<td>Mefloquine (LARIAM and generic)</td>
<td>Prophylaxis in areas with mefloquine-sensitive malaria</td>
<td>228 mg base (250 mg salt) orally, once/week</td>
<td>≤9 kg: 4.6 mg/kg base (5 mg/kg salt) orally, once/week; &gt;9-19 kg: 1/4 tablet once/week; &gt;19-30 kg: 1/2 tablet once/week; &gt;31-45 kg: 3/4 tablet once/week; ≥45 kg: 1 tablet once/week</td>
<td>Begin 1-2 weeks before travel to malarious areas. Take weekly on same day of the week while in malarious area and for 4 weeks after leaving such areas. Contraindicated in persons allergic to mefloquine or related compounds (e.g., quinine, quinidine) and in persons with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in persons with psychiatric disturbances or a previous history of depression. Not recommended for persons with cardiac conduction abnormalities.</td>
</tr>
<tr>
<td>Primaquine</td>
<td>Prophylaxis for short-duration travel to areas with principally \textit{P. vivax}</td>
<td>30 mg base (52.6 mg salt) orally, daily</td>
<td>0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, daily</td>
<td>Begin 1-2 days before travel to malarious areas. Take daily at same time each day while in malarious area and for 7 days after leaving such areas. Contraindicated in persons with G6PD$^*$ deficiency, and during pregnancy and lactation unless the infant being breastfed has documented normal G6PD level.</td>
</tr>
<tr>
<td>Primaquine</td>
<td>For presumptive anti-relapse therapy (terminal prophylaxis) to decrease the risk of relapses (\textit{P. vivax, P. ovale})</td>
<td>30 mg base (52.6 mg salt) orally, once/day for 14 days after departure from the malarious area.</td>
<td>0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, once/day for 14 days after departure from the malarious area</td>
<td>Indicated for persons who have had prolonged exposure to \textit{P. vivax} and \textit{P. ovale} or both. Contraindicated in persons with G6PD$^*$ deficiency. Also contraindicated during pregnancy and lactation unless the infant being breastfed has a documented normal G6PD level.</td>
</tr>
</tbody>
</table>

$^*$Glucose-6-phosphate dehydrogenase. All persons who take primaquine should have a documented normal G6PD level before starting the medication. These regimens are based on published recommendations of the United States Centers for Disease Control and Prevention (CDC). These recommendations may change over time. Up-to-date information should be obtained from www.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the latter, some antimalarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous.

<sup>a</sup>Pediatric dosage should never exceed adult dosage.

<sup>b</sup>Extrapolated from chloroquine literature.

<sup>c</sup>Mefloquine should not be used to treat *P. falciparum* infections acquired in the following areas: borders of Thailand with Burma (Myanmar) and Cambodia, western provinces of Cambodia, eastern states of Burma (Myanmar), border between Burma and China, Laos along borders of Laos and Burma (and adjacent parts of Thailand-Cambodia border), and southern Vietnam due to resistant strains.

<sup>d</sup>Quinine sulfate capsule manufactured in the U.S. is in a 324-mg dose; therefore, two capsules should be sufficient for adult dosing.

<sup>e</sup>Nausea, vomiting, headache, tinnitus, deafness, dizziness, and visual disturbances.

<sup>f</sup>Refer to quinine sulfate, package insert (Mutual Pharmaceutical Inc, Philadelphia, PA, Rev 08, November 2009).

<sup>g</sup>Alternative dosing hypoglycemia optic neuritis regimen for quinidine gluconate (IV): 15 mg base/kg (24 mg salt/kg) loading dose IV infused over 4 h, followed by 7.5 mg base/kg (= 12 mg salt/kg) infused over 4 h every 8 h, starting 8 h after the loading dose (see package insert); once parasite density <1% and patient can take oral medication, complete treatment with oral quinine, dose as above Quinidine or quinine course = 7 d in SE Asia (3 d in Africa or South America)

<sup>h</sup>Refer to quinidine gluconate, package insert (Eli Lilly Co, Indianapolis, IN, February 2002).

These regimens are based on published recommendations of the U.S. Centers for Disease Control and Prevention (CDC). Although current at the time of writing, these recommendations may change over time. Up-to-date information should be obtained from the CDC website at [www.cdc.gov/travel](http://www.cdc.gov/travel). Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the latter, some anti-malarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

The derivatives display improved potency and bioavailability and have largely replaced the use of artemisinin. *Dihydroartemisinin* is a reduced product, *artesunate* is the water-soluble hemisuccinate ester of dihydroartemisinin, and *artemether* is a lipophilic methyl ether. Extensive structure-activity studies have confirmed the requirement for an endoperoxide moiety for antimalarial activity.

**Mechanisms of Antimalarial Action and Resistance.** As a class, the artemisinins are very potent and fast-acting antimalarials, inducing more rapid parasite clearance and fever resolution than any other currently licensed antimalarial drug. They are particularly well suited for the treatment of severe *P. falciparum* malaria and are also effective against the asexual erythrocytic stages of *P. vivax*. Increasingly, the standard treatment of malaria employs artemisinin-based combination therapies (ACTs) to increase treatment efficacy and reduce selection pressure for the emergence of drug resistance. Artemisinins cause a significant reduction of the parasite burden, with a four-log₁₀ reduction in the parasite population for each 48-hour cycle of intraerythrocytic invasion, replication, and egress. As such, only three to four cycles (6-8 days) of treatment are required to remove all the parasites from the blood (White, 2008). Additionally, artemisinins possess some gametocytocidal activity, leading to a decrease in malarial parasite transmission. ACTs have low toxicity and are considered safe for use in nonpregnant adults and children. Of concern, however, is the widespread distribution of counterfeit or clinically substandard drugs that contain small quantities of the artemisinin derivative, a practice that threatens the effective administration of ACTs.

The mechanisms by which ACTs exert their antimalarial activity remain contentious (Golenser et al., 2006). Nevertheless, most studies concur that the activity of artemisinin and its potent derivatives results from reductive scission of the peroxide bridge by reduced heme-iron, which is produced inside the highly acidic digestive vacuole (DV) of the parasite as it digests hemoglobin. In addition to the formation of potentially toxic heme-adducts, activated artemisinin (for which the site of action remains unclear) might in turn generate free radicals that alkylate and oxidize proteins and possibly lipids in parasitized erythrocytes (Eastman and Fidock, 2009).

Artemisinins do not display significant clinical cross-resistance with other drugs. Indeed, sensitivity to artemisinins may even be increased in at least some strains of chloroquine-resistant parasites. Recent evidence has nonetheless suggested the emergence of *P. falciparum* isolates with an increased tolerance to artemisinins, manifesting as longer parasite clearance times (Dondorp et al., 2009). This has triggered significant efforts to elucidate the mechanistic basis of resistance and implement means to limit its spread. The World Health Organization (WHO) and most authorities strenuously recommend using artemisinins only in combination therapy, both to increase treatment efficacy and prevent the emergence of drug resistance.

**Absorption, Fate, and Excretion.** The semisynthetic artemisinins have been formulated for oral (dihydroartemisinin, artesunate, and artemether), intramuscular (artesunate and artemether), intravenous (artesunate), and rectal (artesunate) routes. Bioavailability after oral dosing typically is ≤30%. Although artemisinins rapidly achieve peak serum levels; intramuscular administration of the lipid-soluble artemether peaks in 2-6 hours, due to a depot effect at the injection.

These regimens are based on published recommendations of the United States Centers for Disease Control and Prevention (CDC). These recommendations may change over time. Up-to-date information should be obtained from www.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the latter, some antimalarial treatments may be available without prescription but the most effective drugs usually will be controlled by governmental agencies.

site. Both artesunate and artemether have modest levels of plasma protein binding, ranging from 43% to 82%. These derivatives are extensively metabolized and converted to dihydroartemisinin, which has a plasma t1/2 of 1-2 hours (German and Aweke, 2008). Rectal administration of artesunate has emerged as an important administration route, especially in tropical countries where it can be lifesaving. However, drug bioavailability via rectal administration is highly variable among individual patients (Medhi et al., 2009).

With repeated dosing, artemisinin and artesunate induce their own CYP-mediated metabolism, primarily via CYPs 2B6 and 3A4. This may enhance clearance by up to 5-fold. Recent studies have found no clinically significant pharmacokinetic or toxic interactions between artemisinins and its partner drugs.

**Therapeutic Uses.** Given their rapid and potent activity against even multidrug-resistant parasites, the artemisinins are valuable for the treatment of severe *P. falciparum* malaria. Intravenous artesunate is more than comparable to a standard quinine regimen, likely possessing higher efficacy and a better safety profile in many patient populations (Rosenthal, 2008). The artemisinins generally are not used alone because of their limited ability to eradicate infection completely. In numerous studies in Africa, South America, and Asia, artemisinins have proven highly effective, when combined with other antimalarials, for the first-line treatment of malaria (Sinclair et al., 2009). Artemisinins should not be used for chemoprophylaxis because of their short t1/2, which translates into high recrudescence rates. In the U.S., the Food and Drug Administration (FDA) has approved the use of artemether-lumefantrine for oral treatment of uncomplicated *P. falciparum* malaria. Although useful in treating presumptively chloroquine-resistant *P. vivax*, artemether-lumefantrine does not have a formal FDA-approved indication for this infection. Under an investigational new drug (IND) application, intravenous artesunate is now indicated for the treatment of severe malaria; this drug currently can be obtained through the Centers for Disease Control and Prevention (CDC) Drug Service or CDC Quarantine Stations.

**Toxicity and Contraindications.** The increasing usage of ACTs has focused attention on the safety profile of artemisinins, especially with regard to potential toxic effects in infants and during the first trimester of pregnancy. In pregnant rats and rabbits, artemisinins can cause increased embryo lethality or malformations early postconception. Preclinical toxicity studies have identified the heart (brainstem), liver, bone marrow, and fetus as the principal target organs. In patients, the many neurological changes that accompany severe malaria confound the evaluation of drug neurotoxicity; however, no systematic neurological changes were attributable to treatment in patients >5 years of age. As in small animals, patients may develop dose-related and reversible decreases in reticulocyte and neutrophil counts and increases in transaminase levels in patients. About 1 in 3000 patients develops an allergic reaction. Studies of artemisinin treatment during the first trimester have found no evidence of adverse effects on fetal development (Eastman and Fidock, 2009). Nonetheless, out of general concern, it is recommended that ACTs not be used for the treatment of children ≤5 kg or during the first trimester of pregnancy.

**ACT Partner Drugs.** The short plasma t1/2 of artemisinin and its derivatives translates into substantial treatment failure rates when artemisinins are used as monotherapy. Combining an artemisinin derivative with a longer-lasting partner drug assures sustained antimalarial activity. Current ACT regimens that are well tolerated in adults and children ≥5 kg include artemether-lumefantrine, artesunate-mefloquine, artesunate-amodiaquine, artesunate-sulfadoxine-pyrimethamine, and dihydroartemisinin-piperaquine. Artesunate-pyronaridine has also recently completed phase III clinical trials. Combination with mefloquine or sulfadoxine-pyrimethamine is discussed in a separate section. Properties of other partner drugs are discussed later.

**Lumefantrine** shares structural similarities with the arylaminoalcohol drugs mefloquine and halofantrine (Figure 49–2) and is formulated with artemether (COARTEM).

This combination has proven to be highly effective for the treatment of uncomplicated malaria and is the most widely used first-line antimalarial across Africa. The pharmacokinetic properties of lumefantrine include a large apparent volume of distribution and a terminal elimination t1/2 of 4-5 days. Human pharmacokinetic and pharmacodynamic studies correlate the risk of clinical failure (the likelihood to recrudesce) with plasma lumefantrine concentrations falling below 280 ng/mL. These findings, combined with a report of up to 15-fold variability in lumefantrine plasma concentrations in clinical trial volunteers, highlight the importance of appropriate dosing with lumefantrine-containing combinations (Checchi et al., 2006). Administration with a high-fat meal is recommended because it significantly increases absorption. Recently a sweetened dispersible formulation of artemether-lumefantrine (COARTEM Dispersible) has been approved for treatment of children. This formulation has comparable pharmacokinetics to crushed tablets and provides substantially improved ease of administration.

**Amodiaquine** is a congener of chloroquine (Figure 49–2) that is no longer recommended in the U.S. for chemoprophylaxis of *P. falciparum* malaria because of its toxicity (hepatic and agranulocytosis). These adverse events, however, were generally associated with its prophylactic use. A meta-analysis of clinical studies found that therapeutic amodiaquine regimes, with a total dose of up to 35 mg/kg body weight administered over 3 days, were as well tolerated as chloroquine for the treatment of uncomplicated *P. falciparum* malaria (Olliaro and Mussano, 2003). One
Figure 49–2. Chemical structure of antimalarial quinolines and related compounds.
recent study reported an increased risk of neutropenia with amodiaquine therapy in HIV patients receiving antiretroviral therapy (Gasasira et al., 2008).

In vivo, amodiaquine is rapidly converted by hepatic CYPs into monodesethyl-amodiaquine. This metabolite, which retains substantial antimalarial activity, has a plasma t½ of 9-18 days and reaches a peak concentration of ~500 nM 2 hours after oral administration. By contrast, amodiaquine has a t½ of ~3 hours, attaining a peak concentration of ~25 nM within 30 minutes of oral administration (Eastman and Fidock, 2009). In vivo clearance rates of amodiaquine, however, display a variation between individuals that ranges from 78 to 943 mL/min/kg.

Piperaquine, a potent and well-tolerated bisquino- line compound (Figure 49–2) structurally related to chloroquine, became the primary antimalarial in China during the 1970s and 1980s in response to increasing rates of chloroquine resistance.

Piperaquine has a large volume of distribution and reduced rates of excretion after multiple doses. This lipophilic drug is rapidly absorbed, with a T max (time to reach the highest concentration) of 2 hours after a single dose. In clinical trials, the combination of piperaquine and dihydroartemisinin produced cure rates and cleared fever and parasites in a time frame similar to artesunate-mefloquine (Wells et al., 2009). Piperaquine has the longest plasma t½ (5 weeks) of all ACT partner drugs, suggesting that piperaquine-dihydroartemisinin might also be effective in reducing rates of reinfection following treatment.

Pyronaridine, an antimalarial structurally related to amodiaquine (Figure 49–2), was developed by the Chinese in the 1970s.

Pyronaridine is well tolerated and highly potent against both P. falciparum and P. vivax, causing fever to subside in 1-2 days and parasite clearance in 2-3 days. Clinical data from trials of artesunate-pyronaridine should soon be available (Wells et al., 2009).

ATOVAQUONE

History. Based on the antiprotozoal activity of hydroxy-naphthoquinones, atovaquone (MEPRON) was developed as a promising synthetic derivative with potent activity against Plasmodium species and the opportunistic pathogens Pneumocystis jiroveci (previously called Pneumocystis carinii) and Toxoplasma gondii (Schlitzer, 2007). The FDA approved this compound in 1992 for treatment of mild-to-moderate P. jiroveci pneumonia in patients intolerant of trimethoprim-sulfamethoxazole. Subsequent clinical studies in patients with uncomplicated P. falciparum malaria revealed that atovaquone produced good initial responses, but parasites recrudesced and were highly atovaquone resistant. In contrast, the combination of atovaquone and proguanil produced high cure rates with minimal toxicity. A fixed combination of atovaquone with proguanil hydrochloride (MALARONE) is available in the U.S. for malaria chemoprophylaxis and for the treatment of uncomplicated P. falciparum malaria in adults and children (Boggild et al., 2007).

Chemistry. Atovaquone is a highly lipophilic analog of ubiquinone.

Mechanisms of Antimalarial Action and Resistance. Atovaquone is highly active against P. falciparum asexual blood stage parasites in vitro (with low nanomolar activity) and in vivo in humans and the Aotus primate model. This drug is effective against liver stages of P. falciparum but not against P. vivax liver stage hypnozoites. Atovaquone acts selectively on the mitochondrial cytochrome bc 1 complex to inhibit electron transport and collapse the mitochondrial membrane potential (Vaidya and Mather, 2009). The primary function of mitochondrial electron transport in P. falciparum is to regenerate ubiquinone, which is the electron acceptor for parasite dihydroorotate dehydrogenase, an enzyme essential for pyrimidine biosynthesis in the parasite (Painter et al., 2007). Synergy between proguanil and atovaquone results from the ability of nonmetabolized proguanil to enhance the mitochondrial toxicity of atovaquone (Fivelman et al., 2004; Srivastava et al., 1999).

Resistance to atovaquone alone in P. falciparum develops easily in vitro and in vivo, and it is conferred by single non-synonymous nucleotide polymorphisms in the cytochrome b gene located in the mitochondrial genome (Kessl et al., 2007). In the Saccharomyces cerevisiae cytochrome bc 1 complex, atovaquone binding is inhibited by the introduction of resistance mutations found in P. falciparum. Similar mutations have been reported in resistant isolates of rodent malarial species, as well as in T. gondii and perhaps P. jiroveci. Addition of proguanil markedly reduces the frequency of appearance of atovaquone resistance, as based on in vivo treatment cure rate. However, once atovaquone resistance is present, the synergy of the partner drug proguanil diminishes. In the key mutation associated with clinical atovaquone-proguanil resistance, tyrosine is replaced by serine, cysteine, or asparagine at codon 268 (Y268S/C/N) of the cytochrome b gene. Reports of atovaquone-proguanil treatment
Absorption, Fate, and Excretion. Atovaquone absorption after a single oral dose is slow, erratic, and variable due to its highly lipophilic nature and low aqueous solubility. Absorption improves when the drug is taken with a fatty meal (Boggild et al., 2007). More than 99% of the drug is bound to plasma protein, and cerebrospinal fluid levels are <1% of those in plasma. Profiles of drug concentration versus time often show a double peak, albeit with considerable variability. The first peak appears in 1-8 hours, whereas the second occurs 1-4 days after a single dose. This pattern suggests an enterohepatic circulation. In the absence of a CYP-inducing second medication, humans do not metabolize atovaquone significantly. The drug is excreted in bile, and >94% of the drug is recovered in feces; only traces appear in the urine. Atovaquone has a reported elimination half-life from plasma of 2-3 days in adults and 1-2 days in children. Clearance is unaffected by dose or co-administration of proguanil (Boggild et al., 2007).

Therapeutic Uses. Atovaquone-proguanil is used for malaria chemoprophylaxis in adults and children ≥11 kg and for treatment of uncomplicated *P. falciparum* malaria in adults and children ≥5 kg.

A tablet containing a fixed dose of 250 mg atovaquone and 100 mg proguanil hydrochloride, taken orally, is highly effective and safe in a 3-day regimen for treating mild-to-moderate attacks of chloroquine- or sulfadoxine-pyrimethamine-resistant *P. falciparum* malaria (Looareesuwan et al., 1999). Although the same regimen followed by a primaquine course is effective in treatment of *P. vivax* malaria (Lacy et al., 2002), evidence for atovaquone-proguanil efficacy as treatment of non-*P. falciparum* malaria is limited (Boggild et al., 2007). The CDC does not recommend the combination for non-*P. falciparum* treatment, except for malaria caused by chloroquine-resistant *P. vivax*. Atovaquone-proguanil is a standard agent for malaria chemoprophylaxis. It can be discontinued 1 week after leaving the endemic area because both components are active against liver stage parasites. Experience in prevention of non-*P. falciparum* malaria is also limited (Ling et al., 2002). *P. vivax* infection may occur after drug discontinuation, indicating imperfect activity against exo-erythrocytic stages of this parasite.

Toxicity. Atovaquone may cause side effects (abdominal pain, nausea, vomiting, diarrhea, headache, rash) that require cessation of therapy. Vomiting and diarrhea may decrease drug absorption, resulting in therapeutic failure. However, readministration of this drug within an hour of vomiting may still be effective in patients with *P. falciparum* malaria. Atovaquone occasionally causes transient elevations of serum transaminase or amylase.

Precautions and Contraindications. Although atovaquone is generally considered to be safe, it needs further evaluation in children <11 kg, pregnant women, and lactating mothers. Accordingly, although the drug is not formally recommended for these individuals, the risks and benefits of its use (both as chemoprophylaxis and treatment) should be considered carefully for individual patients, taking known toxicities into account. Preclinical evaluations for carcinogenicity, mutagenicity, and teratogenicity have been negative. Atovaquone may compete with certain drugs for binding to plasma proteins, and therapy with rifampin, a potent inducer of CYP-mediated drug metabolism, can reduce plasma levels of atovaquone substantially, whereas atovaquone may raise plasma levels of rifampin. Co-administration with tetracycline is associated with a 40% reduction in plasma concentration of atovaquone.

**DIAMINOPYRIMIDINES**

**History.** Based on their structural analogy with the antimalarial proguanil (see section on proguanil), large numbers of 2,4-diaminopyrimidines were tested for inhibitory activity against malarial parasites, leading to the identification of the potent antimalarial agent pyrimethamine. Studies also observed marked antimalarial synergy between sulfonamides and proguanil. Accordingly, pyrimethamine was formulated and marketed as a fixed combination with sulfadoxine, a sulfonamide with pharmacokinetics that match those of pyrimethamine. For several decades sulfadoxine-pyrimethamine (Fansidar) has been a primary treatment for uncomplicated *P. falciparum* malaria, especially against chloroquine-resistant strains, but widespread resistance now seriously compromises its efficacy and it is no longer recommended for the treatment of uncomplicated malaria.

![Pyrimethamine](image)

**Mechanisms of Antimalarial Action and Resistance.** Pyrimethamine is a slow-acting blood schizontocide with antimalarial effects *in vivo* similar to those of proguanil, resulting from inhibition of folate biosynthesis in *Plasmodium*. However, pyrimethamine has greater antimalarial potency, and its half-life is much longer than that of cycloguanil, the active metabolite of proguanil. The efficacy of pyrimethamine against hepatic forms of *P. falciparum* is less than that of proguanil, and at therapeutic doses pyrimethamine fails to eradicate *P. vivax* hypnozoites or gametocytes of any *Plasmodium* species. It increases the number of circulating *P. falciparum* mature infecting gametocytes, likely leading to increased transmission to mosquitoes during the period of treatment.
The 2,4-diaminopyrimidines more potently inhibit the *Plasmodium* dihydrofolate reductase compared to the mammalian enzyme. Unlike its counterpart in human cells, the malarial dihydrofolate reductase resides on the same polypeptide chain as thymidylate synthase and, importantly, protein production is not increased in response to inhibition. The latter property favors the selective anti-plasmodial toxicity of pyrimethamine (Zhang and Rathod, 2002).

Synergy of pyrimethamine and the sulfonamides or sulfones results from inhibition of two key metabolic steps in folate biosynthesis in the parasite:

- the utilization of *p*-aminobenzoic acid for the synthesis of dihydropteroic acid, which is catalyzed by dihydropteroate synthase and inhibited by sulfonamides
- the reduction of dihydrofolate to tetrahydrofolate, which is catalyzed by dihydrofolate reductase and inhibited by pyrimethamine (Figure 52–2).

Dietary *p*-aminobenzoic acid or folate may affect the therapeutic response to antifolates. Both of these metabolites can be imported by the malarial parasite and can reduce drug efficacy substantially (Hyde, 2007). Resistance to pyrimethamine has developed in regions of prolonged or extensive drug use and can be attributed to mutations in dihydrofolate reductase that decrease the binding affinity of pyrimethamine (Gregson and Plowe, 2005). Interestingly, the pattern of amino acid substitutions is different in parasites resistant to cycloguanil, even though cross-resistance can occur between these structurally related inhibitors of plasmodial dihydrofolate reductase. The key mutation associated with pyrimethamine resistance is the substitution of asparagine for serine at codon 108 (S108N). The stepwise accumulation of additional single-amino-acid changes at codons 51, 59, and 164 is associated with progressively increasing resistance, as determined by *P. falciparum* isolates and with recombinant proteins. The triple mutant N51I/C59R/S108N (predominant in Africa) and the quadruple mutant N51I/C59R/S108N/I164L (predominant in Southeast Asia) exhibit high levels of pyrimethamine resistance and contribute to pyrimethamine-sulfadoxine therapeutic failure. Remarkably, studies exploring the mutational trajectories leading to the most resistant quadruple mutant N51I/C59R/S108N/I164L suggest a specific ordering of mutational events that balance the acquisition of resistance with the maintenance of pathogen fitness (Lozovsky et al., 2009). These studies also suggest that this quadruple mutant is substantially less fit in the absence of drugs when compared to its wild-type counterpart. Compensatory mechanisms might therefore be necessary to alleviate this fitness cost. An increase in the number of copy of the GTP cyclohydrolase I gene, which encodes the first enzyme in the *Plasmodium* folate biosynthesis pathway, is closely associated with the dihydrofolate reductase I164L mutation, suggesting a potential compensatory function (Nair et al., 2008).

**Absorption, Fate, and Distribution.** After oral administration, pyrimethamine is slowly but completely absorbed, reaching peak plasma levels in 2-6 hours. The compound is significantly distributed in the tissues and is ~90% bound to plasma proteins (German and Aweeke, 2008). Pyrimethamine is slowly eliminated from plasma with a t½ of 85-100 hours. Concentrations that are suppressive for responsive *Plasmodium* strains remain in the blood for ~2 weeks, but levels are lower in patients with active infection. Several metabolites of pyrimethamine appear in the urine; however, their identities and antimalarial properties have not been fully characterized. Pyrimethamine also enters the milk of nursing mothers.

**Therapeutic Uses.** Pyrimethamine-sulfadoxine is no longer recommended for the treatment of uncomplicated malaria or for chemoprophylaxis due to increasing drug resistance. However, for those living in malaria-endemic areas, some still recommend it for the intermittent preventive treatment of malaria in pregnancy, and it is being evaluated for intermittent preventive treatment in infants (Aponte et al., 2009). Pyrimethamine is typically administered with either a sulfonamide or sulfone to enhance its antifolate activity. Most malaria-endemic areas currently have a high prevalence of pyrimethamine-resistant parasites.

**Toxicity, Precautions, and Contraindications.** Antimalarial doses of pyrimethamine alone cause minimal toxicity except for occasional skin rashes and reduced hematopoiesis. Excessive doses can produce a megaloblastic anemia, resembling that of folate deficiency, which responds readily to drug withdrawal or treatment with folinic acid. At high doses, pyrimethamine is teratogenic in animals, and in humans the related combination, trimethoprim-sulfamethoxazole, may cause birth defects (Hernandez-Diaz et al., 2000).

Sulfonamides or sulfones, rather than pyrimethamine, usually account for the toxicity associated with coadministration of these antifolate drugs. The combination of pyrimethamine and sulfadoxine is no longer recommended for malaria chemoprophylaxis because in ~1 in 5000 to 1 in 8000 individuals, this combination causes severe and even fatal cutaneous reactions, such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. It has also been associated with serum sickness–type reactions, urticaria, exfoliative dermatitis, and hepatitis. Pyrimethamine-sulfadoxine is contraindicated for individuals with previous reactions to sulfonamides, for lactating mothers, and for infants <2 months of age. Administration of pyrimethamine with dapsone (MALOPRIM), a drug combination unavailable in the U.S., has occasionally been associated with agranulocytosis.

**PROGUANIL**

**History.** Proguanil is the common name for chloroguanide, a biguanide derivative that emerged in 1945 as a product of British antimalarial research. The antimalarial activity of proguanil eventually was ascribed to cycloguanil, a cyclic triazine metabolite and selective inhibitor of the bifunctional plasmodial dihydrofolate reductase-thymidylate synthetase that is crucial for parasite *de novo*
purine and pyrimidine synthesis. Indeed, investigation of compounds bearing a structural resemblance to cycloguanil resulted in the development of antimalarial dihydrofolate reductase inhibitors such as pyrimethamine. Accrued evidence also indicates that proguanil itself has intrinsic antimalarial activity independent of its metabolite’s effect on parasite dihydrofolate reductase-thymidylate synthetase (Fidock and Wellems, 1997).

**Chemistry.** Proguanil and its triazine metabolite cycloguanil have the following chemical structures:

![Chemical structures of proguanil and cycloguanil](image)

Proguanil has the widest margin of safety of a large series of antimalarial biguanide analogs examined. Dihalogen substitution in positions 3 and 4 of the benzene ring yields chlorproguanil, a more potent prodrug than proguanil. Cycloguanil, the metabolite, is structurally related to pyrimethamine.

**Mechanisms of Antimalarial Action and Resistance.** In drug-sensitive *P. falciparum* malaria, proguanil exerts activity against both the primary liver stages and the asexual red blood cell stages, thus adequately controlling the acute attack and usually eradicating the infection. Proguanil is also active against acute *P. vivax* malaria, but because the latent tissue stages of *P. vivax* are unaffected, relapses may occur after the drug is withdrawn. Proguanil treatment does not destroy gametocytes, but oocysts in the gut of the mosquito can fail to develop normally.

Cycloguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, causing inhibition of DNA synthesis and depletion of folate cofactors (Kamchonwongpaisan et al., 2004). As referred to earlier, a series of amino acid changes near the dihydrofolate reductase–binding site have been identified that cause resistance to cycloguanil, pyrimethamine, or both (Gregson and Plowe, 2005). Specifically, resistance to cycloguanil (and chlorcycloguanil) can be linked to mutations leading to paired A16V/S108T substitutions in *Plasmodium* dihydrofolate reductase. In addition, cross-resistance between cycloguanil and pyrimethamine has been observed *in vitro* for both the triple (N51/C59R/S108N) and quadruple (N51/C59R/S108N/I164L) dihydrofolate reductase–thymidylate synthetase mutants, prevalent in Africa and South America, respectively (Peterson et al., 1990). Malarial isolates demonstrate varying degrees of cross-resistance to cycloguanil and pyrimethamine, indicating that the evolution of mutation patterns in individual organisms during treatment may be quite complex.

The presence of *Plasmodium* dihydrofolate reductase is not required for the intrinsic antimalarial activity of proguanil or chlorproguanil (Fidock and Wellems, 1997); however, the molecular basis for this alternative activity remains enigmatic. Proguanil as the biguanide accentuates the mitochondrial membrane-potential-collapsing action of atovaquone against *P. falciparum* but displays no such activity by itself (Vaidya and Mather, 2009) (see section on atovaquone). In contrast to cycloguanil, resistance to the parent drug, proguanil, either alone or in combination with atovaquone, is not well documented.

**Absorption, Fate, and Excretion.** Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, peak plasma concentrations usually are attained within 5 hours. The mean plasma elimination t1/2 is ~180-200 hours or longer (German and Aweeka, 2008).

The metabolism of proguanil in mammals cosegregates with mephenytoin oxidation polymorphisms, controlled by isoforms in the CYP2C subfamily. Only ~3% of whites are deficient in this oxidation phenotype, contrasted with ~20% of Asians and Kenyans. Proguanil is oxidized to two major metabolites, cycloguanil and an inactive 4-chlorophenylbiguanide. On a 200 mg daily dosage regimen, plasma levels of cycloguanil in extensive metabolizers exceed the therapeutic range, whereas cycloguanil levels in poor metabolizers fail to reach a therapeutic level. Proguanil itself does not accumulate appreciably in tissues during long-term administration, except in red blood cells where its concentration is about three times that in plasma. The inactive metabolite 4-chlorophenyl-biguanide is not readily detected in plasma but appears in increased quantities in the urine of poor proguanil metabolizers. In humans, 40-60% of the absorbed proguanil is excreted in urine, either as the parent drug or as the active metabolite.

**Therapeutic Uses.** Proguanil as a single agent is not available in the U.S. but has been prescribed as chemoprophylaxis in England and Europe for individuals traveling to malarious areas in Africa. Strains of *P. falciparum* resistant to proguanil emerge rapidly in areas where the drug is used exclusively, but breakthrough infections may also result from deficient conversion of proguanil to its active antimalarial metabolite. Proguanil has been reported to be ineffective against multidrug-resistant strains of *P. falciparum* in Thailand and New Guinea. This drug can protect against
chloroquine and pyrimethamine-sulfadoxine resistant strains of *P. falciparum* found in sub-Saharan Africa.

Proguanil is effective and tolerated well in combination with atovaquone, once daily for 3 days, to treat drug-resistant strains of *P. falciparum* or *P. vivax* (see section on atovaquone). Indeed, this drug combination has been successful in Southeast Asia, where highly drug-resistant strains of *P. falciparum* prevail. *P. falciparum* readily develops clinical resistance to monotherapy with either proguanil or atovaquone; however resistance to the combination is uncommon unless the strain is initially resistant to atovaquone. In contrast, some strains resistant to proguanil do respond to proguanil plus atovaquone.

**Toxicity and Side Effects.** In chemoprophylactic doses of 200-300 mg daily, proguanil causes relatively few adverse effects, except occasional nausea and diarrhea. Large doses (≥1 g daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and the transient appearance of epithelial cells and casts in the urine. Gross accidental or deliberate overdose (as much as 15 g) has failed to produce lasting sequelae. Doses as high as 700 mg twice daily have been taken for >2 weeks without serious toxicity. Proguanil is considered safe for use during pregnancy. It is remarkably safe when used in conjunction with other antimalarial drugs such as chloroquine, atovaquone, tetracyclines, and other antifolates.

**QUINOLINES AND RELATED COMPOUNDS**

Quinolines have been the mainstay of antimalarial chemotherapy starting with quinine nearly 400 years ago. In the last century, legions of related compounds were synthesized and tested for antimalarial activity. These efforts produced several drugs for the chemoprophylaxis and treatment of malaria. The most important of these are shown in Figure 49–2.

**Chloroquine and Hydroxychloroquine**

**History.** Chloroquine (Aralen) is one of a large series of 4-aminoquinolines synthesized as part of the extensive cooperative program of antimalarial research in the U.S. during World War II. Chloroquine proved most promising and was released for field trial. When hostilities ceased, it was discovered that the compound had been synthesized and studied as early as 1934 under the name of Resochin at the Bayer laboratories in Germany but had been rejected because of toxicity in avian models.

**Chemistry.** The d-, l-, and dl- forms of chloroquine (see structure in Figure 49–2) have equal potency against *P. lophurae* malaria (a duck parasite), but the d-isomer is somewhat less toxic than the l-isomer in mammals. A chlorine atom attached to position 7 of the quinoline ring confers the most potent antimalarial activity in both avian and human malarias. Research on the structure-activity relationships of chloroquine and related alkaloid compounds continues in an effort to find new effective antimalarials with improved safety profiles that can be used successfully against chloroquine- and multidrug-resistant strains of *P. falciparum*. One example is the synthesis of short-chain derivatives that can demonstrate full efficacy against chloroquine-resistant strains of *P. falciparum*. Another important example is piperaquine, a bisquinoline that was extensively used in China to treat chloroquine-resistant malaria. It is highly efficacious in combination with dihydroartemisinin (Davis et al., 2005); see earlier section on artemisinin-based combination therapies.

Hydroxychloroquine, in which one of the N-ethyl substituents of chloroquine is β-hydroxylated, is essentially equivalent to chloroquine against *P. falciparum* malaria. This analog is preferred over chloroquine for treatment of mild rheumatoid arthritis and lupus erythematosus because, in the high doses required, it may cause less ocular toxicity. Care should be taken when these compounds are administered to patients with known G6PD deficiency.

**Mechanisms of Action and Resistance.** Asexual malarial parasites flourish in host erythrocytes by digesting hemoglobin in their acidic digestive vacuoles, a process that generates free radicals and iron-bound heme (ferriprotoporphyrin IX) as highly reactive by-products (Goldberg, 2005). Perhaps aided by histidine-rich proteins and lipids, heme is sequestered as an insoluble, chemically inert malarial pigment termed hemozoin. Many theories for the mechanism of action of chloroquine have been advanced (Valderramos and Fidock, 2006). Current evidence suggests that quinolines interfere with heme detoxification. Chloroquine, a weak base, concentrates in the highly acidic digestive vacuoles of susceptible *Plasmodium*, where it binds to heme and disrupts its sequestration. Failure to inactivate heme or even enhanced toxicity of drug-heme complexes is thought to kill the parasites via oxidative damage to membranes, digestive proteases, or other critical biomolecules. Other quinolines such as quinine, amodiaquine, and mefloquine, as well as other amino alcohol analogs (lumefantrine, halofantrine) and mannich base analogs (pyronaridine), may act by a similar mechanism, although differences in their actions have been proposed (Bray et al., 2005; Eastman and Fidock, 2009).

Resistance of erythrocytic asexual forms of *P. falciparum* to antimalarial quinolines, especially chloroquine, now is common in most parts of the world (Figure 49–3). Reports of chloroquine failures in the treatment of *P. vivax* are fairly common in Indonesia, East Timor, and Papua New Guinea, in which case alternative treatments (mefloquine, or quinine plus doxycycline or tetracycline, or atovaquone-proguanil) should be considered (Price et al., 2009). Chloroquine-resistant *P. vivax* has also been recently detected in Ethiopia, where *P. vivax* is an important cause of morbidity (Yeshiwondim et al., 2010). Chloroquine-resistant *P. vivax* isolates do not appear to have significant alterations in their *pfcr* ortholog and may have a different resistance mechanism.
Forty years ago, Fitch and coworkers noted that chloroquine-sensitive *P. falciparum* parasites concentrated the drug to higher levels than did chloroquine-resistant organisms (Fitch et al., 1969). A parasite-encoded efflux mechanism may account for the reduced levels of chloroquine in the digestive vacuoles of chloroquine-resistant parasites (Martin et al., 2009; Valderramos and Fidock, 2006).

**Figure 49–3.** *Malaria-endemic countries in the Americas (bottom) and in Africa, the Middle East, Asia, and the South Pacific (top), 2007*. CAR, Central African Republic; DCOR, Democratic Republic of the Congo; UAE, United Arab Emirates. (Reproduced with permission from Anthony S. Fauci, Eugene Braunwald, Dennis L. Kasper, Stephen L. Hauser, Dan L. Longo, J Larry Jameson, and Joseph Loscalzo, Eds. *Harrison’s Principles of Internal Medicine, 17 ed.* McGraw-Hill, Inc., New York, 2008. Figure 203-2, p. 1282.)
By studying the progeny of a genetic cross between a chloroquine-sensitive clone and a chloroquine-resistant clone, Wellem, Fidock, and colleagues identified a polymorphic gene (pfcr, for P. falciparum chloroquine resistance transporter) that segregates with chloroquine resistance. Geographically distinct pfcr alleles, possessing 4-8 point mutations compared to the invariant chloroquine-sensitive allele, were found to be highly associated with chloroquine resistance in clinical field isolates from across the malaria-endemic areas of the globe (Fidock et al., 2000). Multiple mutations are needed to confer resistance, including the K76T mutation that is ubiquitous to chloroquine-resistant strains. The pfcr gene encodes a putative transporter that resides in the membrane of the acidic digestive vacuole, the site of hemoglobin degradation and chloroquine action. Its physiological function, however, remains unknown. Chloroquine binding and accumulation studies, with genetically modified isogenic lines differing in their pfcr allele, suggest that mutant pfcr confers chloroquine resistance by actively effluxing chloroquine away from its heme target in the digestive vacuole, seemingly via an energy-dependent process (Sanchez et al., 2007). Heterologous expression of codon-adjusted pfcr alleles in Xenopus laevis oocytes has recently provided compelling evidence that mutant PICRT can efflux chloroquine, and has found that this property was not solely dependent on the K76T mutation (Martin et al., 2009). Genomic studies suggest that pfcr has been under intense selection pressure in recent decades, consistent with its role as the primary resistance determinant and the prevalence of chloroquine use in populations exposed to parasites (Mu et al., 2010). Studies from Malawi have found that mutant pfcr alleles essentially disappear upon prolonged cessation of chloroquine use. This implies that mutant pfcr alleles can impart a significant fitness cost to the organism. This cost of fitness results in attrition of mutant forms in areas where polyclonal infections are common and subjects are sufficiently immune such that a substantial proportion of infections are not subject to the pressure of drug selection.

In addition to chloroquine, variant pfcr alleles may impact parasite susceptibility to other antimalarials. As an example, the 7G8 allele, representative of pfcr sequences from South America and the Pacific region, imparts low-level cross resistance to monodesethylamodiaquine, the active metabolite of amodiaquine (Sidhu et al., 2002). Cross-resistance to quinoline has also been observed with some pfcr alleles in certain genetic backgrounds. In contrast, mutant pfcr increases parasite susceptibility to lumenaftrine and artesiminin derivatives, which bodes well for the use of artemether-lumenaftrine in areas where the prevalence of mutant pfcr is high (Sisowath et al., 2009). In addition to PICRT, the P-glycoprotein transporter encoded by pmdr1, and other transporters including PfMRP, may play a modulatory role in chloroquine resistance (Duraiasingh and Cowman, 2005, Raj et al., 2009), and the glutathione system also could contribute (Ginsburg and Golensker, 2003).

Absorption, Fate, and Excretion. Chloroquine is well absorbed from the GI tract and rapidly from intramuscular and subcutaneous sites. This drug extensively sequesters in tissues, particularly liver, spleen, kidney, lung, melanin-containing tissues, and, to a lesser extent, brain and spinal cord. Chloroquine binds moderately (60%) to plasma proteins and undergoes appreciable biotransformation via hepatic CYPs to two active metabolites, desethylchloroquine and bisdesethylchloroquine (Ducharme and Farinotti, 1996). These metabolites may reach plasma concentrations of 40% and 10% of that of chloroquine, respectively. The renal clearance of chloroquine is about half of its total systemic clearance. Unchanged chloroquine and desethylchloroquine account for >50% and 25% of the urinary drug products, respectively, and the renal excretion of both compounds is increased by acidification of the urine.

Both in adults and in children, chloroquine exhibits complex pharmacokinetics such that plasma levels of the drug shortly after dosing are determined primarily by the rate of distribution rather than the rate of elimination (Krishna and White, 1996). Because of extensive tissue binding, a loading dose is required to achieve effective concentrations in plasma. After parenteral administration, rapid entry into the bloodstream together with slow exit from this compartment can result in transiently high and potentially lethal concentrations of the drug in plasma. Hence, parenteral chloroquine is given either slowly by constant intravenous infusion or in small divided doses by the subcutaneous or intramuscular route. Chloroquine is safer when given orally because the rates of absorption and distribution are more closely matched. Peak plasma levels are achieved in ~3-5 hours after dosing by this route. The t1/2 of chloroquine increases from a few days to weeks as plasma levels decline, reflecting release of drug from extensive tissue stores. The terminal t1/2 ranges from 30 to 60 days, and traces of the drug can be found in the urine for years after a therapeutic regimen.

Therapeutic Uses. Chloroquine is highly effective against the erythrocytic forms of P. vivax, P. ovale, P. malariae, P. knowlesi, and chloroquine-sensitive strains of P. falciparum. For infections caused by P. ovale and P. malariae, it remains the agent of choice for chemoprophylaxis and treatment. Chloroquine is also widely used to treat P. vivax; however, as mentioned earlier, resistant strains have been detected, mostly in Asia and the Pacific region. For P. falciparum this drug has been largely replaced by artesiminin-based combination therapies (Eastman and Fidock, 2009). Gametocytocidal activity has been reported for the four main Plasmodium species infecting humans, with activity against P. falciparum restricted to immature gametocytes exposed to concentrations that are several fold higher than those effective against drug-sensitive asexual blood stage P. falciparum parasites. The drug has no activity against latent hypnozoite forms of P. vivax or P. ovale.

Chloroquine is inexpensive and safe, but its usefulness has declined across most malaria-endemic regions of the world because of the spread of chloroquine-resistant P. falciparum. Except in areas where resistant strains of P. vivax are reported, chloroquine is very effective in chemoprophylaxis or treatment of acute attacks of malaria caused by P. vivax, P. ovale, and P. malariae (Table 49–3). Chloroquine has no activity against primary or latent liver stages of the parasite. To prevent relapses in P. vivax and P. ovale infections, primaquine can be given either with chloroquine or used after a patient leaves an endemic area. Chloroquine rapidly controls the clinical symptoms and parasitemia of acute malarial attacks. Most patients become completely afebrile within 24-48 hours after receiving
Toxicity and Side Effects. Taken in proper doses and for recommended total durations, chloroquine is very safe. However, its safety margin is narrow, and a single dose of 30 mg/kg may be fatal (Taylor and White, 2004).

Acute chloroquine toxicity is encountered most frequently when therapeutic or high doses are administered too rapidly by parenteral routes. Toxic manifestations relate primarily to the cardiovascular system and the CNS. Cardiovascular effects include hypotension, vasodilation, suppressed myocardial function, cardiac arrhythmias, and eventual cardiac arrest. Confusion, convulsions, and coma may also result from overdose. Chloroquine doses of >5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, epinephrine, and diazepam may be lifesaving.

Doses of chloroquine used for oral therapy of the acute malarial attack may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs, most commonly among dark-skinned persons. Prolonged treatment with suppressive doses occasionally causes side effects such as headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleaching of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withdrawn. Rare instances of hemolysis and blood dyscrasias have been reported. Chloroquine may cause discoloration of nail beds and mucous membranes. This drug has also been reported to interfere with the immunogenicity of certain vaccines (Pappiaono et al, 1986).

High daily doses of chloroquine or hydroxychloroquine (>250 mg) leading to cumulative total doses of >1 g/kg, such as those used for treatment of diseases other than malaria, can result in irreversible retinopathy and ototoxicity. Retinopathy presumably is related to drug accumulation in melanin containing tissues and can be avoided if the daily dose is ≤250 mg (Rennie, 1993). Prolonged therapy with high doses of chloroquine or hydroxychloroquine also can cause toxic myopathy, cardiopathy, and peripheral neuropathy. These reactions improve if the drug is withdrawn promptly (Estes et al., 1987). Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

Precautions and Contraindications. Chloroquine is not recommended for treating individuals who have epilepsy or myasthenia gravis. This drug should be used cautiously if at all in the presence of advanced liver disease or severe GI, neurological, or blood disorders. In individuals with decreased renal function, dosage should be adjusted to avoid elevated plasma concentrations. In rare cases, chloroquine can cause hemolysis in patients with G6PD deficiency (see later section on primaquine). Concomitant use of gold or phenylbutazone (no longer available in the U.S.) with chloroquine, in the treatment of rheumatoid arthritis, should be avoided because of the tendency of all three agents to produce dermatitis. Chloroquine should not be prescribed for patients with psoriasis or other exfoliative skin conditions because it can cause severe reactions. Because of the danger of cutaneous reactions, it should also not be used to treat malaria in patients with porphyria cutanea tarda; however it can be used in lower doses for treatment of manifestations of this form of porphyria. Chloroquine inhibits CYP2D6 and interacts with a variety of different drugs. It attenuates the efficacy of the yellow fever vaccine when administered at the same time. It should not be given with mefloquine because of increased risk of seizures and lack of added benefit. Most important, chloroquine opposes the action of anticonvulsants and increases the risk of ventricular arrhythmias when co-administered with amiodarone or halofantrine. By increasing plasma levels of digoxin and cyclosporine, chloroquine also can increase the risk of toxicity from these agents. Patients receiving long-term, high-dose therapy should undergo ophthalmological and neurological evaluations every 3-6 months.

Quinine and Quinidine

History. The medicinal use of quinine dates back >350 years (Rocco, 2003). Quinine is the chief alkaloid of cinchona, the powdered bark of the South American cinchona tree, otherwise known as Peruvian, Jesuit’s, or Cardinal’s bark. It had been used by indigenous Peruvians to treat shivering. In 1633, an Augustinian monk named Calancha, of Lima, Peru, first wrote that a powder of cinchona “given as a beverage, cures the fevers and tertians.” By 1640, cinchona was used to treat fevers in Europe. The Jesuit fathers were the main importers and distributors of cinchona in Europe.

For almost two centuries the bark was employed for medicine as a powder, extract, or infusion. In 1820, Pelletier and Caventou isolated quinine from cinchona. Quinine still is a mainstay for treating attacks of chloroquine- and multidrug-resistant P. falciparum malaria (Table 49–3). However, combination therapy (now standard artemisinin-derivative combinations) with other antimalarials is supplanting quinine regimens because of increasing resistance of P. falciparum to quinine in Southeast Asia and parts of the Amazon basin. Quinine toxicity, usually seen in overdose, can include pulmonary edema, immune thrombocytopenic purpura, irreversible deafness, or arrhythmias.

Oral quinine is FDA approved for the treatment of uncomplicated P. falciparum malaria and is currently available from one manufacturer in the U.S. Intravenous quinine is not available in the U.S. The more potent enantiomer, quinidine, is the preferred intravenous form.
Chemistry. Cinchona contains a mixture of >20 structurally related alkaloids, the most important of which are quinine and quinidine. Both compounds contain a quinoline group attached through a secondary alcohol linkage to a quinuclidine ring (Figure 49–2). A methoxy side chain is attached to the quinoline ring and a vinyl to the quinuclidine. They differ only in the steric configuration at two of the three asymmetrical centers: the carbon bearing the secondary alcohol group and at the quinuclidine junction. Although quinine and quinidine have been synthesized, the procedures are complex; hence they still are obtained from natural sources. Quinine is both somewhat more potent as an antimalarial and more toxic than quinidine (Griffith et al., 2007). Structure-activity analysis of the cinchona alkaloids provided the basis for the discovery of more recent antimalarials such as mefloquine.

Mechanisms of Action and Parasite Resistance. Quinine acts against asexual erythrocytic forms and has no significant effect on hepatic forms of malarial parasites. This drug is more toxic and less effective than chloroquine against malarial parasites susceptible to both drugs. However, quinine, along with its stereoisomer quinidine, is especially valuable for the parenteral treatment of severe illness owing to drug-resistant strains of \emph{P. falciparum}. Of note, however, some strains from Southeast Asia and South America have become more resistant to both agents. Because of its toxicity and short \( t_{1/2} \) quinine is generally not used for chemoprophylaxis.

The antimalarial mechanism of quinine is thought to share similarities to chloroquine in being able to bind heme and prevent its detoxification. The basis of \emph{P. falciparum} resistance to quinine, nonetheless, is complex. Patterns of \emph{P. falciparum} resistance to quinine correlate in some strains with resistance to chloroquine yet in others correlate more closely with resistance to mefloquine and halofantrine. Gene amplification of \emph{pfmdr1} in \emph{P. falciparum}, implicated in resistance to mefloquine and halofantrine, can contribute to reduced quinine susceptibility \emph{in vitro}. Similarly, \emph{pfmdr1} point mutations can also contribute to quinine resistance, in particular the N1042D mutation (Duraiasingh and Cowman, 2005; Sidhu et al., 2005). Despite their close chemical similarity, quinine and quinidine sensitivity can also diverge in some strains harboring novel PFkCRT haplotypes (Cooper et al., 2002). Recent evidence suggests that other transporter genes participate in conferring resistance to quinine, potentially including the sodium-hydrogen exchanger PINHE (Hayton and Su, 2008; Nkrumah et al., 2009).

Action on Skeletal Muscle. Quinine and related cinchona alkaloids exert effects on skeletal muscle that can have clinical implications. Quinine increases the tension response to a single maximal stimulus delivered to muscle directly or through nerves, but it also increases the refractory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor end-plate region decreases so that responses to repetitive nerve stimulation and to acetylcholine are reduced. Thus, quinine can antagonize the actions of physostigmine on skeletal muscle as effectively as curare. Quinine may also produce alarming respiratory distress and dysphagia in patients with myasthenia gravis. The effect on skeletal muscle can be augmented by concurrent administration of gentamicin. Quinine may also cause symptomatic relief of myotonia congenita. This disease is the pharmacological antithesis of myasthenia gravis, such that drugs effective in one syndrome aggravate the other.

Absorption, Fate, and Excretion. Quinine is readily absorbed when given orally or intramuscularly. In the former case, absorption occurs mainly from the upper small intestine and is >80% complete, even in patients with marked diarrhea. After an oral dose, plasma levels reach a maximum in 3–8 hours and, after distributing into an apparent volume of ~1.5 L/kg in healthy individuals, decline with a \( t_{1/2} \) of ~11 hours. The pharmacokinetics of quinine may change according to the severity of malarial infection (Krishna and White, 1996). Values for both the apparent volume of distribution and the systemic clearance of quinine decrease, the latter more than the former, such that the average elimination \( t_{1/2} \) increases to 18 hours. In patients with severe infection, standard therapeutic doses may produce peak plasma levels of quinine as high as 15-20 mg/L without causing major toxicity. In contrast, levels >10 mg/L can produce severe drug reactions. The high levels of plasma \( \alpha \)-acid glycoprotein produced in severe malaria may prevent toxicity by binding quinine and thereby reducing the free fraction of drug. Concentrations of quinine are lower in erythrocytes (33-40%) and CSF (2-5%) than in plasma, and the drug readily reaches fetal tissues.

The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4; thus only ~20% of an administered dose is excreted in an unaltered form in the urine. These drugs do not accumulate in the body upon continued administration. However, the major metabolite of quinine, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure. Renal excretion of quinine itself is more rapid when the urine is acidic.

Therapeutic Uses. Quinine and quinidine have historically been treatments of choice for drug-resistant and severe \emph{P. falciparum} malaria. However, the advent of artemisinin therapy is changing this situation because both oral and intravenous artemisinins have entered clinical practice (Table 49–3). In severe illness, the prompt use of loading doses of intravenous quinine (or quinidine, where intravenous quinine is not available, as is the case in the U.S.) is imperative and can be lifesaving. Oral medication to maintain therapeutic concentrations is then given as soon as tolerated and is continued for 5-7 days. Especially for treatment of infections with multidrug-resistant strains of \emph{P. falciparum}, slower-acting blood schizonticides such as tetracyclines or clindamycin are given concurrently to enhance quinine efficacy. Formulations of quinine and quinidine and specific regimens for their use in the treatment of \emph{P. falciparum} malaria are shown in Table 49–3.

In a series of studies over the past two decades, White and associates designed rational regimens, including the institution of loading doses, for the use of quinine and quinidine in the treatment of \emph{P. falciparum} malaria in Southeast Asia (Krishna and White, 1996). Between 0.2 and 2.0 mg/L has been estimated as the therapeutic range for “free” quinine. Regimens needed to achieve this target may vary
based on patient age, severity of illness, and the responsiveness of *P. falciparum* to the drug. For example, lower doses are more effective in treating children in Africa than adults in Southeast Asia because the pharmacokinetics of quinine differ in the two populations, as does the susceptibility of *P. falciparum* to the drug (Krishna and White, 1996). Dosage regimens for quinidine are similar to those for quinine, although quinidine binds less to plasma proteins and has a larger apparent volume of distribution, greater systemic clearance, and shorter terminal elimination t1/2 than quinine (Griffith et al., 2007; Miller et al., 1989). Thompson et al. (2003) suggest that the dose of quinidine currently recommended by the CDC (10 mg salt/kg initially, followed by 0.02 mg salt/kg per minute) may be too low and should be 10 mg salt/kg and 0.02 mg/kg of base/minute (60% of the salt is base). Clinical data on which to base a firm recommendation are lacking.

*Treatment of Nocturnal Leg Cramps.* It is commonly believed that night cramps might be relieved by quinine taken at bedtime at a dose of 200-300 mg (available until 1995 in products that did not require a prescription). Some consider this condition severe. The degree of symptomatic relief appears to vary substantially between individuals. In 1995, the FDA issued a ruling that required drug manufacturers to stop marketing over-the-counter quinine products for nocturnal leg cramps, stating that data supporting safety and efficacy of quinine for this indication were inadequate and that risks outweighed the potential benefits.

**Toxicity and Side Effects.** The fatal oral dose of quinine for adults is ~2-8 g. Quinine is associated with a triad of dose-related toxicities when given at full therapeutic or excessive doses. These are cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism—consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension—occur frequently and disappear soon after the drug is withdrawn. Hypoglycemia is also common, mostly in the treatment of severe malaria, and can be life threatening if not treated promptly with intravenous glucose. Hypotension is rarer but also serious and most often is associated with excessively rapid intravenous infusions of quinine or quinidine. Prolonged medication or high single doses also may produce GI, cardiovascular, and skin manifestations, as discussed next.

Hearing and vision are particularly affected. Functional impairment of the eighth nerve results in tinnitus, decreased auditory acuity, and vertigo. Visual signs consist of blurred vision, disturbed color perception, photophobia, diplopia, night blindness, constricted visual fields, scotomata, mydriasis, and even blindness (Bateman and Dyson, 1986). These visual and auditory effects probably result from direct neurotoxicity, although secondary vascular changes may have a role. Marked spastic constriction of the retinal vessels leads to retinal ischemia, pale optic discs, and retinal edema, with the potential for severe optic atrophy.

GI symptoms are also prominent in cinchonism. Nausea, vomiting, abdominal pain, and diarrhea result from the local irritant action of quinine, but the nausea and emesis also have a central basis. Cutaneous manifestations may include flushing, sweating, rash, and angioedema, especially of the face. Quinine and quinidine, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells. Despite treatment with glucose infusions, this complication can be serious and possibly life threatening, especially in pregnancy and prolonged severe infection. Hypoglycemia is seen occasionally in uninfected patients who take quinine.

Quinine rarely causes cardiac complications unless therapeutic plasma concentrations are exceeded (Krishna and White, 1996). QTc prolongation is mild and does not appear to be affected by concurrent mefloquine treatment. Acute overdosage also may cause serious and even fatal cardiac dysrhythmias such as sinus arrest, junctional rhythms, AV block, and ventricular tachycardia and fibrillation (Bateman and Dyson, 1986). Quinidine is even more cardiotoxic than quinine. Cardiac monitoring of patients on intravenous quinidine is advisable where possible.

Severe hemolysis can result from hypersensitivity to these cinchona alkaloids. Hemoglobinuria and asthma from quinine may occur more rarely. “Blackwater fever”—the triad of massive hemolysis, hemoglobinemia, and hemoglobinuria leading to anuria, renal failure, and in some instances death—is a rare type of hypersensitivity reaction to quinine therapy that can occur during treatment of malaria. Quinine may cause milder hemolysis upon occasion, especially in people with G6PD deficiency. Thrombotic thrombocytopenic purpura is a rare but clinically significant adverse effect. This reaction can occur even in response to ingestion of tonic water, which has ~4% the therapeutic oral dose per 12 oz (“cocktail purpura”). Other rare adverse effects include hypoprothrombinemia, leukopenia, and agranulocytosis.

**Precautions, Contraindications, and Interactions.** Quinine must be used with considerable caution, if at all, in patients who manifest hypersensitivity (balanced against risks primarily of not urgently treating severe malaria in the absence of other effective antimalarial drugs). Quinine should be discontinued immediately if evidence of hemolysis appears.

This drug should be avoided in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of quinine requires the same precautions as for quinidine. Quinine appears to be safe in pregnancy and is used commonly for the treatment of pregnancy-associated malaria. However, glucose levels must be monitored because of the increased risk of hypoglycemia.

Because parenteral solutions of quinine and quinidine are highly irritating, the drug should not be given subcutaneously. Concentrated solutions may cause abscesses when injected intramuscularly, or thrombophlebitis when infused intravenously. Antacids that contain aluminum can delay absorption of quinine from the GI tract. Quinine and quinidine can delay the absorption and elevate plasma levels of digoxin and related cardiac glycosides. Likewise, these alkaloids may raise plasma levels of warfarin and related anticoagulants. The action of quinine at neuromuscular junctions enhances the effect of neuromuscular blocking agents and opposes the action of acetylcholinesterase inhibitors. Prochlorperazine can amplify quinine’s cardiotoxicity, as can halofantrine. The renal clearance of quinine can be decreased by cimetidine and increased by urine acidification and by rifampin.
Mefloquine

History. Mefloquine (LARIAM) is a product of the Malaria Research Program established by the Walter Reed Institute for Medical Research in 1963 to develop promising new compounds to address the alarming growth of drug-resistant malaria. Of the many 4-quinoline methanols tested based on their structural similarity to quinine, mefloquine displayed high antimalarial activity in animal models, and emerged from clinical trials as safe and effective against drug-resistant strains of *P. falciparum*. Mefloquine was first used to treat chloroquine-resistant *P. falciparum* malaria in Thailand. However, the slow elimination of mefloquine fostered the emergence of drug-resistant parasites.

Chemistry. The structure of the mefloquine raceme is illustrated in Figure 49–2. Recent work has demonstrated that the (−)-enantiotomer is associated with adverse CNS effects, whereas the (+)-enantiotomer retains antimalarial activity with fewer side effects. Mefloquine can be reacted with artesunate, thereby reducing the selection pressure for resistance. This combination has proved efficacious for the treatment of *P. falciparum* malaria, even in regions with high prevalence of mefloquine-resistant parasites.

Mechanisms of Action and Parasite Resistance. Mefloquine is a highly effective blood schizonticide. However, it possesses no activity against hepatic stages or mature gametocytes of *P. falciparum* or latent tissue forms of *P. vivax*.

Earlier work showed that mefloquine associates with intraerythrocytic hemozoin, suggesting similarities to the mode of action of chloroquine (Sullivan et al., 1998). However, evidence that this association might be secondary to a primarily cytosolic mode of action comes from studies with transgenic *P. falciparum* lines expressing different *pfmdr1* copy numbers. Increased *pfmdr1* copy numbers are associated with both reduced parasite susceptibility to mefloquine (and artemisinin) and increased PfMDR1-mediated solute import into the digestive vacuole of intraerythrocytic parasites (Rohrbach et al., 2006). Therefore, if the drug’s target resides outside of this vacuolar compartment, increased import of mefloquine into the digestive vacuole, potentially driven by PfMDR1 activity, would be beneficial for the parasite and reduce its susceptibility to the drug.

A comprehensive clinical and molecular epidemiological study conducted with parasites from Thailand identified *pfmdr1* gene amplification as a major determinant of mefloquine treatment failure and *in vitro* mefloquine resistance (Price et al., 2004). Some individuals in that study nonetheless failed mefloquine treatment despite not having parasites with multiple *pfmdr1* copies, implying secondary mechanisms of resistance. Mefloquine susceptibility *in vitro* can also be affected by the presence of point mutations in *pfmdr1* or *pfcrt* (Valderramos and Fidock, 2006).

Absorption, Fate, and Excretion. Mefloquine is taken orally because parenteral preparations cause severe local reactions. The drug is rapidly absorbed, with marked variability between individuals. Probably owing to extensive enterogastric and enterohepatic circulation, plasma levels of mefloquine rise in a biphasic manner to their peak in ~17 hours. Mefloquine has a variable and long t1/2, 13-24 days, reflecting its high lipophilicity, extensive tissue distribution, and extensive binding (~98%) to plasma proteins. Mefloquine is extensively metabolized in the liver. CYP3A4 has been implicated in the metabolism of mefloquine; this CYP can be inhibited by ketoconazole and induced by rifampicin (German and Aweke, 2008). Excretion of mefloquine is mainly by the fecal route; only ~10% of mefloquine appears unchanged in the urine. The stereoisomers of mefloquine exhibit quite different pharmacokinetic characteristics that relate to their biodisposition (Hellgren et al., 1997).

Therapeutic Uses. Mefloquine should be reserved for the prevention and treatment of malaria caused by drug-resistant *P. falciparum* and *P. vivax*, but it is no longer considered first-line treatment of malaria in most clinical contexts. The drug is especially useful as a chemoprophylactic agent for travelers spending weeks, months, or years in areas where these infections are endemic (Table 49–2). In areas where malaria is due to multiply drug-resistant strains of *P. falciparum* (particularly in Southeast Asia), mefloquine is more effective when used in combination with an artemisinin compound.

Toxicity and Side Effects. The use of mefloquine for the chemoprophylaxis or treatment of malaria must balance concerns about clinically significant risks and benefits. The major adverse effects of mefloquine have been reviewed in detail (Chen et al., 2006). Mefloquine given orally is generally well tolerated at chemoprophylactic dosages, although vivid dreams are common. Significant neuropsychiatric signs and symptoms can occur in 10% (or more) of people receiving treatment doses, although serious adverse events (psychosis, seizures) are rare. Short-term adverse effects of treatment include nausea, vomiting, and dizziness. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within the first hour.

Estimates for frequency of severe CNS toxicity after mefloquine treatment can be as high as 0.5%. Adverse reactions include seizures, confusion or decreased sensorium, acute psychosis, and disabling vertigo. Such symptoms generally are reversible upon drug discontinuation. At chemoprophylactic dosages, the risk of serious neuropsychiatric effects is estimated to be ~0.01% (about the same as for chloroquine). Mild-to-moderate toxicities (e.g., disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at chemoprophylactic dosages. Whether these symptoms are more common than with other antimalarial regimens is debated. Adverse effects usually manifest after the first to third doses and often abate even with continued treatment. Reports of cardiac abnormalities, hemolysis, and agranulocytosis are rare.

Contraindications and Interactions. At very high doses, mefloquine is teratogenic in rodents. Studies have suggested an increased rate of stillbirths with mefloquine use, especially during the first trimester (Taylor and White, 2004). The significance of these data has been debated, but it is fair to say that the evidence for mefloquine’s safety in pregnancy is not convincing, and mefloquine may be used if it is the only available treatment option. Pregnancy should be avoided...
for 3 months after mefloquine use because of the prolonged $t_{1/2}$ of this agent.

This drug is contraindicated for patients with a history of seizures, depression, bipolar disorder and other severe neuropsychiatric conditions, or adverse reactions to quinoline antimalarials such as quinine, quinidine, halofantrine, mefloquine, and chloroquine. Mefloquine may counteract seizures in epileptic patients. Although this drug can be taken safely 12 hours after a last dose of quinine, taking quinine shortly after mefloquine can be very hazardous because the latter is eliminated so slowly. Treatment with or after halofantrine or within 2 months of prior mefloquine administration is contraindicated.

Recent studies do not indicate that mefloquine compromises the performance of tasks that require good motor coordination, e.g., driving or operating machinery. Although some advise against the use of mefloquine for patients in occupations that require focused concentration, dexterity and cognitive function in safety-sensitive settings, such as pilots, controlled studies suggest that mefloquine does not impair performance in persons who tolerate the drug.

Primaquine

**History.** The weak anti-*Plasmodium* activity of methylene blue, first discovered by Ehrlich in 1891, led to the development of the 8-aminoquinoline antimalarials, of which pamaquine was the first introduced into medicine. During World War II the search for more potent and less toxic 8-aminoquinoline antimalarials resulted in the discovery of primaquine (Figure 49–2). Primaquine, in contrast to other antimalarials, acts on exo-erythrocytic tissue stages of plasmodia in the liver to prevent and cure relapsing malaria. The striking hemolysis that may follow primaquine therapy led directly to the landmark discovery of G6PD deficiency, the first genetic disorder associated with an enzyme. Hemolysis remains notoriously identified with primaquine. Patients should be screened for G6PD deficiency prior to therapy with this drug. The pressing need for alternatives to this important drug has resulted in the evaluation of multiple 8-aminoquinoline analogs (Vale et al., 2009). These include tafenoquine, a compound under clinical evaluation that is active against relapsing liver stage forms of *P. vivax*, and multidrug resistant asexual blood stage forms of *P. falciparum* (Wells et al., 2009).

**Mechanisms of Action and Parasite Resistance.** Primaquine acts against primary and latent hepatic stages of *Plasmodium spp.*, and prevents relapses in *P. vivax* and *P. ovale* infections. This drug and other 8-aminoquinolines also display gametocytocidal activity against *P. falciparum* and other *Plasmodium* species. However, primaquine is inactive against asexual blood stage parasites.

The mechanism of action of the 8-aminoquinolines has not been elucidated. Primaquine may be converted to electrophilic intermediates that act as oxidation-reduction mediators. Such activity could contribute to antimalarial effects by generating reactive oxygen species or by interfering with mitochondrial electron transport in the parasite (Vale et al., 2009). Some strains of *P. vivax* can exhibit partial resistance to primaquine (Baird, 2009).

**Absorption, Fate, and Excretion.** Absorption of primaquine from the GI tract approaches 100%. After a single dose, the plasma concentration reaches a maximum within 3 hours and then falls with a variable elimination $t_{1/2}$ averaging 7 hours.

The apparent volume of distribution is several times that of total-body water, due to extensive tissue distribution. Primaquine binds preferentially to the acute-phase reactant protein α1-glycoprotein, which may alter the distribution of free drug depending on its concentration in the blood. Primaquine is metabolized rapidly, and only a small fraction of an administered dose is excreted as the parent drug. Importantly, primaquine induces CYP1A2. Thus, caution should be taken in administering primaquine with drugs metabolized by CYP1A2 (including warfarin) (Hill et al., 2006). The major metabolite, carboxyprimaquine, is inactive.

**Therapeutic Uses.** Primaquine is used primarily for terminal chemoprophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) infections because of its high activity against the latent tissue forms (hypnozoites) of these *Plasmodium* species. The compound is given together with a blood schizonticide, usually chloroquine, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance.

For terminal chemoprophylaxis, primaquine regimens should be initiated shortly before or immediately after a subject leaves an endemic area (Table 49–2). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during an asymptomatic latent period of presumed infection (based on travel to or residence within an endemic region) or during an acute attack. Simultaneous administration of a schizonticidal drug plus primaquine is more effective in radical cure than sequential treatment. Limited studies have shown efficacy in prevention of *P. falciparum* and *P. vivax* malaria when primaquine is taken as chemoprophylaxis (Taylor and White, 2004). Gametocytocidal activity of primaquine should also reduce the transmission potential during drug treatment of *P. falciparum*. However, this approach to prophylaxis is not routine clinical practice. Primaquine is generally well tolerated when taken for up to 1 year.

**Toxicity and Side Effects.** Primaquine has few side effects when given to most whites in the usual therapeutic doses. Primaquine can cause mild to moderate abdominal distress in some individuals. Taking the drug at mealtime often alleviates these symptoms. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60-240 mg daily) worsen the abdominal symptoms and cause some degree of methemoglobinemia in most subjects. Methemoglobinemia can occur even with usual doses of primaquine and can be severe in individuals with congenital deficiency of NADH methemoglobin reductase (Coleman and Coleman, 1996). Chloroquine and dapsone may synergize with primaquine to produce methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdose. Other rare adverse reactions are hypertension, arrhythmias, and symptoms referable to the CNS.
Therapeutic or higher doses of primaquine may cause acute hemolysis and hemolytic anemia in humans with G6PD deficiency (Vale et al., 2009). This X-linked condition, primarily owing to amino acid substitutions in the G6PD enzyme, affects >200 million people worldwide. More than 400 genetic variants of G6PD produce variable responses to oxidative stress. About 11% of African Americans have the A variant of G6PD, and are therefore vulnerable to hemolysis caused by pro-oxidant drugs such as primaquine. G6PD deficiency is uncommon in Latin America but may be present in those residents of African descent. Primaquine-induced hemolysis can be even more severe in white ethnic groups, including Sardinians, Sephardic Jews, Greeks, and Iranians; these populations have a G6PD variant in which two amino acid substitutions impair both enzyme stability and activity. Because primaquine sensitivity is inherited through an X-linked gene, hemolysis is often of intermediate severity in heterozygous females who have two populations of red blood cells, one normal and the other deficient in G6PD. Owing to “variable penetrance,” these females may be affected less frequently than predicted. Primaquine is the prototype of >50 drugs, including antimalarial sulfonamides, that cause hemolysis in G6PD-deficient individuals.

Precautions and Contraindications. G6PD deficiency should be ruled out prior to administration of primaquine. Primaquine has been used cautiously in subjects with the A form of G6PD deficiency, although benefits of treatment may not necessarily outweigh the risks. The drug should not be used in patients with more severe deficiency. If a daily dose of >30 mg primaquine base (>15 mg in potentially sensitive patients) is given, then blood counts should be followed carefully. Patients should be counseled to look for dark or blood-colored urine, which would indicate hemolysis. Primaquine should not be given to pregnant women, and, in treating lactating mothers, it should be prescribed only after ascertaining that the breast-feeding infant has a normal G6PD level (which can be difficult to assess soon after birth).

Primaquine is contraindicated for acutely ill patients suffering from systemic disease characterized by a tendency to granulocytopenia (e.g., active forms of rheumatoid arthritis and lupus erythematosus). Primaquine should not be given to patients receiving other drugs capable of causing hemolysis or depressing the myeloid elements of the bone marrow.

SULFONAMIDES AND SULFONES

**History.** Shortly after their introduction into clinical practice, the sulfonamides were found to have antimalarial activity, a property investigated extensively during World War II. The efficacy of sulfones was demonstrated in the first trial of dapsone against *P. falciparum* in 1943. The sulfonamides combined with pyrimethamine have been used to treat chloroquine-resistant *P. falciparum* malaria, particularly in parts of Africa. The sulfonamides and sulfones are slow-acting blood schizonticides and more active against *P. falciparum* than *P. vivax*.

**Mechanism of Action.** Sulfonamides are *p*-aminobenzoic acid analogs that competitively inhibit *Plasmodium* dihydropteroate synthase. These agents are combined with an inhibitor of parasite dihydrofolate reductase to enhance their antimalarial action. The synergistic “antifolate” combination of sulfadoxine, a long-acting sulfonamide, with pyrimethamine has been extensively used to treat malaria. As observed for pyrimethamine, sulfadoxine resistance appeared quickly in vivo after the introduction of this treatment as monotherapy.

**Drug Resistance.** Sulfadoxine resistance is conferred by several point mutations in the dihydropteroate synthase gene; the more widespread is the substitution Ala437Gly. These sulfadoxine-resistance mutations, when combined with mutations of dihydrofolate reductase and conferring pyrimethamine resistance, greatly increase the likelihood of sulfadoxine-pyrimethamine treatment failure. Sulfadoxine-pyrimethamine, given intermittently during the second and third trimesters of pregnancy, is a routine component of antenatal care throughout Africa. Intermittent preventive treatment strategies might also benefit infants (Aponte et al., 2009). However, there are substantial concerns about these strategies in the face of the expanding profile of resistance to pyrimethamine-sulfadoxine. A recent report found that intermittent preventive treatment in pregnancy exacerbated placental inflammation and caused increased levels of parasitemia and increased selective pressure for drug-resistant infections (Harrington et al., 2009). Thus, there is a clear need to identify alternative intermittent preventive treatment regimens. Generally, one can anticipate that, in the absence of novel antifolates effective against existing drug-resistant strains, the use of these antimalarials for either prevention or treatment will continue to decline.

**TETRACYCLINES AND OTHER ANTIBIOTIC AGENTS**

Tetracyclines are a group of antibiotic agents initially derived from *Streptomyces*. The pharmacological properties of tetracyclines are presented in Chapter 55. Two members of this group, tetracycline and doxycycline, are useful in malaria treatment. In addition, clindamycin, a lincomamide antibiotic (Chapter 55), is also recommended. These agents are slow-acting blood schizonticides that can be used alone for short-term chemoprophylaxis in areas with chloroquine- and mefloquine-resistant malaria (only doxycycline is recommended for malaria chemoprophylaxis). All of these antibiotics act via a delayed death mechanism resulting from their inhibition of protein translation in the parasite plastid. This effect on malarial parasites manifests as death of the progeny of drug-treated parasites, resulting in slow onset of antimalarial activity (Dahl and Rosenthal, 2008). Their relatively slow mode of action makes these drugs ineffective as single agents for malaria treatment. However, their efficacy as treatment is increased when they are used as an adjunct to quinine, quinidine, or artesunate, and in this context, they can be used to treat uncomplicated or severe *P. falciparum* malaria. These antibiotics are not clinically used to eliminate liver stage infection.

Dosage regimens for tetracyclines and clindamycin are listed in Tables 49–2 and 49–3. Because of their adverse effects on bones
and teeth, tetracyclines should not be given to pregnant women or to children <8 years of age. In these subjects, clindamycin is a reasonable alternative. Photosensitivity reactions or drug-induced superinfections may mandate discontinuation of therapy or chemoprophylaxis with tetracyclines. As an alternative antibiotic, the macrolide azithromycin also displays antimalarial activity through a similar delayed-death mechanism and is undergoing further evaluation. As with clindamycin, azithromycin is safe for use in young children and pregnant women.

**PRINCIPLES AND GUIDELINES FOR CHEMOPROPHYLAXIS AND CHEMOTHERAPY OF MALARIA**

Pharmacological prevention of malaria poses a difficult challenge because *Plasmodium falciparum*, which causes nearly all the deaths from human malaria, has become progressively more resistant to available antimalarial drugs. Chloroquine had been the drug of choice to prevent all forms of malaria until resistance became widespread in the past decades. Chloroquine remains effective against malaria caused by *P. ovale*, *P. malariae*, *P. knowlesi*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum* found in some geographic areas. However, chloroquine-resistant strains of *P. falciparum* are now the rule, not the exception, in most malaria-endemic regions except Mexico, Central America west of the Panama Canal Zone, the Caribbean, and parts of the Middle East (Figure 49–3). Except for parts of Africa, extensive geographic overlap also exists between chloroquine resistance and resistance to pyrimethamine-sulfadoxine. Multidrug-resistant *P. falciparum* malaria is especially prevalent and severe in Southeast Asia and Oceania. These infections may not respond adequately even to mefloquine or quinine.

Genetic studies indicate that isolates of *P. falciparum* from patients in highly endemic areas contain many parasite clones with different drug resistance phenotypes (Druilhe et al., 1998). A patient with severe malaria may have up to $10^{12}$ parasites. Because single point mutations occur with an estimated frequency of $10^{-9}$, based on *in vitro* studies (Cooper et al., 2002), single point mutations that confer resistance could potentially arise in virtually every patient and double point mutations would arise occasionally. Most of these new mutant strains will not survive because of immunity, decreased fitness, and additional factors; nonetheless, successful drugs or drug combinations must ideally not be susceptible to resistance resulting from single point mutations. Mutations by gene amplification are expected to be even more frequent than single point mutations (Nair et al., 2008). Looking back in time, one notes that decades of intense chloroquine use preceded development of resistance to this agent. This delay was likely due to the requirement for at least four point mutations in the *pfcrt* gene to confer resistance (Valderramos and Fidock, 2006). Pharmacokinetics can also be a determinant in the generation of resistance. Drugs with a long $t_{1/2}$ are thought to generally be more likely to select for resistance (White, 2004).

On a population level, the fitness of resistant parasites is another important parameter: If mutation causes a reduced ability to survive or grow, the parasites are less likely to spread. However, in the case of antifolates, treatment actually induces gametocyto genesis, which promotes transmission; this effect, together with other forces (intense selection pressure from preventive drug use; parasite migrations driven by humans), may explain the spread of particular resistance alleles across Southeast Asia and Africa. These considerations strongly argue for regimens that combine two or more antimalarial agents with different mechanisms of action (and therefore, hopefully, with different mechanisms of resistance) to treat drug-resistant *P. falciparum* malaria (White, 2004). ACTs are the most important combination treatment currently available.

The following section presents an overview of the chemoprophylaxis and chemotherapy of malaria. For more current details about individual drugs, their clinical and chemoprophylactic applications, and about malaria risk areas, consult the latest information available from the CDC (www.cdc.gov/travel/travel). Consultation and emergency advice about treatment are available 24 hours a day from the duty officer, Division of Parasitic Diseases, CDC.

Current CDC recommendations for drugs and dosing regimens for the chemoprophylaxis and treatment of malaria in nonimmune individuals are shown in Tables 49–2 and 49–3. These will change and should serve only as general guidelines to be modified appropriately according to the status and habitat of the patient; the geographic origin, species, and drug-resistance profile of infecting parasites; and the agents used for malaria prevention.

Importantly, drugs should not replace simple, inexpensive measures for malaria prevention. Individuals visiting malarious areas should take appropriate steps to prevent mosquito bites. One such measure is to avoid exposure to mosquitoes at dusk and dawn, usually the times of maximal feeding. Others include using insect repellents containing at least 30% *N,N*-diethylmetatoluamide (DEET) and sleeping in well-screened rooms or under bed nets impregnated with a pyrethrin insecticide such as permethrin (Kain and Jong, 2003).

**Malaria Chemoprophylaxis.** Regimens for malaria chemoprophylaxis include primarily three drugs: atovaquone-proguanil and doxycycline that can both be used in all areas, and mefloquine that can be used in areas with mefloquine-sensitive malaria. Other available options are chloroquine or hydroxychloroquine (but their use is restricted to the few areas with chloroquine-sensitive malaria), and primaquine (for short duration travel to areas with principally *P. vivax*).
In general, dosing should be started before exposure, ideally before the traveler leaves home, to establish therapeutic blood levels and to detect early signs or symptoms of intolerance so the regimen can be modified before departure. As described earlier, the duration of post-exposure dosing is dictated by the spectrum of drug action (Table 49–1).

In those few areas where chloroquine-sensitive strains of *P. falciparum* are found, chloroquine is still suitable for chemoprophylaxis. It also remains the drug of choice for chemoprophylaxis and control of infections due to *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. In areas where chloroquine-resistant malaria is endemic, mefloquine and atovaquone-proguanil are the regimens of choice for chemoprophylaxis. There is more experience with mefloquine and more evidence for its efficacy against *P. vivax*, an important consideration in areas where this species co-exists with *P. falciparum*. However, there are more contraindications to the use of mefloquine and perhaps greater toxicity than for alternative regimens. Doxycycline is an alternative chemoprophylactic agent. In cases where mefloquine, atovaquone-proguanil, and doxycycline all are contraindicated, primaquine is a possibility for chemoprophylaxis. Primaquine, like atovaquone-proguanil, is active against liver stages and can be discontinued shortly after leaving the endemic area. Attempts at radical cure of *P. vivax* malaria with primaquine should be delayed until the patient leaves an endemic area.

For chemoprophylaxis in long-term travelers, chloroquine is safe at the doses used, but some recommend yearly retinal examinations, and there is a finite dose limit for which chemoprophylaxis with chloroquine is recommended because of ocular toxicity (Tehrani et al., 2008). Mefloquine and doxycycline are well tolerated. Mefloquine is the best documented drug for long-term travelers and, if well tolerated, can be used for prolonged periods. Atovaquone-proguanil has been studied for up to 20 weeks but probably is acceptable for years based on experience with the individual components.

The diagnosis of malaria must be considered for patients presenting with acute febrile illness after returning from a malaria-endemic region (Table 49–5). If proven to be malaria, such an illness should be considered a medical emergency, especially for vulnerable populations such as nonimmune travelers, pregnant women, and young children. Severe *P. falciparum* malaria is as acute as any other life-threatening illness and demands close attention and aggressive treatment. An organized, rational approach to diagnosis, parasite identification, and appropriate treatment is crucial (see Figure 49–4). Treatment with a rapidly acting blood schizonticide must be instituted promptly if *P. falciparum* malaria is suspected from a travel history and clinical findings. One should not wait for a definitive parasitological diagnosis to initiate therapy in such patients because their clinical status may deteriorate rapidly. Moreover, the clinical presentation may be atypical, and thick blood smears may fail to reveal malarial parasites in early stages of this infection.

### Table 49–5

**Criteria for the Diagnosis of Malaria**

<table>
<thead>
<tr>
<th>Signs and symptoms consistent with malaria, including fever, chills, headache, ± severe malaria criteria (below), plus</th>
</tr>
</thead>
<tbody>
<tr>
<td>Demonstration of the presence of malaria parasite:</td>
</tr>
<tr>
<td>Light microscope examination of stained thin or thick smear</td>
</tr>
<tr>
<td>Rapid diagnostic test</td>
</tr>
<tr>
<td>Molecular or biophysical-based testing</td>
</tr>
</tbody>
</table>

**Criteria for the Diagnosis of Severe Malaria**

- Prostration
- Impaired consciousness/coma
- Respiratory distress (acidotic breathing)
- Multiple convulsions
- Circulatory shock
- Pulmonary edema
- Acute respiratory distress syndrome
- Abnormal bleeding

- Jaundice
- Severe anemia
- Acute renal failure
- Disseminated intravascular coagulation
- Acidosis
- Hemoglobinuria
- Parasitemia >5%

Guidelines for treatment of malaria in the U.S. are provided by the CDC and are shown in Table 49–3. Updates should be checked on the CDC website. Figure 49–4 presents an overview of the general strategy for treatment of malaria in the U.S.

**Treatment of Uncomplicated Malaria.** Chloroquine is the drug of choice for *P. ovale, P. malariae, P. knowlesi*, and chloroquine-sensitive strains of *P. vivax* and *P. falciparum*. For *P. vivax* and *P. ovale* infections, a 2-week course of primaquine should be added to eradicate hypnozoites that may remain dormant in the liver, and thus prevent relapse. Some patients with *P. vivax* infection may require more than one course of primaquine to obtain radical cure. Primaquine must not be given to patients with G6PD deficiency or to pregnant women. The oral route of administration should be used if feasible. Within 48–72 hours of initiating therapy, patients should show marked clinical improvement (especially clearance of fever) and a substantial decrease in parasitemia as monitored by daily thin and thick blood smears. Under controlled administration of treatment, lack of such a response or failure to clear asexual forms of the parasite from the blood by 7 days suggests the presence of drug resistance (except for atovaquone-proguanil).

---

Figure 49–4. Approach to the treatment of malaria. Atovaquone-proguanil, mefloquine, artemether-lumefantrine, tetracycline, and doxycycline are not indicated during pregnancy. Tetracycline and doxycycline are not indicated in children <8 years of age. G6PD, glucose-6-phosphate dehydrogenase. (Adapted from Griffith KS, Lewis LS, Mali S, Parise ME. Treatment of malaria in the United States: A systematic review. *JAMA*, 297(20):2264–77, 2007, with permission of the American Medical Association © 2007. All rights reserved.)
For clinical classification of drug resistance, see Bloland (2001). In endemic settings, recrudescence of \textit{P. falciparum} clinical episodes or asymptomatic parasitemia after appropriate treatment can also be due to reinfection.

For uncomplicated malaria caused by chloroquine-resistant \textit{P. falciparum} (suspected either from travel history or lack of response to chloroquine) or by a species not yet identified, four treatment options are available:

- Artemether-lumefantrine
- Atovaquone-proguanil
- Oral quinine given along with other effective but slower-acting blood schizonticides such as tetracyclines (preferably doxycycline) or clindamycin
- Mefloquine

The oral route of drug administration is preferred, but intravenous preparations may be administered until oral medication can be taken. Malaria caused by chloroquine-resistant \textit{P. vivax} can be treated by mefloquine, atovaquone-proguanil, or quinine (plus tetracyclines), all combined with a course of primaquine.

**Treatment of Severe Malaria.** For severe malaria (see Table 49–5 for diagnostic criteria), whatever the region where the infection was acquired, the recommended treatments are based on intravenous artesunate or quinidine plus a second drug (Figure 49–4). Artesunate, now available in the U.S. from the CDC under an investigational new drug protocol, should be followed by atovaquone-proguanil, clindamycin, or mefloquine. Quinidine must be substituted for quinine (no longer available) and combined with doxycycline, tetracycline, or clindamycin (reviewed in Griffith et al., 2007). Exchange transfusion may be of additional value in severe \textit{P. falciparum} malaria with high levels of parasitemia (Griffith et al., 2007; Miller et al., 1989).

Children and pregnant women are the most susceptible to severe malaria. With appropriate dosage adjustments and safety precautions, the treatment of children generally is the same as for adults (pediatric dose should never exceed adult dose). However, tetracyclines should not be given to children <8 years of age except in an emergency, and atovaquone-proguanil as treatment has been approved only for children weighing >5 kg (for current information, see the CDC website and Boggild et al., 2007).

**Chemoprophylaxis and Treatment During Pregnancy.** Pregnant women should be urged not to travel to endemic areas if possible (Freedman, 2008). Chemoprophylaxis during pregnancy is complex, and women should evaluate with expert medical staff the benefits and risks of different strategies with regard to their particular situation. Severe malaria during pregnancy should be treated with intravenous antimalarial treatment according to the general guidelines for severe malaria, taking into account the drugs that should be avoided during pregnancy.

Among the antimalarial treatments available in the U.S., many should not be used during pregnancy because of lack of sufficient formal safety data (antifolates, atovaquone-proguanil, and artemether-lumefantrine) or known potential risks for the fetus (tetra-cycline, doxycycline, primaquine, and mefloquine). The recommended treatment of uncomplicated malaria during pregnancy relies on chloroquine in areas with chloroquine-sensitive parasites, and quinine, alone (in \textit{P. vivax} infections) or in combination with clindamycin (in \textit{P. falciparum} infections), in areas with chloroquine-resistant parasites. Appropriate caution should be exercised when administering quinine, given the frequency of hypoglycemia as an adverse reaction in pregnant women. Pregnant patients with \textit{P. vivax} or \textit{P. ovale} infections should be kept under chloroquine chemoprophylaxis until delivery. After delivery, and after verifying that the patient is not G6PD deficient, treatment with primaquine should be initiated to eradicate hypnozoites. Atovaquone-proguanil and artemether-lumefantrine are not indicated because of lack of safety data. Mefloquine is also not indicated because of a possible association with increased risk of stillbirth. However, if recommended treatments are not available, these alternative options should be considered after balancing the potential benefits and risks for the fetus.

A recent study demonstrated better outcomes when pregnant women were treated with artesunate-atovaquone-proguanil compared with quinine; however, adequate safety data for the developing fetus are lacking (for review, see Dellicour et al., 2007). Another clinical trial recently showed that a standard six-dose oral artemether-lumefantrine regimen was well tolerated and safe in pregnant women with uncomplicated \textit{falciparum} malaria, but efficacy was inferior to 7-day artesunate monotherapy and was unsatisfactory for general deployment along the Thai Cambodian border, probably resulting from low drug concentrations in later pregnancy (McGready et al., 2008). The use of antimalarial drugs in pregnancy has been well reviewed (Ward et al., 2007).

In lactating mothers, treatment with most compounds is acceptable, although chloroquine and hydroxychloroquine are the preferred agents. The use of atovaquone-proguanil is not recommended unless breast-feeding infants weigh >5 kg. Also, the breast-feeding infant should be shown to have a normal G6PD level before receiving primaquine (Schlagenhauf and Petersen, 2008).

**New Targets, New Drugs.**

In the face of evolving drug resistance and the necessity to increase the useful life span of antimalarial drugs through combination therapies, novel and potent antimalarial drugs are urgently needed. The malaria research pipeline includes either compounds derived from known antimalarials through modification of their chemical structure (likely to retain activity against the original targets), drugs previously developed for other infectious organisms or diseases (and likely act on the same target in \textit{Plasmodium}), or inhibitors of novel targets (exploiting differences in the biology of host and parasite). This latter strategy of drug discovery benefits from the genome sequencing projects of the different \textit{Plasmodium} species and the human host. Perspectives in malaria chemotherapy (including new drug targets
and antimalarial drugs in discovery, preclinical and clinical phases) have recently been extensively discussed (Biot and Chibale, 2006; de Beer et al., 2009; Gardiner et al., 2009; Olliaro and Wells, 2009; Wells et al., 2009).

Among the novel antimalarial drugs undergoing clinical development, two notable examples act on new metabolic pathways:

1. **TE3**, a prodrug of a bis-aminomethyl compound that acts on phospholipid metabolism through the inhibition of de novo phospholipid synthesis, combined with a putative activity on heme detoxification. This new class of compounds has shown potent in vivo antimalarial activity in the primate model *Aotus* and is not cross resistance in vitro with known antimalarials.

2. **Fosmidomycin**, which inhibits the 1-desoxy-D-xylulose-5-phosphate reductosorase in the mevalonate-independent pathway of isoprenoid synthesis in the apicoplast (Wiesner and Jomaa, 2007). The apicoplast, a specialized parasite organelle of algal origin, appears to be important for lipid and heme biosynthesis, and is a major focus of current drug development efforts (Wiesner et al., 2008). Fosmidomycin was initially developed as an antibacterial drug, but has shown efficacy in combination with clindamycin or azithromycin against *P. falciparum* malaria.

A nonexhaustive list of the molecular targets under current experimental or clinical investigation includes two clinically validated antimalarial drug targets (dihydrofolate reductase and cytochrome bc1 complex), for which inhibitors are being developed to overcome existing resistance (this strategy is also being explored to derive new 4-aminoquinolines and amino-alcohols) and a series of novel, experimental antimalarial drug targets: dihydro- orotate dehydrogenase (involved in pyrimidine synthesis), purine nucleoside phosphorylase (nucleotide synthesis), adenosine deaminase (regulation of intracellular nucleoside pools), subtilisin-like proteases (egress from erythrocytes), falcipains (hemoglobin proteolysis), histone deacetylase (DNA replication), protein kinases (signal transduction), and fatty acid biosynthesis (apicoplast lipid synthesis). The rationale focusing on these targets for antimalarial drug development can be found in the reviews cited.

**CLINICAL SUMMARY**

Agents available for the treatment of acute malaria due to *Plasmodium falciparum* in the U.S. have been expanded beyond previously used quinolines (chloroquine, quinine/quinidine, mefloquine) with or without adjunctive doxycycline and clindamycin, to include atovaquone-proguanil and artemisinin derivatives: artemether plus lumefantrine approved for oral use, and intravenous artesunate (available from the CDC under an IND protocol). Mefloquine is no longer considered first-line therapy for the treatment of any form of malaria in the U.S. because of adverse effects in the higher treatment doses and the availability of better tolerated alternatives. Sulfadoxine-pyrimethamine is no longer reliable due to widespread resistance and diminished efficacy. Chloroquine resistance must be assumed for *P. falciparum* originating anywhere other than Mexico, Central America, and the Caribbean. Mefloquine resistance is likely for *P. falciparum* arising from border areas along Thailand and infections of similar geographic origin.

Chloroquine is the preferred drug in *P. vivax* infections originating in most geographic regions, with the exception of Papua New Guinea and Indonesia where resistance is prevalent. Radical therapy with primaquine is recommended to eradicate latent infection for both *P. vivax* and *P. ovale*, after normal erythrocyte levels of G6PD are confirmed. Primaquine is most effective if administered concurrently with the indicated therapy for acute malaria, although *P. vivax* in some regions seems to require higher or prolonged dosing to minimize the risk of relapse.

For malaria chemoprophylaxis, long-acting quinolines (chloroquine and mefloquine) are used, although they are of limited utility in specific geographic areas due to drug resistance. Because of a better side-effect profile, atovaquone-proguanil is often preferred. Doxycycline remains a viable option for malaria chemoprophylaxis, particularly in long-term travelers living in malaria-endemic regions where mefloquine resistance is present. Pregnant women should avoid travel to malaria-endemic regions. If travel cannot be avoided and the risk of contracting malaria is considered to exceed the risk of adverse effects on fetus, chloroquine and mefloquine are the drugs of choice.

Atovaquone-proguanil is now the only recommended drug for the presumptive self-treatment of malaria.

**BIBLIOGRAPHY**

Humans host a wide variety of protozoal parasites that can be transmitted by insect vectors, directly from other mammalian reservoirs or from one person to another. Because protozoa multiply rapidly in their hosts and effective vaccines are unavailable, chemotherapy has been the only practical way to both treat infected individuals and reduce transmission. The immune system plays a crucial role in protecting against the pathological consequences of protozoal infections. Thus, opportunistic infections with protozoa are prominent in infants, individuals with cancer, transplant recipients, those receiving immunosuppressive drugs or extensive antibiotic therapy, and persons with advanced human immunodeficiency virus (HIV) infection. Treatment of protozoal infections in immunocompromised individuals is especially difficult, and the outcome is often unsatisfactory.

Most antiprotozoal drugs have been in use for years despite major advances in bioscience relevant to parasite biology, host defenses, and mechanisms of disease. Satisfactory agents for treating important protozoal infections such as African trypanosomiasis (sleeping sickness) and chronic Chagas’ disease still are lacking. Many effective antiprotozoal drugs are toxic at therapeutic doses, a problem exacerbated by increasing drug resistance. Development of drug resistance also poses a serious threat to better tolerated antiprotozoal agents in current use. Unfortunately, many of these diseases afflict the poor in developing countries, and there is little economic incentive for pharmaceutical companies to develop new antiparasitic drugs. Scientists and physicians working in this field must be creative and have turned to drugs developed originally for other indications (e.g., amphotericin and miltefosine for leishmaniasis), to investigational drugs made available directly from the Centers for Disease Control and Prevention (CDC), or to agents developed for veterinary use to discover new antiparasitic therapies.

This chapter describes important human protozoal infections other than malaria and the drugs used to treat them.

**INTRODUCTION TO PROTOZOAL INFECTIONS OF HUMANS**

**Amebiasis.** Amebiasis affects ~10% of the world’s population, causing invasive disease in ~50 million people and death in ~100,000 of these annually (Stanley, 2003). In the U.S., amebiasis is seen most commonly in the states that border Mexico and among individuals living in poverty, crowded conditions, and areas with poor sanitation. Three morphologically identical but genetically distinct species of *Entamoeba* (i.e., *E. histolytica, E. dispar, and E. moshkovskii*) have been isolated from infected persons. Although the proportions vary worldwide, *E. dispar* and *E. moshkovskii* account for ~90% of human infections, with *E. histolytica* responsible for only 10%. However, only *E. histolytica* is capable of causing disease and thus requires treatment.
The organisms can be differentiated by antigen-detection enzyme-linked immunosorbent assays or by polymerase chain reaction (PCR)–based diagnostics. Humans are the only known hosts for these protozoa, which are transmitted almost exclusively by the fecal-oral route. Ingested *E. histolytica* cysts from contaminated food or water survive acid gastric contents and transform into trophozoites that reside in the large intestine. The outcome of *E. histolytica* infection is variable. Many individuals remain asymptomatic but excrete the infectious cyst form, making them a source for further infections. In other individuals, *E. histolytica* trophozoites invade into the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). In a smaller proportion of patients, *E. histolytica* trophozoites invade through the colonic mucosa, reach the portal circulation, and travel to the liver, where they establish an amebic liver abscess.

The cornerstone of therapy for amebiasis is the nitroimidazole compound metronidazole or its analogs tinidazole and ornidazole. Metronidazole and tinidazole are the only nitroimidazoles available in the U.S. and are the drugs of choice for the treatment of amebic colitis, amebic liver abscesses, and any other extraintestinal form of amebiasis. Because metronidazole is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen, and the drug is less effective against cysts. Hence patients with amebiasis (amebic colitis or amebic liver abscess) also should receive a luminal agent to eradicate any *E. histolytica* trophozoites residing within the gut lumen. Luminal agents are also used to treat asymptomatic individuals found to be infected with *E. histolytica*. The nonabsorbed aminoglycoside paromomycin and the 8-hydroxyquinoline compound iodoquinol are two effective luminal agents. Diloxanide furate, previously considered the luminal agent of choice for amebiasis, is no longer available in the U.S. Nitazoxanide (ALINIA), N-(nitrothiazolyl) salicylamide, and tinidazole were approved recently for the treatment of giardiasis in immune-competent children <12 years of age. Furazolidone, previously used for the treatment of giardiasis, has been discontinued in the U.S.

**Giardiasis.** Giardiasis, caused by the flagellated protozoan *Trichomonas vaginalis*. This organism inhabits the genitourinary tract of the human host, where it causes vaginitis in women and, uncommonly, urethritis in men. Trichomoniasis is a sexually transmitted disease, with >200 million people infected worldwide and at least 3 million women infected in the U.S. annually. Infection with *Trichomonas* has been associated with an increased risk of acquiring HIV infection. Only *trophozoites* forms of *T. vaginalis* have been identified in infected secretions.

Metronidazole remains the drug of choice for the treatment of trichomoniasis. However, treatment failures owing to metronidazole-resistant organisms are becoming more frequent (Dunne et al., 2003). Tinidazole, another nitroimidazole that was approved recently by the FDA, appears to be better tolerated than metronidazole and has been used successfully at higher doses to treat metronidazole-resistant *T. vaginalis* (Sobel et al., 2001). Nitazoxanide shows activity against *T. vaginalis* in vitro but has not undergone clinical trials and is not licensed for the treatment of trichomoniasis.

**Toxoplasmosis.** Toxoplasmosis is a cosmopolitan zoonotic infection caused by the obligate intracellular protozoan *Toxoplasma gondii* (Montoya and Liesenfeld, 2004). Although cats and other feline species are the natural hosts, tissue cysts (*bradyzoites*) have been
recovered from all mammalian species examined. The four most common routes of infection in humans are:

- ingestion of undercooked meat containing tissue cysts
- ingestion of vegetable matter contaminated with soil containing infective oocysts
- direct oral contact with feces of cats shedding oocysts
- transplacental fetal infection with tachyzoites from acutely infected mothers

Primary infection with *T. gondii* produces clinical symptoms in ~10% of immunocompetent individuals. The acute illness is usually self-limiting, and treatment rarely is required. Individuals who are immunocompromised, however, are at risk of developing toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain. The vast majority of cases of toxoplasmic encephalitis are seen in patients with AIDS, in whom the disease is fatal if it is not recognized and treated appropriately. Clinical manifestations of congenital toxoplasmosis vary widely, but chorioretinitis, which may present decades after perinatal exposure, is the most commonly recognized finding.

The primary treatment for toxoplastic encephalitis consists of the antifolates pyrimethamine (DARAPRIM) and sulfadiazine along with folinic acid (leucovorin). However, therapy must be discontinued in ~40% of cases because of toxicity owing primarily to the sulfadiazine compound. In this instance, clindamycin can be substituted for sulfadiazine without loss of efficacy. Alternative regimens combining azithromycin, clarithromycin, atovaquone, or dapsone with either trimethoprim-sulfamethoxazole or pyrimethamine and folinic acid are less toxic but also less effective than the combination of pyrimethamine and sulfadiazine.

Spiramycin, which concentrates in placental tissue, is used for the treatment of acute acquired toxoplasmosis in pregnancy to prevent transmission to the fetus. If fetal infection is detected, the combination of pyrimethamine, sulfadiazine, and folinic acid is administered to the mother (only after the first 12-14 weeks of pregnancy) and to the newborn in the postnatal period. Spiramycin is not available in the U.S.

**Cryptosporidiosis.** Cryptosporidia are coccidian protozoan parasites that can cause diarrhea in a number of animal species, including humans (Ramirez et al., 2004). Their taxonomy is evolving, but *Cryptosporidium parvum* and the newly named *C. hominis* appear to account for almost all infections in humans.

Infectious oocysts in feces may be spread either by direct human-to-human contact or by contaminated water supplies, the latter being recognized as an established route of epidemic infection. Groups at risk include travelers, children in day-care facilities, male homosexuals, animal handlers, veterinarians, and other healthcare personnel. Immunocompromised individuals are especially vulnerable. After ingestion, the mature oocyte is digested, releasing *sporozoites* that invade host epithelial cells, penetrating the cell membrane but not actually entering the cytoplasm. In most individuals, infection is self-limited. However, in AIDS patients and other immunocompromised individuals, the severity of voluminous, secretory diarrhea may require hospitalization and supportive therapy to prevent severe electrolyte imbalance and dehydration.

The most effective therapy for cryptosporidiosis in AIDS patients is restoration of their immune function through highly active antiretroviral therapy (HAART) (Chapter 59). Nitazoxanide has shown activity in treating cryptosporidiosis in immunocompetent children and is possibly effective in immunocompetent adults (Rossignol et al., 2001). Its efficacy in children and adults with HIV infection and AIDS is not clearly established, although some studies showed a modest benefit in a subset of adult men with AIDS and chronic cryptosporidiosis (Rossignol, 2006; Sears and Kirkpatrick, 2007). Nevertheless, nitazoxanide is currently the only drug approved for the treatment of cryptosporidiosis in the U.S.

**Trypanosomiasis.** African trypanosomiasis, or “sleeping sickness,” is caused by subspecies of the hemoflagellate *Trypanosoma brucei* that are transmitted by bloodsucking tsetse flies of the genus *Glossinida* (Barrett et al., 2007; Kennedy, 2008; Stuart et al., 2008). Largely restricted to sub-Saharan Africa, the infection causes serious human illness and also threatens livestock (*nagana*), leading to protein malnutrition. In humans, the infection is fatal unless treated. Owing to strict surveillance, vector control, and early therapy, the prevalence of African sleeping sickness declined to its nadir in the early 1960s. However, relaxation of these measures, together with massive population displacement and breakdowns in societal infrastructure owing to armed conflict, led to a resurgence of this disease in the 1990s. An estimated 500,000 Africans carry the infection, and >50 million people are at risk for the disease. It is extremely rare in travelers returning to the U.S. and can be difficult to diagnose in its more chronic form (Lejon et al., 2003).

The parasite is entirely extracellular, and early human infection is characterized by the finding of replicating parasites in the bloodstream or lymph without CNS involvement (stage 1); stage 2 disease is characterized by CNS involvement (Blum et al., 2006). Symptoms of early-stage disease include febrile illness, lymphadenopathy, splenomegaly, and occasional myocarditis that result from systemic dissemination of the parasites. There are two types of African trypanosomiasis, the East African (Rhodesian) and West
African (Gambian), caused by *T. brucei rhodesiense* and *T. brucei gambiense*, respectively. *T. brucei rhodesiense* produces a progressive and rapidly fatal form of disease marked by early involvement of the CNS and frequent terminal cardiac failure; *T. brucei gambiense* causes illness that is characterized by later involvement of the CNS and a more long-term course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion, poor coordination, sensory deficits, an array of psychiatric signs, disruption of the sleep cycle, and eventual progression into coma and death.

Four drugs are used for the treatment of sleeping sickness, and only one, eflornithine, has been developed since the 1950s (Barrett et al., 2007; Croft, 2008; Fries and Fairlamb, 2003; Kennedy, 2008; Stuart et al., 2008). Standard therapy for early-stage disease is pentamidine for *T. brucei gambiense* and suramin for *T. brucei rhodesiense*. Both compounds must be given parenterally over long periods and are not effective against late-stage disease. The CNS phase has traditionally been treated with melarsoprol (available from the CDC), which is a highly toxic agent that causes a fatal reactive encephalopathy in 2-10% of treated patients. Moreover, lack of response to this agent is leading to increasing numbers of treatment failures (Pepin and Mpia, 2005, Robays et al., 2008b). Eflornithine, which was developed originally as an anticancer agent and approved as an orphan drug, offers the only alternative for the treatment of late-stage disease. This compound is an inhibitor of ornithine decarboxylase, a key enzyme in polyamine metabolism. It has shown marked efficacy against both early and late stages of human *T. brucei gambiense* infection; however, it is ineffective as monotherapy for infections of *T. brucei rhodesiense*. Notably, eflornithine has significantly fewer side effects than melarsoprol and is more effective than melarsoprol for treatment of late-stage Gambian trypanosomiasis, suggesting that eflornithine is the best available first-line treatment for this form of the disease (Chappuis, 2007). Although eflornithine is expensive and difficult to administer, nifurtimox-eflornithine combination therapy (NECT) allows a shorter exposure to eflornithine with good efficacy and a reduction in adverse events (Priotto et al., 2009).

Recent efforts by not-for-profit agencies have fostered significant new efforts to develop new therapies for the neglected tropical diseases including African sleeping sickness, Chagas’ disease, and Leishmaniasis (Croft, 2007; Frearson et al., 2007; Nwaka and Hudson, 2006; Pink et al., 2005; Stuart et al., 2008). These efforts involve partnerships with academic and industrial groups. The recent increase in high throughput screening centers within academic groups with interest in developing drugs for these applications is also helping to fuel discovery of lead compounds. The genome data is being exploited to develop publicly accessible databases that organize data relevant to drug discovery projects (Aguero et al., 2008). From these efforts an orally available novel diamidine, pafuramidine maleate (DB289), was recently advanced to phase IV trials for the treatment of early-stage (stage 1) sleeping sickness, representing the only new clinical candidate since the discovery of eflofithine (Mdachi et al., 2009). Although the trials were stopped due to toxicity issues (Kennedy, 2008), the discovery of pafuramidine provides hope that the current approaches and increased effort will yield new clinical entities for these diseases in the near future.

**American trypanosomiasis**, or *Chagas’ disease*, a zoonotic infection caused by *Trypanosoma cruzi*, affects ~15 million people from Mexico to Argentina and Chile, with 50,000-200,000 new infections added each year (Bern et al., 2007; Stuart et al., 2008; Tarleton et al., 2007). The chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megacolon, and death. Blood-sucking triatomid bugs infesting poor rural dwellings most commonly transmit this infection to young children; transplacental transmission also may occur in endemic areas.

Reactivation of disease also may occur in patients who are immunosuppressed after organ transplantation or because of infection (e.g., AIDS, leukemia, and other neoplasias). Occurrences of *T. cruzi* infection in transplant patients or through blood transfusions have been reported in the U.S., and as a consequence the FDA-approved diagnostic blood screening for the parasite (Bern et al., 2008). Reports of autochthonous Chagas cases are also on the rise in the U.S. Acute infection is evidenced by a raised tender skin nodule (*chagoma*) at the site of inoculation; other signs may be absent or range from fever, adenitis, skin rash, and hepatosplenomegaly to, albeit rarely, acute myocarditis, and death. Invading metacyclic trypomastigotes penetrate host cells, especially macrophages, where they proliferate as amastigotes. These then differentiate into trypomastigotes that enter the bloodstream. Circulating trypomastigotes do not multiply until they invade other cells or are ingested by an insect vector during a blood meal. After recovery from the acute infection that lasts a few weeks to months, individuals usually remain asymptomatic for years despite sporadic parasitemia. During this period, their blood can transmit the parasites to transfusion recipients and accidentally to laboratory workers. Approximately 20-30% of infected individuals eventually progress to clinically evident disease that is characterized by chronic disease of the heart and GI tract as they age. Progressive destruction of myocardial cells and neurons of the myenteric plexus results from the special tropism of *T. cruzi* for muscle cells. Recent studies with improved techniques indicate the presence of *T. cruzi* at sites of cardiac lesions, and it is now well recognized that parasite persistence is linked directly to pathology and disease outcome (Tarleton, 2003). Whether an undefined autoimmune response also contributes to the pathogenesis of *Chagas’ disease* is unknown; however, the data indicate that immunological defenses, especially cell-mediated immunity, do modulate the course of disease.

Two nitroheterocyclic drugs, nifurtimox (available from the CDC) and benznidazole are used to treat
this infection (Bern et al., 2007; Croft, 2008; Tarleton et al., 2007). Both agents suppress parasitemia and can cure the acute phase of Chagas’ disease in 60-80% of cases; however, both drugs are toxic and must be taken for long periods. A long-term clinical trial with results expected in 2011 (BENEFIT) is currently underway to provide clarification of the role of treatment in modulating disease progression and preventing death (http://clinicaltrials.gov/show/NCT00123916; Marin-Neto et al., 2008). Field isolates vary with respect to their susceptibility to nifurtimox and benznidazole. Moreover, cross-resistance to both compounds can be induced in the laboratory (Wilkinson et al., 2008).

Clearly, new drugs with better potency against parasites in the chronic phase and with reduced toxicities are needed. A key factor in new drug development for Chagas’ disease is the need for better methods to assess parasitological cure. Several important reports documenting significant advances in this area have recently been published (Bustamante et al., 2008; Cooley et al., 2008). Additionally, some promising strides toward the development of new agents have been made. Inhibitors of an essential protease, cruzipain, have anti-parasite activity, and one (K777) is in preclinical development for the treatment of Chagas’ disease (Doyle et al., 2007). In the absence of new drugs, however, alternative measures such as improved vector control and housing accommodations have been used to reduce the transmission of Chagas’ disease substantially in Brazil, Chile, and Venezuela (World Health Organization, 1999).

Leishmaniasis. Leishmaniasis is a complex vector-borne zoonosis caused by ~20 different species of obligate intramacrophage protozoa of the genus Leishmania (Chappuis et al., 2007; Croft 2008; Stuart et al., 2008). Small mammals and canines generally serve as reservoirs for these pathogens, which can be transmitted to humans by the bites of some 30 different species of female phlebotomine sandflies.

Various forms of leishmaniasis affect people in southern Europe and many tropical and subtropical regions throughout the world. Flagellated extracellular free promastigotes, regurgitated by feeding flies, enter the host, where they attach to and become phagocytized by tissue macrophages. These transform into amastigotes, which reside and multiply within phagolysosomes until the cell bursts. Released amastigotes then propagate the infection by invading more macrophages. Amastigotes taken up by feeding sandflies transform back into promastigotes, thereby completing the transformation cycle. The particular localized or systemic disease syndrome caused by Leishmania depends on the species or subspecies of infecting parasite, the distribution of infected macrophages, and especially the host’s immune response. In increasing order of systemic involvement and potential clinical severity, major syndromes of human leishmaniasis have been classified into cutaneous, mucocutaneous, diffuse cutaneous, and visceral (kala azar) forms. Leishmaniasis increasingly is becoming recognized as an AIDS-associated opportunistic infection.

The classification, clinical features, course, and chemotherapy of human leishmaniasis syndromes as well as the biochemistry and immunology of the parasite and host germs to chemotherapy have been recently reviewed (Chappuis et al., 2007; Croft and Coombs, 2003; Stuart et al., 2008). Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring in 3-18 months after infection. However, this form of the disease can leave disfiguring scars. The mucocutaneous, diffuse cutaneous, and visceral forms of the disease do not resolve without therapy. Visceral leishmaniasis caused by L. donovani is fatal unless treated.

The list of current drugs useful for the treatment of all forms of leishmaniasis has been described (Alvar et al., 2006; Croft, 2008; Olliaro et al., 2005). The classic therapy for all species of Leishmania is pentavalent antimony (sodium antimony gluconate; sodium stibogluconate; PENTOSTAM); resistance to this compound has led to widespread failure of this drug in India, although it remains useful in other parts of the world. As an alternative, liposomal amphotericin B is a highly effective agent for visceral leishmaniasis, and it is currently the drug of choice for antimony-resistant disease (Chappuis et al., 2007) (Chapter 57). Importantly, treatment of leishmaniasis has undergone major changes owing to the success of the first orally active agent, miltefosine, in clinical trials (Berman, 2008; Bhattacharya et al., 2007). Miltefosine was approved in India for the treatment of visceral leishmaniasis in 2002. The drug also appears to have promise for the treatment of the cutaneous disease and for the treatment of dogs, which serve as an important animal reservoir of the disease (Berman, 2008). Paromomycin has been used with success as a parenteral agent for visceral disease (Sundar et al., 2007), and topical formulations of paromomycin have efficacy against cutaneous disease. Pentamidine may also be used for cutaneous disease (Croft, 2008).

Other Protozoal Infections. Just a few of the many less common protozoal infections of humans are highlighted here.

Babesiosis, caused by either Babesia microti or B. divergens, is a tick-borne zoonosis that superficially resembles malaria in that the parasites invade erythrocytes, producing a febrile illness, hemolysis, and hemoglobinuria. This infection usually is mild and self-limiting but can be severe or even fatal in asplenic or severely immunocompromised individuals. Currently recommended therapy is with a combination of clindamycin and quinine for severe disease, and the combination of azithromycin and atovaquone for mild or moderate infections.

Balantidiasis, caused by the ciliated protozoan Balantidium coli, is an infection of the large intestine that may be confused with amebiasis. Unlike amebiasis, however, this infection usually responds to tetracycline therapy.
Isospora belli, a coccidian parasite, causes diarrhea in AIDS patients and responds to treatment with trimethoprim-sulfamethoxazole. Cyclospora cayetanensis, another coccidian parasite, causes self-limited diarrhea in normal hosts and can cause prolonged diarrhea in individuals with AIDS. It is susceptible to trimethoprim-sulfamethoxazole.

Microsporidia are spore-forming unicellular eukaryotic fungal parasites that can cause a number of disease syndromes, including diarrhea in immunocompromised individuals. Infections with microsporidia of the Encephalitozoon genus, including E. hellem, E. intestinalis, and E. cuniculi, have been treated successfully with albendazole, a benzimidazole derivative and inhibitor of β-tubulin polymerization (Gross, 2003) (Chapter 51). Immunocompromised individuals with intestinal microsporidiosis due to E. bieneusi (which does not respond as well to albendazole) have been treated successfully with the antibiotic fumagillin (Molina et al., 2002).

**ANTI-PROTOZOAL DRUGS**

The myriad agents used to treat nonmalarial protozoal diseases are presented alphabetically.

Amphotericin B

The pharmacology, formulation, and toxicology of amphotericin B are presented in Chapter 57. Only those features of the drug pertinent to its use in leishmaniasis are described here.

Antiprotozoal Effects. In 1997, the FDA approved liposomal amphotericin B (AMBISOME) for the treatment of visceral leishmaniasis. Amphotericin B is a highly effective antileishmanial agent that cures >90% of the cases of visceral leishmaniasis in clinical studies, and it has become the drug of choice for antimonial-resistant cases (Bern et al., 2006; Croft, 2008, Olliaro et al., 2005). It is considered a second-line drug for cutaneous or mucosal leishmaniasis, where it has been shown effective for the treatment of immunocompromised patients (Alvar et al., 2006). However, because cutaneous leishmaniasis is typically self-limiting, the drug has not been evaluated for treatment of a broader range of patient populations. The lipid preparations of the drug have reduced toxicity, but the cost of the drug and the difficulty of administration remain a problem in endemic regions.

The mechanism of action of amphotericin B against leishmania is similar to the basis for the drug’s antifungal activities (Chapter 57). Amphotericin B complexes with ergosterol precursors in the cell membrane, forming pores that allow ions to enter the cell. Leishmania has a similar sterol composition to fungal pathogens, and the drug binds to these sterols preferentially over the host cholesterol. No significant resistance to the drug has been encountered after nearly 30 years of use as an antifungal agent.

Therapeutic Uses. Numerous dosing schedules have been reported for the treatment of visceral leishmaniasis, with most achieving high cure rates and good safety (Alvar et al., 2006, Bern et al., 2006; Olliaro et al., 2005). Typical schemes of 10-20 mg/kg total dose given in divided doses over 10-20 days by intravenous infusion have yielded >95% cure rates. In the U.S., the FDA recommends 3 mg/kg intravenously on days 1-5, 14, and 21 for a total dose of 21 mg/kg (Meyerhoff, 1999). Shorter courses of the drug have been tested with good efficacy and provide a potential alternative with lower cost, although only a limited number of patients have been tested: Cure rates of 89-91% were observed for single doses of 3.75, 5, and 7.5 mg/kg. Recent data suggest that a single dose of 5 mg/kg followed by 7-14 days treatment with oral miltefosine was effective at curing visceral leishmaniasis, and this dosing scheme warrants additional study (Sundar et al., 2008).

Chloroquine

The pharmacology and toxicology of chloroquine are presented in Chapter 49 (anti-malarials). Chloroquine does have an FDA-approved use for extra-intestinal amebiasis at a dose of 1 g (600 mg base) daily for 2 days, followed by 500 mg daily for at least 2-3 weeks. Treatment is usually combined with an effective intestinal amebicide. The interested reader should consult the 11th edition of this book for further details.

Diloxanide Furoate

Diloxanide furoate (FURAMIDE, others) is the furoate ester of diloxanide, a derivative of dichloroacetamide. Diloxanide furoate is a very effective luminal agent for the treatment of E. histolytica infection but is no longer available in the U.S. The interested reader should consult the 10th edition of this book for further details on this agent.

Eflornithine

Eflornithine (α-D,L difluoromethylornithine, DFMO, ORNIDYL) is an irreversible catalytic (suicide) inhibitor of ornithine decarboxylase, the enzyme that catalyzes the first and rate-limiting step in the biosynthesis of polyamines (Casero and Marton, 2007). The polyamines—putrescine, spermidine, and in mammals, spermine—are required for cell division and for normal cell differentiation. In trypanosomes, spermidine additionally is required for the synthesis of trypanothione, which is a conjugate of spermidine and glutathione that replaces many of the functions of glutathione in the parasite cell (Fries and Fairlamb, 2003).

Eflornithine has been shown to be effective for the treatment of visceral leishmaniasis, and this dosing scheme warrants additional study (Sundar et al., 2008).

Both in animal models and in vitro, eflornithine arrests the growth of several types of tumor cells, providing the basis for its clinical evaluation as an antitumor agent. The discovery that eflornithine cured rodent infections with T. brucei first focused attention on protozoal polyamine biosynthesis as a potential target for chemotherapeutic attack (Bacchi et al., 1980). Eflornithine currently is used to treat West African (Gambian) trypanosomiasis caused by T. brucei gambiense (Balasegaram et al., 2006a, 2006b; Chappuis,
In contrast, the drug is largely ineffective for East African trypanosomiasis. Eflornithine’s difficult treatment regimen is the primary limitation to its use in the field. However, the negotiation of the World Health Organization (WHO) of a stable supply of eflornithine through 2011 has led to the widespread availability of the drug and to its use in control and research programs run by world health agencies.

Eflornithine is both safer and more efficacious than melarsoprol for late-stage Gambian sleeping sickness, and it is now the recommended first-line treatment for this disease when adequate care can be provided for its administration. Eflornithine is no longer available for systemic use in the U.S. but is available for treatment of Gambian trypanosomiasis by special request from the CDC.

**Antitrypanosomal Effects.** The effects of eflornithine have been evaluated both on drug-susceptible and drug-resistant *T. brucei in vitro* and in infections with these parasites in rodent models (reviewed in: Barrett et al., 2007). Eflornithine is a cytostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion. The polyamine putrescine is depleted to undetectable levels, intracellular levels of spermidine and trypanothione are reduced by 25-50%, and methionine metabolism is altered. Depletion of the polyamines, or of trypanothione, would be expected to be lethal to the cells based on genetic studies that have disrupted the biosynthetic genes in the pathway. As a consequence, macromolecular biosynthesis is depressed, and the parasites transform from the long, slender dividing forms into the short, stumpy nonreplicating forms. These latter parasites are unable to synthesize variable cell surface glycoprotein and eventually are cleared by the immune system.

The molecular mechanism of eflornithine action clearly is inhibition of ornithine decarboxylase. Eflornithine irreversibly inhibits both mammalian and trypanosomal ornithine decarboxylases, thereby preventing the synthesis of putrescine, a precursor of polyamines needed for cell division. Eflornithine inactivates the enzyme through covalent labeling of an active-site cysteine residue, and an X-ray structure of the *T. brucei* enzyme bound to the drug has been reported (Grishin et al., 1999). A number of studies demonstrate conclusively that ornithine decarboxylase is the target of eflornithine action that leads to cell death. Mutant bloodstream trypanosomes lacking ornithine decarboxylase or wild-type trypanosomes treated with eflornithine cannot replicate, and mice inoculated with these null parasites become resistant to infection by wild-type parasites (Mutomba et al., 1999). The product of the ornithine decarboxylase reaction, putrescine, rescues the growth deficit in both the mutant parasites and eflornithine-treated cells. The null mutant parasites grown with putrescine are not affected by eflornithine, demonstrating the selectivity of the drug for the target enzyme.

The mechanisms of selective toxicity between the host and parasite, or between the different species of *T. brucei*, are less clear (Barrett et al., 2007). The parasite and human enzymes are equally susceptible to inhibition by eflornithine; however, the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable, and this difference likely plays a role in the selective toxicity. In addition, mammalian cells may be able to replenish polyamine pools through uptake of extracellular polyamines, whereas the slender bloodstream forms of human trypanosomes divide within human blood, which contains only very low levels of these essential compounds. Further, the parasites lack efficient transport mechanisms.

*T. brucei rhodesiense* cells are less sensitive to eflornithine inhibition than *T. brucei gambiense* cells, and studies in *vivo* suggest that the effective doses are increased by 10-20 times in the refractory cells. The molecular basis for the higher dose requirement in *T. brucei rhodesiense* is still poorly understood; however, it has been postulated to involve differences both in enzyme stability and in the metabolism of S-adenosylmethionine compared with the sensitive *T. brucei gambiense* cell lines.

**Absorption, Fate, and Excretion.** Eflornithine is given by intravenous infusion. The drug does not bind to plasma proteins but is well distributed and penetrates into the CSF, where it is estimated that concentrations of at least 50 μM must be reached to clear parasites (Burri and Brun, 2003). Despite the ability of the drug to penetrate the blood-brain barrier, studies in mice suggest that eflornithine crosses the healthy blood-CNS interface poorly, and that it is the breakdown of this barrier caused by *T. brucei* infection that allows greater penetration to occur (Sanderson et al., 2008). In these studies, suramin enhanced eflornithine uptake into the CNS, suggesting that this combination might lead to lower dose requirements for eflornithine. Renal clearance after intravenous administration is rapid (2 mL/minute per kilogram), with >80% of the drug cleared by the kidney largely in unchanged form (Burri and Brun, 2003). There is some evidence that eflornithine displays dose-dependent pharmacokinetics at the highest doses used clinically.

**Therapeutic Uses.** Eflornithine is used for the treatment of late-stage West African trypanosomiasis caused by *T. brucei gambiense* (Balasegaram et al., 2006a, 2008; Chappuis, 2007; Chappuis et al., 2005; Priotto et al., 2006, 2008; Robays et al., 2008a). Most patients in the reported studies had advanced disease with CNS complications. The preferred regimen for adult patients was found to be 100 mg/kg given intravenously every 6 hours as a 2-hour infusion for 14 days. Virtually all patients improved on this regimen unless they were extremely ill, and the WHO and Médecins Sans Frontières report improved rates >90%. The probability of disease-free survival 2 years after treatment was calculated to be 0.88 in one study (Priotto et al., 2008) and the case-fatality rate of 1% for eflornithine was the lowest reported for second-stage sleeping sickness in any study (Chappuis et al., 2005). Children (<12 years of age) received higher doses of eflornithine (150 mg/kg given intravenously every 6 hours for 14 days) based on prior findings that eflornithine trough concentrations in both the CSF and blood were significantly lower among children than in adults (Milord et al., 1993). Patients who failed therapy in this study tended to have trough CSF concentrations <50 μM. Equal doses of eflornithine were less effective when given by the oral route probably because of limited bioavailability. The problem cannot be overcome simply by increasing the oral dose because of ensuing osmotic diarrhea.

Eflornithine has proven to be less successful for treating AIDS patients with West African trypanosomiasis, presumably because host defenses play a critical role in clearing drug-treated *T. brucei gambiense* from the bloodstream.

The standard course eflornithine treatment regime is very challenging to administer in rural settings in Africa. A randomized phase III trial testing nifurtimox-eflornithine combination therapy for second-stage *T. brucei gambiense* suggested that the treatment course for eflornithine could be reduced to 7 days in combination with nifurtimox. A recently concluded clinical trial confirms the efficacy of
nifurtimox used in combination with eflornithine (NECT) (Priotto, 2009). This new protocol uses a shortened course of eflornithine in combination with oral nifurtimox, with dosing as follows: 400 mg/kg per day given intravenously every 12 h by 2 h infusion for 7 days plus nifurtimox (orally at 15 mg/kg per day in 3 divided doses [every 8 h]) for 10 days. This combination is logistically easier to administer and it requires less eflornithine, which is expensive to synthesize. Importantly, compared to eflornithine alone, NECT achieves a higher cure rate (96.5% vs. 91.5%). NECT has been added to the WHO essentials medicines list and is likely to become the front line treatment for the indication. Drug combination may also reduce the potential for eflornithine resistance to develop in the field. Given the paucity of drugs available for the treatment of late stage disease, the development of eflornithine resistance would represent a very serious problem.

**Toxicity and Side Effects.** Eflornithine is reported to cause adverse reactions in most of the treated patients (Balasegaram et al., 2008; Burri and Brun, 2003; Chappuis, 2007; Chappuis et al., 2005; Priotto et al., 2006, 2008); however, they are generally reversible on withdrawal of the drug. Abdominal pain, both mild and moderate, and headache were the predominant complaints followed by reactions at the injection sites. Tissue infections and pneumonia were also observed. The most severe reactions reported for one study, with numbers given for events classified as major, included fever peaks (6%), seizures (4%), and diarrhea (2%) (Priotto et al., 2008). The case fatality rate for eflornithine (~1.2%) is significantly lower than for melarsoprol (4.9%), and overall eflornithine is superior to melarsoprol with respect to both safety and efficacy. Reversible hearing loss can occur after prolonged therapy with oral doses. Although this has been a problem in the use of eflornithine for cancer chemotherapy, hearing loss has not been observed during the treatment of sleeping sickness.

Therapeutic doses of eflornithine are large and require co-administration of substantial volumes of intravenous fluid. This poses significant practical limitations in remote settings and can cause fluid overload in susceptible patients. For NECT, the severe adverse events were reduced compared to eflornithine alone (14% vs. 29%), and treatment related deaths were also fewer (0.7% vs. 2%) (Priotto, 2009). Both NECT and eflornithine alone showed significantly fewer treatment-related deaths than what has been reported for melarsoprol. With eflornithine alone, most reported deaths were due to septic shock. The typical side effects of eflornithine (diarrhea, fever, infection, hypertension, and skin rash) were reduced in the NECT arm of the study, however more patients experienced tremors, nausea and vomiting.

**Emetine and Dehydroemetine**

The use of emetine, an alkaloid derived from *ipecac* (“Brazil root”), as a direct-acting systemic amebicide dates from the early part of the 20th century. Dehydroemetine (MEBADIN) has similar pharmacological properties but is considered to be less toxic. Although both drugs were once used widely to treat severe invasive intestinal amebiasis and extraintestinal amebiasis, they have been replaced by metronidazole, which is as effective and far safer. Thus, emetine and dehydroemetine should not be used unless metronidazole is contraindicated. In the U.S., dehydroemetine is available under an investigational new drug protocol from the CDC drug service. Details of the pharmacology and toxicology of emetine and dehydroemetine are presented in the fifth and earlier editions of this book.

**Fumagillin**

Fumagillin (*Fumidil B, others*) is an acyclic polyene macrolide produced by the fungus *Aspergillus fumigatus*.

Both fumagillin and its synthetic analog TNP-470 are toxic to microsporidia, and fumagillin is used widely to treat the microsporidian *Nosema apis*, a pathogen of honey bees. Fumagillin and TNP-470 also inhibit angiogenesis and suppress tumor growth, and TNP-470 is undergoing clinical trials as an anticancer agent (Chapter 61). Human methionine-aminopeptidase-2 (MetAP2) has been identified as the target for the drugs’ antitumor activity, and a gene encoding MetAP2 has been identified in the genome of the microsporidian parasite *E. cuniculi*.

Fumagillin is used topically to treat keratoconjunctivitis caused by *E. hellem* at a dose of 3–10 mg/mL in a balanced salt suspension. For the treatment of intestinal microsporidiosis caused by *E. bieneusi*, fumagillin was used at a dose of 20 mg orally three times daily for 2 weeks (Molina et al., 2002). Adverse effects of fumagillin may include abdominal cramps, nausea, vomiting, and diarrhea. Reversible thrombocytopenia and neutropenia also have been reported (Molina et al., 2002). Fumagillin has not been approved for the systemic treatment of microsporidiosis infection in the U.S.

**8-Hydroxyquinolines**

The halogenated 8-hydroxyquinolines iodoquinol (diiodohydroxyquin) and clioquinol (iodochlorhydroxyquin) have been used as luminal agents to eliminate intestinal colonization with *E. histolytica*. Iodoquinol (*YODOXIN*) is the safer of the two agents and is the only one available for use as an oral agent in the U.S. When used at appropriate doses (never to exceed 2 g/day and duration of therapy not greater than 20 days in adults), adverse effects are unusual. However, the use of these drugs, especially at doses exceeding 2 g/day, for long periods is associated with significant risk. The most important toxic reaction, which has been ascribed primarily to clioquinol, is subacute myelo-optic neuropathy. This disease is a myelitis-like illness that was first described in epidemic form (thousands of afflicted patients) in Japan; only sporadic cases have been reported elsewhere, but the actual prevalence is undoubtedly higher. Peripheral neuropathy is a less severe manifestation of neurotoxicity owing to these drugs. Administration of iodoquinol in high doses to children with chronic diarrhea has been associated with optic atrophy and permanent loss of vision.

Because of its superior adverse-event profile, paromomycin is preferred by many authorities as the luminal agent used to treat amebiasis; however, iodoquinol is a reasonable alternative. Iodoquinol is used in combination with metronidazole to treat...
Melarsoprol

In 1949, Friedheim demonstrated that melarsoprol, the dimercaptopropanol derivative of melarsen oxide, was effective in the treatment of late-stage trypanosomiasis. It was considerably safer than other trypanocides available at the time. Despite the fact that it causes an often fatal encephalopathy in 2-10% of the patients, melarsoprol has remained the only drug for the treatment of late (CNS) stages of East African trypanosomiasis caused by T. brucei rhodesiense (Barrett et al., 2007; Croft, 2008; Kennedy, 2008). Although melarsoprol is also effective against late-stage West African trypanosomiasis caused by T. brucei gambiense, eflornithine has become the first-line treatment for this disease. The continued use of melarsoprol in the field is indicative of the paucity of alternative therapies for late-stage sleeping sickness.

Melarsoprol (MEL B; ARSOBAL), consisting of two arsenic-containing stereoisomers in a 3:1 ratio, is insoluble in water and is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the U.S. only from the CDC.

**Antiprotozoal Effects.** Melarsoprol has many wide-ranging nonspecific effects on both the trypanosome and host cells (Fries and Fairlamb, 2003). Melarsoprol is a prodrug and is metabolized rapidly (\( t_{1/2} = 30 \) minutes) to melarsen oxide, the active form of the drug. Arsen-oxides react avidly and reversibly with vicinal sulfhydryl groups, including those of proteins, and thereby inactivate a great number and variety of enzymes. The same nonspecific mechanisms by which melarsoprol is lethal to parasites are probably responsible for its toxicity to host tissues. The basis for the trypanocidal action of melarsoprol is not understood, probably owing to its high reactivity with many biomolecules. Disruption of energy metabolism by inhibition of glycolytic enzyme was long thought to explain its trypanocidal activity. Other evidence suggests, however, that this is not a primary effect. Melarsoprol reacts with trypanothione, the spermidine-glutathione adduct that substitutes for glutathione in these parasites. Binding of melarsoprol to trypanothione results in formation of melarsen oxide-trypanothione adduct (Mel T), a compound that is a potent competitive inhibitor of trypanothione reductase, the enzyme responsible for maintaining trypanothione in its reduced form. Both the sequestering of trypanothione and the inhibition of trypanothione reductase would be expected to have lethal consequences to the cell. However, critical evidence directly linking melarsoprol’s action on the trypanothione system to parasite death is still lacking.

The pharmacology and toxicology of the 8-hydroxyquinolines are described in greater detail in the fifth and earlier editions of this book.

**Absorption, Fate, and Excretion.** Melarsoprol is always administered intravenously. A small but therapeutically significant amount of the drug enters the CSF and has a lethal effect on trypanosomes infecting the CNS. The compound is excreted rapidly, with 70-80% of the arsenic appearing in the feces.

**Therapeutic Uses.** Melarsoprol is the only effective drug available for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis, which is 100% fatal if untreated. The drug is also effective in the early hemolymphatic stage of these infections, but because of its toxicity, it is reserved for therapy of late-stage infections. Patients infected with T. brucei rhodesiense who relapse after a course of melarsoprol usually respond to a second course of the drug. In contrast, patients infected with T. brucei gambiense who are not cured with melarsoprol rarely benefit from repeated treatment with this drug. Such patients often respond well to eflornithine.

The original treatment schedules for melarsoprol were derived empirically >40 years ago; new clinical trials have been undertaken with dosage schemes based on a better knowledge of melarsoprol pharmacokinetics, and these have yielded new recommendations for treatment protocols (Pepin and Mpia, 2006; Schmid et al., 2005). Melarsoprol is administered by slow intravenous injection, with care to avoid leakage into the surrounding tissues because the drug is intensely irritating. For T. brucei gambiense a continuous 10-day course of 2.2 mg/kg per day is equivalent to the longer course treatment and is now recommended (Pepin and Mpia, 2006; Schmid et al., 2005). The 10-day therapy has not reduced the incidence of
encephalopathy (the treatment-related death rate was still 5.9% for this protocol), but it has the advantage of easier administration, and in an area where hospitalization is difficult, this is particularly important. These studies further demonstrated that historically used graded dosing schemes led to increased incidence of convulsions and reduced efficacy; thus these schedules should not be used for the treatment of T. brucei gambiense (Pepin and Mpia, 2006).

The 10-day therapy is currently undergoing clinical testing for T. brucei rhodesiense. However, until clinical data are available to support a dosing change, patients with Rhodesian sleeping sickness should instead receive one of several older schedules developed for this disease. A number of dosing schemes are in use or recommended by various agencies, including the WHO (1998) and Médecins Sans Frontières (2007). In the U.S., the CDC recommends the following treatment schedule: three series of three daily doses with a 7-day rest period between series. The first series gives 1.8, 2.7, and 3.6 mg/kg on days 1, 2, and 3, respectively. The subsequent series are 3.6 mg/kg daily. Encephalopathy develops more frequently in patients with T. brucei rhodesiense compared to T. brucei gambiense, possibly related to this graded dosing regimen. Concurrent administration of prednisolone is frequently employed throughout the treatment course; prednisolone is not proven to reduce the frequency of reactive encephalopathy (Schmid et al., 2005) but it does help to control hypersensitivity reactions that occur most often during the second or subsequent courses of melarsoprol therapy.

Toxicity and Side Effects. Treatment with melarsoprol is associated with significant toxicity and morbidity (Balasegaram et al., 2006b; Burri and Brun, 2003; Kennedy, 2008; Schmid et al., 2005). A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. The most serious complications involve the nervous system. A reactive encephalopathy occurs in ~5-10% of patients, leading to death in about half of these. The cause is unknown, but encephalopathy, when it occurs, typically develops 9-11 days after treatment starts (Schmid et al., 2005). Peripheral neuropathy, noted in ~10% of patients receiving melarsoprol, probably is due to a direct toxic effect of the drug. Hypertension and myocardial damage are not uncommon, although shock is rare. Albuminuria occurs frequently, and occasionally the appearance of numerous casts in the urine or evidence of hepatic disturbances may necessitate modification of treatment. Vomiting and abdominal colic also are common, but their incidence can be reduced by injecting melarsoprol slowly into the supine, fasting patient. The patient should remain in bed and not eat for several hours after the injection is given.

Precautions and Contraindications. Melarsoprol should be given only to patients under hospital supervision so that the dosage regimen may be modified if necessary. Initiation of therapy during a febrile episode has been associated with an increased incidence of reactive encephalopathy. Administration of melarsoprol to leprous patients may precipitate erythema nodosum. Use of the drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with deficiency of glucose-6-phosphate dehydrogenase. Pregnancy is not a contraindication for treatment with melarsoprol.

Metronidazole

Isolation of the antibiotic azomycin (2-nitro-imidazole) from a streptomyecete by Maeda and collaborators in 1953 and demonstration of its trichomonacidal properties by Horie in 1956 led to the chemical synthesis and biological testing of many nitroimidazoles. One compound, 1-(β-hydroxyethyl)-2-methyl-5-nitroimidazole, or metronidazole (FLAGYL, others), had especially high activity in vitro and in vivo against the anaerobic protozoa T. vaginalis and E. histolytica. In 1960, Durell and associates reported that oral doses of the drug imparted trichomonacidal activity to semen and urine and that high cure rates could be obtained in both male and female patients with trichomoniasis. Later studies revealed that metronidazole had extremely useful clinical activity against a variety of anaerobic pathogens that included both gram-negative and gram-positive bacteria and the protozoan G. lamblia (Freeman et al., 1997). Other clinically effective 5-nitroimidazoles closely related in structure and activity to metronidazole include tinidazole (TINDAMAX, FASIGYN, others), secnidazole (SECZOL-DS, others), and ornidazole (TIBERAL, others). Among these, only tinidazole is available in the U.S. Benznidazole (ROCHAGAN), another 5-nitroimidazole derivative, is unusual in that it is effective in acute Chagas’ disease.

\text{METRONIDAZOLE}
\end{align*}
\]

Antiparasitic and Antimicrobial Effects. Metronidazole and related nitroimidazoles are active in vitro against a wide variety of anaerobic protozoal parasites and anaerobic bacteria (Freeman et al., 1997). The compound is directly trichomonacidal. Sensitive isolates of T. vaginalis are killed by ≤0.05 μg/mL of the drug under anaerobic conditions; higher concentrations are required when 1% oxygen is present or to affect isolates from patients who display poor therapeutic responses to metronidazole. The drug also has potent amebicidal activity against E. histolytica. Trophozoites of G. lamblia are affected by metronidazole at concentrations of 1-50 μg/mL in vitro. In vitro studies on drug-sensitive and drug-resistant protozoal parasites indicate that the nitro group on C5 of metronidazole is essential for activity and that substitutions at the 2 position of the imidazole ring that enhance the resonance conjugation of the chemical structure increase antiprotozoal activity. In contrast, substitution of an acyl group at the 2 position ablates such conjugation and reduces antiprotozoal activity (Upcroft et al., 1999).

Metronidazole manifests antibacterial activity against all anaerobic cocci and both anaerobic gram-negative bacilli, including Bacteroides spp., and anaerobic spore-forming gram-positive bacilli. Nonsporulating gram-positive bacilli often are resistant, as are aerobic and facultatively anaerobic bacteria.

Metronidazole is clinically effective in trichomoniasis, amebiasis, and giardiasis, as well as in a variety of infections caused by obligate anaerobic bacteria, including Bacteroides, Clostridium, and
microaerophilic bacteria such as Helicobacter and Campylobacter spp. Metronidazole may facilitate extraction of adult guinea worms in dracunculiasis even though it has no direct effect on the parasite (Chapter 51).

**Mechanism of Action and Resistance.** Metronidazole is a prodrug; it requires reductive activation of the nitro group by susceptible organisms. Its selective toxicity toward anaerobic and microaerophilic pathogens such as the amitochondriate protozoa T. vaginalis, E. histolytica, and G. lamblia and various anaerobic bacteria derives from their energy metabolism, which differs from that of aerobic cells (Land and Johnson, 1997; Samuelson, 1999; Upcroft and Upcroft, 1999). These organisms, unlike their aerobic counterparts, contain electron transport components such as ferredoxins, small Fe–S proteins that have a sufficiently negative redox potential to donate electrons to metronidazole. The single electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA and possibly other vital biomolecules. Metronidazole is catalytically recycled; loss of the active metabolite’s electron regenerates the parent compound. Increasing levels of O₂ inhibit metronidazole-induced cytotoxicity because O₂ competes with metronidazole for electrons generated by energy metabolism. Thus, O₂ can both decrease reductive activation of metronidazole and increase recycling of the activated drug. Anaerobic or microaerophilic organisms susceptible to metronidazole derive energy from the oxidative fermentation of ketoacids such as pyruvate. Pyruvate decarboxylation, catalyzed by pyruvate:ferredoxin oxidoreductase (PFOR), produces electrons that reduce ferredoxin, which, in turn, catalytically donates its electrons to biological electron acceptors or to metronidazole.

Clinical resistance to metronidazole is well documented for T. vaginalis, G. lamblia, and a variety of anaerobic and microaerophilic bacteria but has yet to be shown for E. histolytica. Resistant strains of T. vaginalis derived from nonresponsive patients have shown two major types of abnormalities when tested under aerobic conditions. The first correlates with impaired oxygen-scavenging capabilities, leading to higher local O₂ concentrations, decreased activation of metronidazole, and futile recycling of the activated drug. The second type is associated with lowered levels of PFOR and ferredoxin, the latter owing to reduced transcription of the ferredoxin gene. That PFOR and ferredoxin are not completely absent may explain why infections with such strains usually respond to higher doses of metronidazole or more prolonged therapy. Studies on metronidazole-resistant isolates of G. intestinalis indicate that similar mechanisms may be operating, with PFOR levels reduced 5-fold compared with susceptible strains (Upcroft and Upcroft, 2001). Metronidazole resistance has not been found in clinical isolates of E. histolytica but has been induced in vitro by culturing trophozoites in gradually increasing concentrations of the drug. Interestingly, although some decrease in PFOR levels was reported, metronidazole resistance was mediated primarily by increased expression of superoxide dismutase and peroxiredoxin in amebic trophozoites (Wassmann et al., 1999). Resistance of anaerobic bacteria to metronidazole is being recognized increasingly and has important clinical consequences. In the case of Bacteroides spp., metronidazole resistance has been linked to a family of nitroimidazoles (nim) resistance genes, nimA, -B, -C, -D, -E, and -F, that can be encoded chromosomally or episomally (Gal and Brazier, 2004). The exact mechanisms underlying resistance are not known, but nim genes appear to encode a nitroimidazole reductase capable of converting a 5-nitroimidazole to a 5-aminomidazole, thus stopping the formation of the reactive nitroso group responsible for microbial killing. Metronidazole has been used widely for the treatment of the microaerophilic organism Helicobacter pylori, the major cause of ulcer disease and gastritis worldwide. However, Helicobacter can develop resistance to metronidazole rapidly. Multiple mechanisms probably are operating, but there are data associating loss-of-function mutations in an oxygen-independent NADPH nitroreductase (rdxA gene) with resistance to metronidazole (Mendz and Mégraud, 2002).

**Absorption, Fate, and Excretion.** The pharmacokinetic properties of metronidazole and its two major metabolites have been investigated intensively (Lamp et al., 1999). Preparations of metronidazole are available for oral, intravenous, intravaginal, and topical administration. The drug usually is absorbed completely and promptly after oral intake, reaching concentrations in plasma of 8–13 μg/mL within 0.25-4 hours after a single 500-mg dose. (Mean effective concentrations of the compound are ≤8 μg/mL for most susceptible protozoa and bacteria.) A linear relationship between dose and plasma concentration pertains for doses of 200-2000 mg. Repeated doses every 6-8 hours result in some accumulation of the drug; systemic clearance exhibits dose dependence. The t₁/₂ of metronidazole in plasma is ~8 hours; its volume of distribution approximates total body water. Less than 20% of the drug is bound to plasma proteins. With the exception of the placenta, metronidazole penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, breast milk, and CSF.

After an oral dose, ≥75% of labeled metronidazole is eliminated in the urine largely as metabolites; ~10% is recovered as unchanged drug. The liver is the main site of metabolism, and this accounts for ≥50% of the systemic clearance of metronidazole. The two principal metabolites result from oxidation of side chains, a hydroxy derivative and an acid. The hydroxy metabolite has a longer t₁/₂ (~12 hours) and has ~50% of the antitrichomonal activity of metronidazole. Formation of glucuronides also is observed. Small quantities of reduced metabolites, including ring-cleavage products, are formed by the gut flora. The urine of some patients may be reddish brown owing to the presence of unidentified pigments derived from the drug. Oxidative metabolism of metronidazole is induced by phenobarbital, prednisone, rifampin, and possibly ethanol. Cimetidine appears to inhibit hepatic metabolism of the drug.

**Therapeutic Uses.** The uses of metronidazole for anti-protozoal therapy have been reviewed extensively (Freeman et al., 1997; Nash, 2001; Stanley, 2003). Metronidazole cures genital infections with T. vaginalis in both females and males in ≥90% of cases. The preferred treatment regimen is 2 g metronidazole as a single oral dose for both males and females. Tinidazole, which has a longer t₁/₂ than metronidazole, is also used at a 2-g single dose and appears to provide equivalent or better responses than metronidazole. For patients who cannot tolerate a single 2-g dose of metronidazole (or 1 g twice daily in the same day), an alternative regimen is a 250-mg dose given three times daily or a 375-mg dose given twice daily for 7 days. When repeated courses or higher doses of the drug are required for uncured or recurrent infections, it is recommended that intervals of 4-6 weeks
elapse between courses. In such cases, leukocyte counts should be carried out before, during, and after each course of treatment.

Treatment failures owing to the presence of metronidazole-resistant strains of *T. vaginalis* are becoming increasingly common. Most of these cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner. In addition to oral therapy, the use of a topical gel containing 0.75% metronidazole or a 500- to 1000-mg vaginal suppository will increase the local concentration of drug and may be beneficial in refractory cases. Metronidazole is an effective amebicide and is the agent of choice for the treatment of all symptomatic forms of amebiasis, including amebic colitis and amebic liver abscesses. The recommended dose is 500-750 mg metronidazole taken orally three times daily for 7-10 days, or for children, 35-50 mg/kg/day given in three divided doses for 7-10 days.

Although standard recommendations are for 7-10 days’ duration of therapy, amebic liver abscess has been treated successfully by short courses (2.4 g daily as a single oral dose for 2 days) of metronidazole or tinidazole (Stanley, 2003). *E. histolytica* persist in most patients who recover from acute amebiasis after metronidazole therapy, so it is recommended that all such individuals also be treated with a luminal amebicide.

Although effective for the therapy of giardiasis, metronidazole has yet to be approved for treatment of this infection in the U.S. However, tinidazole is approved for the treatment of giardiasis as a single 2-g dose and is appropriate first-line therapy. Metronidazole is a relatively inexpensive, highly versatile drug with clinical efficacy against a broad spectrum of anaerobic and microaerophilic bacteria. It is used for the treatment of serious infections owing to susceptible anaerobic bacteria, including *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptococcus*, *Peptostreptococcus*, *Eubacterium*, and *Helicobacter*. The drug is also given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. Metronidazole achieves clinically effective levels in bones, joints, and the CNS. Metronidazole can be given intravenously when oral administration is not possible. A loading dose of 15 mg/kg is followed 6 hours later by a maintenance dose of 7.5 mg/kg every 6 hours, usually for 7-10 days. Metronidazole is used as a component of prophylaxis for colorectal surgery and is employed as a single agent to treat bacterial vaginosis. It is used in combination with other antibiotics and a proton pump inhibitor in regimens to treat infection with *H. pylori* (Chapter 45).

Metronidazole is used as primary therapy for *Clostridium difficile* infection, the major cause of pseudomembranous colitis. Given at doses of 250-500 mg orally three times daily for 7-14 days (or even longer), metronidazole is an effective and cost-saving alternative to oral vancomycin therapy. However, a reported increase in treatment failures and higher rates of disease recurrence with metronidazole (as compared to oral vancomycin) are raising questions about the role of metronidazole as first-line therapy (McFarland, 2008). Finally, metronidazole is also used in the treatment of patients with Crohn’s disease who have perianal fistulas, and it can help control colonic (but not small bowel) Crohn’s disease. However, high doses (750 mg three times daily) for prolonged periods may be necessary, and neurotoxicity may be limiting (Podolsky, 2002). Metronidazole and other nitroimidazoles can sensitize hypoxic tumor cells to the effects of ionizing radiation, but these drugs are not used clinically for this purpose.

**Toxicity, Contraindications, and Drug Interactions.** The toxicity of metronidazole has been reviewed (Raether and Hanel, 2003). Side effects only rarely are severe enough to discontinue therapy. The most common are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Furry tongue, glossitis, and stomatitis occurring during therapy may be associated with an exacerbation of candidiasis. Dizziness, vertigo, and very rarely, encephalopathy, convulsions, incoordination, and ataxia are neurotoxic effects that warrant discontinue of metronidazole. The drug also should be withdrawn if numbness or paresthesias of the extremities occur. Reversal of serious sensory neuropathies may be slow or incomplete. Urticaria, flushing, and pruritus are indicative of drug sensitivity that can require withdrawal of metronidazole. Metronidazole is a rare cause of Stevens-Johnson syndrome (toxic epidermal necrolysis); one report described a high rate of this syndrome among individuals receiving high doses of metronidazole and concurrent therapy with the antihelminthic mebendazole (Chen et al., 2003).

Dysuria, cystitis, and a sense of pelvic pressure have been reported. Metronidazole has a well-documented disulfiram-like effect, and some patients experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy with this drug. Patients should be cautioned to avoid consuming alcohol during metronidazole treatment even though the risk of a severe reaction is low. By the same token, metronidazole and disulfiram or any disulfiram-like drug should not be taken together because confusional and psychotic states may occur. Although related chemicals have caused blood dyscrasias, only a temporary neutropenia, reversible after discontinuation of therapy, occurs with metronidazole.

Metronidazole should be used with caution in patients with active disease of the CNS because of its potential neurotoxicity. The drug also may precipitate CNS signs of lithium toxicity in patients receiving high doses of lithium. Plasma levels of metronidazole can be elevated by drugs such as cimetidine that inhibit hepatic microsomal metabolism. Moreover, metronidazole can prolong the prothrombin time of patients receiving therapy with coumadin anticoagulants. The dosage of metronidazole should be reduced in patients with severe hepatic disease.

Given in high doses for prolonged periods, metronidazole is carcinogenic in rodents; it also is mutagenic in bacteria (Raether and Hanel, 2003). Mutagenic activity is associated with metronidazole and several of its metabolites found in the urine of patients treated with therapeutic doses of the drug. However, there is no evidence that therapeutic doses of metronidazole pose any significant increased risk of cancer to human patients. There is conflicting evidence about the teratogenicity of metronidazole in animals. Although metronidazole has been taken during all stages of pregnancy with no apparent adverse effects, its use during the first trimester generally is not advised.

**Miltefosine**

Miltefosine (IMPAVIDO) is an alkylphosphocholine (APC) analog that was developed originally as an anti-cancer agent. Its antiprotozoal activity was discovered in the 1980s during the time that it was being evaluated for cancer chemotherapy. In 2002, it was
approved in India as the first orally active treatment available for visceral leishmaniasis. Miltefosine is the first orally available therapy for leishmaniasis. It is highly curative against visceral leishmaniasis in the trials conducted to date and also appears to be effective against the cutaneous forms of the disease (Berman, 2008; Bhattacharya et al., 2007). Its main drawback is its teratogenicity; consequently, it must not be used in pregnant women.

\[
\text{MILTEFOSINE}
\]

**Antiprotozoal Effects.** In vitro analysis of a large number of alkylglycerophosphoethanolamines (AGPEs), alkylglycerophosphocholines (AGPCs), and APCs, originally developed as anticancer agents, demonstrated that a number of these compounds had potent antileishmanial activity against cultured promastigote or amastigote parasites (Croft et al., 2003). Of the APCs, miltefosine demonstrated the best activity against both stages of parasites. The potency of miltefosine varies for different *Leishmania* spp., with *L. donovani* being the most sensitive (1.2 < ED\(_{50}\) < 5 \(\mu\)M against amastigotes) and *L. major* being the least sensitive (8 < ED\(_{50}\) < 40 \(\mu\)M against amastigotes). Several phospholipid analogs also had good potency against cultured *T. cruzi* parasites, whereas they were relatively inactive against *T. brucei*. In vivo, miltefosine had the best activities of the tested APCs, and by 5 days of treatment with 20 mg/kg orally, it gave >95% suppression of *L. donovani* and *L. infantum* amastigotes in the affected organs of mice. It also had good activity when administered as a 6% ointment to skin lesions of *L. mexicana* or *L. major* on BALB/c mice.

Against visceral leishmaniasis, 95-98% cure rates were observed with a 100 mg/day oral dose for 28-42 days (Croft et al., 2003) and 95% with a 28-day regimen of 100 mg/day orally for adults and 2.5 mg/kg daily for children (Bhattacharya et al., 2007). Thus, oral miltefosine appears to be a safe and effective treatment for visceral leishmaniasis (Berman, 2008). Recent studies of oral miltefosine also have shown >90% efficacy against some species of cutaneous leishmaniasis (registered in Colombia for this use in 2005). However, significant strain variation has been observed in the clinical trials (Soto and Berman, 2006; Soto et al., 2007): For *L. panamensis* in Colombia, cure rates were from 84-91% (versus the placebo cure rate of 37%), and it was considerably less effective for *L. brasilensis* in Guatemala.

The mechanism of action of miltefosine is not yet understood. Potential targets in mammalian cells include PKC; CTP:phosphocholine-cytidylyltransferase inhibition, which disrupts phosphatidylcholine biosynthesis; and altered sphingomyelin biosynthesis, where increased levels of cellular ceramide may trigger apoptosis (Croft et al., 2003). Studies in *Leishmania* suggest that the drug may alter ether-lipid metabolism, cell signaling, or glycosphosphatidylinositol anchor biosynthesis. A transporter for miltefosine has been cloned recently by functional rescue of a laboratory-generated resistant strain of *L. donovani*. The transporter is a P-type ATPase that belongs to the aminophospholipid translocase subfamily, and the basis for the drug resistance appears to be point mutation in the transporter leading to decreased drug uptake. Mutations in this transporter lead to miltefosine resistance in laboratory models (Croft et al., 2006; Seifert et al., 2007).

**Absorption, Fate, and Excretion.** Miltefosine is well absorbed orally and distributed throughout the human body. Detailed pharmacokinetic data are lacking, with the exception that miltefosine has a long t\(_{1/2}\) in humans (Berman, 2008). Plasma concentrations are proportional to the dose, and maximum serum concentrations for dosing of 50-150 mg per day were 20-70 \(\mu\)g/mL with a t\(_{1/2}\) of 1 week and a terminal t\(_{1/2}\) of ~4 weeks. The C\(_{max}\) in children was ~30% less than in adults.

**Therapeutic Uses.** Oral miltefosine is registered for use in India for the treatment of visceral leishmaniasis with clinical trial study patients receiving the following oral doses (Bhattacharya, 2007): for adults >25 kg, 100 mg daily divided into two parts, and for adults <25 kg, 50 mg daily in 1 dose for 28 days; for children, 2.5 mg/kg/day in two divided doses. For cutaneous disease, the dose in clinical testing is 2.5 mg/kg per day orally (maximum, 150 mg/day) for 28 days. In the U.S., the recommended dose for both visceral and cutaneous disease is 2.5 mg/kg per day (maximum dose of 150 mg/day) for 28 days, given in two divided doses (Medical Letter, 2007). Miltefosine is also available in Afghanistan, Pakistan, and South America. Because of its teratogenic potential, miltefosine is contraindicated in pregnant women. Women should receive a negative pregnancy test prior to treatment, and birth control is required during and for at least 2 months after treatment. The compound cannot be given intravenously because it has hemolytic activity.

**Toxicity and Side Effects.** Vomiting and diarrhea have been reported as frequent side effects in up to 60% of the patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These effects are typically mild and reversible, and they resolve quickly once the drug is withdrawn.

**Nifurtimox and Benznidazole**

A variety of nitrofurans and nitroimidazole analogs are effective in experimental infections with American trypanosomiasis caused by *T. cruzi* (Bern et al., 2007; Tarleton et al., 2007). Of these, nifurtimox and benznidazole are currently used clinically to treat the disease. Nifurtimox (Bayer 2502, LAMPII), a nitrofuran analog, and benznidazole (Roche 7-1051, ROCAGAN), a nitroimidazole analog, can be obtained in the U.S. from the CDC.

\[
\text{NIFURTIMOX}
\]

\[
\text{BENZNIDAZOLE}
\]

**Antiprotozoal Effects and Mechanisms of Action.** Nifurtimox and benznidazole are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi*. Nifurtimox also has activity against
Nitazoxanide

*Nitazoxanide* (*N*-nitrothiazolyl salicylamide, ALINA) is an oral synthetic broad-spectrum antiparasitic agent that was synthesized originally in the 1980s based on the structure of the antihelminthic niclosamide (Chapter 51). It was found initially to have activity against tape-worms (Rossier and Maisonneuve, 1984); subsequent *in vitro* studies suggested that it was effective against a number of intestinal helminths and protozoans. Nitazoxanide is FDA-approved for the treatment of cryptosporidiosis and giardiasis in children.

**Antimicrobial Effects.** Nitazoxanide and its active metabolite, nitizoxanide (desacetyl-nitazoxanide), inhibit the growth of sporozoites...
and oocytes of *C. parvum* and inhibit the growth of the trophozoites of *G. intestinalis*, *E. histolytica*, and *T. vaginalis* in vitro (Adagu et al., 2002). Activity against other protozoans, including *Blastocystis hominis*, *Isospora belli*, and *Cyclospora cayetanensis* also has been reported. Nitazoxanide also demonstrated activity against the intestinal helminths: *Hymenolepis nana*, *Trichuris trichiura*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Ancylostoma duodenale*, *Strongyloides stercoralis*, and the liver fluke *Fasciola hepatica*. Effects against some anaerobic or microaerophilic bacteria, including *Clostridium* spp. and *H. pylori*, also have been reported. Nitazoxanide reportedly displays antiviral activity and is now undergoing clinical trials for the treatment of hepatitis C (Rossignol and Keeffe, 2008).

**Mechanism of Action and Resistance.** Nitazoxanide interferes with the PFOR enzyme-dependent electron-transfer reaction, which is essential to anaerobic metabolism in protozoan and bacterial species. One proposed mechanism of nitazoxanide is blockade of the first step in the PFOR chain by inhibiting the binding of pyruvate to the thiamine pyrophosphate cofactor (Hoffman et al., 2007). Resistance to nitazoxanide has been induced in *Giardia* isolates resistant to metronidazole. Nitazoxanide is a pregnancy Category B agent, based on animal teratogenicity and fertility studies, but there is no clinical experience with its use in pregnant women or nursing mothers.

**Paromomycin**

Paromomycin (aminosidine, HUMATIN) is an aminoglycoside of the neomycin/kanamycin family (Chapter 54) that is used as an oral agent to treat *E. histolytica* infection. The drug is not absorbed from the GI tract and thus the actions of an oral dose are confined to the GI tract. Paromomycin also has been used orally to treat cryptosporidiosis and giardiasis. A topical formulation has been used to treat trichomoniasis, and parenteral administration has been used for visceral leishmaniasis.

**Mechanism of Action.** Paromomycin shares the same mechanism of action as neomycin and kanamycin (binding to the 30S ribosomal subunit) and has the same spectrum of antibacterial activity. Paromomycin is available only for oral use in the U.S. Following oral administration, 100% of the drug is recovered in the feces, and even in the absence of compromised gut integrity, there is little evidence for clinically significant absorption of paromomycin. Parenteral administration carries the same risks of nephrotoxicity and ototoxicity seen with other aminoglycosides.

**Antimicrobial Effects; Therapeutics Uses.** Paromomycin is the drug of choice for treating intestinal colonization with *E. histolytica*. It is used in combination with metronidazole to treat amebic colitis and amebic liver abscess and can be used as a single agent for asymptomatic individuals found to have *E. histolytica* intestinal colonization. Recommended dosing for adults and children is 25-35 mg/kg per day orally in three divided doses. Adverse effects are rare with oral usage but include abdominal pain and cramping, epigastric pain, nausea, and vomiting, steatorrhea, and diarrhea. Rarely, rash and headache have been reported. Paromomycin has been used to treat cryptosporidiosis in AIDS patients both as a single agent and in combination with azithromycin, but in a randomized controlled trial, paromomycin was no more effective than placebo for this indication (Hewitt et al., 2000). Paromomycin has been advocated as a treatment for giardiasis in pregnant women, especially during the first trimester, when metronidazole is contraindicated and as an alternative agent for metronidazole-resistant isolates of *G. intestinalis*. Although there is limited clinical experience, response rates of 55-90% have been reported (Gardner and Hill, 2001). Dosing in adults is 500 mg orally three times daily for 10 days,
whereas children have been treated with 25-30 mg/kg per day in three divided oral doses. Paromomycin formulated as a 6.25% cream has been used to treat vaginal trichomoniasis in patients who had failed metronidazole therapy or could not receive metronidazole. Some cures have been reported, but vulvovaginal ulcers and pain have complicated treatment and absorption via this route (and the possibility of aminoglycoside-related toxicities) must be anticipated.

Paromomycin is also efficacious as a topical formulation containing 15% paromomycin in combination with 12% methylbenzo-nium chloride for the treatment of cutaneous leishmaniasis (Alvar et al., 2006). The drug has been administered parenterally alone or in combination with antimony to treat visceral leishmaniasis. Paromomycin (intramuscular injection, 11 mg/kg per day for 21 days) produced a cure rate for visceral leishmaniasis (94.6%) that was statistically equivalent to liposomal amphotericin B (Sundar et al., 2007). However, adverse events were more common with paromomycin than with liposomal amphotericin B.

**Pentamidine**

Pentamidine is a positively charged aromatic diamine that was discovered in 1937 as a fortuitous consequence of the search for hypoglycemic compounds that might compromise parasite energy metabolism. Of the compounds tested, three were found to possess outstanding activity: stilbamidine, pentamidine, and propamidine. Pentamidine was the most useful clinically because of its relative stability, lower toxicity, and ease of administration. Pentamidine is a broad-spectrum agent with activity against several species of pathogenic protozoa and some fungi.

![Pentamidine molecule](image)

Pentamidine as the di-isethionate salt is marketed for injection (PENTAM 300, others) or for use as an aerosol (NEBUPENT). One milligram of pentamidine base is equivalent to 1.74 mg of the pentamidine isethionate. The di-isethionate salt is highly water soluble; however, solutions should be used promptly after preparation because pentamidine is unstable in solution.

**Antiprotozoal and Antifungal Effects.** The positively charged aromatic diamidines are toxic to a number of different protozoa yet show rather marked selectivity of action. Pentamidine is used for the treatment of early-stage *T. brucei gambiense* infection (Barrett et al., 2007; Kennedy, 2008) but is ineffective in the treatment of late-stage disease and has reduced efficacy against *T. brucei rhodesiense*. Its use is therefore limited to treatment of first-stage *T. bruc- eii gambiense* sleeping sickness. Pentamidine is an alternative agent for the treatment of cutaneous leishmaniasis (Alvar et al., 2006; Croft, 2008). It has been used for the treatment of visceral disease but less toxic agents are preferred. Pentamidine is an alternative agent for the treatment and prophylaxis of Pneumocystis pneumo-nia caused by the ascomycetous fungus *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) (Thomas and Limper, 2004).

**Mechanism of Action and Resistance.** The mechanism of action of the diamidines is unknown. The dicationic compounds appear to display multiple effects on any given parasite and act by disparate mechanisms in different parasites (Barrett et al., 2007). In *T. brucei*, for example, the diamidines are concentrated via an energy-dependent high-affinity uptake system to millimolar concentrations in cells; this selective uptake is essential to their efficacy. The best-characterized diamidine transporter is the P2 purine transporter used by the melamine-based arsenicals, which explains the cross-resistance to diamidines exhibited by certain arsenical-resistant strains of *T. brucei in vitro* (de Koning, 2008). It is increasingly clear that multiple transporters are responsible for pentamidine uptake, and this may account for the fact that little resistance to this drug is observed in field isolates despite its years of use as a prophylactic agent. Although failure to concentrate diamidines is the usual cause of pentamidine resistance in *vivo*, other mechanisms also may be involved.

The positively charged hydrophobic diamidines may exert their trypanocidal effects by reacting with a variety of negatively charged intracellular targets. Indeed, ribosomal aggregation, inhibition of DNA and protein synthesis, inhibition of several enzymes, and loss of trypanosomal kinetoplast DNA have been reported. The loss of kinetoplast DNA may be mediated through inhibition of topoisomerase II. It is doubtful that an effect on topoisomerase accounts for the drug’s broad antimicrobial activity or fully explains its mechanism of action. Inhibition of S-adenosyl-L-methionine decarboxylase in *vivo* (but no change in polyamine levels in vivo) and inhibition of a plasma Ca²⁺, Mg²⁺-ATPase also have been reported.

**Absorption, Fate, and Excretion.** The pharmacokinetics and biodisposition of pentamidine isethionate have been studied most extensively in AIDS patients with *P. jiroveci* infections (Vöhringer and Arastéh, 1993); information from patients with Gambian trypanosomiasis is more limited (Bronner et al., 1995). Pentamidine isethionate is fairly well absorbed from parenteral sites of administration. Following a single intravenous dose, the drug disappears from plasma with an apparent t₁/₂ of several minutes to a few hours and maximum plasma concentrations after intramuscular injection occurring at 1 hour. The t₁/₂ of elimination is very slow, lasting from weeks to months, and the drug is 70% bound to plasma proteins. This highly charged compound is poorly absorbed orally and does not cross the blood-brain barrier, explaining why it is ineffective against late-stage trypanosomiasis.

After multiple parenteral doses, the liver, kidney, adrenal, and spleen contain the highest concentrations of drug, whereas only traces are found in the brain (Donnelly et al., 1988). The lungs contain intermediate but therapeutic concentrations after five daily doses of 4 mg/kg. Inhalation of pentamidine aerosols is used for prophylaxis of *Pneumocystis* pneumonia; delivery of drug by this route results in little systemic absorption and decreased toxicity compared with intravenous administration in both adults and children (Hand et al., 1994; Leoung et al., 1990). The actual dose delivered to the
lungs depends on both the size of particles generated by the nebulizer and the patient’s ventilatory patterns.

**Therapeutic Uses.** Pentamidine isethionate is used for the treatment of early-stage *T. brucei gambiense* and is given by intramuscular injection in single doses of 4 mg/kg per day for 7 days. Pentamidine has been used successfully in courses of 15-20 intramuscular doses of 4 mg/kg every other day to treat visceral leishmaniasis (Alvar et al., 2006). This compound provides an alternative to antimonials, lipid formulations of amphotericin B, or miltefosine but it is overall the least well tolerated of the available therapies and is not used routinely for this disease. Pentamidine isethionate given as 4-7 intramuscular doses of 4 mg/kg every other day has enjoyed some success in the treatment of cutaneous leishmaniasis (Oriental sore caused by *L. tropica*) but is not used routinely to treat this infection (Alvar et al., 2006).

Pentamidine is one of several drugs or drug combinations used to treat or prevent *Pneumocystis* infection. *Pneumocystis pneumonia* (PCP) is a major cause of mortality in individuals with HIV infection and AIDS and can occur in patients who are immunosuppressed by other mechanisms (e.g., high-dose corticosteroids or underlying malignancy). The availability of highly active antiretroviral therapy (HAART) has reduced the number of cases of PCP significantly within the U.S. and E.U. and greatly reduced the number of individuals requiring prophylaxis for PCP. Trimethoprim-sulfamethoxazole is the drug of choice for the treatment and prevention of PCP (Chapter 52). Pentamidine is reserved for two indications. Pentamidine given intravenously as a 4 mg/kg single daily dose for 21 days is used to treat severe PCP in individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not candidates for alternative agents such as atovaquone or the combination of clindamycin and primaquine. Pentamidine has been recommended as a “salvage” agent for individuals with PCP who failed to respond to initial therapy (usually trimethoprim-sulfamethoxazole), but a meta-analysis suggested that pentamidine is less effective than other therapies (specifically the combination of clindamycin and primaquine or atovaquone) for this indication (Smego et al., 2001). Pentamidine administered as an aerosol preparation is used for the prevention of PCP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not deemed candidates for either dapsone (alone or in combination with pyrimethamine) or atovaquone. Candidates for PCP prophylaxis are individuals with HIV infection and a CD4 count of ≤200/mm³ and individuals with HIV infection and persistent unexplained fever or oropharyngeal candidiasis. Secondary prophylaxis is recommended for everyone with a documented PCP episode. For prophylaxis, pentamidine isethionate is given monthly as a 300-mg dose in a 5-10% nebulized solution over 30-45 minutes. Although the monthly dosage regimen is convenient, aerosolized pentamidine has several disadvantages, including its failure to treat any extrapulmonary sites of *Pneumocystis*, the lack of efficacy against any other potential opportunistic pathogens (compared with trimethoprim-sulfamethoxazole), and a slightly increased risk for pneumothorax. Long-term aerosolized pentamidine prophylaxis (≥5 years) has not been associated with the development of any pulmonary disease (Obaji et al., 2003). For individuals who receive HAART and develop CD4 counts persistently above 200/mm³ for 3 months, primary or secondary PCP prophylaxis can be stopped.

**Toxicity and Side Effects.** Pentamidine is a toxic agent, and ~50% of individuals receiving the drug at recommended doses (4 mg/kg per day) show some adverse effect. Intravenous administration of pentamidine may be associated with hypotension, tachycardia, and headache. These effects are probably secondary to the ability of pentamidine to bind imidazoline receptors (Chapter 14) and can be ameliorated by slowing the rate of the intravenous infusion (Wood et al., 1998). As noted earlier, the diamidines were designed originally for use as hypoglycemics, and pentamidine retains that property. Hypoglycemia, which can be life threatening, may occur at any time during pentamidine treatment, even weeks into therapy. Careful monitoring of blood sugar is key. Paradoxically, pancreatitis, hyperglycemia, and the development of insulin-dependent diabetes have been seen in some patients. Pentamidine is nephrotoxic (~25% of treated patients show signs of renal dysfunction), and if the serum creatinine concentration rises >1.0-2.0 mg/dL, it may be necessary to withhold the drug temporarily or change to an alternative agent. Individuals developing pentamidine-induced renal dysfunction are at higher risk for hypoglycemia. Other adverse effects include skin rashes, thrombophlebitis, anemia, neutropenia, and elevation of hepatic enzymes. Intramuscular administration of pentamidine, while effective, is associated with the development of sterile abscesses at the injection site, which can become infected secondarily. For this reason, most authorities recommend intravenous administration. Aerosolized pentamidine is associated with few adverse events.

**Quinacrine**

Quinacrine is an acridine derivative used widely during World War II as an antimalarial agent. *Quinacrine hydrochloride* is very effective against *G. lamblia*, producing cure rates of at least 90%. However, quinacrine is no longer available in the U.S. For a description of the pharmacology and toxicology of quinacrine, consult the fifth and earlier editions of this book.

**Sodium Stibogluconate**

Antimonials were introduced in 1945 and have been used for therapy of leishmaniasis and other protozoal infections (Alvar et al., 2006; Croft, 2008; Olliaro et al., 2005). The first trivalent antimonial compound used to treat cutaneous leishmaniasis and kala azar was antimony potassium tartrate (tartar emetic), which was both toxic and difficult to administer. Tartar emetic and other trivalent arsenicals eventually were replaced by pentavalent antimonial derivatives of phenylstibonic acid. An early member of this family of compounds was sodium stibogluconate (sodium antimony gluconate, PENTOSTAM). This drug is used widely today and, together with meglumine antimonate (GLUCANTIME), is the drug of choice for the treatment and prevention of visceral leishmaniasis (Chapter 50). In addition, sodium stibogluconate is a useful salvage therapy for patients who fail to respond to initial therapy. A single intravenous injection of 20-25 mg/kg or a 100-mg/kg daily dose for 10-21 days is used for treatment of visceral leishmaniasis in adults and older children. For treatment of cutaneous leishmaniasis, sodium stibogluconate is given intramuscularly as a single dose of 20-25 mg/kg or a 100-mg/kg daily dose for 10-21 days. Sodium stibogluconate is available in vials containing a pyrogen-free purified water solution that must be reconstituted before use. It is not nephrotoxic, is well tolerated, and produces cure rates of at least 90%. Stibogluconate sodium is not recommended for the treatment of American cutaneous leishmaniasis or cutaneous leishmaniasis in newborns or infants. Stibogluconate sodium is not given to children younger than 12 years of age or adults weighing less than 50 kg. Decreased urination and dark yellow or brown urine are typical; gastrointestinal distress, nausea, vomiting, and anorexia may occur. Arsenic toxicity in blood and urine is produced by stibogluconate sodium, as indicated by the increased excretion of arsenic in the urine. Arsenic can be removed from the organism by providing large quantities of vitamin C or an ascorbic acid solution. In rare instances, skin reactions resembling eczema may develop.
2006), where lipid-based amphotericin B and miltefosine are now recommended instead.

Clinical formulations of sodium stibogluconate consist of multiple uncharacterized molecular forms, some of which have higher molecular masses than the compound shown. Typical preparations contain 30-34% pentavalent antimony by weight and m-chlorocresol (as a preservative). In the U.S., sodium stibogluconate can be obtained from the CDC.

**Antiprotozoal Effects and Drug Resistance.** The mechanism of the antileishmanial action of sodium stibogluconate remains an active area of research, and recent studies have provided interesting new insights (Croft et al., 2006). These studies support the old hypothesis that relatively nontoxic pentavalent antimonials act as prodrugs. These compounds are reduced to the more toxic Sb$^{3+}$ species that kill amastigotes within the phagolysosomes of macrophages. This reduction preferentially occurs in the intracellular amastigote stage, and recently an enzyme, As$^{5+}$ reductase, was characterized that is able to reduce Sb$^{5+}$ to the active Sb$^{3+}$ form. Furthermore, the overexpression of this enzyme in promastigotes increased their sensitivity to the drugs. Classically, it was thought that the antiparasitic effects of antimonials occurred through inhibition of glucose catabolism and fatty acid oxidation; however, recent studies suggest that the drugs operate by interfering with the trypanothione redox system. In drug-sensitive cell lines, Sb$^{3+}$ induces a rapid efflux of trypanothione and glutathione from the cells, and also inhibits trypanothione reductase, thereby causing a significant loss of thiol reduction potential in the cells. This hypothesis is further supported by the observation that laboratory-generated resistance to antimonials leads to overexpression of glutathione and polyamine biosynthetic enzymes, resulting in increased trypanothione levels, which conjugate to the drug. Elevated levels of ABC efflux transporters (see Chapter 5) were observed, though these transporters seem to play only a minor role in drug resistance.

**Absorption, Fate, and Excretion.** The pentavalent antimonials attain much higher concentrations in plasma than do the trivalent compounds. Consequently, most of a single dose of sodium stibogluconate is excreted in the urine within 24 hours. Its pharmacokinetic behavior is similar whether the drug is given intravenously or intramuscularly; it is not active orally (Chulay et al., 1988). The agent is absorbed rapidly, distributed in an apparent volume of ~0.22 L/kg, and eliminated in two phases. The first has a t$_1$ of ~2 hours, and the second is much slower (t$_{1/2}$ = 33-76 hours). The prolonged terminal elimination phase may reflect conversion of the Sb$^{5+}$ to the more toxic Sb$^{3+}$ that is concentrated and slowly released from tissues. Indeed, ~20% of the plasma antimony is present in the trivalent form after pentavalent antimonial administration. Sequestration of antimony in macrophages also may contribute to the prolonged antileishmanial effect after plasma antimony levels have dropped below the minimal inhibitory concentration observed in vitro.

**Therapeutic Uses.** The changing use of sodium stibogluconate, meglumine antimonate, and other agents for the chemotherapy of leishmaniasis has been reviewed extensively (Alvar et al., 2006; Croft, 2008; Olliaro et al., 2005). Sodium stibogluconate is given parenterally, with the dosage regimen individualized depending on the local responsiveness of a particular form of leishmaniasis to this compound. The standard course is 20 mg/kg per day for 21 days for cutaneous disease and for 28 days for visceral disease. In some regions of the world prolonged dosage schedules with maximally tolerated doses are now needed for successful therapy of visceral, mucosal, and some cutaneous forms of leishmaniasis, in part to overcome increasing clinical resistance to antimonial drugs. Even high-dose regimens may no longer produce satisfactory results. Increased resistance has greatly compromised the effectiveness of these drugs, and the drug is now obsolete in India. This is in contrast to previous cure rates of >85% for both visceral and cutaneous disease. Liposomal amphotericin B is the recommended alternative for treatment of either visceral leishmaniasis (kala azar) in India or mucosal leishmaniasis in general; the orally effective compound miltefosine is likely to see much wider use in the coming years. Intraleisonal treatment has also been advocated as a safer, alternative method for treating cutaneous disease (Munir et al., 2008).

Children usually tolerate the drug well, and the dose per kilogram is the same as that given to adults. Patients who respond favorably show clinical improvement within 1-2 weeks of initiation of therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals. Patients infected with HIV present a challenge because they usually relapse after successful initial therapy with either pentavalent antimonials or amphotericin B.

**Toxicity and Side Effects.** The toxicity of the pentavalent antimonials is best evaluated in patients without systemic disease (i.e., visceral leishmaniasis). In general, high-dose regimens of sodium stibogluconate are fairly well tolerated; toxic reactions usually are reversible, and most subside despite continued therapy. Effects noted most commonly include pain at the injection site after intramuscular administration; chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminase levels; bone marrow suppression manifested by decreased red cell, white cell, and platelet counts in the blood; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and skin rashes. Changes in the electrocardiogram that include T-wave flattening and inversion and prolongation of the QT interval found in patients with systemic disease are uncommon in other forms of leishmaniasis (Navin et al., 1992). Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of antimonial toxicity, as are shock and sudden death.

**Suramin**

Based on the trypanocidal activity of the dyes trypan red, trypan blue, and afridol violet, research in Germany resulted in the introduction of suramin into therapy in 1920. Today, the drug is used primarily for
treatment of African trypanosomiasis; it has no clinical utility against American trypanosomiasis. Although suramin is effective in clearing adult filariae in onchocerciasis, ivermectin has supplanted suramin for the treatment of this condition (Chapter 51). Suramin is a potent inhibitor of retroviral reverse transcriptase in vitro, but it is ineffective in HIV infection. The antiproliferative activity of suramin led to its experimental use, alone and with other compounds, for the therapy of a variety of tumors, particularly in androgen-independent prostate cancer. However, only modest palliative effects were observed and treatment for this indication was complicated by high toxicity. The antiparasitic and antineoplastic properties of suramin, along with its clinical uses and limitations, have been the topic of numerous reviews (Kennedy, 2008; McGeeary et al., 2008).

\[ \text{Suramin sodium (BAYER 205, formerly GERMANIN, others)} \]

is soluble in water, but solutions deteriorate quickly in air; only freshly prepared solutions should be used. In the U.S., suramin is available only from the CDC.

**Antiparasitic Effects.** Suramin is a relatively slowly acting trypanocide (>6 hours in vitro) with high clinical activity against both T. b. gambiense and T. b. rhodesiense. Its mechanism of action is unknown (Barrett et al., 2007). Selective toxicity is likely to result from the ability of the parasite to take up the drug by receptor-mediated endocytosis of the protein-bound drug, with low-density lipoproteins the most important interacting proteins for this event. Suramin reacts reversibly with a variety of biomolecules in vitro, inhibiting many trypanosomal and mammalian enzymes and receptors unrelated to its antiparasitic effects. Compartmentation protects many vital molecules, such as the glycolytic enzymes inside trypanosomal glycosomes, from suramin because this compound does not cross membrane barriers by passive diffusion. Suramin-treated trypanosomes exhibit damage to intracellular membrane structures other than lysosomes, but whether or not this relates to the drug’s primary action is unknown. Inhibition of a trypanosomal cytosolic serine oligopeptidase may account for part of the activity of suramin, but the drug is also an inhibitor of dihydrofolate reductase, thymidine kinase, and several glycolytic enzymes. No clear consensus for the mechanism of action has emerged, and the lack of any significant field resistance points to multiple potential targets.

**Absorption, Fate, and Excretion.** The clinical pharmacology of suramin was determined during clinical trials for its application as an antitumor agent. Because it is not absorbed after oral intake, suramin is given intravenously to avoid local inflammation and necrosis associated with subcutaneous or intramuscular injections. After its administration, the drug displays complex pharmacokinetics with marked interindividual variability. The drug is 99.7% serum protein bound and has a terminal elimination t1/2 of 41-78 days. Suramin is not appreciably metabolized, and renal clearance accounts for elimination of ~80% of the compound from the body. This large polar anion does not enter cells readily, and tissue concentrations are uniformly lower than those in plasma. In experimental animals the kidneys contain considerably more suramin than do other organs. Such retention may account for the fairly frequent occurrence of albuminuria following injection of the drug in humans. Very little suramin penetrates the CSF, consistent with its lack of efficacy once the CNS has been invaded by trypanosomes.

**Therapeutic Uses.** Suramin is the first-line therapy for early-stage T. brucei rhodesiense infection (Barrett et al., 2007; Kennedy, 2008). Although it shows activity against T. brucei gambiense, it is not used for this application because other drugs are available for the treatment of this disease that are not complicated by the high activity of suramin against Onchocerca and Brugia, and possible immunological reactions resulting from killing of these parasitic worms. Because only small amounts of the drug enter the brain, suramin is used only for the treatment of early-stage African trypanosomiasis (before CNS involvement). Suramin will clear the hemolymphatic system of trypanosomes even in late-stage disease, so it is often administered before initiating melarsoprol to reduce the risk of reactive encephalopathy associated with the administration of that arsenical. Suramin is given by slow intravenous injection as a 10% aqueous solution. Treatment of active African trypanosomiasis should not be started until 24 hours after diagnostic lumbar puncture to ensure no CNS involvement, and caution is required if the patient has onchocerciasis (river blindness) because of the potential for eliciting a Mazzotti reaction (i.e., pruritic rash, fever, malaise, lymph node swelling, eosinophilia, arthralgias, tachycardia, hypotension, and possibly permanent blindness). The normal single dose for adults with T. brucei rhodesiense infection is 1 g. It is advisable to employ a test dose of 200 mg initially to detect sensitivity, after which the normal dose is given intravenously on days 1, 3, 7, 14, and 21, although a wide range of schedules are in use. The pediatric dose is 20 mg/kg, given according to the same schedule. Patients in poor condition should be treated with lower doses during the first week. Patients who relapse after suramin therapy should be treated with melarsoprol.

**Toxicity and Side Effects.** Suramin can cause a variety of untoward reactions that vary in intensity and frequency and tend to be more severe in debilitated patients. Fortunately, the most serious immediate reaction consisting of nausea, vomiting, shock, and loss of consciousness is rare (~1 in 2000 patients). Malaise, nausea, and fatigue are also common immediate reactions. Parasite destruction may cause febrile episodes and skin hypersensitivity rashes that are reduced by pretreatment with glucocorticoids; concomitant onchocerciasis optimally should be treated first with ivermectin to minimize these reactions (Chapter 51). The most common problem encountered after several doses of suramin is renal toxicity, manifested by albuminuria, and delayed neurological complications, including headache, metallic taste, paresthesias, and peripheral neuropathy. These complications usually disappear spontaneously despite continued therapy. Other, less prevalent reactions include vomiting, diarrhea,
stomatitis, chills, abdominal pain, and edema. Laboratory abnormalities noted in 12-26% of patients with AIDS include leukopenia and occasional agranulocytosis, thrombocytopenia, proteinuria, and elevations of plasma creatinine, transaminases, and bilirubin, which are reversible. Unexpected findings in patients with AIDS include adrenal insufficiency and vortex keratopathy.

Precautions and Contraindications. Patients receiving suramin should be followed closely. Therapy should not be continued in patients who show intolerance to initial doses, and the drug should be employed with great caution in individuals with renal insufficiency. Moderate albuminuria is common during control of the acute phase, but persisting, heavy albuminuria calls for caution as well as modification of the treatment schedule. If casts appear, treatment with suramin should be discontinued. The occurrence of palmar-plantar hyperesthesia may presage peripheral neuritis.

Infections with helminths, or parasitic worms, affect more than two billion people worldwide. In regions of rural poverty in the tropics, where prevalence is greatest, simultaneous infection with more than one type of helminth is common. The relative incidence of common helminthic infections in humans worldwide is illustrated in Figure 51–1.

Worms pathogenic for humans are Metazoa and can be classified into roundworms (nematodes) and two types of flatworms, flukes (trematodes) and tapeworms (cestodes). These biologically diverse eukaryotes vary with respect to life cycle, bodily structure, development, physiology, localization within the host, and susceptibility to chemotherapy. Immature forms invade humans via the skin or GI tract and evolve into well-differentiated adult worms with characteristic tissue distributions. With few exceptions, such as Strongyloides and Echinococcus, these organisms cannot complete their life cycle and replicate within the human host to produce mature offspring. Therefore, the extent of exposure to these parasites dictates the number of parasites infecting the host, a characteristic recognized as infection intensity, which itself determines the morbidity caused by infection. Secondly, any reduction in the number of adult organisms by chemotherapy is sustained unless reinfection occurs. The burden of parasitic helminths within an infected population is not uniformly distributed, and it typically displays a negative binomial distribution whereby relatively few persons carry the heaviest parasite burden, resulting in increased morbidity in these individuals who also contribute disproportionately to transmission.

Anthelmintics are drugs that act either locally within the gut lumen to cause expulsion of worms from the GI tract, or systemically against helminths residing outside the GI tract. Safe and effective broad-spectrum anthelmintics, initially developed for veterinary use, are currently available for use in humans. However, therapy for many tissue-dwelling helminths, such as filarial parasites, is not fully effective. For many reasons, including their long-lived and relatively complex life cycles, acquired resistance to anthelmintics in humans has yet to become a major clinical problem. However, with the increasing deployment of mass drug therapy, and considering the veterinary experience with resistance, the potential for drug resistance among helminths in humans requires monitoring.

Primarily as a result of stepped-up advocacy by the World Health Organization (WHO), the World Bank, the Global Network for Neglected Tropical Diseases, and smaller nongovernmental organizations such as the London-based Partnership for Child Development (PCD), there is increasing appreciation for the impact of helminth infections on the health and education of school-aged children. These organizations have promoted the periodic and frequent use of anthelmintic drugs in schools as a means to control morbidity caused by soil-transmitted helminths and schistosomes in developing countries. In addition, interest has grown in eliminating arthropod-borne helminth infections by interrupting their transmission through the widespread use of anthelmintics. Today, control programs employing anthelmintics rank among the world’s largest health efforts, and hundreds of millions of people receive treatment annually (Hotez et al., 2009).

This chapter is divided into two main parts:

- clinical presentation and recommended chemotherapy for common helminth infections in humans
- pharmacological properties of specific anthelmintics
HELMINTH INFECTIONS AND THEIR TREATMENT

Nematodes (Roundworms)

The major nematode parasites of humans include the soil-transmitted helminths (STHs; sometimes referred to as “geohelminths”) and the filarial nematodes.

The major STH infections (ascariasis [roundworm], trichuriasis [whipworm], and hookworm infection) are among the most prevalent infections in developing countries. Because STH worm burdens are higher in school-aged children than in any other single group, the WHO and the PCD advocate school-based administration of broad-spectrum anthelmintics on a periodic and frequent basis. The agents most widely employed for reducing morbidity are the benzimidazole anthelmintics (BZ), either albendazole (ALBENZA and ZENTEL) or mebendazole (VERMOX, others) (Table 51–1, p. 1450).

Single dose therapy with a BZ reduces worm burden to a varying degree, with greatest efficacy for ascariasis, followed by whipworm and hookworm (Keiser and Utzinger, 2008) and subsequently reduces morbidity attributable to the parasite. Treatment improves host iron stores and hemoglobin levels, physical growth, cognition, educational achievement, and school absenteeism, as well as having a positive influence on the entire community by reducing transmission (Bethony et al., 2006). In 2001, the World Health Assembly adopted a resolution urging that by 2010 member states should regularly administer anthelmintics to at least 75% of all school-age children at risk for morbidity (WHO, 2002). Concerns with this recommendation have included:

- The scope of the undertaking
- The high rate of post-treatment reinfection that occur in areas of high transmission
- Documented drug failures against hookworm with mebendazole
- The possibility that widespread treatment will lead to the emergence of BZ drug resistance
- The possibility that by focusing exclusively on school-aged children, other groups and vulnerable populations, such as preschool children and women of reproductive age, will be omitted

In addition to targeting STH infections among school-aged children, there are ongoing programs to eliminate lymphatic filariasis (LF) and onchocerciasis (river blindness) over the next 10-20 years (Molyneux and Zagaria, 2002; Molyneux et al., 2003). The term elimination, as opposed to eradication, refers to the reduction of disease incidence to zero or close to zero, with a requirement for ongoing control efforts (Hotz et al., 2004). The major goals for the LF elimination program (and to some extent, the onchocerciasis elimination programs) are to interrupt arthropod-borne transmission by administering combination therapy with either diethylcarbamazine (DEC; HETRAZAN; available from CDC in the U.S.) and albendazole (in LF-endemic regions such as India and Egypt), or ivermectin (STROMECTOL) and albendazole (in LF regions where onchocerciasis and/or loiasis are co-endemic). For onchocerciasis, ivermectin also reduces the microfilarial load in the skin, leading to reductions in so-called troublesome itching and ultimately, in preventing river blindness. DEC and ivermectin target the microfilarial stages of the parasite, which circulate in blood and are taken up by arthropod vectors where further parasite development takes place. Both control programs rely heavily on the generosity of major drug companies that donate ivermectin and albendazole, respectively (Burnham and Mebrahtu, 2004; Molyneux et al., 2003).

**Ascaris lumbricoides and Toxocara canis.** Ascaris lumbricoides, known as the “roundworm,” parasitizes a billion or more people worldwide (de Silva et al., 2003; Hotze et al., 2009). Ascariasis may affect from 70-90% of persons in some tropical regions; it is also seen in temperate climates. People become infected by ingesting food or soil contaminated with embryonated A. lumbricoides eggs. The highest ascaris worm burdens occur in school-aged children in whom the parasite can cause intestinal obstruction or hepatobiliary ascariasis (Crompton, 2001).

Effective and safe anthelmintics have replaced the older ascaricides. The preferred agents are the benzimidazoles (BZ), mebendazole and albendazole, and the broad spectrum drug pyrantel pamoate. Cure with any of these drugs can be achieved in nearly 100% of cases. Mebendazole and albendazole are preferred for therapy of asymptomatic to moderate ascariasis, as well as for mass drug administration campaigns because those agents have a broad spectrum of activity against GI nematodes. Both compounds should be used with caution to treat heavy Ascaris infections, alone...
or with hookworms. In rare instances, following chemotherapy hyperactive ascarids may migrate to unusual loci and cause serious complications such as appendicitis, occlusion of the common bile duct, and intestinal obstruction and perforation with peritonitis. For this reason, some clinicians recommend the use of pyrantel for heavy *Ascaris* infections because this agent paralyzes the worms prior to their expulsion. Surgery may be required to alleviate obstructive complications. Pyrantel is considered safe for use during pregnancy, whereas BZ should be avoided during the first trimester. Albendazole is available off-label for treatment of ascariasis in the U.S.

Toxocariasis, a zoonotic infection caused by the canine ascarid *Toxocara canis*, is a common helminthiasis in North America and Europe. Although precise information is not available, toxocariasis may have displaced pinworm as the most common helminth infection in the U.S. (Hotez and Wilkins, 2009). In the U.S., the highest rates of infection are found within African American and Hispanic American populations, with some evidence to suggest that toxocariasis is the most common neglected infection associated with poverty (Hotez, 2008; Hotez and Wilkins, 2009).

Three major syndromes are caused by *T. canis* infection: visceral larva migrans (VLM), ocular larva migrans (OLM), and covert toxocariasis (CTox). CTox may represent an under-appreciated cause of asthma and seizures (Sharshir et al., 2001). Specific treatment of VLM is reserved for patients with severe, persistent, or progressive symptoms (Bethany et al., 2006). Albendazole is the drug of choice. In contrast, anthelmintic therapy for treatment of OLM and CT is controversial. In the case of OLM, surgical management often is indicated, sometimes accompanied by systemic or topical steroids (Sabrosa and de Souza, 2001).

**Hookworm**

*Necator americanus*, *Ancylostoma duodenale*. These closely related hookworm species infect ~1 billion people in developing countries (Figure 51–1).

*N. americanus* is the predominant hookworm worldwide, especially in the Americas, sub-Saharan Africa, South China, and Southeast Asia, whereas *A. duodenale* is focally endemic in Egypt and in parts of northern India and China. Infection also occurs farther north in unusual but relatively warm settings such as mines and large mountain tunnels, hence the terms miner’s disease and tunnel disease. Hookworm larvae live in the soils and penetrate exposed skin. After reaching the lungs, the larvae migrate to the oral cavity and are swallowed. After attaching to the small intestinal mucosa, the derived adult worms feed on host blood. There is a general relationship between the number of hookworms (hookworm burden) as determined by quantitative fecal egg counts and fecal blood loss. In individuals with low iron reserves, the correlation extends to hookworm burden and degree of iron-deficiency anemia. Unlike heavy *Ascaris* and *Trichuris* infections, which occur predominantly in children, heavy hookworm infections also occur in adults, including women of reproductive age. In some endemic areas, the heaviest hookworm burdens occur exclusively in adult populations.

Although iron supplementation (and transfusion in severe cases) often is helpful in individuals with severe iron-deficiency anemia, the major goal of treatment is to remove blood-feeding adult hookworms from the intestines. Albendazole is the agent of first choice against both *A. duodenale* and *N. americanus*. This drug has the advantage of activity against other GI nematodes (Hotez, 2009). Mebendazole is also commonly used; however, especially when used in a single dose, albendazole is considered far superior to mebendazole at removing adult hookworms from the GI tract (Keiser and Utzinger, 2008). Oral albendazole is the drug of choice for treating cutaneous larva migrans, or “creeping eruption,” which is due most commonly to skin migration by larvae of the dog hookworm, *A. braziliense*. Oral ivermectin or topical thiabendazole also can be used.

**Trichuris trichiura.** *Trichuris* (whipworm) infection occurs in ~1 billion people in developing countries (Bethony et al., 2006; de Silva et al., 2003; Hotez et al, 2009). The infection is acquired by ingestion of embryonated eggs. In children, heavy *Trichuris* worm burdens can lead to colitis, *Trichuris* dysentery syndrome, and rectal prolapse (Bundy and Cooper, 1989).

Mebendazole and albendazole are the most effective agents for treatment of whipworm, either as a single agent or together with *Ascaris* and hookworm infections. Both drugs provide significant reductions in host worm burdens even when used in a single dose, such as what might be used in mass drug administration campaigns (Hotez, 2009). However, single-dose therapy with either drug is often ineffective for achieving “cure” (i.e., total worm burden removal), so that a 3-day course of therapy is typically required (Keiser and Utzinger, 2008).

**Strongyloides stercoralis.** *S. stercoralis*, sometimes called the threadworm or dwarf threadworm, is almost unique among helminths in being able to complete its life cycle within the human host. The organism infects 30–100 million people worldwide, most frequently in the tropics and other hot, humid locales. In the U.S., strongyloidiasis is still endemic in the Appalachian region and in parts of the American South (Hotez, 2008). It also is found in institutionalized individuals living in unsanitary conditions and in immigrants, travelers, and military personnel who lived in endemic areas.

Infective larvae in fecally contaminated soil penetrate the skin or mucous membranes, travel to the lungs, and ultimately mature into adult worms in the small intestine, where they reside. Many infected individuals are asymptomatic, but some experience skin rashes, nonspecific GI symptoms, and cough. Life-threatening disseminated disease, known as the hyperinfection syndrome, can occur in immunosuppressed persons, even decades after the initial infection when parasite replication in the small intestine is unchecked by a competent immune response. Most deaths caused by parasites in the U.S. probably are due to *Strongyloides*...
hyperinfection. Ivermectin is the drug of choice for treatment of strongyloidiasis. Hyperinfection may require prolonged or repeated therapy. Although the BZ drugs show some efficacy, they are less effective than ivermectin.

Enterobius vermicularis. Enterobius, the pinworm, is one of the most common helminth infections in temperate climates, including the U.S. Although this parasite rarely causes serious complications, pruritus in the perianal and perineal region can be severe, and scratching may cause secondary infection. In female patients, worms may wander into the genital tract and penetrate into the peritoneal cavity. Salpingitis or even peritonitis may ensue. Because the infection easily spreads throughout members of a family, a school, or an institution, the physician must decide whether to treat all individuals in close contact with an infected person. More than one course of therapy may be required.

Pyrantel pamoate, mebendazole, and albendazole are highly effective. Single oral doses of each should be repeated after 2 weeks. When their use is combined with rigid standards of personal hygiene, a very high proportion of cures can be obtained. Treatment is simple and almost devoid of side effects.

Trichinella spiralis. T. spiralis is an ubiquitous zoonotic nematode parasite. Trichinosis in the U.S. and the developing world is usually caused by eating under- or uncooked venison and wild pigs. When released by acid stomach contents, encysted larvae mature into adult worms in the intestine. Adults then produce infectious larvae that invade tissues, especially skeletal muscle and heart.

Severe infection can be fatal, but more typically causes marked muscle pain and cardiac complications. Fortunately, infection is readily preventable. All pork, including pork sausages, should be thoroughly cooked before being eaten. The encysted larvae are killed by exposure to heat of 60°C for 5 minutes.

Albendazole and mebendazole are effective against the intestinal forms of T. spiralis that are present early in infection. The efficacy of these agents or any anthelmintic agent on larvae that have migrated to muscle is questionable. Glucocorticoids may be of considerable value in controlling the acute and dangerous manifestations of established infection, although steroids can alter the metabolism of albendazole.

Lymphatic Filariasis: Wuchereria bancrofti, Brugia malayi, and B. timori. Adult worms that cause human lymphatic filariasis (LF) dwell in the lymphatic vessels. Transmission occurs through the bite of infected mosquitoes; ~90% of cases are due to W. bancrofti, most of the rest are due to B. malayi. The major endemic regions are sub-Saharan Africa, the Indian subcontinent, Southeast Asia and the Pacific region, and in four tropical countries of the Americas (Haiti, Dominican Republic, Guyana, and Brazil).

In LF, host reaction to the adult worms initially cause lymphatic inflammation manifested by fevers, lymphangitis, and lymphadenitis. This can progress to lymphatic obstruction and is often exacerbated by secondary attacks of bacterial cellulitis, leading to lymphedema manifested by hydrocele and elephantiasis. An accentuated immune reaction to microfilariae, termed tropical pulmonary eosinophilia, also occurs in some persons.

The Global Program for the Elimination of LF recommends that all at-risk individuals be treated once yearly with an oral two-drug combination (Molyneux and Zagaria, 2002). Today, >500 million people are treated annually (Hotez, 2009). For most countries, the WHO recommends diethylcarbamate (DEC) for its micro- and macrofilaricidal effect in combination with albendazole to enhance macrofilaricidal activity. The exceptions are in many parts of sub-Saharan Africa and Yemen, where either loiasis or onchocerciasis are co-endemic. In these regions, ivermectin is substituted for DEC (Molyneux et al., 2003). DEC and ivermectin clear circulating microfilariae from infected subjects (Molyneux and Zagaria, 2002), thereby reducing the likelihood that mosquitoes will transmit LF to other individuals. The number of serious adverse events from LF-control chemotherapy programs has been remarkably low, 1 out of 4.5 million subjects treated (Molyneux et al., 2003).

DEC is the drug of choice for specific therapy directed against adult worms. However, the anthelmintic effect on the adult worms is variable. Although chemotherapy decreases the incidence of filarial lymphangitis, it is unclear whether it reverses lymphatic damage or other chronic manifestations of LF. In longstanding elephantiasis, surgical measures may be required to improve lymph drainage and remove redundant tissue.

Loa loa (loiasis). L. loa is a tissue-migrating filarial parasite found in large river regions of Central and West Africa; the parasite is transmitted by deerflies. Adult worms reside in subcutaneous tissues, and infection may be recognized when these migrating worms cause episodic and transient subcutaneous “Calabar” swellings. Adult worms may also pass across the sclera, causing “eyeworm.” Rarely, encephalopathy, cardiopathy, or nephropathy occurs in association with heavy infection, particularly following chemotherapy.

DEC currently is the best single drug for the treatment of loiasis, but it is advisable to start with a small initial dose to diminish host reactions that result from destruction of microfilariae. Glucocorticoids may be administered to ameliorate post-treatment acute reactions. In rare instances, life-threatening encephalopathy follows the treatment of loiasis, probably due to the inflammatory reaction to dead or dying microfilariae lodged in the cerebral microvasculature. Guidelines have been developed aimed at screening out populations with heavy infection so that they are not administered ivermectin, which has also been associated with fatal encephalopathy. The potential complications of unmonitored DEC treatment of loiasis are a major reason why this agent is not recommended for mass chemoprophylaxis of LF in regions of sub-Saharan Africa where L. loa is co-endemic.

Onchocerca volvulus (Onchocerciasis or River Blindness). Transmitted by blackflies near fast-flowing
streams and rivers, *O. volvulus* infects 17-37 million people in 22 countries in sub-Saharan Africa (Hotez et al., 2009; Molyneux et al., 2003), and <100,000 people in six Latin American countries (Mexico, Guatemala, Ecuador, Colombia, Venezuela, and Brazil). Cases also occur in Yemen. Inflammatory reactions, primarily to microfilariae rather than adult worms, affect the subcutaneous tissues, lymph nodes, and eyes. Onchocerciasis is a leading cause of infectious blindness worldwide and results from the cumulative destruction of microfilariae in the eyes, a process that evolves over decades.

Ivermectin is the drug of choice for control and treatment of onchocerciasis. DEC is no longer recommended because ivermectin produces far milder systemic reactions and few if any ocular complications. Ivermectin treatment clears microfilariae in the tissues, prevents the development of blindness, and interrupts transmission. It also results in delayed resumption of production of microfilariae in the uterus of female worms. The African Programme for Onchocerciasis Control coordinates treatment of river blindness in Central and West Africa (www.who.int/pbd/blindness/onchocerciasis). Although suramin (Chapter 50) kills adult *O. volvulus* worms, treatment with this relatively toxic agent is generally not advised.

**Dracunculus medinensis.** Known as the guinea, dragon, or Medina worm, this parasite causes dracunculiasis, an infection in decline with <5000 cases as of 2009, most of which occurred in rural Sudan, Ghana, and Mali. People become infected by drinking water containing copepods that carry infective larvae. After ~1 year, the adult female worms migrate and emerge through the skin, usually of the lower legs or feet. Through the advocacy and work of the Carter Center in partnership with WHO, strategies such as filtering drinking water and reducing contact of infected individuals with water have markedly reduced the transmission and prevalence of dracunculiasis in most endemic regions.

There is no effective anthelmintic for treatment of *D. medinensis* infection. Traditional treatment for this disabling condition is to draw the live adult female worm out day by day by rolling it onto a small piece of wood. This procedure risks significant secondary bacterial infection. Metronidazole, 250 mg given three times a day for 10 days, may provide symptomatic and functional relief by facilitating removal of the worm through indirect suppression of host inflammatory responses.

**Cestodes (Flatworms)**

**Taenia saginata.** Humans are the definitive hosts for *Taenia saginata*, known as the beef tapeworm. This most common form of tapeworm usually is detected after passage of proglottids from the intestine. It is cosmopolitan, occurring most commonly in sub-Saharan Africa and the Middle East, where undercooked or raw beef is consumed. Preventable by cooking beef to 60°C for >5 minutes, this infection rarely produces serious clinical disease, but it must be distinguished from that produced by *Taenia solium*.

Praziquantel (BILTRICIDE) is the drug of choice for treatment of infection by *T. saginata*, although niclosamide can also be used. Both drugs are very effective, simple to administer, and comparatively free from side effects. Assessment of cure can be difficult because the worm (segments as well as scolex) usually is passed in a partially digested state. If the parasitological diagnosis is uncertain, niclosamide (not available in the U.S.) is the preferred drug because of the danger of an inadvertent secondary inflammatory response to occult cysticercosis.

**Taenia solium.** *Taenia solium*, or pork tapeworm, also has a cosmopolitan distribution; immigrant populations are a common source of infection in the U.S. This cestode causes two types of infection. The intestinal form with adult tapeworms is caused by eating undercooked meat containing cysticerci, or more commonly by fecal-oral transmission of infective *T. solium* eggs from another infected human host. Cysticercosis, the far more dangerous systemic form that usually co-exists with the intestinal form, is caused by invasive larval forms of the parasite (Garcia and Del Brutto, 2000). Systemic infection results either from ingestion of fecally contaminated infectious material, or from eggs liberated from a gravid segment passing upward into the duodenum, where the outer layers are digested. In either case, larvae gain access to the circulation and tissues, exactly as in their cycle in the intermediate host, usually the pig. The seriousness of the resulting disease depends on the particular tissue involved. Invasion of the brain (neurocysticercosis) is common and dangerous. Epilepsy, meningitis, and increased intracranial pressure can develop, depending on the inflammatory reactions to the cysticerci and/or their size and location.

Niclosamide is preferred for treatment of intestinal infections with *T. solium* because it will have no effect on occult neurocysticercosis. Albendazole is the drug of choice for treating cysticercosis. The advisability of chemotherapy for neurocysticercosis is controversial (Salinas and Prasad, 2000), being appropriate only when it is directed at live cysticerci and not against dead or dying cysticerci (as evidenced by neuroimaging using contrast agents) or in settings where cerebral imaging reveals a large burden of parasites. Pretreatment with glucocorticoids is strongly advised in this situation to minimize inflammatory reactions to dying parasites (Evans et al., 1997). Anthelmintic treatment can shrink brain cysts but also can have adverse consequences leading to seizures and hydrocephalus especially if corticosteroids are not administered beforehand. Some experts advocate use of albendazole therapy for patients with multiple cysts or viable cysts (as determined by absence of ring enhancement on contrast neuroimaging studies).
**Diphyllobothrium latum.** *Diphyllobothrium latum*, the fish tapeworm, is found most commonly in rivers and lakes of the Northern Hemisphere. In North America, the pike is the most common second intermediate host. The eating of inadequately cooked infested fish introduces the larvae into the human intestine; the larvae can develop into adult worms up to 25 m long. Most infected individuals are asymptomatic. The most frequent manifestations include abdominal symptoms and weight loss; megaloblastic anemia develops due to a deficiency of vitamin B\textsubscript{12}, which is taken up by the parasite.

Therapy with praziquantel readily eliminates the worm and ensures hematological remission.

**Hymenolepis nana.** *Hymenolepis nana*, the dwarf tapeworm, is the smallest and most common tapeworm parasitizing humans. Infection with this cestode is cosmopolitan, more prevalent in tropical than temperate climates, and most common among institutionalized children, including those in the southern U.S. *H. nana* is the only cestode that can develop from ovum to mature adult in humans without an intermediate host. Cysticerci develop in the villi of the intestine and then regain access to the intestinal lumen where larvae mature into adults. Treatment therefore must be adapted to this cycle of autoinfection.

Praziquantel is effective against *H. nana* infections, but higher doses than used for other tapeworm infections usually are required. In addition, therapy may have to be repeated. Treatment failure or reinfection is indicated by the appearance of eggs in the stool 4 weeks after the last dose. Albendazole is partially efficacious against *H. nana*; in 277 cases from 11 studies, 69.5% of patients were cured by albendazole (400 mg daily for 3 days) (Horton, 2000).

**Echinococcus Species.** Humans serve as one of several intermediate hosts for larval forms of *Echinococcus* species that cause “cystic” (*E. granulosus*) and “alveolar” (*E. multilocularis* and *E. vogeli*) hydatid disease. Dogs and related canids are definitive hosts for these tapeworms. Parasite eggs from canine stools are a major worldwide cause of disease in associated livestock (e.g., sheep and goats). *E. granulosus* produces unilocular, slowly growing cysts, most often in liver and lung, whereas *E. multilocularis* creates multilocular invasive cysts, predominantly in the same organs. Removal of the cysts by surgery is the preferred treatment, but leakage from ruptured cysts may spread disease to other organs.

Prolonged regimens of albendazole, either alone or as an adjunct to surgery, are reportedly of some benefit. However, some patients are not cured despite multiple courses of therapy, especially in alveolar echinococcosis where lifelong therapy with albendazole may be required. Treatment of infected dogs with praziquantel eradicates adult worms and interrupts transmission of these infections. New treatment methods, such as percutaneous puncture, aspiration, injection of scolicidal agents, and re-aspiration–based techniques, have received much attention, and they yield rates of cure and relapse equivalent to those following surgery. Benzimidazole treatment should be administered in the perioperative period (Kern, 2003).

**Trematodes (Flukes)**

**Schistosoma haematobium,** **Schistosoma mansoni,** **Schistosoma japonicum.** These are the main species of blood flukes that cause human schistosomiasis; less common species are *Schistosoma intercalatum* and *Schistosoma mekongi.* The infection affects >200 million people (Figure 51–1), and >700 million are at risk (Steinmann et al., 2006). In the Americas, schistosomiasis occurs in Brazil, Suriname, Venezuela and certain Caribbean islands (*S. mansoni*), much of Africa and the Arabian Peninsula (*S. mansoni* and *S. haematobium*), and China, the Philippines, and Indonesia (*S. japonicum*). More than 90% of the cases of schistosomiasis occur in sub-Saharan Africa, with approximately two-thirds of the cases caused by *S. haematobium* and one-third caused by *S. mansoni.* Infected freshwater snails act as intermediate hosts for transmission of the infection, which continues to spread as agriculture and water resources increase. Like most helminth infections, the clinical manifestations of schistosomiasis generally correlate with the intensity of infection, with pathology primarily involving the liver, spleen, and GI tract (for *S. mansoni* and *S. japonicum*) or the urinary and genital tracts (*S. haematobium*). Heavy infection with *S. haematobium* predisposes to squamous cell carcinoma of the bladder. Chronic infections can cause porto-systemic shunting due to hepatic granuloma formation and periportal fibrosis in the liver.

Praziquantel is the drug of choice for treatment of schistosomiasis. The drug is safe and effective when given in single or divided oral doses on the same day. These properties make praziquantel especially suitable for population-based chemotherapy. Moreover, repeated chemotherapy with praziquantel is thought to accelerate protective immune responses by increasing exposure to antigens released from dying worms that induce a Th\textsubscript{2} response (Mutapi et al., 1998). In sub-Saharan Africa, praziquantel is typically administered in mass drug administration campaigns for populations infected with schistosomiasis, with the use of a height pole as a guide to drug dosage. Sadly, even the modest cost of US $0.08 per tablet is beyond the health budgets of many sub-Saharan African countries (Hotz et al., 2009). Although not effective clinically against *S. haematobium* and *S. japonicum,* oxamniquine is effective for treatment of *S. mansoni* infections, particularly in South America, where the sensitivity of most strains may permit single-dose therapy. However, resistance has
been reported and higher doses of the drug are required to treat
African strains than to treat Brazilian strains of *S. mansoni*. 
Metrifonate (trichlorfon) has been used with considerable success in 
the treatment of *S. haematobium* infections, but the drug is not effective 
against *S. mansoni* and *S. japonicum*. Metrifonate is relatively 
inexpensive and can be combined with oxamnique for treatment of 
mixed infections with *S. haematobium* and *S. mansoni*.

The artemisinin derivative artemether (Chapter 49) shows 
promise as an anti-schistosomal agent. Artemether targets the lar-
val schistosomula stages of the parasite. Clinical trials confirmed 
that artemether (administered in an oral dose of 6 mg/kg once 
every 2-3 weeks) significantly reduced the incidence and intensity 
of schistosome infections without adverse reactions. In animals 
harboring juvenile and adult schistosome worms, the combination 
of artemether and praziquantel resulted in significantly reductions 
of worm burden than each drug administered singly (Xiao et al., 
1985). There is concern, however, that widespread use of 
artemether as an anthelmintic may induce drug-resistant malaria 
in areas where multidrug resistant plasmodia still respond to 
artemether therapy.

**Paragonimus westermani and Other Paragonimus Species.** Lung flukes, including several *Paragonimus* 
species, infect humans and carnivores; *P. westermani* is the most common. Found in the Far East and on the 
African and South American continents, these parasites 
have two intermediate hosts: snails and crustaceans. 
Humans become infected by eating raw or undercooked 
crabs or crayfish. Disease is caused by reactions to adult 
worms in the lungs or ectopic sites.

Praziquantel is effective, as is triclabendazole (EGATEN), in a 
dose of 10 mg/kg daily for 3 days (Gao et al., 2003). Bithionol is 
considered a second-line agent; it is available in the U.S. through 
the Centers for Disease Control and Prevention (CDC).

**Clonorchis sinensis, Opisthorchis viverrini, Opisthorchis felineus.** These closely related trematodes exist in 
the Far East (*C. sinensis*, “the Chinese liver fluke,” and *O. viverrini*) and parts of Eastern Europe (*O. felineus*). 
Metacercariae released from poorly cooked infected 
cyprinoid fish mature into adult flukes that inhabit 
the human biliary system. Heavy infections can cause 
obstructive liver disease, inflammatory gallbladder 
pathology associated with cholangiocarcinoma, and 
obstructive pancreatitis.

One-day therapy with praziquantel is highly effective against 
these parasites.

**Fasciola hepatica.** Humans are only accidentally 
infected with *F. hepatica*, the large liver fluke that exists 
worldwide and primarily affects herbivorous ruminants 
such as cattle and sheep. Eating contaminated freshwater 
plants such as watercress initiates the infection. 
Migratory larvae penetrate the intestine, invade the liver 
from the peritoneum, end eventually reside in the bil-

The acute illness is characterized by fever, 
urticaria, and abdominal symptoms, whereas chronic 
infection resembles that caused by other hepatic flukes. 
Unlike other flukes, *Fasciola* spp. do not respond to praziquantel.

Triclabendazole, given as a single oral dose of 10 mg/kg, or 
in cases of severe infection 20 mg/kg divided into two doses, is the 
drug of choice for treatment of fascioliasis. In the U.S., this agent 
is available only from the manufacturer (Novartis). The cure rate 
among a cohort of Turkish patients was 78%, and the addition of 
another course(s) increased this to 90%. No significant side effects 
were reported (Saba et al., 2004). Bithionol was previously the rec-

commended drug.

**Fasciolopsis buski, Heterophyes heterophyes, Metagonimus yokogawai, Nanophyetus salmincola.** 
Obtained by eating contaminated water chestnuts and 
other cattlrops in Southeast Asia, *F. buski* is one of the 
largest parasites causing human infection. Undercooked 
fish transmit infection with the other, much smaller GI 
trematodes that are widely distributed geographically. 
Abdominal symptoms produced by reactions to these 
flukes usually are mild, but heavy infections with *F. buski* 
can cause intestinal obstruction and peritonitis.

Infections with all the intestinal trematodes respond well to 
single-day therapy with praziquantel.

### ANTHELMINTIC DRUGS

#### Benzimidazoles (BZ)

**History.** The discovery by Brown and coworkers that thiabendazole 
possessed potent activity against GI nematodes sparked development 
of the benzimidazoles as broad-spectrum anthelmintic agents against 
parasites of importance in both veterinary and human medicine. Of 
the hundreds of derivatives tested, those most therapeutically useful 
have modifications at the 2 and/or 5 positions of the benzimidazole 
ring system. Three compounds, thiabendazole, mebendazole, and 
 albendazole, have been used extensively for the treatment of human 
 helmint infections. The chemical structures of these drugs are shown in Table 51–1.

Thiabendazole, which contains a thiazole at position 2, is 
active against a wide range of nematodes that infect the GI tract. 
However, its clinical value against these organisms has declined 
markedly because of thiabendazole’s toxicity (particularly unwanted 
central nervous system [CNS], liver, hypersensitivity, and visual side 
effects) relative to that of other equally effective drugs. Mebendazole, the prototype benzimidazole carbamat, was intro-
duced for the treatment of intestinal roundworm infections as a result 
of research carried out >30 years ago. Albendazole is a newer ben-
zimidazole carbamate that is used worldwide, both for treatment of 
intestinal nematodes and cestodes, but also because of the systemic 
bioavailability of its sulphoxide metabolite against tissue-dwelling 
nematodes and cestodes (Venkatesan, 1998). Albendazole has 
become the drug of choice for treating cysticercosis (Garcia and Del
CHEMOTHERAPY OF MICROBIAL DISEASES

Haemonchus contortus reduced affinity binding to 1994) In drug-resistant isolates of (Driscoll et al., 1989) and of BZ resistance in the sheep nematode Haemonchus contortus have provided insights into the mechanisms of action of BZ drugs and of the mechanism of resistance (Prichard, 1994) In drug-resistant isolates of H. contortus, BZ drugs display reduced affinity binding to β-tubulin and specific mutations occur in the β-tubulin gene (Kwa et al., 1995; Roos, 1997). The major mechanism of drug resistance in nematodes involves selection of a naturally occurring “resistant” genotype entailing a Phe → Tyr change at position 200 of β-tubulin (Sangster and Gill, 1999). Evidence for the emergence of β-tubulin gene mutations associated with resistance among human nematodes is confined to T. trichuria (Diarwata et al., 2009) and W. bancrofti (Schwab et al., 2005). Drug treatment failures have been reported in hookworm infections (Flohr et al., 2007), but there is little evidence of widespread dissemination of resistant forms. However, these recent observations, and the increasing use of BZs in parasite control programs, suggest that monitoring for BZ resistance is critically important, especially as veterinary experience indicates that drug-resistant helminths can persist even after selection pressure is withdrawn.

The BZs, exemplified by mebendazole and albendazole, are versatile anthelmintic agents, particularly against GI nematodes, where their action is not limited by a requirement for absorption. Appropriate doses of mebendazole and albendazole are highly effective in treating most of the major STH infections (ascariasis, enterobiasis, trichuriasis, and hookworm) as well as less common human nematode infections. These drugs are active against both larval and adult stages of nematodes that cause these infections, and they are ovicidal for Ascaris and Trichuris. Immobilization and death of susceptible GI parasites occur slowly, and their clearance from the GI tract may not be complete until several days after treatment.

Removal of STHs in children by a single-dose treatment with either albendazole or mebendazole improves their health, as evidenced by post-treatment catch-up growth and replenishment of iron stores (Hotez et al., 2004, 2009). In addition, BZ treatment of STH infections results in improvements in childhood intellectual and cognitive development (Drake et al., 2000). These observations have led to advocacy for the implementation of large-scale STH control programs that target school-aged children (Hotez et al., 2009; WHO, 2002).

Albendazole is superior to mebendazole in curing hookworm and trichuriasis infections in children (de Silva et al., 2003), especially when used as a single dose (Keiser and Utzinger, 2008). Moreover, albendazole is more effective than mebendazole against strongyloidiasis (Liu and Weller, 1993) and is superior to mebendazole against all tissue-dwelling helminths due to its active metabolite albendazole sulfoxide. It is therefore the drug of choice against cystic and alveolar hydatid disease caused by Echinococcus granulosus and E. multilocularis (Davis et al., 1989; Horton, 1997), and neurocysticercosis caused by larval forms of Taenia solium (Evans et al., 1997; Garcia and Del Brutto, 2000). The BZs probably are active against the intestinal stages of Trichinella spiralis in humans but probably do not affect the larval stages in tissues. Albendazole is highly effective against the migrating forms of dog and cat hookworms that cause cutaneous larval migrans, although thiabendazole can be applied topically for this purpose. Microsporidal species that cause intestinal infections in HIV-infected individuals respond partially (Enterocytozoon bieneusi) or completely (Encephalitozoon intestinalis and related Encephalitozoon species) to albendazole. The sulfoxide metabolite of albendazole appears to be especially effective against these parasites in vitro (Katjyar and Edlin, 1997). Albendazole also has efficacy against anaerobic protozoa such as Trichomonas vaginalis and Giardia lamblia (Ottesen et al., 1999). Although BZs exert antifungal activity in vitro, they have no clinical utility in human mycoses.

### Absorption, Fate, and Excretion

Thiabendazole is soluble in water; mebendazole and albendazole are poorly soluble in aqueous solution. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass hepatic metabolism. Co-administration of cimetidine will increase plasma levels of mebendazole, possibly due to

Brutto, 2000) and cystic hydatid disease (Horton, 1997). When used in single dose in conjunction with either ivermectin or DEC, it has shown additive effect in the control of lymphatic filariasis and related tissue filarial infections (Molyneux and Zagaria, 2002; Molyneux et al., 2003). Of note, albendazole lacks activity against the liver fluke F. hepatica.

**Anthelmintic Action.** The primary mechanism of action of BZ is thought to be inhibition of microtubule polymerization by binding to β-tubulin (Prichard, 1994). The selective toxicity of these agents against helminths results from their higher affinity for parasite β-tubulin than for the same target in higher eukaryotes. A range of other biochemical changes are found in nematodes following BZ exposure, including inhibition of mitochondrial fumarate reductase, reduced glucose transport, and uncoupling of oxidative phosphorylation.

Studies of BZ resistance by site-directed mutagenesis of the β-tubulin gene in the free-living nematode Caenorhabditis elegans (Driscoll et al., 1989) and of BZ resistance in the sheep nematode Haemonchus contortus have provided insights into the mechanisms of action of BZ drugs and of the mechanism of resistance (Prichard, 1994) In drug-resistant isolates of H. contortus, BZ drugs display reduced affinity binding to β-tubulin and specific mutations occur in the β-tubulin gene (Kwa et al., 1995; Roos, 1997). The major mechanism of drug resistance in nematodes involves selection of a naturally occurring “resistant” genotype entailing a Phe → Tyr change at position 200 of β-tubulin (Sangster and Gill, 1999). Evidence for the emergence of β-tubulin gene mutations associated with resistance among human nematodes is confined to T. trichuria (Diarwata et al., 2009) and W. bancrofti (Schwab et al., 2005). Drug treatment failures have been reported in hookworm infections (Flohr et al., 2007), but there is little evidence of widespread dissemination of resistant forms. However, these recent observations, and the increasing use of BZs in parasite control programs, suggest that monitoring for BZ resistance is critically important, especially as veterinary experience indicates that drug-resistant helminths can persist even after selection pressure is withdrawn.

The BZs, exemplified by mebendazole and albendazole, are versatile anthelmintic agents, particularly against GI nematodes, where their action is not limited by a requirement for absorption. Appropriate doses of mebendazole and albendazole are highly effective in treating most of the major STH infections (ascariasis, enterobiasis, trichuriasis, and hookworm) as well as less common human nematode infections. These drugs are active against both larval and adult stages of nematodes that cause these infections, and they are ovicidal for Ascaris and Trichuris. Immobilization and death of susceptible GI parasites occur slowly, and their clearance from the GI tract may not be complete until several days after treatment.

Removal of STHs in children by a single-dose treatment with either albendazole or mebendazole improves their health, as evidenced by post-treatment catch-up growth and replenishment of iron stores (Hotez et al., 2004, 2009). In addition, BZ treatment of STH infections results in improvements in childhood intellectual and cognitive development (Drake et al., 2000). These observations have led to advocacy for the implementation of large-scale STH control programs that target school-aged children (Hotez et al., 2009; WHO, 2002).

Albendazole is superior to mebendazole in curing hookworm and trichuriasis infections in children (de Silva et al., 2003), especially when used as a single dose (Keiser and Utzinger, 2008). Moreover, albendazole is more effective than mebendazole against strongyloidiasis (Liu and Weller, 1993) and is superior to mebendazole against all tissue-dwelling helminths due to its active metabolite albendazole sulfoxide. It is therefore the drug of choice against cystic and alveolar hydatid disease caused by Echinococcus granulosus and E. multilocularis (Davis et al., 1989; Horton, 1997), and neurocysticercosis caused by larval forms of Taenia solium (Evans et al., 1997; Garcia and Del Brutto, 2000). The BZs probably are active against the intestinal stages of Trichinella spiralis in humans but probably do not affect the larval stages in tissues. Albendazole is highly effective against the migrating forms of dog and cat hookworms that cause cutaneous larval migrans, although thiabendazole can be applied topically for this purpose. Microsporidal species that cause intestinal infections in HIV-infected individuals respond partially (Enterocytozoon bieneusi) or completely (Encephalitozoon intestinalis and related Encephalitozoon species) to albendazole. The sulfoxide metabolite of albendazole appears to be especially effective against these parasites in vitro (Katjyar and Edlin, 1997). Albendazole also has efficacy against anaerobic protozoa such as Trichomonas vaginalis and Giardia lamblia (Ottesen et al., 1999). Although BZs exert antifungal activity in vitro, they have no clinical utility in human mycoses.

**Absorption, Fate, and Excretion.** Thiabendazole is soluble in water; mebendazole and albendazole are poorly soluble in aqueous solution. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass hepatic metabolism. Co-administration of cimetidine will increase plasma levels of mebendazole, possibly due to
inhibition of first-pass CYP-mediated metabolism (Dayan, 2003). The small proportion of mebendazole that is absorbed is ~95% bound to plasma proteins and is extensively metabolized. Mebendazole, rather than its metabolites, appears to be the active drug form (Gottschall et al., 1990). Conjugates of mebendazole and its metabolites have been found in bile, but little unchanged mebendazole appears in the urine.

Albendazole is variably and erratically absorbed after oral administration; absorption is enhanced by the presence of fatty foods and possibly by bile salts. A fatty meal or eating enhances absorption by up to 5-fold in humans (Dayan, 2003). After a 400-mg oral dose, albendazole cannot be detected in plasma because the drug is rapidly metabolized in the liver and possibly in the intestine, to albendazole sulfoxide, which has potent anthelmintic activity (Redondo et al., 1999).

Both the (+) and (–) enantiomers of albendazole sulfoxide are formed, but the (+) enantiomer reaches much higher peak plasma concentrations in humans and is cleared much more slowly than the (–) form (Marques et al., 1999). Albendazole sulfoxide is ~70% bound to plasma proteins and has a highly variable plasma t_{1/2} of 4-15 hours (Marques et al., 1999). It is well distributed into various tissues including hydatid cysts, where it reaches a concentration of ~20% that in plasma (Morris et al., 1987). The bioavailability of parent drug and activity of albendazole sulfoxide explain why albendazole is more effective than mebendazole for treatment of tissue-dwelling helminths. Oxidation of the sulfoxide derivatives to the nonchiral sulfone metabolite of albendazole, which is pharmacologically inactive, is probably rate limiting in determining the clearance and plasma t_{1/2} of the bioactive (+) sulfoxide metabolite. In animal models, BZs can induce their own metabolism (Gleizes et al., 1991). Albendazole metabolites are excreted mainly in the urine.

Therapeutic Uses. The introduction of thiabendazole (MINTEZOL) was a major advance in anthelmintic chemotherapy, but its clinical use is now limited, due to the better tolerability and generally better activity of mebendazole and albendazole. Thiabendazole remains a useful drug when applied topically for treatment of cutaneous larva migrans (creeping eruption). Most patients thus treated experience a cure after topical treatment with an extemporaneous preparation, usually begun before initiating albendazole therapy and continued for several days after institution of therapy to reduce the incidence of side effects resulting from inflammatory reactions to dead and dying cysticerci. Glucocorticoids increase plasma levels of albendazole sulfoxide. Prior to initiating chemotherapy for neurocysticercosis, physicians should consult with a neurologist and/or neurosurgeon regarding anticonvulsant therapy, the possible development of complications of arachnoiditis, vasculitis, or cerebral edema, and the need for surgical intervention should obstructive hydrocephalus occur.

Albendazole is also the preferred treatment of neurocysticercosis caused by larval forms of Taenia solium (Evans et al., 1997; Garcia and Del Brutto, 2000). The recommended dosage is 400 mg given twice a day for adults for 8-30 days, depending on the number, type, and location of the cysts. For children, the dose is 15 mg/kg per day (maximum: 800 mg) in two doses for 8-30 days. For both adults and children, the course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. Glucocorticoid therapy is usually begun before initiating albendazole therapy and continued for several days after institution of therapy to reduce the incidence of side effects resulting from inflammatory reactions to dead and dying cysticerci. Glucocorticoids increase plasma levels of albendazole sulfoxide. Prior to initiating chemotherapy for neurocysticercosis, physicians should consult with a neurologist and/or neurosurgeon regarding anticonvulsant therapy, the possible development of complications of arachnoiditis, vasculitis, or cerebral edema, and the need for surgical intervention should obstructive hydrocephalus occur.

Albendazole, 400 mg per day, also has shown efficacy for therapy of microsporidial intestinal infections in patients with AIDS. Infection with Capillaria philippinensis can be treated with a 10-day treatment regimen with albendazole (400 mg/day).

Albendazole has been combined with either DEC or ivermectin in programs directed toward controlling LF (Molyneux and Zagaria, 2002; Ottesen et al., 1999). The strategy is annual dosing...
with combination therapy for 4-6 years to maintain the microfilaria at such low levels that transmission cannot occur. The period of therapy is estimated to correspond to the duration of fecundity of adult worms. Albendazole is given with DEC to control LF in most parts of the world. However, to avoid serious reactions to dying microfilariae, the albendazole/ivermectin combination is recommended in locations where filariasis co-exists with either onchocerciasis or loiasis. Recently, the benefits of adding albendazole to either DEC or ivermectin for LF control were evaluated (Addiss et al., 2004); there currently is insufficient reliable research to confirm or refute whether adding albendazole has an effect on LF.

**Toxicity, Side Effects, Precautions, and Contraindications.** Excluding thiabendazole, the BZs have excellent safety profiles. To date millions of children have been treated in mass deworming chemotherapy programs. Overall, the incidence of side effects, primarily mild GI symptoms, occur in only 1% of treated children (Urbani and Albonico, 2003).

The clinical utility of thiabendazole in adults is compromised by its toxicity. Side effects frequently encountered with therapeutic doses include anorexia, nausea, vomiting, and dizziness.

Less frequently, diarrhea, fatigue, drowsiness, giddiness, or headache occur. Occasional fever, rashes, erythema multiforme, hallucinations, sensory disturbances, and Stevens-Johnson syndrome have been reported. Angioedema, shock, tinnitus, convulsions, and intrahepatic cholestasis are rare complications of therapy. Some patients excrete a metabolite that imparts an odor to the urine much like that occurring after ingestion of asparagus. Crystalluria without hematuria has been reported on occasion; it promptly subsides with discontinuation of therapy. Transient leukopenia has been noted in a few patients on thiabendazole therapy. Because CNS side effects occur frequently, activities requiring mental alertness should be avoided during therapy. Thiabendazole has hepatotoxic potential and should be used with caution in patients with hepatic disease or decreased hepatic function. The effects of thiabendazole in pregnant women have not been studied adequately, so it should be used in pregnancy only when the potential benefit justifies the unknown risk.

**Mebendazole** does not cause significant systemic toxicity in routine clinical use, even in the presence of anemia and malnutrition. This probably reflects its low systemic bioavailability. Transient symptoms of abdominal pain, distention, and diarrhea have occurred in cases of massive infestation and expulsion of GI worms.

Rare side effects in patients treated with high doses of mebendazole include allergic reactions, alopecia, reversible neutropenia, agranulocytosis, and hypospermia. Reversible elevation of serum transaminases has been observed when the drug was given in long courses for treatment of hydatid disease. Mebendazole treatment has been associated with occipital seizures (Wilmshurst and Robb, 1998). Mebendazole is a potent embryo toxin and teratogen in laboratory animals; effects may occur in pregnant rats at single oral doses as low as 10 mg/kg. However, there is no evidence for teratogenicity in humans, probably due to its poor systemic bioavailability. Although the general advice is that mebendazole should not be given to pregnant women or to children <2 years of age, it has been safely used after the first trimester of pregnancy for its beneficial effect on anemia due to clearance of hookworm (WHO, 2006). Because the soil-transmitted helminths are important causes of maternal and child morbidity during pregnancy, the WHO recommends its use for infected pregnant women in the second or third trimester.

Albendazole produces few side effects when used for short-term therapy of GI helminth infections, even in patients with heavy worm burdens. Transient mild GI symptoms (epigastric pain, diarrhea, nausea, and vomiting) occur in ~1% of treated individuals. Dizziness and headache occur on occasion. In school-age mass treatments, the incidence of side effects with albendazole is very low (Horton, 2000).

Even in long-term therapy of cystic hydatid disease and neurocysticercosis, albendazole is well tolerated by most patients. The most common side effect is liver dysfunction, generally manifested by an increase in serum transaminase levels; rarely jaundice may be noted, but enzyme activities return to normal after therapy is completed.

A pharmaco-epidemiological analysis concluded that long-term treatment of echinococcosis or cysticercosis with high-dose albendazole accounted for most of the adverse drug reactions attributed to anthelmintic therapy (Bagheri et al., 2004). Therefore, liver function tests should be monitored during protracted albendazole therapy, and the drug is not recommended for patients with cirrhosis (Davis et al., 1989). Especially if not pretreated with glucocorticoids, some patients with neurocysticercosis may experience serious neurological sequelae that depend on the location of inflamed cysts with dying cysticerci. Other side effects during extended therapy include GI pain, severe headaches, fever, fatigue, loss of hair, leukopenia, and thrombocytopenia. Albendazole is teratogenic and embryotoxic in animals, and it should not be given to pregnant women. The safety of albendazole in children <2 years of age has not been established.

The BZs as a group display remarkably few clinically significant interactions with other drugs. The most versatile member of this family, albendazole, probably induces its own metabolism, and plasma levels of its sulfoxide metabolites can be increased by co-administration of glucocorticoids and possibly praziquantel. Caution is advised when using high doses of albendazole together with general inhibitors of hepatic CYPs. As indicated earlier, co-administration of cimetidine can increase the bioavailability of mebendazole.

**Use in Pregnancy.** Because of the ongoing and anticipated widespread use of BZs in global control programs for both STH and filarial infections, there is a high level of interest about their use in young children and in the second and third trimesters of pregnancy.

As indicated earlier, both albendazole and mebendazole are embryotoxic and teratogenic in pregnant rats, and they are not generally recommended for use in pregnancy (Bethony et al., 2006). However, in postmarketing surveys on women who inadvertently consumed mebendazole during the first trimester, the incidence of spontaneous abortion and malformations did not exceed that of the
general population; comparable studies with albendazole are not available. A review of the risk of congenital abnormalities from BZs concluded that their use during pregnancy was not associated with an increased risk of major congenital defects; nonetheless, it is recommended that treatment should be avoided during the first trimester of pregnancy (Urbani and Albonico, 2003).

Hookworm occurs in many pregnant women in developing countries, including up to one-third of pregnant women in sub-Saharan Africa (Brooker et al., 2008). Because some of these infected women may develop iron-deficiency anemia leading to adverse pregnancy outcomes, BZ treatment would be beneficial during the second and third trimesters of pregnancy (WHO, 2002, 2006). There is no evidence that maternal BZ therapy presents a risk to breast-fed infants (Urbani and Albonico, 2003).

Use in Young Children. The BZs have not been extensively studied in children <2 years of age. The WHO concluded that BZs may be used to treat children >1 year if the risks from adverse consequences caused by STHs are justified. The recommended dose is 200 mg of albendazole in children between the ages of 12 and 24 months (WHO, 2006).

**Diethylcarbamazine (DEC)**

Diethylcarbamazine (DEC) is a first-line agent for control and treatment of lymphatic filariasis caused by *Wuchereria bancrofti* and *Brugia malayi* and for therapy of tropical pulmonary eosinophilia, an uncommon manifestation of lymphatic filarial infection (Ottesen and Ramachandran, 1995). DEC is also the drug of choice for treatment of loiasis, caused by infection with the filarial parasite *L. loa*. However, caution must be used in treatment of high-grade *L. loa* infection because the rapid killing of large numbers of microfilariae can cause life-threatening post-treatment complications. Annual singledose combination chemotherapy with both DEC and albendazole show considerable promise for the control of lymphatic filariasis in geographic regions where onchocerciasis and loiasis are not endemic (Molyneux and Zagaria, 2002; Molyneux et al., 2003).

**Chemistry.** Diethylcarbamazine (HETRAN) is formulated as the water-soluble citrate salt containing 51% by weight of the active base. Because the compound is tasteless, odorless, and stable to heat, it also can be taken in the form of fortified table salt containing 0.2-0.4% by weight of the base. The drug is available outside the U.S.; in the U.S., it is supplied by the CDC.

**Anthelmintic Action.** The mechanism of action of DEC against susceptible filarial species is not well understood, but the drug appears to exert a direct effect on *W. bancrofti* microfilariae by causing organelle damage and apoptosis (Peixoto et al., 2004). The mechanism of filaricidal action of DEC against adult worms is unknown. Some studies suggest that DEC compromises intracellular processing and transport of certain macromolecules to the plasma membrane (Spiro et al., 1986). The drug also may affect specific immune and inflammatory responses of the host by undefined mechanisms (Martin et al., 1997).

Microfilarial forms of susceptible filarial species are most affected by DEC. These developmental forms of *W. bancrofti*, *B. malayi*, and *L. loa* rapidly disappear from human blood after consumption of the drug. Microfilariae of *O. volvulus* rapidly disappear from skin after DEC administration, but the drug does not kill microfilariae in nodules that contain the adult (female) worms. The drug has some activity against the adult lifecycle stages of *W. bancrofti*, *B. malayi*, and *L. Loa* but negligible activity against adult *O. volvulus*.

**Absorption, Fate, and Excretion.** DEC is absorbed rapidly from the GI tract. Peak plasma levels occur within 1-2 hours after a single oral dose, and the plasma t½ varies from 2-10 hours, depending on the urinary pH. DEC is excreted by both urinary and extra-urinary routes; >50% of an oral dose appears in acidic urine as the unchanged drug, but this value is decreased when the urine is alkaline. Indeed, alkalinizing the urine can elevate plasma levels, prolong the plasma t½, and increase both the therapeutic effect and toxicity of DEC (Awadzi et al., 1986). Therefore, dosage reduction may be required for people with renal dysfunction or sustained alkaline urine. Metabolism is rapid and extensive; a major metabolite, DEC-N-oxide, is active.

**Therapeutic Uses.** Dosages of DEC citrate used to prevent or treat filarial infections have evolved empirically and vary according to local experience. Recommended regimens differ according to whether the drug is used for population-based chemotherapy, treatment of confirmed filarial infection, or prophylaxis against infection.

*W. bancrofti, B. malayi,* and *B. timori.* The standard regimen for the treatment of LF traditionally has been a 12-day, 72-mg/kg (6 mg/kg per day) course of DEC. In the U.S., it is common practice to administer small test doses of 50-100 mg (1-2 mg/kg for children) over a 3-day period prior to beginning the 12-day regimen. However, a single dose of 6 mg/kg had comparable macrofilaricidal and microfilaricidal efficacy to the standard regimen (Addiss and Dreyer, 2000). Single-dose therapy may be repeated every 6-12 months, as necessary.

Although DEC does not usually reverse existing lymphatic damage, early treatment of asymptomatic individuals may prevent new lymphatic damage. In men, the effect of the drug can be monitored by scrotal ultrasound ~2-4 weeks following treatment. Repeat treatment sometimes is recommended if microfilariae remain in the circulation or if motile adult worms remain visible on the ultrasound.
(Addiss and Dreyer, 2000). Expanded use of ultrasound also has facilitated the identification of infected individuals who are microfilaria negative on blood examination. These individuals also benefit from DEC treatment. During acute episodes of lymphangitis, treatment with DEC is not recommended until acute symptoms subside (Addiss and Dreyer, 2000).

For mass treatment with the objective of reducing microfilarialaemia to levels whereby transmission is interrupted, effective strategies have included the introduction of DEC into table salt (0.2-0.4% by weight of the base) (Gelband, 1994). DEC, given annually as a single oral dose of 6 mg/kg, is most effective in reducing microfilariaemia when co-administered with either albendazole (400 mg) or ivermectin (0.2-0.4 mg/kg) (Ottesen et al., 1999). Although the adverse reactions to microfilarial destruction are greater after the oral therapy with DEC tablets than when the mass drug administration is administered by medicated table salt, therapy is usually well tolerated.

**O. volvulus and L. loa.** DEC is contraindicated for the treatment of onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions. Thus use of DEC for control is considered contraindicated in areas where onchocerciasis is endemic (Molyneux et al., 2003). Such reactions are far less severe in response to ivermectin, the preferred drug for this infection. Despite its drawbacks, DEC remains the best available drug for therapy of loiasis. Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2-3 days, escalating to maximally tolerated daily doses of 9 mg/kg in three doses for a total of 2-3 weeks.

In patients with high-grade microfilaraemia, low test doses are used, often accompanied by pretreatment with glucocorticoids or antihistamines, to minimize reactions to dying microfilariae. Such reactions may manifest as severe allergic reactions, and occasionally meningoencephalitis and coma likely caused by CNS effects of dying microfilariae. Repeated courses of DEC treatment, separated by 3-4 weeks, may be required to cure loiasis. Although ivermectin is not a good alternative to DEC for treatment of loiasis, albendazole may be useful in patients who either fail therapy with DEC or who cannot tolerate the drug (Klion et al., 1999).

DEC is clinically effective against microfilariae and adult worms of *Dipetalonema streptocerca*, but filariasis due to *Mansonella perstans*, *M. ozzardi*, or *Dirofilaria immitis* responds minimally to this agent. DEC is no longer recommended as a first-line drug for the treatment of toxocariasis.

**Toxicity and Side Effects.** Below a daily dose of 8-10 mg/kg, direct toxic reactions to DEC are rarely severe and usually disappear within a few days despite continuation of therapy. These reactions include anorexia, nausea, headache, and, at high doses, vomiting. Major adverse effects result directly or indirectly from the host response to destruction of parasites, primarily microfilariae.

Delayed reactions to dying adult worms may result in lymphangitis, swelling, and lymphoid abscesses in bancroftian and brugian filariasis, and small skin wheals in loiasis. Reactions typically are most severe in patients heavily infected with *O. volvulus*, less serious in *B. malayi* or *L. loa* infections, and mild in bancroftian filariasis. As noted, the drug occasionally causes severe side effects in heavy *L. loa* infections, including retinal hemorrhages and severe encephalopathy. In patients with onchocerciasis, the *Mazzotti reaction* typically occurs within a few hours after the first dose, and it manifests as intense itching, a popular rash, enlargement and tenderness of the lymph nodes, and sometimes fever, tachycardia, arthralgia, and headache. This reaction persists for 3-7 days and then subsides. Ocular complications include limbitis, punctate keratitis, uveitis, and atrophy of the retinal pigment epithelium (Dominquez-Vazquez et al., 1983). DEC appears to be safe for use during pregnancy.

**Precautions and Contraindications.** Population-based therapy with DEC should be avoided where onchocerciasis or loiasis is endemic, although the drug can be used to protect foreign travelers from these infections. Pretreatment with glucocorticoids and antihistamines often is undertaken to minimize indirect reactions to DEC that result from release of antigen by dying microfilariae. Dosage reduction may be appropriate for patients with impaired renal function or persistent alkaline urine.

**Doxycline**

The discovery that filarial parasites, including *W. bancrofti* and *O. volvulus*, harbor bacterial symbionts of the genus *Wolbachia* led to studies that have established the efficacy of courses of doxycycline of duration ≥6 weeks in bancroftian filariasis and onchocerciasis (Taylor and Hoerauf, 2001). A 6-week regimen of doxycycline (100 mg daily), by killing the *Wolbachia*, leads to sterility of adult female *Onchocerca* worms (Hoerauf et al., 2000). Studies using shorter treatment courses and alternative antibiotics including rifampicin are in progress. The pharmacology of doxycycline is discussed in Chapter 55.

**Ivermectin**

**History.** In the mid-1970s, surveys of natural products revealed that a fermentation broth of the soil actinomycete Streptomyces avermitilis ameliorated infection with *Nematospiroides dubius* in mice. Isolation of the anthelmintic components from cultures of this organism led to discovery of the avermectins, a novel class of 16-membered macrocyclic lactones (Campbell, 1989). Ivermectin (MECTIZAN; STROMECTOL; 22,23-dihydroavermectin B1a) is a semisynthetic analog of avermectin B1a (abamectin), an insecticide developed for crop management. Ivermectin now is used extensively to control and treat a broad spectrum of infections caused by parasitic nematodes (roundworms) and arthropods (insects, ticks, and mites) that plague livestock and domestic animals (Campbell, 1993).
Chemistry. Ivermectin exists as an odorless off-white powder with high lipophilic solubility but poor solubility in water. It is a mixture of at least 80% 22,23-dihydroavermectin B1a and no more than 20% 22,23-dihydroavermectin B1b. B1a and B1b have nearly identical antiparasitic activities. The hydrogenation of avermectin B1 at the C22-23 linkage confers increased activity against *Haemonchus contortus*, an important veterinary parasite, and against the cattle parasite *Onchocerca cervicalis*.

Antiparasitic Activity and Resistance. Ivermectin immobilizes affected organisms by inducing a tonic paralysis of the musculature. Studies of *Caenorhabditis elegans* indicate that avermectins induce paralysis by activating a family of ligand-gated Cl⁻ channels, particularly glutamate-gated Cl⁻ channels that are found only in invertebrates. There is close correlation among activation and potentiation by avermectins and milbemycin D of glutamate-sensitive Cl⁻ current, nematicidal activity, and membrane binding affinity (Arena et al., 1995; Cully et al., 1996). Moreover, glutamate-gated Cl⁻ channels are expressed in the pharyngeal muscle cells of these worms, consistent with the marked and potent inhibitory effect of avermectins on the feeding behavior of the organisms (Sangster and Gill, 1999). Therefore, ivermectin probably binds to glutamate-activated Cl⁻ channels found in nematode nerve or muscle cells, and causes hyperpolarization by increasing intracellular chloride concentration. This results in paralysis of the parasite. Resistance or relative unresponsiveness to avermectin action has been observed in different nematodes, especially those species parasitizing livestock.

Several different avermectin-“resistant” developmental and physiological phenotypes have been described, but definitive relationships among these phenotypes and native avermectin receptor subtypes, locations, numbers, and binding affinities require clarification (Hejmadi et al., 2000; Sangster and Gill, 1999). Alterations in genes encoding ATP-dependent P-glycoprotein transporters that bind avermectins and milbemycin D of glutamate-sensitive Cl⁻ current, nematicidal activity, and membrane binding affinity (Arena et al., 1995; Cully et al., 1996). Moreover, glutamate-gated Cl⁻ channels are expressed in the pharyngeal muscle cells of these worms, consistent with the marked and potent inhibitory effect of avermectins on the feeding behavior of the organisms (Sangster and Gill, 1999). Therefore, ivermectin probably binds to glutamate-activated Cl⁻ channels found in nematode nerve or muscle cells, and causes hyperpolarization by increasing intracellular chloride concentration. This results in paralysis of the parasite. Resistance or relative unresponsiveness to avermectin action has been observed in different nematodes, especially those species parasitizing livestock.

Glutamate-gated Cl⁻ channels probably are one of several sites of ivermectin action among invertebrates (Zufall et al., 1989). Avermectins also bind with high affinity to γ-aminobutyric acid (GABA)-gated and other ligand-gated Cl⁻ channels in nematodes such as *Ascaris* and in insects, but the physiological consequences are less well defined. Lack of high-affinity avermectin receptors in cestodes and trematodes may explain why these helminths are not sensitive to ivermectin (Shoop et al., 1995). Avermectins also interact with GABA receptors in mammalian brain, but their affinity for invertebrate receptors is ~100-fold higher (Schaefer and Haines, 1989).

In humans infected with *O. volvulus*, ivermectin causes a rapid, marked decrease in microfilarial counts in the skin and ocular tissues that lasts for 6-12 months (Newland et al., 1988). The drug has little discernible effect on adult parasites, even at doses as high as 800 μg/kg (Molyneux et al., 2003) but affects developing larvae and blocks egress of microfilariae from the uterus of adult female worms (Court et al., 1985). By reducing microfilariae in the skin, ivermectin decreases transmission to the *Simulium* black fly vector (Cupp et al., 1989). Regular treatment with ivermectin also has been conjectured to act prophylactically against the development of *Onchocerca* infection (Molyneux et al., 2003).

Ivermectin also is effective against microfilaria but not against adult worms of *W. bancrofti*, *B. malayi*, *L. loa*, and *M. ozzardi*. The drug exhibits excellent efficacy in humans against *Ascaris lumbricoides*, *Strongyloides stercoralis*, and cutaneous larva migrans. Other GI nematodes are either variably affected (*Trichuris trichura* and *Enterobius vermicularis*), or unresponsive (*Necator americanus* and *Ancylostoma duodenale*).

Absorption, Fate, and Excretion. In humans, peak levels of ivermectin in plasma are achieved within 4-5 hours after oral administration. The long terminal *t1/2* (~57 hours in adults) primarily reflects a low systemic clearance (~1-2 L/hour) and a large apparent volume of distribution. Ivermectin is ~93% bound to plasma proteins. The drug is extensively converted by hepatic CYP3A4 to at least 10 metabolites, mostly hydroxylated and demethylated derivatives (Zeng et al., 1998). Virtually no ivermectin appears in human urine in either unchanged or conjugated form (Krishna and Klotz, 1993). Studies in transgenic mice lacking a P-glycoprotein efflux pump showed neurotoxicity, indicating that this drug transporter, located in the endothelium of brain microvasculature, reduces ivermectin penetration to the CNS (Schinkel et al., 1994). This, and the relatively lower affinity of ivermectin for mammalian CNS receptors, may explain the paucity of CNS side effects and the relative safety of this drug in humans.

Therapeutic Uses

**Onchocerciasis.** Ivermectin administered as a single oral dose (150 to 200 μg/kg) given every 6-12 months is the drug of choice for treatment of onchocerciasis, in adults and children ≥5 years of age (Goa et al., 1991). Ivermectin given in mass drug administration programs has become a critical component of onchocerciasis control programs in the Americas and in sub-Saharan Africa. Equally important, such therapy results in reversal of inflammatory changes in ocular tissues and arrests the development of further ocular pathology due to microfilariae. Marked reduction of microfilariae in the skin results in major relief of the intense pruritus that is a feature of onchocerciasis. Clearance of microfilariae from skin and ocular tissues occurs within a few days and lasts for 6-12 months; the dose then should be repeated. The drug is not curative, however, because ivermectin has little effect on adult *O. volvulus*. Ivermectin has been used since 1987 as the mainstay for onchocerciasis control programs in all of Africa and in the Middle East and Latin America, where the disease is endemic. Nearly 20 million people have received at least one dose of the drug, and many have received six to nine doses (Dull and Meredith, 1998). The Onchocerciasis Elimination Programme in the Americas (OEPA) has effectively reduced transmission in the endemic nations of the Americas, Brazil, Colombia, Ecuador, Guatemala, Mexico, and Venezuela through biannual treatment with
ivermectin (Molyneux et al., 2003), and there is interest in extending biannual ivermectin coverage to the endemic regions of sub-Saharan Africa. Annual doses of the drug are quite safe and substantially reduce transmission of this infection (Boatin et al., 1998; Brown, 1998). How long such therapy should continue is unknown.

Resistance to ivermectin and the related agent moxidectin have been reported in a variety of parasites of veterinary importance, as have poor parasitological responses to ivermectin in the onchocerciasis control program (Osei-Atweneboana et al., 2007). Recent laboratory work with C. elegans has shown that exposure to increasing doses of ivermectin resulted in the development of a stable multidrug resistance phenotype with cross-resistance to the related drug moxidectin and to other anthelmintics, levamisole and pyrantel, but not albendazole (James and Davey, 2009). The potential for the development of similar resistance in human parasites exists, particularly in the setting of mass treatment campaigns.

**Lymphatic Filariasis.** Initial studies indicated that single annual doses of ivermectin (400 μg/kg) was both effective and safe for mass chemotherapy of infections with W. bancrofti and B. malayi (Ottesen and Ramachandran, 1995). Ivermectin is as effective as DEC for controlling lymphatic filariasis, and unlike DEC, it can be used in regions where onchocerciasis, loiasis, or both are endemic. Although ivermectin as a single agent can reduce W. bancrofti microfilaremia, the duration of treatment required to eliminate LF at 65% coverage of the affected population presumably would be >6 years (Molyneux et al., 2003). More recent evidence indicates that a single annual dose of ivermectin (200 μg/kg) and a single annual dose of albendazole (400 mg) are even more effective in controlling lymphatic filariasis than either drug alone (www.filariasis.org). The duration of treatment is at least 5 years, based on the estimated fecundity of the adult worms. This dual-drug regimen also reduces infections with intestinal nematodes. Facilitated by corporate donation of ivermectin and albendazole, the drug combination now serves as the treatment standard for mass chemotherapy and control of lymphatic filariasis (Ottesen et al., 1999).

**Strongyloidiasis.** Ivermectin administered as a single dose of 150 to 200 μg/kg is the drug of choice for treatment of human strongyloidiasis (Marti et al., 1996). It is at least as active as the older drug of choice, thiabendazole, and significantly better tolerated. It is generally recommended that a second dose be administered a week following the first dose. It is more efficacious than a 3-day course of albendazole (Marti et al., 1996). In the life-threatening Strongyloides hyperinfection syndrome where GI absorption of oral dose may be poor, parenteral veterinary ivermectin has been administered “off-label” to human subjects by the subcutaneous route (Chiodini et al., 2000).

**Infections with Other Intestinal Nematodes.** Ivermectin also is variably effective against other intestinal nematodes. It is more effective in ascariasis and enterobiasis than in trichuriasis or hookworm infection (Keiser and Utzinger, 2008). In the latter two infections, although it is not curative, it significantly reduces the intensity of infection.

**Other Indications.** Although ivermectin has activity against microfilaria (but not adult worms) of *L. loa* and *M. ozzardi*, it is not used clinically to treat infections with these parasites. Taken as a single 200-μg/kg oral dose, ivermectin is a first-line drug for treatment of cutaneous larva migrans caused by dog or cat hookworms. Ivermectin, administered orally in a dose of 200 μg/kg, is an effective treatment of scabies. In uncomplicated scabies, two doses should be administered, 1-2 weeks apart. It should be used in severe (crusted) scabies in repeated doses, with one recommended regimen entailing 7 doses of 200 μg/kg given with food, on days 1, 2, 8, 9, 15, 22, and 29 (Roberts et al., 2005). The drug appears to be effective against human head lice as well.

**Toxicity, Side Effects, and Precautions.** Ivermectin is well tolerated by uninfected humans.

In filarial infection, ivermectin therapy frequently causes a Mazzotti-like reaction to dying microfilariae. The intensity and nature of these reactions relate to the microfilarial burden. After treatment of *O. volvulus* infections, these side effects usually are limited to mild itching and swollen, tender lymph nodes, which occur in 5-35% of people, last just a few days, and are relieved by aspirin and antihistamines (Goa et al., 1991). Rarely, more severe reactions occur that include high fever, tachycardia, hypotension, prostration, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may respond to glucocorticoid therapy. Ivermectin induces milder side effects than does DEC, and unlike the latter, it seldom exacerbates ocular lesions in onchocerciasis. The drug can cause rare but serious side effects including marked disability and encephalopathies in patients with heavy *L. loa* microfilaria (Gardon et al., 1997). *Loa* encephalopathy is associated with ivermectin treatment of individuals with *Loa* microfilariaemia levels ≥30,000 microfilariae per milliliter of blood (Molyneux et al., 2003). There is little evidence that ivermectin is teratogenic or carcinogenic.

Possible adverse interactions of ivermectin with other drugs that are extensively metabolized by hepatic CYP3A4 have yet to be evaluated. Because of its effects on GABA receptors in the CNS, ivermectin is contraindicated in conditions associated with an impaired blood-brain barrier (e.g., African trypanosomiasis and meningitis). Ivermectin is not approved for use in children <5 years of age or in pregnant women. Lactating women taking the drug secrete low levels in their milk; the consequences for nursing infants are unknown. Currently, the WHO recommends against ivermectin treatments in mass drug administration campaigns for pregnant women, lactating women in the first week after birth, children <90 cm in height (~15 kg in body weight), and the severely ill (WHO, 2006).

**Praziquantel**

Praziquantel (BILTRICIDE, DISTOCIDE) is a pyrazinoquinoline derivative developed after this class of compounds was discovered to have anthelmintic activity in 1972. The (–) isomer is responsible for most of the drug’s anthelmintic activity.

The drug shows useful activity against most cestodes and trematodes that infect humans, whereas nematodes generally are unaffected (Andrews, 1985; Symposium, 1981). The drug is best studied and most commonly used for treatment of schistosomiasis, caused by *S. mansoni*, *S. haematobium*, and *S. japonicum*. [Praziquantel](#)
**Anthelmintic Action.** After rapid and reversible uptake, praziquantel has two major effects on adult schistosomes. At the lowest effective concentrations, it causes increased muscular activity, followed by contraction and spastic paralysis. Affected worms detach from blood vessel walls and migrate from the mesenteric veins to the liver. At slightly higher concentrations, praziquantel causes tegumental damage and exposes a number of tegumental antigens (Redman et al., 1996). The clinical efficacy of this drug correlates better with tegumental action (Xiao et al., 1985). The drug is ineffective against juvenile schistosomes and therefore is relatively ineffective in early infection. An intact immune response is believed to be important for the clinical efficacy of the drug.

The primary site of action of praziquantel is uncertain (Aragon et al., 2009). The drug may act through generation of reactive oxygen species. It also promotes an influx of Ca²⁺, and possibly interacts with the variant Ca²⁺ channel Ca-vaβ (Jeziorski and Greenberg, 2006), which is found in schistosomes and other praziquantel-sensitive parasites. However, Ca²⁺ influx does not correlate with sensitivity to the drug an all settings (Pica-Mattoccia et al., 2008). Praziquantel inhibits adenosine flux (Angelucci et al., 1996), but definitive evidence that this action contributes to the anthelmintic effect is lacking.

**Absorption, Fate, and Excretion.** Praziquantel is readily absorbed after oral administration, the drug reaching maximal levels in human plasma in 1-2 hours. The pharmacokinetics of praziquantel are dose related. Extensive first-pass metabolism to many inactive hydroxylated and conjugated products limits the bioavailability of this drug and results in plasma concentrations of metabolites at least 100-fold higher than that of praziquantel. The drug is ~80% bound to plasma proteins. Its plasma t₁/₂ is 0.8-3 hours, depending on the dose, compared with 4-6 hours for its metabolites; this may be prolonged in patients with severe liver disease, including those with hepatosplenic schistosomiasis. About 70% of an oral dose of praziquantel is recovered as metabolites in the urine within 24 hours; most of the remainder is metabolized in the liver and eliminated in the bile.

**Therapeutic Uses.** Praziquantel is approved in the U.S. for therapy of schistosomiasis and liver fluke infections. However, the drug has activity against many other trematodes and cestodes. Praziquantel should be stored at temperatures <30°C and swallowed with water without chewing because of its bitter taste.

Praziquantel is the drug of choice for treating schistosomiasis caused by all *Schistosoma* species that infect humans. Although dosage regimens vary, a single oral dose of 40 mg/kg or three doses of 20 mg/kg each, given 4-6 hours apart, generally produce cure rates of 70-95% and consistently high reductions (>85%) in egg counts. Tablets of 600 mg currently are available from generic manufacturers; on average, treatment of a school-aged child in Africa requires 2.5 tablets (WHO, 2002).

The absence of weighing scales in Africa and elsewhere in developing countries led to the development dosing in proportion to height (WHO 2006; www.who.int/wormcontrol).

Strains of *S. mansoni* and *S. japonicum* resistant to praziquantel have been selected in laboratory studies (Fallon et al., 1996). Moreover, decreased clinical efficacy of praziquantel against infections with *S. mansoni* has been reported in two human populations (Ismail et al., 1999). However, praziquantel-tolerant or -resistant schistosome strains are not currently of clinical importance (Fallon et al., 1996). Three doses of 25 mg/kg taken 4-8 hours apart on the same day result in high rates of cure for infections with either the liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini*, or the intestinal flukes *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai*. The same three-dose regimen, used over 2 days, is highly effective against infections with the lung fluke, *Paragonimus westermani*. Of note, the liver fluke *Fasciola hepatica* is resistant to praziquantel and should be treated with the BZ drug triclabendazole.

Low doses of praziquantel can be used successfully to treat intestinal infections with adult cestodes, for example, a single oral dose of 25 mg/kg for *Hymenolepis nana* and 10 to 20 mg/kg for *Diphyllobothrium latum*, *Taenia saginata*, or *T. solium*. Retreatment after 7-10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent, but its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be co-administered in this condition (Evans et al., 1997). Neither the “cystic” nor “alveolar” hydatid disease caused by larval stages of *Echinococcus* tapeworms responds to praziquantel, but the drug may have a role in the uncommon setting of perioperative cyst spillage (Horton, 1997; Schantz, 1999).

**Toxicity, Precautions, and Interactions.** Abdominal discomfort, particularly pain and nausea, diarrhea, headache, dizziness, and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden and are therefore believed to be a consequence of parasite killing and antigen release. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, mental changes, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2-3 days, and respond to appropriate symptomatic therapy such as analgesics and anticonvulsants.

Praziquantel is considered safe in children >4 years of age (or >94 cm in height), who probably tolerate the drug better than adults. Low levels of the drug appear in the breast milk, but there is no evidence that this compound is mutagenic or carcinogenic. High doses of praziquantel increase abortion rates in rats, but a retrospective study showed that treatment of pregnant women in Sudan resulted in no significant differences between treated and untreated women in the rates of abortion or preterm deliveries. Moreover, no congenital abnormalities were noted by clinical examination in any of the infants born to either group (Adam et al., 2004).

The bioavailability of praziquantel is reduced by inducers of hepatic CYPs such as carbamazepine and phenobarbital; predictably, co-administration of the CYP inhibitor, cimetidine, has the opposite effect (Dachman et al., 1994). Dexamethasone reduces the
bioavailability of praziquantel. Under certain conditions, praziquantel may increase the bioavailability of albendazole (Homeida et al., 1994).

Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Shortly after taking the drug, driving, operating machinery, and other tasks requiring mental alertness should be avoided. Severe hepatic disease can prolong the $t_1/2$ of praziquantel, requiring dosage adjustment in such patients (Mandour et al., 1990).

**Metrifonate**

Metrifonate (trichlorfon; BILARCIL) is an organophosphorus compound used initially as an insecticide and later as an anthelmintic, especially for treatment of *Schistosoma haematobium*.

\[
\text{Metrifonate} \quad \text{MRTIFONATE}
\]

Metrifonate is a prodrug; at physiological pH, it is converted nonenzymatically to dichlorvos (2,2-dichlorovinyl dimethyl phosphate, DDVP), a potent cholinesterase inhibitor (Chapter 10). However, inhibition of cholinesterase alone is unlikely to explain the antischistosomal properties of metrifonate (Bloom, 1981). *In vitro*, dichlorvos is about equally potent as an inhibitor of both *S. mansoni* and *S. haematobium* acetylcholinesterases, yet metrifonate is effective clinically only against infections with *S. haematobium*. The molecular basis for this species-selective effect is not understood. Trichlorfon is the formulation of metrifonate approved for veterinary purposes in the U.S. More complete information on the pharmacology and therapeutic uses of metrifonate can be found in the tenth edition of this book.

**Oxamniquine**

Oxamniquine is a 2-aminomethyltetrahydroquinoline derivative that is used as a second-line drug after praziquantel for the treatment of *Schistosoma mansoni* infection. *S. haematobium* and *S. japonicum* are refractory to this drug. Although it has largely been replaced by praziquantel and is not commercially available in the U.S., it continues to be used in *S. mansoni* control programs, especially in South America. More details on the pharmacology and therapeutic uses of oxamniquine may be found in the ninth edition of this book.

**Niclosamide**

Niclosamide, a halogenated salicylanilide derivative, was introduced in the 1960s for human use as a taeniacide. This compound was considered as a second-choice drug to praziquantel for treating human intestinal infections with *Taenia saginata*, *Diphyllobothrium latum*, *Hymenolepis nana*, and most other cestodes because it was cheap, effective, and readily available in many parts of the world. However, therapy with niclosamide poses a risk to people infected with *T. solium* because ova released from drug-damaged gravid worms develop into larvae that can cause cysticercosis, a dangerous infection that responds poorly to chemotherapy. Niclosamide is no longer approved for use in the U.S. More complete information on the pharmacology and therapeutic uses of niclosamide can be found in the ninth edition of this book.

**Piperazine**

Piperazine, a cyclic secondary amine, has been superseded as a first-line anthelmintic by the better tolerated and more easily administered benzimidazole anthelmintics (BZs). Piperazine is highly effective against *Ascaris lumbricoides* and *Enterobius vermicularis*. The predominant effect of piperazine on *Ascaris* is a flaccid paralysis that results in expulsion of the worm by peristalsis. Affected worms recover if incubated in drug-free medium. Piperazine acts as a GABA-receptor agonist. By increasing chloride ion conductance of *Ascaris* muscle membrane, the drug produces hyperpolarization and reduced excitability that leads to muscle relaxation and flaccid paralysis (Martin, 1985). Piperazine and dipiperazine are licensed as veterinary medications in the U.S. More complete information on the pharmacology and therapeutic uses of piperazine may be found in the tenth edition of this book.

**Pyrantel Pamoate**

Pyrantel pamoate first was introduced into veterinary practice as a broad-spectrum anthelmintic directed against pinworm, roundworm, and hookworm infections. Its effectiveness and lack of toxicity led to its trial against related intestinal helminths in humans. Oxantel pamoate, an m-oxyphenol analog of pyrantel, is effective for single-dose treatment of trichuriasis.

**Antihelmintic Action.** Pyrantel and its analogs are depolarizing neuromuscular blocking agents. They open nonspecific cation channels and induce persistent activation of nicotinic acetylcholine receptors and spastic paralysis of the worm (Robertson et al., 1994).

Pyrantel also inhibits cholinesterases. It causes a slowly developing contracture of isolated preparations of *Ascaris* at 1% of the concentration of acetylcholine required to produce the same effect. Pyrantel exposure leads to depolarization and increased spike discharge frequency, accompanied by increases in tension, in isolated helminth muscle preparations. Pyrantel is effective against hookworm, pinworm, and roundworm but is ineffective against *Trichuris trichiura*, which responds paradoxically to the analog oxantel.

**Absorption, Fate, and Excretion.** Pyrantel pamoate is poorly absorbed from the GI tract, a property that confines its action to intraluminal GI nematodes. Less than 15% is excreted in the urine as parent drug and metabolites. The major proportion of an administered dose is recovered in the feces.
**Therapeutic Uses.** Pyrantel pamoate is an alternative to mebendazole or albendazole in the treatment of ascariasis and enterobiasis. High cure rates have been achieved after a single oral dose of 11 mg/kg, to a maximum of 1 g. Pyrantel also is effective against hookworm infections caused by *Ancylostoma duodenale* and *Necator americanus*, although repeated doses are needed to cure heavy infections by *N. americanus*. The drug should be used in combination with oxantel for mixed infections with *T. trichiura*. In the case of pinworm, it is wise to repeat the treatment after an interval of 2 weeks. In the U.S., pyrantel is sold as an over-the-counter pinworm treatment (PIN-x, others).

**Precautions.** When given parenterally to experimental animals, pyrantel can produce complete neuromuscular blockade; only very large oral doses produce toxic effects. Transient and mild GI symptoms occasionally are observed in humans, as are headache, dizziness, rash, and fever. Pyrantel pamoate has not been studied in pregnant women. Thus its use in pregnant patients and children <2 years of age is not recommended. Because pyrantel pamoate and piperazine are mutually antagonistic with respect to their neuromuscular effects on parasites, they should not be used together.

Sulfonamides, Trimethoprim-Sulfamethoxazole, Quinolones, and Agents for Urinary Tract Infections
William A. Petri, Jr.

### Sulfonamides

The sulfonamide drugs were the first effective chemotherapeutic agents to be employed systemically for the prevention and cure of bacterial infections in humans. The considerable medical and public health importance of their discovery and their subsequent widespread use was quickly reflected in the sharp decline in morbidity and mortality figures for treatable infectious diseases. The advent of penicillin and subsequently of other antibiotics has diminished the usefulness of the sulfonamides, and they presently occupy a relatively small place in the therapeutic armamentarium of the physician. However, the introduction in the mid-1970s of the combination of trimethoprim and sulfamethoxazole has increased the use of sulfonamides for the prophylaxis and treatment of specific microbial infections.

**History.** Investigations in 1932 at the I. G. Farbenindustrie resulted in the patenting of PRONTOSIL and several other azo dyes containing a sulfonamide group. Prompted by the knowledge that synthetic azo dyes had been studied for their action against streptococci, Domagk tested the new compounds and observed that mice with streptococcal and other infections could be protected by PRONTOSIL. In 1933, Foerster reported giving PRONTOSIL to a 10-month-old infant with staphylococcal septicemia and achieving a dramatic cure. Favorable clinical results with PRONTOSIL and its active metabolite, sulfanilamide, in puerperal sepsis and meningococcal infections awakened the medical profession to the new field of antibacterial chemotherapy, and experimental and clinical articles soon appeared in profusion. The development of the carbonic anhydrase inhibitor–type diuretics and the sulfonylurea hypoglycemic agents followed from observations made with the sulfonamide antibiotics. For discovering the chemotherapeutic value of PRONTOSIL, Domagk was awarded the Nobel Prize in Medicine for 1938 (Lesch, 2007).

**Chemistry.** The term sulfonamide is employed herein as a generic name for derivatives of para-aminobenzenesulfonamide (sulfanilamide); the structural formulas of selected members of this class are shown in Figure 52–1. Most of them are relatively insoluble in water, but their sodium salts are readily soluble. The minimal structural prerequisites for antibacterial action are all embodied in sulfanilamide itself. The S(O)₂NH₂ group is not essential as such, but the important feature is that the sulfur is linked directly to the benzene ring. The para-NH₂ group (the N of which has been designated as N4) is essential and can be replaced only by moieties that can be converted in vivo to a free amino group. Substitutions made in the amide NH₂ group (position N1) have variable effects on antibacterial activity of the molecule. However, substitution of heterocyclic aromatic nuclei at N1 yields highly potent compounds.

### Effects on Microbes

Sulfonamides have a wide range of antimicrobial activity against both gram-positive and gram-negative bacteria. However, resistant strains have become common, and the usefulness of these agents has diminished correspondingly. In general, the sulfonamides exert only a bacteriostatic effect, and cellular and humoral defense mechanisms of the host are essential for final eradication of the infection.

**Antibacterial Spectrum.** Resistance to sulfonamides is increasingly a problem. Microorganisms that may be susceptible in vitro to sulfonamides include *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Haemophilus ducreyi*, *Nocardia*, *Actinomyces*, *Calymmatobacterium granulomatis*, and *Chlamydia trachomatis*. Minimal inhibitory concentrations (MICs) range from 0.1 μg/mL for *C. trachomatis* to 4-64 μg/mL for *Escherichia coli*. Peak plasma drug concentrations achievable in vivo are ~100-200 μg/mL.
Although sulfonamides were used successfully for the management of meningococcal infections for many years, most isolates of Neisseria meningitidis of serogroups B and C in the U.S. and group A isolates from other countries are now resistant. A similar situation prevails with respect to Shigella. Strains of E. coli isolated from patients with urinary tract infections (community acquired) often are resistant to sulfonamides, which are no longer the therapy of choice for such infections.

**Mechanism of Action.** Sulfonamides are competitive inhibitors of dihydropteroate synthase, the bacterial enzyme responsible for the incorporation of PABA into dihydropteroic acid, the immediate precursor of folic acid (Figure 52–2). Thus, these structural analogs of para-aminobenzoic acid (PABA) prevent normal bacterial use of PABA for the synthesis of folic acid (pteroyl-glutamic acid). Sensitive microorganisms are those that must synthesize their own folic acid; bacteria that can use preformed folate are not affected. Bacteriostasis induced by sulfonamides is counteracted by PABA competitively. Mammalian cells require preformed folic acid, cannot synthesize it, and are insensitive to drugs acting by this mechanism. Thus, mammalian cells are comparable to sulfonamide-insensitive bacteria that use preformed folate.

**Synergists of Sulfonamides.** One of the most active agents that exerts a synergistic effect when used with a sulfonamide is trimethoprim (Bushby and Hitchings, 1968). This compound is a potent and selective competitive inhibitor of microbial dihydrofolate reductase, the enzyme that reduces dihydrofolate to tetrahydrofolate. It is this reduced form of folic acid that is required for one-carbon transfer reactions. The simultaneous administration of a sulfonamide and trimethoprim thus introduces sequential blocks in the pathway by which microorganisms synthesize tetrahydrofolate from precursor molecules (Figure 52–2). The expectation that

---

**Figure 52–1.** Structural formulas of selected sulfonamides and para-aminobenzoic acid. The N of the para-NH₂ group is designated as N4; that of the amide NH₂, as N1.

**Figure 52–2.** Steps in folate metabolism blocked by sulfonamides and trimethoprim.
such a combination would yield synergistic antimicrobial effects has been realized both in vitro and in vivo.

**Acquired Bacterial Resistance to Sulfonamides.** Bacterial resistance to sulfonamides presumably originates by random mutation and selection or by transfer of resistance by plasmids (Chapter 48). Such resistance, once it is maximally developed, usually is persistent and irreversible, particularly when produced in vivo. Acquired resistance to sulfonamide usually does not involve cross-resistance to antimicrobial agents of other classes. The in vivo acquisition of resistance has little or no effect on either virulence or antigenic characteristics of microorganisms.

Resistance to sulfonamide probably is the consequence of an altered enzymatic constitution of the bacterial cell; the alteration may be characterized by (1) a lower affinity of dihydropteroate synthase for sulfonamides, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) an increased production of an essential metabolite or drug antagonist. For example, some resistant staphylococci may synthesize 70 times as much PABA as do the susceptible parent strains. Nevertheless, an increased production of PABA is not a constant finding in sulfonamide-resistant bacteria, and resistant mutants may possess enzymes for folate biosynthesis that are less readily inhibited by sulfonamides. Plasmid-mediated resistance is due to plasmid-encoded drug-resistant dihydropteroate synthetase.

**Absorption, Fate, and Excretion**

Except for sulfonamides especially designed for their local effects in the bowel (Chapter 47), this class of drugs is absorbed rapidly from the GI tract. Approximately 70-100% of an oral dose is absorbed, and sulfonamide can be found in the urine within 30 minutes of ingestion. Peak plasma levels are achieved in 2-6 hours, depending on the drug. The small intestine is the major site of absorption, but some of the drug is absorbed from the stomach. Absorption from other sites, such as the vagina, respiratory tract, or abraded skin, is variable and unreliable, but a sufficient amount may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly to albumin. The extent to which this occurs is determined by the hydrophobicity of a particular drug and its $pK_a$; at physiological pH, drugs with a high $pK_a$ exhibit a low degree of protein binding, and vice versa.

Sulfonamides are distributed throughout all tissues of the body. The diffusible fraction of sulfadiazine is distributed uniformly throughout the total-body water, whereas sulfisoxazole is confined largely to the extracellular space. The sulfonamides readily enter pleural, peritoneal, synovial, ocular, and similar body fluids and may reach concentrations therein that are 50-80% of the simultaneously determined concentration in blood. Because the protein content of such fluids usually is low, the drug is present in the unbound active form.

After systemic administration of adequate doses, sulfadiazine and sulfisoxazole attain concentrations in cerebrospinal fluid that may be effective in meningeal infections. At steady state, the concentration ranges between 10% and 80% of that in the blood. However, because of the emergence of sulfonamide-resistant microorganisms, these drugs are used rarely for the treatment of meningitis.

Sulfonamides pass readily through the placenta and reach the fetal circulation. The concentrations attained in the fetal tissues are sufficient to cause both antibacterial and toxic effects.

The sulfonamides undergo metabolic alterations in vivo, especially in the liver. The major metabolic derivative is the N4-acetylated sulfanamide. Acetylation, which occurs to a different extent with each agent, is disadvantageous because the resulting products have no antibacterial activity and yet retain the toxic potential of the parent substance.

Sulfonamides are eliminated from the body partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the $t_{1/2}$ of sulfonamides in the body thus depends on renal function. In acid urine, the older sulfonamides are insoluble and may precipitate, forming crystalline deposits that can cause urinary obstruction. Small amounts are eliminated in the feces, bile, milk, and other secretions.

**Pharmacological Properties of Individual Sulfonamides**

The sulfonamides may be classified on the basis of the rapidity with which they are absorbed and excreted (Table 52–1):

- agents that are absorbed and excreted rapidly, such as sulfisoxazole and sulfadiazine
- agents that are absorbed very poorly when administered orally and hence are active in the bowel lumen, such as sulfasalazine
- agents that are used mainly topically, such as sulfacetamide, mafenide, and silver sulfadiazine
- long-acting sulfonamides, such as sulfadoxine, that are absorbed rapidly but excreted slowly

**Rapidly Absorbed and Eliminated Sulfonamides**

**Sulfisoxazole.** Sulfisoxazole is a rapidly absorbed and excreted sulfonamide with excellent antibacterial activity. Because its high solubility eliminates much of the renal toxicity inherent in the use of older sulfonamides, it has essentially replaced the less soluble agents.

Sulfisoxazole is bound extensively to plasma proteins. Following an oral dose of 2-4 g, peak concentrations in plasma of 110-250 µg/mL are found in 2-4 hours. From 28-35% of sulfisoxazole in the blood and ~30% in the urine is in the acetylated form. The kidney excretes ~95% of a single dose in 24 hours. Concentrations of the drug in urine thus greatly exceed those in blood and may be bactericidal. The concentration in cerebrospinal fluid averages about a third of that in the blood.
readily than the free fraction, and the administration of alkali accelerates the renal clearance of both forms by further diminishing their tubular reabsorption.

In adults and children who are being treated with sulfadiazine, every precaution must be taken to ensure fluid intake adequate to produce a urine output of at least 1200 mL in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may be given to reduce the risk of crystalluria.

### Poorly Absorbed Sulfonamides

**Sulfasalazine.** Sulfasalazine (AZULFIDINE, others) is very poorly absorbed from the GI tract. It is used in the therapy of ulcerative colitis and regional enteritis (Chapter 47). Intestinal bacteria break sulfasalazine down to sulfapyridine, an active sulfonamide that is absorbed and eventually excreted in the urine, and 5-aminosalicylate (5-ASA, mesalamine; Figures 47–2 through 47–4), which reaches high levels in the feces. Whereas sulfapyridine is responsible for most of the toxicity 5-ASA is the effective agent in inflammatory bowel disease. Toxic reactions include Heinz-body anemia, acute hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency, and agranulocytosis. Nausea, fever, arthralgias, and rashes occur in up to 20% of patients treated with the drug; desensitization has been an effective treatment. Sulfasalazine can cause a reversible infertility in males owing to changes in sperm number and morphology.

### Sulfonamides for Topical Use

**Sulfacetamide.** Sulfacetamide is the N1-acetyl-substituted derivative of sulfanilamide. Its aqueous solubility (1:140) is ~90 times that of sulfadiazine. Solutions of the sodium salt of the drug are employed extensively in the management of ophthalmic infections. Although topical sulfonamide for most purposes is discouraged because of lack of efficacy and a high risk of sensitization, sulfacetamide has certain advantages. Very high aqueous concentrations are not irritating to the eye and are effective against susceptible microorganisms. A 30% solution of the sodium salt has a pH of 7.4, whereas the solutions of sodium salts of other sulfonamides are highly alkaline. The drug penetrates into ocular fluids and tissues in high concentration. Sensitivity reactions to sulfacetamide are rare, but the drug should not be used in patients with known hypersensitivity to sulfonamides. See Chapters 64 and 65 for ocular and dermatological uses.

**Silver Sulfadiazine.** Silver sulfadiazine (sILVADENE, others) inhibits the growth in vitro of nearly all pathogenic bacteria and fungi, including some species resistant to sulfonamides. The compound is used topically to reduce microbial colonization and the incidence of infections from burns. It should not be used to treat an established deep infection. Silver is released slowly from the preparation in concentrations that are selectively toxic to the microorganisms. However, bacteria may develop resistance to silver sulfadiazine. Although little silver is absorbed, the plasma concentration of sulfadiazine may approach therapeutic levels if a large surface area is involved. Adverse reactions—burning, rash, and itching—are infrequent. Silver sulfadiazine is considered by most authorities to be an agent of choice for the prevention of burn infections.

**Mafenide.** This sulfonamide (α-amino-p-toluene-sulfonamide) is marketed as mafenide acetate (SULFAMYLON). When applied topically, it effectively prevents colonization of burns by a large variety of gram-negative and gram-positive bacteria. It should not be used in
treatment of an established deep infection. Superinfection with 
Candida occasionally may be a problem. The cream is applied once 
or twice daily to a thickness of 1-2 mm over the burned skin. 
Cleansing of the wound and removal of debris should be carried out 
before each application of the drug. Therapy is continued until skin 
grafting is possible. Mafenide is rapidly absorbed systemically and 
converted to para-carboxybenzenesulfonylamine. Studies of absorp-
tion from the burn surface indicate that peak plasma concentrations 
are reached in 2-4 hours. Adverse effects include intense pain at sites 
of application, allergic reactions, and loss of fluid by evaporation 
from the burn surface because occlusive dressings are not used. The 
drug and its primary metabolite inhibit carbonic anhydrase, and the 
urine becomes alkaline. Metabolic acidosis with compensatory 
tachypnea and hyperventilation may ensue; these effects limit the 
usefulness of mafenide.

**Long-Acting Sulfonamides**

**Sulfadoxine.** This agent, N1-[5,6-dimethoxy-4-pyrimidiny] sulfanil-
amide, has a particularly long plasma t1/2 (7-9 days). It is used in 
combination with pyrimethamine (500 mg sulfadoxine plus 25 mg 
pyrimethamine as FANSIDAR) for the prophylaxis and treatment of 
malaria caused by mefloquine-resistant strains of *Plasmodium falciparum* (Chapter 49). However, because of severe and sometimes 
fatal reactions, including the Stevens-Johnson syndrome, and the 
emergence of resistant strains, the drug has limited usefulness for 
the treatment of malaria.

**Sulfonamide Therapy**

The number of conditions for which the sulfonamides are 
therapeutically useful and constitute drugs of first 
choice has been reduced sharply by the development of 
more effective antimicrobial agents and by the gradual 
increase in the resistance of a number of bacterial 
species to this class of drugs. However, the combina-
tion of sulfamethoxazole and trimethoprim is widely 
employed.

**Urinary Tract Infections.** Because a significant percentage of uri-
inary tract infections in many parts of the world are caused by 
sulfonamide-resistant microorganisms, sulfonamides are no longer 
a therapy of first choice. Trimethoprim-sulfamethoxazole, a 
quinolone, trimethoprim, fosfomycin, or ampicillin are the preferred 
agents. However, sulfisoxazole may be used effectively in areas 
where the prevalence of resistance is not high or when the organism 
is known to be sensitive. The usual dosage is 2-4 g initially followed 
by 1-2 g, orally four times a day for 5-10 days. Patients with acute 
pyelonephritis with high fever and other severe constitutional man-
ifestations are at risk of bacteremia and shock and should not be 
treated with a sulfonamide.

**Nocardiosis.** Sulfonamides are of value in the treatment of infec-
tions due to *Nocardia* spp. A number of instances of complete 
recovery from the disease after adequate treatment with a sulfon-
amide have been recorded. Sulfisoxazole or sulfadiazine may be 
given in dosages of 6-8 g daily. Concentrations of sulfonamide in 
plasma should be 80-160 μg/mL. This schedule is continued for 
several months after all manifestations have been controlled. The 
administration of sulfonamide together with a second antibiotic 
has been recommended, especially for advanced cases, and ampi-
cillin, erythromycin, and streptomycin have been suggested for this 
purpose. The clinical response and the results of sensitivity testing 
may be helpful in choosing a companion drug. Notably, there are 
no clinical data to show that combination therapy is better than 
therapy with a sulfonamide alone. Trimethoprim-sulfamethoxazole 
also has been effective, and some authorities consider it to be the 
drug of choice.

**Toxoplasmosis.** The combination of pyrimethamine and sulfadiazine 
is the treatment of choice for toxoplasmosis (Montoya et al., 2005) 
(Chapter 50). Pyrimethamine is given as a loading dose of 75 mg 
followed by 25 mg orally per day, with sulfadiazine 1 g orally every 
6 hours, plus folic acid (leucovorin) 10 mg orally each day for at 
least 3-6 weeks. Patients should receive at least 2 L of fluid intake 
daily to prevent crystalluria during therapy.

**Use of Sulfonamides for Prophylaxis.** The sulfonamides are as effi-
cacious as oral penicillin in preventing streptococcal infections and 
recurrences of rheumatic fever among susceptible subjects. Despite 
the efficacy of sulfonamides for long-term prophylaxis of rheumatic 
fever, their toxicity and the possibility of infection by drug-resistant 
streptococci make sulfonamides less desirable than penicillin for this 
purpose. They should be used, however, without hesitation in 
patients who are hypersensitive to penicillin. If untoward responses 
occur, they usually do so during the first 8 weeks of therapy; serious 
reactions after this time are rare. White blood cell counts should be 
carried out once weekly during the first 8 weeks.

**Untoward Reactions to Sulfonamides**

The untoward effects that follow the administration of 
sulfonamides are numerous and varied; the overall inci-
dence of reactions is ~5%.

**Disturbances of the Urinary Tract.** Although the risk of crystal-
luria was relatively high with the older, less soluble sulfonamides, 
the incidence of this problem is very low with more soluble agents 
such as sulfisoxazole. Crystalluria has occurred in dehydrated 
patients with acquired immune deficiency syndrome (AIDS) who 
were receiving sulfadiazine for *Toxoplasma* encephalitis. Fluid 
intake should be sufficient to ensure a daily urine volume of at least 
1200 mL (in adults). Alkalization of the urine may be desirable if 
urine volume or pH is unusually low because the solubility of sul-
fisoxazole increases greatly with slight elevations of pH.

**Disorders of the Hematopoietic System.**

**Acute Hemolytic Anemia.** The mechanism of the acute hemolytic ane-
mia produced by sulfonamides is not always readily apparent. In 
some cases, it may be a sensitization phenomenon; in other 
instances, the hemolysis is related to an erythrocytic deficiency of 
glucose-6-phosphate dehydrogenase activity. Hemolytic anemia is 
rare after treatment with sulfadiazine (0.05%); its exact incidence 
following therapy with sulfisoxazole is unknown.

**Agranulocytosis.** Agranulocytosis occurs in ~0.1% of patients who 
receive sulfadiazine; it also can follow the use of other sulfonamides. 
Although return of granulocytes to normal levels may be delayed for 
weeks or months after sulfonamide is withdrawn, most patients 
cover spontaneously with supportive care.
Aplastic Anemia. Complete suppression of bone marrow activity with profound anemia, granulocytopenia, and thrombocytopenia is an extremely rare occurrence with sulfonamide therapy. It probably results from a direct myelotoxic effect and may be fatal. However, reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (e.g., patients with AIDS or those receiving myelosuppressive chemotherapy).

Drug Interactions. The introduction of trimethoprim in combination with sulfamethoxazole constitutes an important advance in the development of clinically effective antimicrobial agents and represents the practical application of a theoretical consideration; that is, if two drugs act on sequential steps in the pathway of an obligate enzymatic reaction in bacteria (Figure 52–2), the result of their combination will be synergistic (Hitchings, 1961). In much of the world the combination of trimethoprim with sulfamethoxazole is known as cotrimoxazole. In addition to its combination with sulfamethoxazole (BACTRIM, SEPTRA, others), trimethoprim also is available as a single-entity preparation.

Chemistry. Sulfamethoxazole was discussed earlier in this chapter, and its structural formula is shown in Figure 52–1. Trimethoprim, a diaminopyrimidine, inhibits bacterial dihydrofolate reductase. The drug’s properties are reviewed in Chapter 49.

**Antibacterial Spectrum.** The antibacterial spectrum of trimethoprim is similar to that of sulfamethoxazole, although the former drug usually is 20-100 times more potent than the latter. Most gram-negative and gram-positive microorganisms are sensitive to trimethoprim, but resistance can develop when the drug is used alone. *Pseudomonas aeruginosa*, *Bacteroides fragilis*, and enterococci usually are resistant. There is significant variation in the susceptibility of Enterobacteriaceae to trimethoprim in different geographic locations because of the spread of resistance mediated by plasmids and transposons (see Chapter 48).

**Efficacy of Trimethoprim-Sulfamethoxazole in Combination.** *Chlamydia diphtheriae* and *N. meningitidis* are susceptible to trimethoprim-sulfamethoxazole. Although most *S. pneumoniae* are susceptible, there has been a disturbing increase in resistance. From 50-95% of strains of *Staphylococcus aureus*, *Staphylococcus epidermidis*, *S. pyogenes*, the viridans group of streptococci, *E. coli*, *Proteus mirabilis*, *Proteus morganii*, *Proteus rettgeri*, *Enterobacter* spp., *Salmonella*, *Shigella*, *Pseudomonas*, *E. coli* spp., *Alcaligenes* spp., *Brucella abortus*, *Pasteurella haemolytica*, *Yersinia pseudotuberculosis*, *Yersinia enterocolitica*, and *Nocardia asteroides* are resistant. Also sensitive are *Klebsiella* spp., *Brucella* spp., *Pasteurella* spp., *Yersinia* spp., and *Nocardia* spp.

**Mechanism of Action.** The antimicrobial activity of the combination of trimethoprim and sulfamethoxazole results from its actions on two steps of the enzymatic pathway for the synthesis of tetrahydrofolic acid. Sulfonamide inhibits the incorporation of PABA into folic acid, and trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (Figure 52–2). Tetrahydrofolate is essential for one-carbon transfer reactions (e.g., the synthesis of thymidylate from deoxyuridylate). Selective toxicity for microorganisms is achieved in two ways. Mammalian cells use preformed folates from the diet and do not synthesize the compound. Furthermore, trimethoprim is a highly selective inhibitor of dihydrofolate reductase of lower organisms: ~100,000 times more drug is required to inhibit human reductase than the bacterial enzyme. This relative selectivity is vital because this enzymatic function is essential to all species.

**TRIMETHOPRIM-SULFAMETHOXAZOLE**

The introduction of trimethoprim in combination with sulfamethoxazole constitutes an important advance in the development of clinically effective antimicrobial agents and represents the practical application of a theoretical consideration; that is, if two drugs act on sequential steps in the pathway of an obligate enzymatic
The synergistic interaction between sulfonamide and trimethoprim is predictable from their respective mechanisms. There is an optimal ratio of the concentrations of the two agents for synergism that equals the ratio of the minimal inhibitory concentrations of the drugs acting independently. Although this ratio varies for different bacteria, the most effective ratio for the greatest number of microorganisms is 20 parts sulfamethoxazole to 1 part trimethoprim. The combination is thus formulated to achieve a sulfamethoxazole concentration in vivo that is 20 times greater than that of trimethoprim. The pharmacokinetic properties of the sulfonamide chosen to be in combination with trimethoprim are critical because relative constancy of the concentrations of the two compounds in the body is desired.

**Bacterial Resistance.** Bacterial resistance to trimethoprim-sulfamethoxazole is a rapidly increasing problem, although resistance is lower than it is to either of the agents alone. Resistance often is due to the acquisition of a plasmid that codes for an altered dihydropyrimidinase. Resistance to trimethoprim-sulfamethoxazole is reportedly formed in almost 30% of urinary isolates of *E. coli* (Olson, et al., 2009).

**Absorption, Distribution, and Excretion.** The pharmacokinetic profiles of sulfamethoxazole and trimethoprim are closely but not perfectly matched to achieve a constant ratio of 20:1 in their concentrations in blood and tissues. The ratio in blood is often >20:1, and that in tissues is frequently less. After a single oral dose of the combined preparation, trimethoprim is absorbed more rapidly than sulfamethoxazole. The concurrent administration of the drugs appears to slow the absorption of sulfamethoxazole. Peak blood concentrations of trimethoprim usually occur by 2 hours in most patients, whereas peak concentrations of sulfamethoxazole occur by 4 hours after a single oral dose. The half-lives of trimethoprim and sulfamethoxazole are ~11 and 10 hours, respectively.

When 800 mg sulfamethoxazole is given with 160 mg trimethoprim (the conventional 5:1 ratio) twice daily, the peak concentrations of the drugs in plasma are ~40 and 2 μg/mL, the optimal ratio. Peak concentrations are similar (46 and 3.4 μg/mL) after intravenous infusion of 800 mg sulfamethoxazole and 160 mg trimethoprim over a period of 1 hour.

Trimethoprim is distributed and concentrated rapidly in tissues, and ~40% is bound to plasma protein in the presence of sulfamethoxazole. The volume of distribution of trimethoprim is almost nine times that of sulfamethoxazole. The drug readily enters cerebrospinal fluid and sputum. High concentrations of each component of the mixture also are found in bile. About 65% of sulfamethoxazole is bound to plasma protein.

About 60% of administered trimethoprim and from 25% to 50% of administered sulfamethoxazole are excreted in the urine in 24 hours. Two-thirds of the sulfonamide is unconjugated. Metabolites of trimethoprim also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

**Therapeutic Uses.**

**Urinary Tract Infections.** Treatment of uncomplicated lower urinary tract infection (UTI) with trimethoprim-sulfamethoxazole often is highly effective for sensitive bacteria. The preparation has been shown to produce a better therapeutic effect than does either of its components given separately when the infecting microorganisms are of the family Enterobacteriaceae. Single-dose therapy (320 mg trimethoprim plus 1600 mg sulfamethoxazole in adults) has been effective in some cases for the treatment of acute uncomplicated UTI, but a minimum of 3 days of therapy is more likely to be effective (Fihn, 2003; Zinner and Mayer, 2005).

The combination appears to have special efficacy in chronic and recurrent infections of the urinary tract. Small doses (200 mg sulfamethoxazole plus 40 mg trimethoprim per day and postcoitaly or 2-4 times these amounts once or twice per week) effectively reduce the number of recurrent urinary tract infections in women. This effect may be related to the presence of therapeutic concentrations of trimethoprim in vaginal secretions. Enterobacteriaceae surrounding the urethral orifice may be eliminated or markedly reduced in number, thus diminishing the chance of an ascending reinfection. Trimethoprim also is found in therapeutic concentrations in prostatic secretions, and trimethoprim-sulfamethoxazole is often effective for the treatment of bacterial prostatitis.

**Bacterial Respiratory Tract Infections.** Trimethoprim-sulfamethoxazole is effective for acute exacerbations of chronic bronchitis. Administration of 800-1200 mg sulfamethoxazole plus 160-240 mg trimethoprim twice a day appears to be effective in decreasing fever, purulence and volume of sputum, and sputum bacterial count. Trimethoprim-sulfamethoxazole should not be used to treat streptococcal pharyngitis because it does not eradicate the microorganism. It is effective for acute otitis media in children and acute maxillary sinusitis in adults caused by susceptible strains of *H. influenzae* and *S. pneumoniae*.

**GI Infections.** The combination is an alternative to a fluoroquinolone for treatment of shigellosis because many strains of the causative agent now are resistant to ampicillin; however, resistance to trimethoprim-sulfamethoxazole is increasingly common. It also is a second-line drug (ceftriaxone or a fluoroquinolone is the preferred treatment) for typhoid fever, but resistance is an increasing problem. In adults, trimethoprim-sulfamethoxazole appears to be effective when the dose is 800 mg sulfamethoxazole plus 160 mg trimethoprim every 12 hours for 15 days. The same regimen has been used for 5 days for Travelers’ diarrhea.

Trimethoprim-sulfamethoxazole appears to be effective in the management of carriers of sensitive strains of *Salmonella typhi* and other *Salmonella* spp. One proposed schedule is the administration of 800 mg sulfamethoxazole plus 160 mg trimethoprim twice a day for 3 months; however, failures have occurred. The presence of chronic disease of the gallbladder may be associated with a high incidence of failure to clear the carrier state. Acute diarrhea owing to sensitive strains of enteropathogenic *E. coli* can be treated or prevented with either trimethoprim or trimethoprim plus sulfamethoxazole (Hill et al., 2006). However, antibiotic treatment (either trimethoprim-sulfamethoxazole or cephalosporin) of diarrheal illness owing to enterohemorrhagic *E. coli* O157:H7 may increase the risk of hemolytic-uremic syndrome, perhaps by increasing the release of Shiga toxin by the bacteria (Wong et al., 2000).

**Infection by Pneumocystis jiroveci.** High-dose therapy (trimethoprim 15-20 mg/kg per day plus sulfamethoxazole 75-100 mg/kg per day in three or four divided doses) is effective for this severe infection in patients with AIDS (Thomas and Limper, 2004). This combination compares favorably with pentamidine for treatment of this disease. Adjunctive corticosteroids should be given at the onset of
**THE QUINOLONES**

The first quinolone, *nalidixic acid*, was isolated as a by-product of the synthesis of *chloroquine* and made available for the treatment of urinary tract infections. The introduction of fluorinated 4-quinolones, such as ciprofloxacin (CIPRO, others), and moxifloxacin (AVELOX), represents a particularly important therapeutic advance: These agents have broad antimicrobial activity and are effective after oral administration for the treatment of a wide variety of infectious diseases (Table 52–2) (Hooper, 2005a). Rare and potentially fatal side effects, however, have resulted in the withdrawal from the U.S. market of lomefloxacin (phototoxicity, QTc prolongation), gatifloxacin (hypoglycemia), temafloxacin (immune hemolytic anemia), trovafloxacin (hepatotoxicity), grepafloxacin (cardiotoxicity), and clinafloxacin (phototoxicity). In all these cases, the side effects were detected by postmarketing surveillance (Sheehan and Chew, 2003).

**Chemistry.** The compounds that are currently available for clinical use in the U.S. are quinolones containing a carboxylic acid moiety at position 3 of the primary ring structure. Many of the newer fluoroquinolones also contain a fluorine substituent at position 6 and a piperazine moiety at position 7 (Table 52–2).

**Mechanism of Action.** The quinolone antibiotics target bacterial DNA gyrase and topoisomerase IV (Hooper, 2005a). For many gram-positive bacteria (such as *S. aureus*), topoisomerase IV is the primary activity inhibited by the quinolones. In contrast, DNA gyrase is the primary quinolone target in many gram-negative microbes (such as *E. coli*) (Alovero et al., 2000; Hooper, 2005a). Individual strands of double-helical DNA must be separated to permit DNA replication or transcription. However, anything that separates the strands results in “overwinding” or excessive positive supercoiling of the DNA in front of the point of separation. To combat this mechanical obstacle, the bacterial enzyme DNA gyrase is responsible for the continuous introduction of negative supercoils into...

* (Fused dioxolo ring)
DNA via an ATP-dependent reaction requiring that both strands of the DNA be cut to permit passage of a segment of DNA through the break; the break then is resealed.

The DNA gyrase of *E. coli* is composed of two 105,000 Da A subunits and two 95,000 Da B subunits encoded by the gyra and gyrB genes, respectively. The A subunits, which carry out the strand-cutting function of the gyrase, are the site of action of the quinolones (Figure 52–3). The drugs inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with those required to inhibit bacterial growth (0.1-10 μg/mL). Mutations of the gene that encodes the A subunit polypeptide can confer resistance to these drugs (Hooper, 2005a).

Topoisomerase IV is also composed of four subunits encoded by the parC and parE genes in *E. coli* (Hooper, 2005a). Topoisomerase IV separates interlinked (catenated) daughter DNA molecules that are the product of DNA replication. Eukaryotic cells do not contain DNA gyrase, but they do contain a conceptually and mechanistically similar type II DNA topoisomerase that removes positive supercoils from DNA to prevent its tangling during replication. This enzyme is the target for some antineoplastic agents (Chapters 60 and 61). Quinolones inhibit eukaryotic type II topoisomerase only concentrations (100-1000 μg/mL) much higher than those that inhibit bacterial DNA gyrase (Mitscher and Ma, 2003).

**Antibacterial Spectrum.** The fluoroquinolones are potent bactericidal agents against *E. coli* and various species of *Salmonella, Shigella, Enterobacter, Campylobacter*, and *Neisseria* (Hooper, 2005a). MICs of the fluoroquinolones for 90% of these strains (MIC90) usually are <0.2 μg/mL. Ciprofloxacin is more active than norfloxacin (NOROXIN) against *P. aeruginosa*; values of MIC90 range from 0.5-6 μg/mL. Fluoroquinolones also have good activity against staphylococci, but not against methicillin-resistant strains (MIC90 = 0.1-2 μg/mL).

Activity against streptococci is limited to a subset of the quinolones, including levofloxacin (LEVAQUIN), gatifloxacin, and moxifloxacin (AVELOX) (Hooper, 2005a). Several intracellular bacteria are inhibited by fluoroquinolones at concentrations that can be achieved in plasma; these include species of *Chlamydia, Mycoplasma, Legionella, Brucella*, and *Mycobacterium* (including *Mycobacterium tuberculosis*) (American Thoracic Society, 2003). Ciprofloxacin (CIPRO, others), ofloxacin (FLOXIN), and pefloxacin have MIC90 values from 0.5-3 μg/mL for *M. fortuitum, M. kansasi*, and *M. tuberculosis*; ofloxacin and pefloxacin (not available in U.S.) are active in animal models of leprosy (Hooper, 2005a). However, clinical experience with these pathogens remains limited.

Several fluoroquinolones, including garenoxacin (not available in U.S.) and gemifloxacin, have activity against anaerobic bacteria (Medical Letter, 2000, 2004). Resistance to quinolones may develop during therapy via mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV or by active transport of the drug out of the bacteria (Oethinger et al., 2000). No quinolone-modifying or -inactivating activities have been identified in bacteria (Gold and Moellering, 1996). Resistance has increased after the introduction of fluoroquinolones, especially in *Pseudomonas* and staphylococci. Increasing fluoroquinolone resistance also is being observed in *C. jejuni, Salmonella, N. gonorrhoeae*, and *S. pneumoniae*.

As mentioned in Chapter 48, the pharmacokinetic and pharmacodynamic parameters of antimicrobial agents are important in preventing the selection and spread of resistant strains and have led to description of the mutation-prevention concentration, which is the lowest concentration of antimicrobial that prevents selection of resistant bacteria from high bacterial inocula. β-Lactams are time-dependent agents without significant post-antibiotic effects, resulting in bacterial eradication when unbound serum concentrations exceed MICs of these agents against infecting pathogens for >40-50% of the dosing interval. By contrast, fluoroquinolones are concentration- and time-dependent agents, resulting in bacterial eradication when unbound serum area under the curve-to-MIC ratios exceed 25-30. An extended release formulation of ciprofloxacin (PROQUIN XR) exemplifies this principle.

**Absorption, Fate, and Excretion.** The quinolones are well absorbed after oral administration and are distributed widely in body tissues. Peak serum levels of the fluoroquinolones are obtained within 1-3 hours of an oral dose of 400 mg, with peak levels ranging from 1.1 μg/mL for ciprofloxacin to 6.4 μg/mL for levofloxacin. Relatively low serum levels are reached with norfloxacin and limit its usefulness to the treatment of urinary tract infections. Food does not impair oral absorption but may delay the time to peak serum concentrations. Oral doses in adults are 200-400 mg every 12 hours for ofloxacin, 400 mg every 12 hours for norfloxacin and pefloxacin, and 250 to 750 mg every 12 hours for ciprofloxacin. Bioavailability of the fluoroquinolones is >50% for all agents and >95% for several. The serum t1/2 is 3-5 hours for norfloxacin and ciprofloxacin. The volume of distribution of quinolones is high, with concentrations of quinolones in urine, kidney, lung and prostate tissue, stool, bile, and macrophages and neutrophils higher than serum levels. Quinolone

![Figure 52–3. Model of the formation of negative DNA supercoils by DNA gyrase.](image-url)

The enzyme binds to two segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (–) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and, at higher concentrations, block the decatenating activity of topoisomerase IV. From Cozzarelli NR. DNA gyrase and the supercoiling of DNA. *Science*, 1980, 207:953–960. Reprinted with permission from AAAS.
concentrations in cerebrospinal fluid, bone, and prostatic fluid are lower than in serum. Pefloxacin and ofloxacin levels in ascites fluid are close to serum levels, and ciprofloxacin, ofloxacin, and pefloxacin have been detected in human breast milk.

Most quinolones are cleared predominantly by the kidney, and dosages must be adjusted for renal failure. Exceptions are pefloxacin and moxifloxacin, which are metabolized predominantly by the liver and should not be used in patients with hepatic failure. None of the agents is removed efficiently by peritoneal dialysis or hemodialysis.

**Therapeutic Uses**

**Urinary Tract Infections.** Nalidixic acid is useful only for UTI caused by susceptible microorganisms. The fluoroquinolones are significantly more potent and have a much broader spectrum of antimicrobial activity. Norfloxacin is approved for use in the U.S. only for urinary tract infections. Comparative clinical trials indicate that the fluoroquinolones are more efficacious than trimethoprim-sulfamethoxazole for the treatment of UTI (Hooper, 2005b). Ciprofloxacin XR is FDA-approved only for UTI.

**Prostatitis.** Norfloxacin, ciprofloxacin, and ofloxacin all have been effective in uncontrolled trials for the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4-6 weeks appear to be effective in patients not responding to trimethoprim-sulfamethoxazole.

**Sexually Transmitted Diseases.** The quinolones are contraindicated in pregnancy. Fluoroquinolones lack activity for *Treponema pallidum* but have activity in vitro against *C. trachomatis* and *H. ducreyi*. For chlamydial urethritis/cervicitis, a 7-day course of ofloxacin is an alternative to a 7-day treatment with doxycycline or a single dose of azithromycin; other available quinolones have not been reliably effective. A single oral dose of a fluoroquinolone such as ofloxacin or ciprofloxacin had been effective treatment for sensitive strains of *N. gonorrhoeae*, but increasing resistance to fluoroquinolones has led to ceftriaxone being the first-line agent for this infection (Newman et al., 2004). Chancroid (infection by *H. ducreyi*) can be treated with 3 days of ciprofloxacin.

**GI and Abdominal Infections.** For traveler’s diarrhea (frequently caused by enterotoxigenic *E. coli*), the quinolones are equal to trimethoprim-sulfamethoxazole in effectiveness, reducing the duration of loose stools by 1-3 days (Hill et al., 2006). Norfloxacin, ciprofloxacin, and ofloxacin given for 5 days all have been effective in the treatment of patients with shigellosis, with even shorter courses effective in many cases. Ciprofloxacin and ofloxacin treatment cures most patients with enteric fever caused by *S. typhi*, as well as bacteremic nontyphoidal infections in AIDS patients, and it clears chronic fecal carriage. Shigellosis is treated effectively with sensitive bacteria. Fluoroquinolones administered for 4-6 weeks may require treatment for 4-6 weeks or more. Dosage should be reduced for patients with severely impaired renal function. Clinical failures have been as high as 75% in chronic osteomyelitis in which gram-negative rods predominated (Hooper, 2005b). Failures have been associated with the development of resistance in *S. aureus*, *P. aeruginosa*, and *Serratia marcescens*. In diabetic foot infections, which are commonly caused by a mixture of bacteria including gram-negative rods, anaerobes, streptococci, and staphylococci, the fluoroquinolones in combination with an agent with antianaerobic activity are a reasonable choice.

**Other Infections.** Ciprofloxacin received wide usage for the prophylaxis of anthrax and has been shown to be effective for the treatment of tularemia (Chocarro et al., 2000; Swartz, 2001). The quinolones may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and for the treatment of atypical mycobacterial infections as well as *Mycobacterium avium* complex infections in AIDS (Chapter 56). Quinolones, when used as prophylaxis in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias (Hughes et al., 2002).

**Adverse Effects.** Quinolones and fluoroquinolones generally are well tolerated (Mandell, 2003). The most common adverse reactions involve the GI tract, with 3-17% of patients reporting mostly mild nausea, vomiting, and/or abdominal discomfort. Ciprofloxacin is the most common cause of *C. difficile* colitis. Gatifloxacin is associated with both hypo- and hyperglycemia in older adults (Park-Wyllie et al., 2006). CNS side effects, predominantly mild headache and dizziness, have been seen in 0.9-11% of patients. Rarely, hallucinations, delirium, and seizures have occurred, predominantly in patients who...
were also receiving theophylline or a nonsteroidal anti-inflammatory drug. Ciprofloxacin and pefloxacin inhibit the metabolism of theophylline, and toxicity from elevated concentrations of the methylxanthine may occur (Schwartz et al., 1988). Nonsteroidal anti-inflammatory drugs may augment displacement of γ-aminobutyric acid (GABA) from its receptors by the quinolones (Halliwell et al., 1993). Rashes, including photosensitivity reactions, also can occur. Achilles tendon rupture or tendinitis is a recognized adverse effect, especially in those >60 years old, patients taking corticosteroids, and in solid organ transplant recipients (Mandell, 2003). All these agents can produce arthropathy in several species of immature animals. Traditionally, the use of quinolones in children has been contraindicated for this reason. However, children with cystic fibrosis given ciprofloxacin, norfloxacin, and nalidixic acid have had few, and reversible, joint symptoms (Burkhardt et al., 1997; Sabharwal & Marchant, 2006). Therefore, in some cases the benefits may outweigh the risks of quinolone therapy in children. Ciprofloxacin should not be given to pregnant women.

Leukopenia, eosinophilia, and mild elevations in serum transaminases occur rarely. QT, interval (QT interval corrected for heart rate) prolongation has been observed with sparfloxacin and to a lesser extent with gatifloxacin and moxifloxacin. Quinolones probably should be used only with caution in patients on class III (amiodarone) and class IA (quinidine, procainamide) antiarrhythmics (Chapter 29).

ANTISEPTIC AND ANALGESIC AGENTS FOR URINARY TRACT INFECTIONS

Urinary tract antiseptics are concentrated in the renal tubules where they inhibit the growth of many species of bacteria. These agents cannot be used to treat systemic infections because effective concentrations are not achieved in plasma with safe doses; however, they can be administered orally to treat infections of the urinary tract. Furthermore, effective antibacterial concentrations reach the renal pelvis and the bladder. Treatment with such drugs can be thought of as local therapy: Only in the kidney and bladder, with the rare exceptions mentioned below, are adequate therapeutic levels achieved (Hooper, 2005b).

Methenamine. Methenamine is a urinary tract antiseptic and pro-drug that owes its activity to its capacity to generate formaldehyde.

\[
\text{NH}_4(\text{CH}_2)_6 + 6\text{H}_2\text{O} + 4\text{H}^+ \rightarrow 4\text{NH}_4^+ + 6\text{HCHO}
\]

At pH 7.4, almost no decomposition occurs; the yield of formaldehyde is 6% of the theoretical amount at pH 6 and 20% at pH 5. Thus, acidification of the urine promotes formaldehyde formation and the formaldehyde-dependent antibacterial action. The decomposition reaction is fairly slow, and 3 hours are required to reach 90% completion.

Antimicrobial Activity. Nearly all bacteria are sensitive to free formaldehyde at concentrations of ~20 μg/mL. Urea-splitting microorganisms (e.g., Proteus spp.) tend to raise the pH of the urine and thus inhibit the release of formaldehyde. Microorganisms do not develop resistance to formaldehyde.

Pharmacology and Toxicology. Methenamine is absorbed orally, but 10–30% decomposes in the gastric juice unless the drug is protected by an enteric coating. Because of the ammonia produced, methenamine is contraindicated in hepatic insufficiency. Excretion in the urine is nearly quantitative. When the urine pH is 6 and the daily urine volume is 1000-1500 mL, a daily dose of 2 g will yield a urine concentration of 18-60 µg/mL of formaldehyde; this is more than the MIC for most urinary tract pathogens. Various poorly metabolized acids can be used to acidify the urine. Low pH alone is bacteriostatic, so acidification serves a double function. The acids commonly used are mandelic acid and hippuric acid (UREX, HIPREX). GI distress frequently is caused by doses >500 mg four times a day, even with enteric-coated tablets. Painful and frequent micturition, albuminuria, hematuria, and rashes may result from doses of 4 to 8 g/day given for longer than 3–4 weeks. Once the urine is sterile, a high dose should be reduced. Because systemic methenamine has low toxicity at the typically used doses, renal insufficiency does not constitute a contraindication to the use of methenamine alone, but the acids given concurrently may be detrimental; methenamine mandelate is contraindicated in renal insufficiency. Crystalluria from the mandelate moiety can occur. Methenamine combines with sulfamethizole and perhaps other sulfonamides in the urine, which results in mutual antagonism; therefore, these drugs should not be used in combination.

Therapeutic Uses and Status. Methenamine is not a primary drug for the treatment of acute urinary tract infections, but it is of value for chronic suppressive treatment (Fihn, 2003). The agent is most useful when the causative organism is E. coli, but it usually can suppress the common gram-negative offenders and often S. aureus and S. epidermidis as well. Enterobacter aerogenes and Proteus vulgaris are usually resistant. Urea-splitting bacteria (mostly Proteus) make it difficult to control the urine pH. The physician should strive to keep the pH ≤5.5.

Nitrofurantoin. Nitrofurantoin (FURADANTIN, MACROBID, others) is a synthetic nitrofuran that is used for the prevention and treatment of infections of the urinary tract.
**Antimicrobial Activity.** Enzymes capable of reducing nitrofurantoin appear to be crucial for its activation. Highly reactive intermediates are formed, and these seem to be responsible for the observed capacity of the drug to damage DNA. Bacteria reduce nitrofurantoin more rapidly than do mammalian cells, and this is thought to account for the selective antimicrobial activity of the compound. Bacteria that are susceptible to the drug rarely become resistant during therapy. Nitrofurantoin is active against many strains of *E. coli* and enterococci. However, most species of *Proteus* and *Pseudomonas* and many species of *Enterobacter* and *Klebsiella* are resistant. Nitrofurantoin is bacteriostatic for most susceptible microorganisms at concentrations of ≤32 μg/mL or less and is bactericidal at concentrations of ≥100 μg/mL. The antibacterial activity is higher in an acidic urine.

**Pharmacology and Toxicity.** Nitrofurantoin is absorbed rapidly and completely from the GI tract. The macrocrystalline form of the drug is absorbed and excreted more slowly. Antibacterial concentrations are not achieved in plasma following ingestion of recommended doses because the drug is eliminated rapidly. The plasma t$_1/2$ is 0.3–1 hour; ~40% is excreted unchanged into the urine. The average dose of nitrofurantoin yields a concentration in urine of ~200 μg/mL. This concentration is soluble at pH >5, but the urine should not be alkalized because this reduces antimicrobial activity. The rate of excretion is linearly related to the creatinine clearance, so in patients with impaired glomerular function, the efficacy of the drug may be decreased and the systemic toxicity increased. Nitrofurantoin colors the urine brown.

The most common untoward effects are nausea, vomiting, and diarrhea; the macrocrystalline preparation is better tolerated than traditional formulations. Various hypersensitivity reactions occur occasionally. These include chills, fever, leukopenia, granulocytopenia, hemolytic anemia (associated with G6PD deficiency), cholestatic jaundice, and hepatocellular damage. Chronic active hepatitis is an uncommon but serious side effect. Acute pneumonia with fever, chills, cough, dyspnea, chest pain, pulmonary infiltration, and eosinophilia may occur within hours to days of the initiation of therapy; these symptoms usually resolve quickly after discontinuation of the drug. More insidious subacute reactions also may be noted, and interstitial pulmonary fibrosis can occur in patients taking the drug chronically. This appears to be due to generation of oxygen radicals as a result of redox cycling of the drug in the lung. Elderly patients are especially susceptible to the pulmonary toxicity of nitrofurantoin. Megaloblastic anemia is rare. Various neurological disorders are observed occasionally. Headache, vertigo, drowsiness, muscular aches, and nystagmus are readily reversible, but severe polyneuropathies with demyelination and degeneration of both sensory and motor nerves have been reported; signs of denervation and muscle atrophy result. Neuropathies are most likely to occur in patients with impaired renal function and in persons on long-continued treatment.

The oral dosage of nitrofurantoin for adults is 50-100 mg four times a day with meals and at bedtime, less for the macrocrystalline formulation (100 mg every 12 hours for 7 days). Alternatively, the daily dosage is better expressed as 5-7 mg/kg in four divided doses (not to exceed 400 mg). A single 50-100-mg dose at bedtime may be sufficient to prevent recurrences. The daily dose for children is 5 to 7 mg/kg but may be as low as 1 mg/kg for long-term therapy. A course of therapy should not exceed 14 days, and repeated courses should be separated by rest periods. Pregnant women, individuals with impaired renal function (creatinine clearance <40 mL/minute), and children <1 month of age should not receive nitrofurantoin.

Nitrofurantoin is approved only for the treatment of urinary tract infections caused by microorganisms known to be susceptible to the drug. Currently, bacterial resistance to nitrofurantoin is more frequent than resistance to fluoroquinolones or trimethoprim-sulfamethoxazole, making nitrofurantoin a second-line agent for treatment of urinary tract infections (Fihn, 2003). Nitrofurantoin is not recommended for treatment of pyelonephritis or prostatitis.

**Phenazopyridine.** Phenazopyridine hydrochloride (PYRIDIUM, others) is *not* a urinary antiseptic. However, it does have an analgesic action on the urinary tract and alleviates symptoms of dysuria, frequency, burning, and urgency.

The usual dose is 200 mg three times daily. The compound is an azo dye, which colors urine orange or red; the patient should be so informed. GI upset is seen in up to 10% of patients and can be reduced by administering the drug with food; overdosage may result in methemoglobinemia. Phenazopyridine has been marketed since 1925 and has had dual prescription/over-the-counter (OTC) marketing status since 1951. As part of their ongoing review of OTC drug products, the Food and Drug Administration (FDA) is currently in the process of evaluating products containing <200 mg phenazopyridine to determine whether these products generally are recognized as safe and effective as urinary analgesics. The outcome of this evaluation will determine the continued availability of OTC phenazopyridine products in the U.S. Products containing 200 mg phenazopyridine are sold by prescription, but their long-term availability in the marketplace also may be affected by the FDA’s final OTC ruling. Phenazopyridine is no longer available in Canada.

**BIBLIOGRAPHY**

The β-lactam antibiotics are useful and frequently prescribed antimicrobial agents that share a common structure and mechanism of action: inhibition of synthesis of the bacterial peptidoglycan cell wall. The group includes penicillins, cephalosporins, and carbapenems.

The penicillins consist of penicillins G and V, which are highly active against susceptible gram-positive cocci; penicillinase-resistant penicillins such as nafcillin, which are active against penicillinase-producing Staphylococcus aureus; ampicillin and other agents with an improved gram-negative spectrum, especially when combined with a β-lactamase inhibitor; and extended-spectrum penicillins with activity against Pseudomonas aeruginosa, such as piperacillin.

The β-lactams also include the cephalosporin antibiotics, which are classified by generation: First-generation agents have excellent gram-positive and modest gram-negative activity; second-generation agents have somewhat better activity against gram-negative organisms and include some agents with antianaerobe activity; third-generation agents have activity against gram-positive organisms and much more activity against the Enterobacteriaceae, with a subset active against P. aeruginosa; and fourth-generation agents encompass the antimicrobial spectrum of all the third-generation agents and have increased stability to hydrolysis by inducible chromosomal β-lactamases.

Carbapenems, including imipenem, doripenem, ertapenem and meropenem, have the broadest antimicrobial spectrum of any antibiotic, whereas the monobactam aztreonam has a gram-negative spectrum resembling that of the aminoglycosides.

β-Lactamase inhibitors such as clavulanate are used to extend the spectrum of penicillins against β-lactamase-producing organisms. Bacterial resistance against the β-lactam antibiotics continues to increase at a dramatic rate. Mechanisms of resistance include not only production of β-lactamases that in some cases destroy all β-lactam antibiotics, but also alterations in or acquisition of novel penicillin-binding proteins PBPs and decreased entry and/or active efflux of the antibiotic. It is not an exaggeration to state that we are re-entering the pre-antibiotic era, with many nosocomially acquired gram-negative bacterial infections resistant to all available antibiotics.

THE PENICILLINS

Despite the existence of microbial resistance, the penicillins constitute one of the most important groups of antibiotics. Many of these have unique advantages such that members of this group of antibiotics are currently the drugs of choice for a large number of infectious diseases.

History. The history of the brilliant research that led to the discovery and development of penicillin is well chronicled. In 1928, while studying Staphylococcus variants in the laboratory at St. Mary’s Hospital in London, Alexander Fleming observed that a mold contaminating one of his cultures caused the bacteria in its vicinity to undergo lysis. Broth in which the fungus was grown was markedly inhibitory for many microorganisms. Because the mold belonged to the genus Penicillium, Fleming named the antibacterial substance penicillin.

A decade later, penicillin was developed as a systemic therapeutic agent by the concerted research of a group of investigators at Oxford University headed by Florey, Chain, and Abraham. By May 1940, a crude preparation was found to produce dramatic therapeutic effects when administered parenterally to mice with streptococcal infections. Sufficient penicillin was accumulated by 1941 to conduct therapeutic trials in several patients desperately ill with staphylococcