximab binds membrane-bound TNF-α and may cause lysis of these cells by antibody-dependent or cell-mediated cytotoxicity. Thus, infliximab may deplete specific populations of subepithelial inflammatory cells. These effects, together with its mean terminal plasma t1/2 of 8-10 days, may explain the prolonged clinical effects of infliximab.

Infliximab (5 mg/kg infused intravenously at intervals of several weeks to months) decreases the frequency of acute flares in approximately two-thirds of patients with moderate to severe Crohn’s disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn’s disease (Present et al., 1999). Its longer-term role in Crohn’s disease is evolving, but emerging evidence supports its efficacy in maintaining remission (Rutgeerts et al., 2004) and in preventing recurrence of fistulas (Sands et al., 2004). The combination of infliximab and azathioprine is more effective than infliximab alone in induction of remission and mucosal healing in steroid-resistant patients (Rutgeerts et al., 2009). In contrast, there appears to be no synergistic benefit of the combination of methotrexate and infliximab. Infliximab has also proven to be an effective treatment for refractory ulcerative colitis (Rutgeerts et al., 2009).

The use of infliximab as a biological response modifier raises several important considerations. Both acute (fever, chills, urticaria, or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after infliximab infusion, but a frank lupus-like syndrome occurs only rarely. Antibodies to infliximab can decrease its clinical efficacy. Each year, at least 10% of patients on infliximab have to stop therapy because of loss of response or intolerance (Rutgeerts et al., 2009). Strategies to minimize the development of these antibodies (e.g., treatment with glucocorticoids or other immunosuppressives) may be critical to preserving infliximab efficacy for either recurrent or chronic therapy (Farrell et al., 2003). Other proposed strategies to overcome the problem of “antibody resistance” include increasing the dose of infliximab or decreasing the interval between infusions.

Infliximab therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or other granulomatous infections with subsequent dissemination. The FDA recommends that candidates for infliximab therapy be tested for latent tuberculosis with purified protein derivative (PPD) skin testing initially and every 12 months thereafter. A positive skin test indicates that the patient has been previously exposed to Mycobacterium tuberculosis and is at risk for active disease. Infliximab can be used in patients who test negative or who have had a negative previous tuberculin skin test with a subsequent positive test (Sandborn, 1995). It appears to have comparable efficacy to that of adalimumab and certolizumab pegol (Cimzia) in fistulizing Crohn’s disease (Rutgeerts et al., 2009). Unfortunately, adalimumab cannot be used to rescue patients who have lost responsiveness to another anti-TNF-α antibody, such as infliximab. Certolizumab pegol (Cimzia) is a pegylated humanized fragment antigen binding (Fab) that binds TNF-α. It is approved in the U.S. for the treatment of Crohn’s disease. Although direct comparative studies have not been performed (Rutgeerts et al., 2009). With both adalimumab and certolizumab pegol, immunogenicity appears to be less of a problem that that associated with infliximab.

Another anti-TNF-α agent, Etanercept (Enbrel), is a fusion protein of the ligand-binding portion of the TNF-α receptor and the Fc portion of human IgG. This construct binds to TNF-α and blocks its biologic effects but is ineffective in Crohn’s disease.

Natalizumab (Tysabri) is a humanized monoclonal antibody against α4-integrin (also known as VLA-4). Binding of the antibody to this adhesion molecule will reduce extravasation of certain leukocytes (e.g., lymphocytes), preventing them from migrating to sites of inflammation where they may exacerbate tissue injury. In 2008, natalizumab was approved in the U.S. for induction and maintenance of remission of moderate to severe Crohn’s disease. Natalizumab had previously been withdrawn from the market and carries a black box warning because it appears to interact with other immunomodulating drugs to increase the risk of progressive multifocal leukoencephalopathy (PML). Thus, natalizumab is contraindicated for use with other immunomodulators. Because of the capacity of corticosteroids to produce immunosuppression, patients taking natalizumab...
for the treatment of Crohn’s disease should have their doses reduced before starting natalizumab treatment.

The role of anti-TNF therapies for steroid-refractory or steroid-dependent ulcerative colitis is less clear. The rationale for their use is based on finding elevated levels of TNFα in the mucosa of patients. Large controlled clinical trials have demonstrated that anti-TNF agents significantly reduce the severity of the inflammation. The rates of clinical remission range from 26-34%, with endoscopic healing in about half the treated patients. Unlike Crohn’s disease, ulcerative colitis is cured with surgery; thus the cost and serious adverse events associated with anti-TNF therapy need to be balanced with the effectiveness of the drug at preventing the need for colectomy. Currently, it is not known how effective anti-TNF therapies are for prevention, as opposed to delay, of colectomy.

**ANTIBIOTICS AND PROBIOTICS**

An emerging concept is that a balance in the GI tract normally exists among the mucosal epithelium, the normal gut flora, and the immune response (Preidis & Versalovic, 2009). Moreover, there are experimental and clinical data that colonic bacteria may either initiate or perpetuate the inflammation of IBD (Salzmann and Bevins, 2008), and, as mentioned earlier (“Pathogenesis of Inflammatory Bowel Disease”), recent studies have implicated specific bacterial antigens in the pathogenesis of Crohn’s disease. Thus, certain bacterial strains may be either pro- (e.g., *Bacteroides*) or anti-inflammatory (e.g., *Lactobacillus*), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used to this end, most prominently in Crohn’s disease. More recently, probiotics have been used to treat specific clinical situations in IBD.

Antibiotics can be used as:

- adjunctive treatment along with other medications for active IBD
- treatment for a specific complication of Crohn’s disease
- prophylaxis for recurrence in postoperative Crohn’s disease

Metronidazole (Sutherland et al., 1991), ciprofloxacin (Arnold et al., 2002), and clarithromycin are the antibiotics used most frequently. They are more beneficial in Crohn’s disease involving the colon than in disease restricted to the ileum. Specific Crohn’s disease-related complications that may benefit from antibiotic therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small-bowel bacterial overgrowth secondary to partial small-bowel obstruction, secondary infections with organisms such as *C. difficile*, and post-operative complications. Metronidazole may be particularly effective for the treatment of perianal disease. Post-operatively, metronidazole and related compounds have been shown to delay the recurrence of Crohn’s disease. In one study, a 3-month course of metronidazole (20 mg/kg per day) prolonged the time to both endoscopic and clinical recurrence (Rutgeerts et al., 1995). The significant side effects of prolonged systemic antibiotic use must be balanced against their potential benefits, and definitive data to support their routine use are lacking.

Probiotics are mixtures of putatively beneficial lyophilized bacteria given orally. Several studies have provided evidence for beneficial effects of probiotics in ulcerative colitis and pouchitis (Hedin et al., 2007). However, the studies have involved relatively small numbers of patients and the various studies had different end points. Thus, the utility of probiotics as a primary therapy for IBD remains unclear.

**SUPPORTIVE THERAPY IN INFLAMMATORY BOWEL DISEASE**

Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. These drugs should be individualized based on a patient’s symptoms and are supplementary to anti-inflammatory medications. Oral iron, folate, and vitamin B₁₂ should be administered as indicated. Loperamide or diphenoxylate (Chapter 46) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease; these agents are contraindicated in patients with severe disease because they may predispose to the development of toxic megacolon. Cholestyramine can be used to prevent bile salt–induced colonic secretion in patients who have undergone limited ileocolic resections. Anticholinergic agents (dicyclomine hydrochloride, etc.; Chapter 9) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected. Care should be taken to differentiate exacerbation of IBD from symptoms that may be related to coexistent functional bowel disease (Chapter 46).

**THERAPY OF INFLAMMATORY BOWEL DISEASE DURING PREGNANCY**

IBD is a chronic disease that affects women in their reproductive years; thus, the issue of pregnancy often has a significant impact on medical management. The effects of IBD on pregnancy and the effects of pregnancy on IBD are beyond the scope of this chapter. In general, decreased disease activity increases fertility and improves pregnancy outcomes. At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease.
Mesalazine and glucocorticoids are FDA Category B drugs that are used frequently in pregnancy and generally are considered safe, whereas methotrexate is clearly contraindicated in pregnant patients. The use of thiopurine immunosuppressives is more controversial. Because these medications are given long term, both their initiation and discontinuation are major management decisions. Although there are no controlled trials of these medications in pregnancy, considerable experience has emerged over the last several years. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives (Francell et al., 2003). Nonetheless, decisions regarding the use of these medications in patients contemplating pregnancy are complex and necessarily must involve consideration of the risks and benefits involved.

**CLINICAL SUMMARY**

The treatment of IBD in any given patient may have several different goals, such as relief of symptoms, induction of remission in patients with active disease, prevention of relapse (i.e., maintenance therapy), healing of fistulas, and avoidance of emergent surgery. Further, therapy may be tailored to some extent to the severity and location of disease. Acute exacerbations of ulcerative colitis are treated with colonic-release preparations of 5-ASA and, in most patients with significant inflammation, with glucocorticoids. For milder cases involving only the rectum, these drugs may be given topically (by enema). Maintenance therapy for patients with ulcerative colitis is principally in the form of 5-ASA compounds, which generally are effective and safe. In patients who relapse on these preparations, purine metabolites (e.g., azathioprine–mercaptopurine) may be used. Other approaches being tested in this setting include the use of probiotic bacteria.

Drugs used in mild to moderately active Crohn’s disease include sulfasalazine, budesonide, and oral corticosteroids. In contrast to their use in ulcerative colitis, the role of 5-ASA preparations in maintenance therapy of Crohn’s disease is limited. Patients who relapse frequently may be treated with immunosuppressive agents (azathioprine–mercaptopurine or methotrexate). Glucocorticoid-dependent patients may be treated with long-term budesonide. Infliximab is particularly useful in closing fistulas associated with Crohn’s disease; increasingly, along with other biological agents, it is used in acute flares of this condition. The efficacy of the biological agents in maintaining patients in remission must be balanced against the risk of adverse effects. Antibiotics, particularly metronidazole, may be useful adjuncts for the acute treatment of complications associated with Crohn’s disease (including perianal disease) but are not established as a routine therapy in this disorder.

SCIENTIFIC BASIS OF ANTIMICROBIAL CHEMOTHERAPY

An important revolution in human understanding of nature was the germ theory of disease based on the work of Louis Pasteur and Robert Koch, which linked specific microorganisms to specific diseases (Koch, 1876; Pasteur, 1861). Modern chemotherapy is predicated on this idea, radical in its time. The germ theory developed considerably in the 20th century, with identification and characterization of many microbial pathogens and their pathogenic mechanisms and the introduction of antimicrobial drugs. With the use of these drugs came issues of appropriate regimens, drug resistance, drug interactions, and toxicity.

Although the antimicrobials are a large group of diverse structures with myriad mechanisms of actions against bacteria, viruses, fungi, and parasites, we can, nonetheless, develop generalizations about important issues surrounding the use of antimicrobial agents. This chapter reviews the general classes of antimicrobial drugs, their mechanisms of action, mechanisms of resistance, and patterns of kill by different classes of the drugs. It also discusses principles for the selection of an appropriate antibiotic, dose, dose schedule, and type of antibiotic therapy. The pharmacological properties and uses of individual classes of antimicrobials are discussed in Chapters 49 through 59.

Classes and Actions of Antimicrobial Agents. Microorganisms of medical importance fall into four categories: bacteria, viruses, fungi, and parasites. The first broad classification of antibiotics follows this classification closely, so that we have (1) antibacterial, (2) antiviral, (3) antifungal, and (4) antiparasitic agents. Within each of these major categories, drugs are further categorized by their biochemical properties.

Antimicrobial molecules should be viewed as ligands whose receptors are microbial proteins. The term pharmacophore, first introduced by Ehrlich, defines that active chemical moiety of the drug that binds to the microbial receptor. The microbial proteins targeted by the antibiotic are essential components of biochemical reactions in the microbes, and interference with these physiological pathways kills the microorganisms. To the extent that an antimicrobial agent targets a protein that is not widely expressed in other bacteria, the drug will be relatively selective in its antimicrobial effect. The biochemical processes commonly inhibited include cell wall synthesis in bacteria and fungi, cell membrane synthesis, synthesis of 30s and 50s ribosomal subunits, nucleic acid metabolism, function of topoisomerases, viral proteases, viral integrases, viral envelope fusion proteins, folate synthesis in parasites, and parasitic chemical detoxification processes. Classification of an antibiotic is based on:

- the class and spectrum of microorganisms it kills
- the biochemical pathway it interferes with
- the chemical structure of its pharmacophore

Because antimicrobial agents are ligands that bind to their targets to produce effects, the relationship between drug concentration and effect on a population of organisms is still modeled using the standard Hill-type curve for receptor and agonist (Chapters 2 and 3), characterized by three parameters: the inhibitory concentration 50, or IC$_{50}$ (also termed EC$_{50}$), a measure of the antimicrobial agent’s potency; the maximal effect, E$_{\text{max}}$; and H, the slope of the curve, or Hill factor. In antimicrobial therapy, the relationship is often expressed as an inhibitory sigmoid E$_{\text{max}}$ model, to take into account the control bacterial population without treatment (E$_{\text{con}}$) as a fourth parameter (Equation 48–1 and
Figure 48–1, where E is effect as measured by microbial burden.

\[ E = E_{\text{con}} - E_{\text{max}} \times \frac{[IC]^{t1}}{[IC]^{t1} + [IC_{50}]^{t1}} \]  
(Equation 48–1)

THE PHARMACOKINETIC BASIS OF ANTIMICROBIAL THERAPY

Penetration of Antimicrobial Agents into Anatomic Compartments. In many infections, the pathogen causes disease not in the whole body, but in specific organs. Moreover, only specific pathological compartments may be infected within these organs. Antibiotics are often administered far away from these sites of infection. To be effective, each antibiotic has to get to where the pathogen is, to penetrate into the infected compartment. Therefore, in choosing an antimicrobial agent for therapy, a crucial consideration is whether the drug can penetrate to the site of infection.

For example, the antibiotic levofloxacin achieves skin tissue/plasma peak concentration ratio of 1.4, epithelial lining fluid to plasma ratio of 2.8, and urine to plasma ratios of 67 (Chow et al., 2002; Conte et al., 2006; Wagenlehner et al., 2006). In a clinical trial on patients treated with levofloxacin, the two most important factors in predicting successful clinical and microbiological outcomes in the patients were a sufficient maximal plasma concentration of the drug \( (C_{P_{\text{max}}}) \), which needed to achieve a level of 12 times the minimum inhibitory concentration (MIC) \( (C_{P_{\text{max}}}/\text{MIC} \geq 12) \), and the site of infection. The failure rate of therapy was 0% in patients with urinary tract infections, 3% in patients with pulmonary infections, and 16% in patients with skin and soft tissue infections (Preston et al., 1998). Clearly, the poorer the penetration into the anatomical compartment, the higher the likelihood of failure.

The penetration of a drug into an anatomical compartment depends on the physical barriers that the molecule must traverse, the chemical properties of the drug, and the presence of multidrug transporters. The physical barriers are usually due to layers of epithelial and endothelial cells, and the type of junctions formed between these cells. Penetration across this physical barrier generally correlates with the octanol-water partition coefficient of the antimicrobial agent, a measure of the hydrophilicity or hydrophobicity of a chemical. Hydrophobic molecules get concentrated in the bi-lipid cell membrane bi-layer, whereas hydrophilic molecules tend to concentrate in the blood, the cytosol, and other aqueous compartments. Thus, the higher the octanol-water partition coefficient (P), the greater the likelihood that an antimicrobial agent will cross physical barriers erected by layers of cells. Conversely, the more charged a molecule is, and the larger it is, the poorer its penetration across membranes and other physical barriers (see Figure 2–3).

Another barrier is due to membrane transporters, which actively export drugs from the cellular or tissue compartment back into the blood (Chapter 5). A well-known example is the P-glycoprotein. Although the octanol-water partition coefficient would favor lipophilic molecules to transverse across cell barriers, P-glycoprotein exports structurally unrelated amphiphilic and lipophilic molecules of 3-4 kDa, reducing their effective penetration. Examples of antimicrobial agents that are P-glycoprotein substrates include HIV protease inhibitors, the antiparasitic agent ivermectin, the antibacterial agent telithromycin, and the antifungal agent itraconazole.

The central nervous system (CNS) is guarded by the blood-brain barrier. The movement of antibiotics across the blood-brain barrier is restricted by tight junctions that connect endothelial cells of cerebral microvessels to one another in the brain parenchyma, as well as by protein transporters (Miller et al., 2008). Antimicrobial agents that are polar at physiological pH generally penetrate poorly; some, such as penicillin G, are actively transported out of the cerebrospinal fluid (CSF) and achieve CSF concentrations of only 0.5-5% of that achieved in plasma. However, the integrity of the blood-brain barrier is diminished during active bacterial infection; tight junctions in cerebral capillaries open, leading to a marked increase in the penetration of antimicrobials.
of even polar drugs (Quagliarello and Scheld, 1997). As the infection is eradicated and the inflammatory reaction subsides, penetration diminishes to normal. Because this may occur while viable microorganisms persist in the CSF, drug dosage should not be reduced as the patient improves.

Drug penetration into the eye is especially pertinent in the treatment of endophthalmitis (infection and inflammation of ocular cavity and surrounding tissue) and infections of the retina. There is generally poor penetration of drug from plasma to this compartment, so that the standard therapy is direct instillation of antibiotics into the ocular cavity. In fungal endophthalmitis, however, systemic administration of amphotericin B and triazole is recommended (Pappas et al., 2009) because these agents, especially the triazoles, have sufficient penetration ratios into the vitreous space.

In patients with pulmonary infections such as pneumonia, drugs must penetrate into the epithelial lining fluid, where the pathogens are found. Among bacterial agents, many β-lactam antibiotics have poor epithelial lining fluid-to-plasma ratios (0.1-0.4:1); macrolides have ratios of 2-40:1; fluoroquinolones have ratios ≥1:1; pyrazinamide has ratios of >20:1; isoniazid, >1:1; and linezolid, 2.4-4:2:1 (Kiern and Schentag, 2008).

Other important compartments requiring special drug penetration are endocardial vegetations and the biofilm formed by bacteria and fungi on prosthetic devices such as artificial heart valves, long-dwelling intravascular catheters, artificial hips, and devices for internal fixation of bone fractures. Bacterial and fungal biofilms are colonies of slowly growing cells that are enclosed within an exopolymer matrix. The exopolysaccharide is negatively charged, which restricts positively charged antibiotics from reaching their target. This physical barrier restricts the diffusion of antimicrobial molecules and sometimes binds them (Lewis, 2001). To be effective against infections in these compartments, antibiotics have to be able to penetrate the biofilm and endothelial barriers.

**Pharmacokinetic Compartments.** Once an antibiotic has penetrated to the site of infection, it may be subjected to processes of elimination and distribution that differ from those in the blood. These sites where the concentration-time profiles differ from each other are considered separate pharmacokinetic compartments, thus, the human body is viewed as multicompartamental. The concentration of antibiotic within each compartment is assumed to be homogeneous. If two compartments have similar concentration profiles, then they may be considered a single compartment. Antibiotic concentrations can be analyzed by using any number of such compartments, with the best number of compartments chosen based on the least number of compartments that can adequately explain the findings. The model is also defined as open or not open; an open model is one in which the drug is eliminated out of the body from the compartment (e.g., kidneys). The order of the process must also be specified (Chapter 2): a first-order process is directly correlated to concentration of drug D, or |D|t, as opposed to zero order, which is independent of |D| and reflects a process that is saturated at ambient levels of D (such as the elimination of ethanol; Chapter 23).

Suppose a patient has pneumonia with the pathogen in the lung epithelial lining fluid (ELF). The patient ingests an antibiotic that is absorbed via the GI tract (g) into blood or central compartment (compartment 1), as a first-order input. In this process, the transfer constant from the GI tract to central compartment is termed the absorption constant and is designated ka. The antibiotic in the central compartment is then delivered to the lungs where it penetrates into the ELF (compartment 2). However, it also penetrates into other tissues of the body peripheral to the site of infection, termed the peripheral compartment (compartment 3). Thus, we have four compartments (including g), each with its own concentration-time profile, as shown in Figure 48–2. The penetration of drug from compartment 1 to 2 is based on the penetration factors discussed earlier and is defined by the transfer constant k12. However, the drug also redistributes from compartment 2 back to 1, defined by transfer constant k12. A similar process between the blood and peripheral tissues leads to transfer constants k13 and k31. The drug may also be lost from the body (i.e., open system) via the lungs and other peripheral tissues (e.g., kidneys or liver) at a rate proportional to the concentration.

Antibiotic concentrations within each compartment change with time. The changes in the amount of antibiotic in each compartment with time are described using standard differential equations (Gibaldi and Perrier, 1975). If X is the amount of antibiotic in a compartment, SCL the drug clearance, and Vc the volume of central compartment, then equations for absorption compartment (Equation 48–2), central compartment (Equation 48–3), site of infection or compartment 2 (Equation 48–4), and peripheral compartment (Equation 48–5) are as follows:

\[
\frac{dX_1}{dt} = -K_a \cdot X_g \quad \text{(Equation 48–2)}
\]

\[
\frac{dX_1}{dt} = K_a \cdot X_g - [(SCL/Vc) + K_{12} + K_{13}] \cdot X_1 + K_{21} \cdot X_2 + K_{31} \cdot X_3 \quad \text{(Equation 48–3)}
\]

\[
\frac{dX_2}{dt} = K_{12} \cdot X_1 - K_{21} \cdot X_2 \quad \text{(Equation 48–4)}
\]

\[
\frac{dX_3}{dt} = K_{13} \cdot X_1 - K_{31} \cdot X_3 \quad \text{(Equation 48–5)}
\]

Such models have been used in conjunction with population pharmacokinetics to describe and model a plethora of antimicrobials used to treat bacteria, fungi, viruses, and parasites (Hope et al., 2007; Tarning et al., 2008; Wilkins et al., 2008; Zhou et al., 1999).

In recent years, semi-mechanistic models have related pathogen response to drug concentrations within these pharmacokinetic compartments in preclinical disease models and in patients (Gumbo et al., 2006; Jumbe et al., 2003; Neumann et al., 1998; Pukrittayakamee et al., 2003; Talal et al., 2006). Pathogens within one or more of these compartments are exposed to dynamic drug concentrations within the compartments, as described by Equations 48–2 to 48–5. A pathogen population (N) may be described as consisting of at least two subpopulations, drug-susceptible (N3) and drug-resistant (N4) organisms. The organisms are either killed,
inhibited, or continued to grow in response to the antibiotic concentration. For some pathogens such as fungi and bacteria, it is assumed they are in logarithmic growth phase in the absence of drug, exhibiting an exponential density-limited growth rate so that they will reach a stationary phase at a maximal pathogen density, POPMAX. E is a logistic carrying function, so that

\[ E = 1 - \left( \frac{N}{POPMAX} \right) \]  

(Equation 48–6)

where N is the pathogen burden in a particular compartment. For replications rates of parasites and viruses, unique models may be specified. The drug will affect the growth rate either independent of kill or via killing the pathogen. The drug effect that is independent of kill is through a saturable Michaelis-Menten-type kinetic event (L).

\[ L = \frac{X}{V_c} \cdot \frac{1}{H} \left( 1 + \frac{IC_{50}}{H} \right) \]

(Equation 48–7)

where H and IC_{50} are as described in Equation 48–1. Microbial kill is based on the concentrations within the compartment, and is modeled as a sigmoid E_{max} effect model M:

\[ M = \frac{K_{max} \cdot (X/V_c) \cdot (X/V_c)^{H} + IC_{50}^{H}}{H_{k,s} \text{ or } H_{k,r}} \]

(Equation 48–8)

where K_{max} is the maximal kill rate. Because the microbial density (N) is in fact a balance between growth (maximal growth rate = K_{gmax}) and microbial kill, the change in pathogen density as a function of time is described by Equation 48–9:

\[ \frac{dN}{dt} = K_{gmax} \cdot N \cdot E - K_{kmax} \cdot M \cdot N \]

(Equation 48–9)

The changes in drug-susceptible subpopulation of pathogen with time and the drug-resistant subpopulation are described by:

\[ \frac{dN_{s}}{dt} = K_{gmax} \cdot (1 - Ls) \cdot N_{s} \cdot E - K_{kmax} \cdot Ms \cdot N_{s} \]

(Equation 48–10)

\[ \frac{dN_{r}}{dt} = K_{gmax} \cdot (1 - Lr) \cdot N_{r} \cdot E - K_{kmax} \cdot Mr \cdot N_{r} \]

(Equation 48–11)

This can be made more complex and predictive adding parameters describing the effect of inoculum, delay in microbial effect, or splitting the drug-resistant population to smaller subpopulations based on molecular mechanism of resistance (Bulitta et al., 2009).

Population Pharmacokinetics and Variability in Drug Response. The framework for the models central to population pharmacokinetics evolved from a series of publications by Lewis Sheiner (Sheiner et al., 1977). What are population pharmacokinetics? Consider a simple example. When multiple patients are treated with the same dose of a drug, each patient will achieve pharmacokinetic parameters that differ from others. This is termed between-patient variability. Even when the same dose is administered to the same patient on two separate occasions, the patient may achieve a different concentration-time profile of the drug between the two occasions. This is termed inter-occasion or within-patient variability. The variability is reflected at the level of the compartmental pharmacokinetic parameters such as k_{a}, k_{12}, k_{21}, SCL, V_{c}, and so on. Even when a recommended dose is administered, the drug may fail to reach a therapeutic concentration in some patients. In other patients, the drug may reach high and toxic concentrations. Such variability could be due to factors that can be explained, such as genetic variability. In addition, anthropometric measures such as weight, height, and age also lead to variability. Furthermore, patients may have comorbid conditions such as renal
and liver dysfunction, which may lead to variability. Drug interactions are an important source of variability with potentially dangerous consequences. These interactions usually occur when one drug inhibits or induces uptake or clearance mechanisms affecting another drug (i.e., modulation of the activities of xenobiotic metabolic enzymes, drug transporters, and excretion mechanisms; Chapters 5 and 6).

Even when such factors are accounted for, there remains residual variability due to computational noise, assay variability, and unexplainable factors. The common practice of using an “average” value of data or “naive pooling,” has implications of smoothing out data and failing to recognize subgroups of patients at risk for therapeutic failure or increased toxicity of antibiotic. Thus the variability itself, the extent of such variability, and any factors that may explain part of the variability of drug response are more important to understand than measures of central tendency and dispersion for a hypothetical average patient. Such variability reflects the fact that pathogens within patients given the same dose of antibiotic will be exposed to different antibiotic concentrations from patient to patient, leading to effective kill in some and resistance emergence in others. Knowledge of covariates associated with pharmacokinetic variability leads to better dose adjustments, or switching therapy from one antibiotic to another, or changing concomitant medications.

**IMPACT OF SUSCEPTIBILITY TESTING ON SUCCESS OF ANTIMICROBIAL AGENTS**

The microbiology laboratory plays a central role in the decision to choose a particular antimicrobial agent over others. First, identification and isolation of the culprit organism takes place when the patients’ specimens are sent to the microbiology laboratory. Once the microbial species causing the disease has been identified, a rational choice of the class of antibiotics likely to work in the patient can be made. The microbiology laboratory then plays a second role, which is to perform susceptibility testing. This step is crucial in narrowing down the list of possible antimicrobials that could be used.

Millions of individuals across the globe get infected by many different isolates of the same species of pathogen. Evolutionary processes cause each isolate to be slightly different from the next, so that each will have a unique susceptibility to antimicrobial agents. As the microorganisms divide within the patient, they may undergo further evolution between the time of infection and when the disease is diagnosed. As an example, a relatively narrow range of variants are transmitted when patients become infected with HIV. However, HIV replication has poor fidelity and has replication rates that result in up to $10^{10}$ viral particles each day. Moreover, viral recombination occurs commonly. Over many months, under immune pressure, numerous variants arise. The emergence of a quasi species that harbors a mutation associated with drug resistance to at least one drug is high, based on probability factors in the context of high replication rates and the massive numbers of viral particles. Therefore, we expect that there will be a wide distribution of concentrations of antimicrobial agents that can kill pathogens. Often, this distribution is Gaussian, with a skew that depends on where the patient lives. These factors will affect the shape of the inhibitory sigmoid $E_{\text{max}}$ model curve described by Equation 48–1.

With changes in susceptibility, the sigmoid $E_{\text{max}}$ curve shifts in one of two basic ways. The first is a shift to the right, an increase in $IC_{50}$, as shown in Figure 48–3A. This means that much higher concentrations than before are now needed to show specific effect. Susceptibility tests for bacteria, fungi, parasites, and viruses have been developed to determine whether these shifts have occurred at a sufficient magnitude to warrant higher doses of drug to achieve particular effect. The change in $IC_{50}$ may become so large that it is not possible to overcome the concentration deficit by increasing the antimicrobial dose without causing toxicity to the patient. At that stage, the organism is now “resistant” to the particular antibiotic. A second possible change in the curve is decrease in $E_{\text{max}}$ (Figure 48–3B), such that increasing the dose of the antimicrobial agent beyond a certain point will achieve no further effect; i.e., changes in the microbe are such that eradication of the microbe by the particular drug can never be achieved. This occurs because the available target proteins have been reduced or the microbe has developed an alternative pathway to overcome the biochemical inhibition. As an example, maraviroc is an allosteric, noncompetitive antagonist that binds to the CCR5 receptor of patient’s CD4 cells to deny HIV entry into the cell. Viral resistance occurs by a mechanism that involves HIV adapting to use of the maraviroc-bound CCR5, which results in decrease of $E_{\text{max}}$ in phenotypic susceptibility assays (Hirsch et al., 2008).

**Bacteria.** For bacteria, dilution tests employ antibiotics in serially diluted concentrations on solid agar or in
broth medium that contains a culture of the test microorganism. The lowest concentration of the agent that prevents visible growth after 18-24 hours of incubation is known as the minimum inhibitory concentration (MIC).

Automated systems also use a broth-dilution method. The optical density of a broth culture of the clinical isolate incubated in the presence of drug is determined. If the density of the culture exceeds a threshold optical density, then growth has occurred at that concentration of drug. The MIC is the concentration at which the optical density remains below the threshold.

The disk-diffusion technique provides only qualitative or semi-quantitative information on antimicrobial susceptibility. The test is performed by applying commercially available filter-paper disks impregnated with a specific amount of the drug onto an agar surface, over which a culture of the microorganism has been streaked. After 18-24 hours of incubation, the size of the clear zone of inhibition around the disk is measured. The diameter of the zone depends on the activity of the drug against the test strain. Standardized values for zone sizes for each bacterial species and antibiotic permit classification of the clinical isolate as either resistant or susceptible. A variant of the disk diffusion tests is the Epsilometer test, or E-test. A rectangular test strip impregnated with changing concentrations of antimicrobial agent, usually across 15 dilutions, is placed on an agar plate that has a heavy inoculum of test organism. The drug concentrations are printed along this long test strip. The cultures are then incubated under favorable conditions for 24 hours, 48 hours, or 5 days, depending on the test organism. There is no growth with higher concentrations and heavy microbial growth where there is lower drug concentration, so that a clear elliptical zone is formed that bisects the test strip at the MIC. This test has the virtue of determining an actual MIC value, rather than the dichotomous categorization of “susceptible” or “resistant.” There are test strips for hundreds of antibacterial agents as well as for some antifungal agents active against Candida species.

Sometimes, a biochemical or immunological reaction that leads to a color change is used to detect susceptibility. As an example, methicillin resistance in *Staphylococcus aureus* (methicillin-resistant *S. aureus*, or MRSA) occurs because of acquisition of a low-affinity penicillin-binding protein 2' (2a), or PBP2' (PBP2a). The PBP2' is extracted from isolates of the MRSA, and supernatant mixed with a latex reagent with monoclonal antibody against PBP2'. Visible clumping within 3 minutes indicates presence of PBP2' indicating MRSA.

**Fungi.** For fungi that are yeasts (i.e., Candida), susceptibility testing methods are similar to those used for bacteria. However, the definitions of MIC differ based on drug and the type of yeast, so there are cutoff points of 50% decrease in turbidity compared to controls at 24 hours, or 80% at 48 hours, or total clearance of the turbidity. Susceptibility tests and MICs for triazoles have been extensively shown to correlate with clinical outcomes.

Standardized tests for echinocandin antifungals and amphotericin B-based compounds are available. However, the correlation of these tests with clinical outcomes is still weak. Susceptibility tests for molds have also been developed, but the clinical correlations are still being examined. Different terminology from MICs has been adopted when evaluating echinocandins against molds because the fungal burden can not be measured by counting discrete cells in molds, given that hyphae will break up into unpredictable numbers of discrete fungi when under antifungal pressure. Furthermore, echinocandins often do not completely inhibit mold growth, but instead cause damage reflected by morphological changes in hyphae. Thus, the minimum effective concentration (MEC) for echinocandins is the lowest drug concentration at which short, stubby, and highly branched hyphae are observed on microscopic examination.

**Viruses.** In HIV phenotypic assays, the patient’s HIV-RNA is extracted from plasma, and genes for targets of antiretroviral drugs such as reverse transcriptase and protease are amplified. The genes are then inserted into a standard HIV vector that lacks analogous gene sequences to produce a recombinant virus, which is co-incubated with drug of interest in a mammalian cell
viability assay (Hanna and D’Aquila, 2001; Hertogs et al., 1998; Petropoulos et al., 2000). Growth is compared to a standardized wild-type control virus. For HIV reverse transcriptase, e.g., <4-fold increase in IC₅₀ is defined as “sensitive,” 4- to 10-fold increase in IC₅₀ is “intermediate,” and >10-fold increase is “resistant” (Hanna and D’Aquila, 2001). Further use has been made of the viral IC₅₀ to establish the inhibitory quotient (IQ). The IQ is the ratio of plasma concentration of antiviral drug to the IC₅₀. The phenotypic IQ is the ratio of plasma trough concentration to the IC₅₀.

Genotypic tests are now a standard part of HIV care in many parts of the world, although the tests are rarely used in clinical practice in resource-poor settings. The simplest tests measure presence of mutations associated with loss of function of a drug. This loss of function means that the organism is “resistant” to drug and the drug should not be used to treat that patient. The absence of mutation means the drug has an increased likelihood of working against the pathogen. There are some situations with antiretroviral therapy, however, when presence of such mutations may paradoxically lead to choice of the drug to be part of combination therapy. A famous example is that of the reverse transcriptase inhibitors zidovudine (AZT) and lamivudine (3TC) in the treatment of HIV-1, in which an M184V mutation that causes resistance to 3TC increases viral sensitivity to AZT up to 10-fold. Therefore, although presence of a mutation in a genotype assay may strongly argue for exclusion of some drugs in a regimen, the interpretation can be complex. Indeed, this is one of the limitations of this method in that the true meaning of a mutation may be unclear and interpreted differently by healthcare practitioners.

**Parasites.** Susceptibility testing for parasites, especially malaria, has been performed in the laboratory. The tests are similar to the broth tests for bacteria, fungi, and viruses. *Plasmodium* species in the patient’s blood are cultured ex vivo in the presence of different dilutions of antimalarial drug (Stepniewska et al., 2007). A sigmoid $E_{\text{max}}$ curve for effect versus drug concentration is used to identify IC₅₀ and Eₙ₉₀. These susceptibility tests are usually field tests at sentinel sites that are used to determine if there is drug resistance in a particular area or not, and they are not used as a routine test for clinical decision making for individual patients. In general, susceptibility tests for parasitic infections are not standardized. These tests are primarily used in the research setting and not for individualization of therapy.

**Basis for Selection of Dose and Dosing Schedule**

Even though susceptibility testing is central to decision making, it does not completely predict patient response. Unlike in susceptibility tests in the laboratory where drug concentrations are static by design, microorganisms in patients are exposed to dynamic concentrations of drug. In addition, the antibiotics are prescribed at a certain schedule (e.g., three times a day) so that there is a periodicity in the fluctuations of drug at the site of infection. Therefore, the microbe is exposed to a particular shape of the concentration-time curve. Harry Eagle performed studies on penicillin and discovered that the shape of the concentration-time profile was an important determinant of the efficacy of the antibiotic (Eagle et al., 1950). This important observation was forgotten until William Craig and colleagues rediscovered it and performed systematic studies on several classes of antibiotics (Craig, 1998, 2007; Vogelman et al., 1988), initiating the era of antimicrobial pharmacokinetics-pharmacodynamics (PK/PD) (Ambrose et al., 2007; Craig, 1998).

The first basic lesson is based on susceptibility (MIC or EC₉₀) of the organism to the antimicrobial agent. The response of the microbe to a fixed dose of antibiotic differs based on susceptibility of the organism. As an example, vancomycin resistance is said to be present when MIC >2.0 mg/L. When patients with MRSA infection were treated with vancomycin, the success rate was 61% in patients infected with isolates that had an MIC of 0.5 mg/L, 28% for MIC of 1.0 mg/L, and only 11% for MIC of 2.0 mg/L (Moise-Broder et al., 2004). As expected, outcomes were poorer with increasing MIC. This is not a surprise because the IC₅₀ shifts to the right with decrease in susceptibility (Figure 48–3A). The important point is that in determining therapeutic outcomes, it is important to index drug exposure to MIC.

Second, dose itself is a poor measure of drug exposure, given between-patient and within-patient pharmacokinetic variability. Rather, actual drug concentration achieved at site of infection is the important measure. The shape of the relationship between nonprotein-bound antibiotic concentration (exposure) versus microbial kill is the inhibitory sigmoid $E_{\text{max}}$ curve of Figure 48–1 (Craig, 2007; Craig and Kunin, 1976). Maximal kill is actually on an asymptote, so that nonprotein-bound antimicrobial exposures associated with 80-90% of $E_{\text{max}}$ are termed “optimal” concentrations. The optimal dose of the antibiotic for a patient is the dose that achieves IC₉₀ to IC₉₀ exposures at the site of infection. This exposure can often be easily identified in preclinical models and directly applied to patient populations, provided interspecies differences in protein binding and pharmacokinetic variability are taken into account.
Third, optimal microbial kill by the antibiotic may be best achieved by maximizing certain shapes of the concentration-time curve. Certain dose schedules maximize antimicrobial effect. As an example, consider an antibiotic with a serum t1/2 of 3 hours that is being used to treat a bloodstream infection by a pathogen with an MIC of 0.5 mg/L, administered with a dosing interval of 24 hours (that is, a once-daily schedule). Figure 48–4A depicts the concentration-time curve of the antibiotic, with definitions of peak concentration (C_{\text{max}}), area under the curve (AUC), and the fraction of the dosing interval for which the drug concentration remains above the MIC (T > MIC), as shown. The AUC is a measure of the total concentration of drug and is calculated by taking an integral between two time points, 0-24 hours (AUC_{0-24}) in this case. Now, if one were to change the dosing schedule of the same antibiotic amount by splitting it into three equal doses administered at 0, 8, and 16 hours, the shape of the concentration-time curves changes to that shown in Figure 48–4B. Because the same cumulative dose has been given for the dosing interval of 24 hours, the AUC_{0-24} will be similar whether it was given once a day or three times a day. For the same pathogen, therefore, the change in dose schedule does not change the AUC_{0-24}/MIC (or AUC_{0-24}/EC_{90}). However, the C_{\text{max}} will decrease by a third when the total dose is split into thirds and administered more frequently (Figure 48–4B). Thus, when a dose is fractionated and administered more frequently, the C_{\text{max}}/MIC ratio decreases. In contrast, the time that the drug concentration persists above MIC (T > MIC) will increase with the more frequent dosing schedule, despite the same cumulative dose being administered. Which of the three indices (AUC/MIC, or C_{\text{max}}/MIC or T>MIC) is the most important to the outcome being assessed (i.e., microbial kill)? A common simple approach to the answer is to determine which of these patterns best approximates a perfect inhibitory sigmoid E_{\text{max}} curve (based on various statistical assessments of goodness of fit).

Some classes of antimicrobial agents kill best when concentration persists above MIC for longer durations of the dosing interval while kill is decreased by reducing the time above MIC. Indeed, increasing the drug concentration beyond 4-6 times the MIC does not increase microbial kill. Two good examples are β-lactam antibiotics (e.g., penicillin) and the antifungal agent 5-fluorocytosine (5-FC) (Ambrose et al., 2007; Andes and van Ogtrop, 2000). In fact, there are usually good biochemical explanations for this pattern for the drugs. The clinical implication, however, is that a drug optimized by T > MIC should be dosed more frequently, or if possible should have its t1/2 prolonged by other drugs, so that drug concentrations persist above MIC (or EC_{90}) as long as possible. Thus the effectiveness of penicillin is enhanced when it is given as a continuous infusion. HIV protease inhibitors are often “boosted” with ritonavir. This “boosting” inhibits the metabolism of the protease inhibitors by CYPs 3A4 and 2D6, thereby prolonging time above EC_{95}.

However, the peak concentration is what matters for some antimicrobial agents. Persistence of concentration above MIC has less relevance for these drugs, meaning that these drugs can be dosed more intermittently. Aminoglycosides are a prime example of this class as they used to be given three times a day but are highly effective when given once a day. These C_{\text{max}}/MIC-linked drugs are often able to be administered less frequently due to their long duration of post-antibiotic effect (PAE). In other words, effect continues long after antibiotic concentrations decline below the MIC. An example of such a drug is rifampin (Gumbo et al., 2007a). The entry of rifampin into Mycobacterium tuberculosis increases with increased concentration in the bacillus microenvironment, likely because of a saturable transport process. Once inside the bacteria, the drug’s macrocyclic ring binds the β-subunit of DNA-dependent RNA polymerase (rpoB) to form a very stable drug-enzyme complex within 10 minutes, a process not enhanced by longer incubation of drug and

![Figure 48–4. Effect of different dose schedules on shape of concentration-time curve.](image-url)
enzyme (Harshey and Ramakrishnan, 1976; Wehrli et al., 1968). The PAE of the rifampin is long and concentration dependent (Gumbo et al., 2007a). This means that administering combined doses on a more intermittent basis (i.e., once a day) will maximize effect for these drugs. Toxicity generated by intermittent dosing may preclude such use for some drugs such as rifampin, whereas for others (i.e., aminoglycosides) such infrequent dosing may actually decrease toxicity.

There is a third group of drugs for which dosing schedule has no effect on efficacy, but where it is the cumulative dose that matters. Thus, it is more the total concentration (AUC) to MIC ratio that matters and not the time that concentration persists above a certain threshold. Antibacterial agents such as daptomycin fall into this class (Louie et al., 2001). These agents also have a good PAE. The AUC/IC50 explains why the nucleoside analogue reverse transcriptase inhibitors tenofovir and emtricitabine have been combined into one pill, administered once a day for the treatment of AIDS.

The shape of concentration-time curve that optimizes resistance suppression is often different from that which optimizes microbial kill. In many instances, the drug exposure associated with resistance suppression is much higher than for optimal kill. It should actually be this higher exposure that should be achieved by each dose in patients for optimal effect, rather than the EC80 as discussed earlier. However, this is often precluded by increased drug toxicity when doses are increased. Second, although the relationship between kill and exposure is based on the inhibitory sigmoid $E_{\text{max}}$ model, experimental work with preclinical models demonstrates that this model does not apply to resistance suppression (Gumbo, 2007b; Tam et al., 2007).

The optimal dose should be designed to achieve a high probability of exceeding the EC80 microbial PK/PD index, or index associated with suppression of resistance, given the population pharmacokinetic variability and the MIC distribution of clinical microbe isolates. The population pharmacokinetic variability enables integration of pharmacogenetics, anthropometric measures, and residual variability into the decision to choose optimal dose (Gumbo, 2008). Once that has been achieved, the dose schedule is chosen according to whether efficacy is driven by AUC/MIC (or AUC/EC95), $C_{\text{Pmax}}$/MIC, or $T > \text{MIC}$. Duration of therapy is then chosen, based on best available evidence.

**Types and Goals of Antimicrobial Therapy**

When an infection occurs, the numbers of microorganisms are often small in the beginning. Pathogen burden eventually increases with replication of the organism. Sometimes, the immune system manages to eliminate the infection before it causes any further damage. In other instances, the organism is not entirely eliminated but hides inside the patient’s own cells and become dormant, only to reactivate when immune function is compromised in the future. In some patients, the organism may overcome immune defenses and then cause disease. In a subset of such patients, the disease is self-limited. For example, many viral upper respiratory infections are self-limited and should not be treated with antimicrobial agents. Other diseases, however, require antimicrobial therapy. In these patients, therapy should be discontinued after resolution of disease. In special cases where the immune or anatomical defect that led to the infection is still present, suppressive or “maintenance” therapy may be required. A useful way to organize the types and goals of antimicrobial therapy is to consider where along the disease progression timetable therapy is initiated (Figure 48–5); therapy can be prophylactic, preemptive, empirical, definitive, or suppressive.

**Prophylactic Therapy.** Prophylaxis involves treating patients who are not yet infected or have not yet developed disease. The goal of prophylaxis is to prevent infection in some patients or to prevent development of a potentially dangerous disease in those who already have evidence of infection. Ideally, a single, effective, nontoxic drug is successful in preventing infection by a specific microorganism or eradicating an early infection. The main principle behind prophylaxis is targeted therapy. However, prophylaxis to prevent
colonization or infection by any or all microorganisms present in the environment of a patient often fails.

Prophylaxis is used in immunosuppressed patients such as those with HIV-AIDS or are post-transplantation and on anti-rejection medications. The efficacy of prophylaxis in these patients is based on excellent evidence (Anonymous, 2000; DHHS Panel on Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents, 2008). In these groups of patients, specific antiparasitic, antibacterial, antiviral, and antifungal therapy is administered based on the well-defined pattern of pathogens that are major causes of morbidity during immunosuppression. A risk-benefit analysis is used to determine choice and duration of prophylaxis. Prophylaxis of opportunistic infections in patients with AIDS is started when the CD4 count falls below 200 cells per mm$^3$. In post-transplant patients, prophylaxis depends on time since the transplant procedure, which is related to intensity of use and type of immunosuppressive therapy. Prophylaxis should be discontinued in patients who are doing well at certain time points, such as 1 year post-transplant. In AIDS patients, prophylaxis is discontinued when the CD4 count climbs above 200 cells/mm$^3$. Infections for which prophylaxis is given include Pneumocystis jiroveci, Mycobacterium avium-intracellulare, Toxoplasma gondii, Candida species, Aspergillus species, Cytomegalovirus, and other Herpesviridae. In general, lower doses of prophylactic agent are given compared to when the same drug is used for treatment.

Chemoprophylaxis is also used to prevent wound infections after various surgical procedures. Wound infection results when a critical number of bacteria are present in the wound at the time of closure. Antimicrobial agents directed against the invading microorganisms may reduce the number of viable bacteria below the critical level and thus prevent infection. Several factors are important for the effective and judicious use of antibiotics for surgical prophylaxis. First, antimicrobial activity must be present at the wound site at the time of its closure. Thus, infusion of the first antimicrobial dose should begin within 60 minutes before surgical incision and should be discontinued within 24 hours of the end of surgery (Bratzler and Houck, 2004). Second, the antibiotic must be active against the most likely contaminating microorganisms for that type of surgery. A number of studies indicate that chemoprophylaxis can be justified in dirty or contaminated surgical procedures (e.g., resection of the colon), where the incidence of wound infections is high. These include <10% of all surgical procedures. In clean surgical procedures, which account for ~75% of the total, the expected incidence of wound infection is <5%, and antibiotics should not be used routinely. When the surgery involves insertion of a prosthetic implant (e.g., prosthetic valve, vascular graft, prosthetic joint), cardiac surgery, or neurosurgical procedures, the complications of infection are so drastic that most authorities currently agree to chemoprophylaxis for these indications.

Patients at the highest risk for infective endocarditis for which prophylaxis is recommended fall into four groups (Wilson et al., 2007):

- those with a prosthetic material used for heart valve repair or replacement
- previous infective endocarditis
- congenital heart disease such as unrepaird cyanotic heart disease, or within 6 months of repair of the heart disease with prosthetic material, or those with residual defects adjacent to prosthetic material
- postcardiac transplant patients with heart valve defects

Chemoprophylaxis is reasonable in these patients when undergoing dental procedures if there is manipulation of gingival tissue or periapical region of teeth, or perforation of oral mucosa, but not for other dental procedures. Recommended therapy is a single dose of oral amoxicillin 30 minutes to 1 hour before the procedure or intravenous ampicillin or ceftriaxone in those unable to take oral medication. A macrolide or clindamycin may be administered for patients who are allergic to β-lactam agents. Therapy may be administered no more than 2 hours after the procedure for patients who failed to receive the prophylaxis prior to the procedure (Wilson et al., 2007). Prophylaxis is also reasonable for procedures that will involve infected skin and soft tissues as well as infected respiratory tract, but not in routine genitourinary and GI tract procedures. If the organism causing the infection is known, then the prophylactic antibiotic for patients undergoing these procedures should be tailored toward that particular organism.

Prophylaxis may be used to protect healthy persons from acquisition of or invasion by specific microorganisms to which they are exposed. This is termed post-exposure prophylaxis. Successful examples of this practice include rifampin administration to prevent meningococcal meningitis in people who are in close contact with a case, prevention of gonorrhea or syphilis after contact with an infected person, and macrolides after contact with confirmed cases of pertussis. Post-exposure prophylaxis is recommended in those patients inadvertently exposed to HIV infection. Currently, combination therapy from one of the classes of antiretrovirals, nucleoside reverse transcriptase inhibitors, nucleotide reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, protease inhibitors, and fusion inhibitors is administered for 4 weeks (Panlilio et al., 2005). For influenza, the neuraminidase inhibitor oseltamivir has been recommended for prevention of influenza A and B in healthy adults and children with close contact of laboratory-confirmed cases (Hayden and Pavia, 2006).

Mother-to-child transmission of HIV and syphilis are important public health problems for which specific chemotherapeutic regimens have been devised, based on locality. Anti-retroviral therapy is administered for HIV prophylaxis during the pregnancy and peripartum periods. Prophylactic therapy for syphilis during pregnancy is effective in reducing neonatal death and infant neurological, auditory, and bone malformations.

**Pre-emptive therapy.** Pre-emptive therapy is used as a substitute for universal prophylaxis and as early targeted therapy in high-risk patients who already have a laboratory or other test indicating that an asymptomatic patient has become infected. The principle is that delivery of therapy prior to development of symptoms (presymptomatic) aborts impending disease, and the therapy is for a short and defined duration (Singh, 2001). This has been applied in the clinic to therapy for cytomegalovirus (CMV) after both hematopoietic stem cell transplants and after solid organ transplantation. It is unclear whether this method is superior to keeping all at-risk patients on ganciclovir. Recent evidence in liver transplant patients
suggest this approach may be as efficacious as universal prophylaxis while using far less antiviral medications (Gerna et al., 2008; Singh et al., 2008).

**Empirical Therapy in the Symptomatic Patient.** Once a patient is symptomatic, should the patient be treated immediately? The first consideration in selecting an antimicrobial is to determine if the drug is indicated. The reflex action to associate fever with treatable infections and prescribe antimicrobial therapy without further evaluation is irrational and potentially dangerous.

The diagnosis may be masked if therapy is started and appropriate cultures are not obtained. Antimicrobial agents are potentially toxic and may promote selection of resistant microorganisms. For some diseases, the cost of waiting a few days is low. These patients can wait for microbiological evidence of infection without empirical treatment. In a second group of patients, the risks of waiting are high, based either on the patient’s immune status or other known risk factors for poor outcome with therapy delay. Initiation of optimal empirical antimicrobial therapy should rely on the clinical presentation, which may suggest the specific microorganism, and knowledge of the microorganisms most likely to cause specific infections in a given host. In addition, simple and rapid laboratory techniques are available for the examination of infected tissues.

The most valuable and time-tested method for immediate identification of bacteria is examination of the infected secretion or body fluid with Gram stain. In malaria-endemic areas, or in travelers returning from such an area, a simple thick and thin blood smear may mean the difference between a patient’s receiving appropriate therapy and surviving or death while on wrong therapy for presumed bacterial infection. Such tests help to narrow the list of potential pathogens and permit more rational selection of initial antibiotic therapy. Similarly, neutropenic patients with fever have high risks of mortality, and, when febrile, they are presumed to have either a bacterial or fungal infection; thus a broad-spectrum combination of antibacterial and antifungal agents that cover common infections encountered in granulocytopenic patients are given. Performance of cultures is still mandatory with a view to modify antimicrobial therapy with culture results.

**Definitive Therapy with Known Pathogen.** Once a pathogen has been isolated and susceptibilities results are available, therapy should be streamlined to a narrow targeted antibiotic. Monotherapy is preferred to decrease the risk of antimicrobial toxicity and selection of antimicrobial-resistant pathogens. Proper antimicrobial doses and dose schedules are crucial to maximizing efficacy and minimizing toxicity. In addition, the duration of therapy should be as short as is necessary. The practice of keeping a patient indefinitely on antimicrobial therapy without a particular reason is discouraged. In fact, both experimental and clinical evidence have shown that unnecessarily prolonged therapies lead to the emergence of resistance.

Combination therapy is an exception, rather than a rule. Once a pathogen has been isolated, there should be no reason to use multiple antibiotics, except when evidence overwhelmingly suggests otherwise. Using two antimicrobial agents where one is required leads to increased toxicity and unnecessary damage to the patient’s otherwise protective fungal and bacterial flora. This is true, even when intuition suggests use of two agents. As an example, Cosgrove and colleagues recently demonstrated increased nephrotoxicity of low-dose gentamicin administered only for 4 days as “synergistic therapy” with vancomycin or an antistaphylococcal penicillin for *S. aureus* bacteremia and endocarditis, without improving efficacy (Cosgrove et al., 2009).

However, there are special circumstances where evidence is unequivocal in favor of combination therapy. The principles behind such antimicrobial use include:

- preventing resistance to monotherapy
- accelerating the rapidity of microbial kill
- enhancing therapeutic efficacy by use of synergistic interactions or enhancing kill by a drug based on a mutation generated by resistance to another drug
- paradoxically, reducing toxicity (i.e., when full efficacy of a standard antibacterial agent can only be achieved at doses that are toxic to the patient, and a second drug is co-administered to exert additive effects)

Clinical situations for which combination therapy is advised are discussed in the relevant chapters but include antiretroviral therapy for AIDS, antiviral therapy for hepatitis B and C, the treatment of tuberculosis, *Mycobacterium avium-intracellulare* and leprosy, fixed-dose combinations of antimarial drugs, the treatment of *Cryptococcus neoformans* with flucytosine and amphotericin B, during empirical therapy for patients with febrile neutropenia, and advanced AIDS with fever. The combination of a sulfonamide and an inhibitor of dihydrofolate reductase, such as trimethoprim, is synergistic owing to the blocking of sequential steps in microbial folate synthesis. A fixed combination of sulfamethoxazole and trimethoprim is active against organisms that may be resistant to sulfonamides alone, is effective for many infections, and is rarely given as its separate components.

**Post-treatment suppressive therapy.** In some patients, after the initial disease is controlled by the antimicrobial agent, therapy is continued at a lower dose. This is because in these patients the infection is not completely eradicated and the immunological or anatomical defect that led to the original infection is still present. This is common in AIDS patients and post-transplant patients, for example. The goal is more as secondary prophylaxis. Nevertheless, risks of toxicity from long durations of the therapy are still real. In this group of patients, the suppressive therapy is eventually discontinued if the patient’s immune system improves.

### MECHANISMS OF RESISTANCE TO ANTIMICROBIAL AGENTS

Antimicrobial agents were viewed as miracle cures when first introduced into clinical practice. However, it became evident rather soon after the discovery of
penicillin that resistance developed quickly, terminating the miracle. This serious development is ever present with each new antimicrobial agent and threatens the end of the antimicrobial era. Today, every major class of antibiotic is associated with the emergence of significant resistance. Two major factors are associated with emergence of antibiotic resistance: evolution and clinical/environmental practices. A species that is subjected to pressure, chemical or otherwise, that threatens its extinction often evolves mechanisms to survive under that stress. Pathogens will evolve to develop resistance to the chemical warfare to which we subject them. This evolution is mostly aided by poor therapeutic practices by healthcare workers, as well as indiscriminant use of antibiotics for agricultural and animal husbandry purposes. Poor clinical practices that fail to incorporate the pharmacological properties of antimicrobials amplify the speed of development of drug resistance.

Antimicrobial resistance can develop at any one or more of steps in the processes by which a drug reaches and combines with its target. Thus, resistance development may develop due to:

- reduced entry of antibiotic into pathogen
- enhanced export of antibiotic by efflux pumps
- release of microbial enzymes that destroy the antibiotic
- alteration of microbial proteins that transform pro-drugs to the effective moieties
- alteration of target proteins
- development of alternative pathways to those inhibited by the antibiotic

Mechanisms by which such resistance develops can include acquisition of genetic elements that code for the resistant mechanism, mutations that develop under antibiotic pressure, or constitutive induction.

**Resistance Due to Reduced Entry of Drug into Pathogen.** The outer membrane of gram-negative bacteria is a permeable barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called porins. Absence of, mutation in, or loss of a favored porin channel can slow the rate of drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at the target site. If the target is intracellular and the drug requires active transport across the cell membrane, a mutation or phenotypic change that slows or abolishes this transport mechanism can confer resistance. As an example, *Trypanosoma brucei* is treated with suramin and pentamidine during early stages, but with melarsoprol and eflornithine when CNS disease (sleeping sickness) is present. Melarsoprol is actively taken up by trypanosome P2 protein transporter. When the parasite either lacks the P2 transporter, or has a mutant form, resistance to melarsoprol and cross resistance to pentamidine occur due to reduced uptake (Ouellette, 2001).

**Resistance Due to Drug Efflux.** Microorganisms can overexpress efflux pumps and then expel antibiotics to which the microbes would otherwise be susceptible. There are five major systems of efflux pumps that are relevant to antimicrobial agents:

- the multidrug and toxic compound extruder (MATE)
- the major facilitator superfamily (MFS) transporters
- the small multidrug resistance (SMR) system
- the resistance nodulation division (RND) exporters
- ATP binding cassette (ABC) transporters

Efflux pumps are a prominent mechanism of resistance for parasites, bacteria, and fungi. One of the tragic consequences of resistance emergence has been the development of drug resistance by *Plasmodium falciparum*. Drug resistance to most antimalarial drugs, specifically chloroquine, quinine, mefloquine, halofantrine, lume-fantrine, and the artemether-lumefantrine combination is mediated by an ABC transporter encoded by *Plasmodium falciparum* multidrug resistance gene 1 (PMDR1) (Happi et al., 2009). Point mutations in the PMDR1 gene lead to drug resistance and failure of chemotherapy. Drug efflux sometimes works in tandem with chromosomal resistance, as is seen in *Streptococcus pneumoniae*, and perhaps, *Myobacterium tuberculosis*. In these situations, induction of efflux pumps occurs early, which increases the MIC only modestly. However, this MIC increase is enough to allow further microbial replication and an increased mutation frequency, which enable the development of resistance via more robust chromosomal mutations (Gumbo et al., 2007b; Jumbe et al., 2006).

**Resistance Due to Destruction of Antibiotic.** Drug inactivation is a common mechanism of drug resistance. Bacterial resistance to aminoglycosides and to β-lactam antibiotics usually is due to production of an aminoglycoside-modifying enzyme or β-lactamase, respectively.

**Resistance Due to Reduced Affinity of Drug to Altered Target Structure.** A common consequence of either single point or multiple point mutations is change in amino acid composition and conformation of target protein. This change leads to a reduced affinity of drug for its target, or of a prodrug for the enzyme that converts the prodrug to active drug. Such alterations may be due to mutation of the natural target (e.g., fluoroquinolone resistance), target modification (e.g., ribosomal protection type of resistance to macrolides and tetracyclines), or acquisition of a resistant form of the native, susceptible target (e.g., staphylococcal methicillin resistance caused by production of a low-affinity penicillin-binding protein) (Hooper, 2002; Lim and Strynadka, 2002; Nakajima, 1999). Similarly, in HIV resistance mutations associated with reduced affinity are encountered in protease inhibitors, integrase inhibitors, fusion inhibitors, and non-nucleoside reverse transcriptase inhibitors (Nijhuis et al., 2009). Similarly, benzimidazoles are used against myriad worms and protozoa and work by binding to the parasite’s tubulin; point mutations in the β-tubulin gene lead to modification of the tubulin and drug resistance (Ouellette, 2001).

**Incorporation of Drug.** An uncommon situation occurs when an organism not only becomes resistant to an antimicrobial agent but subsequently starts requiring it for growth. Enterococcus, which easily develops vancomycin resistance, can, after prolonged exposure to the antibiotic, develop vancomycin-requiring strains.
Resistance Due to Enhanced Excision of Incorporated Drug. Nucleoside reverse transcriptase inhibitors such as zidovudine are 2′-deoxyribonucleoside analogs that are converted to their 5′-triphosphate form and compete with natural nucleotides. These drugs are incorporated into the viral DNA chain and cause chain termination. When resistance emerges via mutations at a variety of points in the reverse transcriptase gene, phosphorolytic excision of the incorporated chain-terminating nucleoside analog is enhanced (Arion et al., 1998).

Hetero-resistance and Viral Quasi Species. Hetero-resistance is said to be present when a subset of the total microbial population is resistant, despite the total population being considered susceptible on testing (Falagas et al., 2008; Rinder, 2001). In a way, this should not be a surprise given that chromosomal mutations are a stochastic process and there is a baseline mutation rate for each gene. Therefore, a subclone that has alterations in genes associated with drug resistance is expected to reflect the normal mutation rates and occur at between 10^4 and 10^5 colonies. In bacteria, hetero-resistance has been described especially for vancomycin in *S. aureus*, vancomycin in *Enterococcus faecium*, colistin in *Acinetobacter baumannii-calcoaceticus*, rifampin, isoniazid, and streptomyacin in *M. tuberculosis*, and penicillin in *S. pneumoniae* (Falagas et al., 2008; Rinder, 2001). Increased therapeutic failures and mortality have been reported in patients with hetero-resistant staphylococci and *M. tuberculosis* (Falagas et al., 2008; Hofmann-Thiel et al., 2009). For fungi, hetero-resistance leading to clinical failure has been described for fluconazole in *Cryptococcus neoformans* and *Candida albicans* (Marr et al., 2001; Mondon et al., 1999).

Viral replication is more error prone than replication in bacteria and fungi. Viral evolution under drug and immune pressure occurs relatively easily, commonly resulting in variants or quasi species that may contain drug-resistant subpopulations. This is not often termed hetero-resistance, but the principle is the same as described for bacteria and fungi: A virus may be considered susceptible to a drug because either phenotypic or genotypic tests reveal “lack” of resistance, when there is a resistant subpopulation just below the limit of assay detection. These minority quasi species that are resistant to antiretroviral agents have been associated with failure of antiretroviral therapy (Metzner et al., 2009).

### EVOLUTIONARY BASIS OF RESISTANCE EMERGENCE

**Development of Resistance via Mutation Selection.** Mutation and antibiotic selection of the resistant mutant are the molecular basis for resistance for many bacteria, viruses, and fungi. Mutations may occur in the gene encoding (1) the target protein, altering its structure so that it no longer binds the drug; (2) a protein involved in drug transport; (3) a protein important for drug activation or inactivation; or (4) in a regulatory gene or promoter affecting expression of the target, a transport protein, or an inactivating enzyme. Mutations are not caused by drug exposure per se. They are random events that confer a survival advantage when drug is present. Any large population of drug susceptible bacteria is likely to contain rare mutants that are only slightly less susceptible than the parent. However, suboptimal dosing strategies lead to selective kill of the more susceptible population, which leaves the resistant isolates to flourish.

In some instances, a single-step mutation results in a high degree of resistance. Examples include *M. tuberculosis* katG Ser315 mutations that cause resistance to isoniazid; the M814V mutation in the reverse transcriptase gene of HIV-1, causing resistance to lamivudine; a cytochrome-b gene mutation causing resistance to the antimalaria drug atovaquone; and *Candida albicans* fks1 Ser645 mutations causing resistance to echinocandins.

In other circumstances, however, it is the sequential acquisition of more than one mutation that leads to clinically significant resistance. As an example, the combination of pyrimethamine and sulfadoxine inhibits *Plasmodium falciparum*’s folate biosynthetic pathway via inhibition of dihydrofolate reductase (DHFR) by the pyrimethamine and inhibition of dihydropteroate synthetase (DHPS) by sulfadoxine. Clinically meaningful resistance occurs when there is a single point mutation in the DHPS gene accompanied by at least a double mutation in the DHFR gene.

**Hypermutable Phenotypes.** The ability to protect genetic information from disintegrating and also to be flexible enough to allow genetic changes that lead to adaptation to the environment is essential to all living things. This is accomplished principally by the insertion of the correct base pair by DNA polymerase III, proof-reading by the polymerase, and postreplicative repair. The development of a defect in one of these repair mechanisms leads to a high degree of mutations in many genes; such isolates are termed mutator (Mut) phenotypes and may include mutations in genes causing antibiotic resistance (Giraud et al., 2002). This second-order selection of hypermutable (mutator) alleles based on alterations in DNA repair genes has been implicated in the emergence of multidrug resistant strains of *M. tuberculosis* Beijing genotype (Rad et al., 2003).

**Resistance by External Acquisition of Genetic Elements.** Drug resistance may be acquired by mutation and selection, with passage of the trait vertically to daughter cells. For mutation and selection to be successful in generating resistance, the mutation cannot be lethal and should not appreciably alter virulence. For the trait to be passed on, the original mutant or its progeny must disseminate and replicate; otherwise, the mutation will be lost until it is “rediscovered” by some other mutant arising from within a wild-type population.

Drug resistance more commonly is acquired by horizontal transfer of resistance determinants from a donor cell, often of another bacterial species, by transduction, transformation, or conjugation. Resistance acquired by horizontal transfer can disseminate rapidly and widely either by clonal spread of the resistant strain.
or by subsequent transfers to other susceptible recipient strains. Horizontal transfer of resistance offers several advantages over mutation selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher than that produced by mutation, which tends to yield incremental changes; the gene, which still can be transmitted vertically, can be mobilized and rapidly amplified within a population by transfer to susceptible cells; and the resistance gene can be eliminated when it no longer offers a selective advantage.

**Horizontal Gene Transfer.** Horizontal transfer of resistance genes is greatly facilitated by and is largely dependent on mobile genetic elements. Mobile genetic elements include plasmids and transducing phages. Other mobile elements—transposable elements, integrons, and gene cassettes—also participate in the process. **Transposable elements** are of three general types: insertion sequences, transposons, and transposable phages. Only insertion sequences and transposons are important for resistance.

*Insertion sequences* (Mahillon and Chandler, 1998) are short segments of DNA encoding enzymatic functions (e.g., transposase and resolvase) for site-specific recombination with inverted repeat sequences at either end. They can copy themselves and insert themselves into a chromosome or a plasmid. Insertion sequences do not encode resistance, but they function as sites for integration of other resistance-encoding elements (e.g., plasmids or transposons). **Transposons** are insertion sequences that also code for other functions, one of which can be drug resistance. Because transposons move between chromosome and plasmid, the resistance gene can “hitch-hike” with a transferable element out of the host and into a recipient. Transposons are mobile elements that excise and integrate in the bacterial genomic or plasmid DNA (i.e., from plasmid to plasmid, from plasmid to chromosome, or from chromosome to plasmid). **Integrons** (Fluit and Schmitz, 2004) are not formally mobile and do not copy themselves, but they encode an integrase and provide a specific site into which mobile gene cassettes integrate. **Gene cassettes** encode resistance determinants, usually lacking a promoter, with a downstream repeat sequence. The integrase recognizes this repeat sequence and directs insertion of the cassette into position behind a strong promoter that is present on the integron. Integrons may be located within transposons or in plasmids, and therefore may be mobilizable, or located on the chromosome.

**Transduction** is acquisition of bacterial DNA from a phage (a virus that propagates in bacteria) that has incorporated DNA from a previous host bacterium within its outer protein coat. If the DNA includes a gene for drug resistance, the newly infected bacterial cell may acquire resistance. Transduction is particularly important in the transfer of antibiotic resistance among strains of *S. aureus*. **Transformation** is the uptake and incorporation into the host genome by homologous recombination of free DNA released into the environment by other bacterial cells. Transformation is the molecular basis of penicillin resistance in pneumococci and *Neisseria* (Spratt, 1994). **Conjugation**, as the name implies, is gene transfer by direct cell-to-cell contact through a sex pilus or bridge. This complex and fascinating mechanism for the spread of antibiotic resistance is extremely important because multiple resistance genes can be transferred in a single event. The transferable genetic material consists of two different sets of plasmid-encoded genes that may be on the same or different plasmids. One set encodes the actual resistance; the second encodes genes necessary for the bacterial conjugation process. Conjugation with genetic exchange between nonpathogenic and pathogenic microorganisms probably occurs in the GI tracts of humans and animals. The efficiency of transfer is low; however, antibiotics can exert a powerful selective pressure to allow emergence of the resistant strain. Genetic transfer by conjugation is common among gram-negative bacilli, and resistance is conferred on a susceptible cell as a single event. Enterococci also contain a broad range of host-range conjugative plasmids that are involved in the transfer and spread of resistance genes among gram-positive organisms.

**CLINICAL SUMMARY**

Antimicrobial agents work by targeting specific biochemical properties of pathogens, and therefore have a narrow spectrum of organisms that they can kill. Infection is usually in a particular anatomical compartment. Important determinants of success of antimicrobial therapy include proper selection of antimicrobial therapy based on microbiology results and susceptibility testing, knowledge of drug penetration into the infected compartment, and knowledge of compartmental pharmacokinetics. The proper dose and dosing schedule are chosen by integrating microbial pharmacokinetic-pharmacodynamic information, expected pharmacokinetic variability, and the minimum inhibitory concentration of the pathogen. The goals of therapy should be clear. Prophylaxis, preemptive therapy, empirical therapy, and definitive therapy should have treatment goals and duration of therapy clearly spelled out in the beginning, based on proper evidence. The general rule is monotherapy, except in select situations where combination therapy has been shown to be superior. Poor dosing strategies lead to catastrophic outcomes such as drug-resistant pathogens and untoward toxicity to the patients.

**BIBLIOGRAPHY**

Malaria affects about a quarter of a billion people and leads to almost 900,000 deaths annually (World Health Organization, 2009). This disease is caused by infection with single-celled protozoan parasites of the genus Plasmodium. Five Plasmodium spp. are known to infect humans: P. falciparum, P. vivax, P. ovale, P. malariae, and P. knowlesi. P. falciparum and P. vivax cause most of the malarial infections worldwide. Of these, P. falciparum accounts for the majority of the burden of malaria in sub-Saharan Africa and is associated with the most severe disease. P. vivax accounts for half of the malaria burden in South and East Asia and >80% of the malarial infections in the America. Malaria due to P. ovale and P. malariae is relatively uncommon but requires identification both for treatment (P. ovale, like P. vivax, forms hypnozoites with the potential for relapse) and for epidemiological purposes (malarial infection, due mostly to P. malariae, can arise from blood transfusion). P. knowlesi, previously thought to infect only nonhuman primates, has emerged as a zoonotic malarial parasite and now is an important, sometimes lethal, cause of human malaria in parts of Southeast Asia (including Malaysia, Indonesia, Thailand, Singapore, and the Philippines; Cox-Singh et al., 2008). P. knowlesi should therefore be considered as a potential cause of malaria among travelers returning from this region. The vast majority of malaria cases occur via infection from Anopheles mosquitoes in endemic regions. Infections acquired congenitally or via transfusions or contaminated needles are known to occur but are rare. Screening of blood donors has reduced the risk of transfusion-transmitted malaria to 1:4,000,000 in the U.S.

Research on malaria has entered the genomic era; the complete genome sequence has been determined for multiple Plasmodium species, including P. falciparum, P. vivax, P. knowlesi, and other species infecting rodents and non-human primates. The availability of a robust culture system for P. falciparum erythrocytic stages, combined with methods to experimentally infect mosquitoes and generate sporozoite and liver stage parasites, has generated key platforms for drug discovery. These platforms include genetic modifications by gene knock-out, heterologous expression and complementation, allelic replacement, high throughput screening of the pathogenic asexual blood stage parasites, and lower throughput assays against other stages of the parasite life cycle (Hayton and Su, 2008; Winzeler, 2008). Similar laboratory approaches have not yet been successful for P. vivax. Methods for sustained in vitro culture of blood stage forms of P. vivax are not yet available but are being developed for P. knowlesi and P. cynomolgi, which share important biological similarities with P. vivax.

**BIOLOGY OF MALARIAL INFECTION**

Plasmodium sporozoites, which initiate infection in humans, are inoculated into the dermis and enter the bloodstream following the bite of a Plasmodium-infected female anopheline mosquito. Within minutes, sporozoites travel to the liver, where they infect hepatocytes via cell surface receptor-mediated events. This process initiates the asymptomatic prepatent period, or exoerythrocytic stage of infection, which typically lasts ~1 week. During this period, the parasite undergoes asexual replication within hepatocytes, resulting in production of liver stage schizonts. Upon rupture of the infected hepatocytes, tens of thousands of merozoites are released into the bloodstream and infect red blood cells. After the initial exoerythrocytic stage, P. falciparum and P. malariae are no longer found in the liver. P. vivax and P. ovale, however, can maintain a quiescent
hepatocyte infection as a dormant form of the parasite known as the hypnozoite. Consequently, *P. vivax* and *P. ovale* can reinitiate symptomatic disease long after the initial symptoms of malaria are recognized and treated. Erythrocytic forms cannot reestablish infection of hepatocytes.

Transmission of human-infecting malarial parasites is maintained in human populations both by the extended persistence of hypnozoites (lasting from months to no more than a few years for *P. vivax* and *P. ovale*), by antigenic variation in *P. falciparum* (probably months), and presumably by antigen variation in *P. malariae* (for as long as several decades) (Vinetz et al., 1998).

The *asexual erythrocytic stages* of malarial parasites are responsible for the clinical manifestations of malaria. This part of the *Plasmodium* life cycle is initiated by merozoite recognition of red blood cells, mediated by cell surface receptors, followed by red blood cell invasion. Once inside a red blood cell, the merozoite develops into a ring form, which becomes a trophozoite that matures into an asexually dividing blood stage schizont. Upon rupture of the infected erythrocyte, these schizonts release 8-32 merozoites that can establish new infections in nearby red blood cells. The erythrocytic replication cycle lasts for 24 hours (for *P. knowlesi*), 48 hours (for *P. falciparum, P. vivax, and P. ovale*), and 72 hours (for *P. malariae*). As such, infections due to *P. vivax* and *P. ovale* can produce tertian fever patterns (48 hours), whereas those due to *P. malariae* can result in quartan fever (72 hours, as classically described in Hippocrates’ *Epidemics*). Although most invading merozoites develop into schizonts, a small proportion become gametocytes, the form of the parasite that is infective to mosquitoes. Gametocytes are ingested into the mosquito midgut during an infectious blood meal and then transform into gametes that can fertilize to become zygotes. Zygotes mature into ookinetes, which penetrate the mosquito midgut wall and develop into oocysts. Numerous rounds of asexual replication occur in the oocyst to generate sporozoites over 10-14 days. Fully developed sporozoites rupture from oocysts and invade the mosquito salivary glands, from which they can initiate a new infection during subsequent mosquito blood meals (Figure 49–1). Understanding the subtleties of the life cycles of *Plasmodium* parasites is important for tailoring drug therapies to the various species and geographic contexts.

Mechanisms of erythrocyte invasion include initial binding by merozoites to specific red blood cell surface ligands. *P. falciparum* has a family of binding proteins that can recognize a variety of host cell molecules. *P. falciparum* invades all stages of erythrocytes and therefore can achieve high parasitemias. *P. vivax* selectively binds to the Duffy chemokine receptor protein as well as reticulocyte-specific proteins. Thus, *P. vivax* does not establish infection in Duffy-negative individuals and only invades reticulocytes. (However, *P. vivax* has reportedly mutated in Madagascar to enable infection of Duffy-negative individuals [Ménard et al., 2010].) Because of this restricted subpopulation of suitable erythrocytes, *P. vivax* rarely exceeds 1% parasitemia in the bloodstream. *P. ovale* is similar to *P. vivax* in its predilection for young red blood cells, but the mechanism of its erythrocyte recognition is unknown. *P. malariae* parasitizes senescent red blood cells, maintains a very low parasitemia, and typically causes an indolent infection.

*P. falciparum* assembles cytoadherence proteins (PfEMP1s, encoded by a highly variable family of *var* genes) into structures called knobs that are presented on the erythrocyte surface. Knobs allow the *P. falciparum*-parasitized erythrocyte to bind to postcapillary vascular endothelium, so as to avoid spleen-mediated clearance and allow the parasite to grow in a low oxygen, high carbon dioxide...
Attention is increasingly being focused on measures to prevent parasite transmission from a human host to a mosquito vector. Bed nets and residual indoor insecticide treatment are the mainstay of malaria prevention in endemic areas. Drugs are being used to prevent transmission; but this strategy presents special problems related to toxicity. Whereas some antimalarials, such as 4-aminoquinolines and sulfadoxine-pyrimethamine, promote increased gametocytemia, others, including 8-aminoquinolines and artemisinins, can reduce gametocyte levels and thus reduce transmission. Although the gametocytocidal activity of primaquine and tafenoquine is potentially important, these agents cannot be used for mass treatment without first assessing glucose-6-phosphate dehydrogenase (G6PD) levels, because of the potential for hemolytic anemia in G6PD-deficient individuals.

**Clinical Manifestations of Malaria**

The cardinal signs and symptoms of malaria are high, spiking fevers (with or without periodicity), chills, headaches, myalgias, malaise, and GI symptoms. Severe headache, a characteristic early symptom in malaria caused by all *Plasmodium* spp., often heralds the onset of infection, before fever and chills. *P. falciparum* causes the most severe disease and may lead to organ failure and death. Placental malaria, of particular danger for primigravidae, is due to *P. falciparum* adherence to chondroitin sulfate A (CSA) in the placenta. This often leads to severe complications, including miscarriage. When treated early, symptoms of malarial infection usually improve within 24-48 hours.

Acute illness due to *P. vivax* infection may appear severe due to high fever and prostration. Indeed, the pyrogenic threshold of this parasite (i.e., parasite burden associated with fever) is lower than that of *P. falciparum*. Nonetheless, *P. vivax* malaria generally has a low mortality rate. *P. vivax* malaria is characterized by relapses caused by the reactivation of latent tissue forms. Clinical manifestations of relapse are the same as those of primary infection. In recent years, severe *P. vivax* malaria from Oceania (Papua New Guinea, Indonesia) and India possess important similarities to severe malaria caused by *P. falciparum*. These include neurological symptoms (diminished consciousness, seizure) and pulmonary edema. Rare but life-threatening complications can occur, including splenic rupture, acute lung injury, and profound anemia.

*P. ovale* causes a clinical syndrome similar to that of *P. vivax* but may be milder with lower levels of parasitemia. It shares with *P. vivax* the ability to form the hypnozoite (dormant liver stage) that may relapse after months to 2 years later. *P. ovale* is more common in sub-Saharan Africa and some islands in Oceania.

*P. malariae* causes a generally indolent infection with very low levels of parasitemia and often does not produce clinical symptoms. This parasite can be found in all malaria-endemic areas but is most common in sub-Saharan Africa and the southwest Pacific. Interestingly, *P. malariae* prevalence increases during the dry season and can be found as a co-infection with *P. falciparum*. Although uncommon, a potentially fatal complication of *P. malariae* is a glomerulonephritis syndrome that does not respond to antimalarial treatment.

*P. knowlesi* infection is often misdiagnosed as *P. malariae* by light microscopy. This infection is distinguished by a shorter erythrocytic cycle (24 hours compared with 72 hours for *P. malariae*) and higher levels of parasitemia. Like *P. malariae*, *P. knowlesi* is generally sensitive to chloroquine, but patients presenting with advanced disease nonetheless may progress to death despite adequate drug dosing.

Asymptomatic *P. falciparum* and *P. vivax* infections are common in endemic regions, and they represent important potential reservoirs for malaria transmission. Although different studies are not entirely consistent in the definition of “asymptomatic,” generally this state implies a lack of fever, headache, and other systemic complaints, within a defined time period prior to a positive test for malaria parasitemia. Migration of asymptomatic individuals, to areas where malaria is not present but vector mosquitoes are (i.e., anophelism without malaria), is an important mechanism for the introduction or reintroduction of malaria, in addition to facilitating the spread of drug-resistant isolates. Novel approaches to preventing transmission from asymptomatic reservoirs—whether through new drugs or vaccines—will be essential for future malaria control, elimination, and eradication strategies.
of agents (artemisinins, chloroquine, mefloquine, quinine and quinidine, pyrimethamine, sulfadoxine, and tetracycline) are not reliably effective against primary or latent liver stages. Instead, their action is directed against the asexual blood stages responsible for disease. These drugs will treat, or prevent, clinically symptomatic malaria. When used as chemoprophylaxis, these drugs must continue to be taken for several weeks after exposure, until parasites complete their intrahepatic stage of development and become susceptible to therapy.

The spectrum is somewhat expanded for a second category of drugs (typified by atovaquone and proguanil), which target not only the asexual erythrocytic forms but also the primary liver stages of *P. falciparum*. This additional activity shortens to several days the required period for postexposure chemoprophylaxis.

The third category, currently comprised solely of primaquine, is effective against primary and latent liver stages as well as gametocytes. Primaquine has no place in the treatment of symptomatic malaria but rather is used most commonly to eradicate the intrahepatic hypnozoites of *P. vivax* and *P. ovale* that are responsible for relapsing infections. Primaquine also has anti-gametocytic activity.

Aside from their antiparasitic activity, the utility of antimalarials for chemoprophylaxis or therapy depends on their pharmacokinetics and their safety. Thus quinine and primaquine, which have significant toxicity and relatively short half-lives, generally are reserved for the treatment of established infection and are not used for chemoprophylaxis in a healthy traveler. In contrast, chloroquine is relatively free from toxicity and has a long $t_{1/2}$ that is convenient for chemoprophylactic dosing (in those few areas still reporting chloroquine-sensitive malaria).

Regimens currently recommended for chemoprophylaxis in travelers are given in Table 49–2, whereas regimens for the treatment and presumptive self-treatment (based on symptom presentation) of malaria in travelers are provided in Table 49–3 and Table 49–4, respectively. Individual agents are discussed in greater detail later in this chapter, listed alphabetically.

### Artemisinin and Derivatives

**History.** Artemisinin is a sesquiterpene lactone endoperoxide derived from *qing hao* (*Artemisia annua*), also called *sweet wormwood* or *annual wormwood*. The Chinese have ascribed medicinal value to this plant for >2000 years (White, 2008). As early as 340 A.D., Ge Hong prescribed tea made from *qing hao* as a remedy for fevers, and in 1596, Li Shizhen recommended it to relieve malarial symptoms. By 1972, Chinese scientists had identified the major antimalarial ingredient, *qinghaosu*, now known as artemisinin.

**Chemistry.** The structures of artemisinin and its three major semi-synthetic derivatives in clinical use, dihydroartemisinin, artemether, and artesunate, are as follows:
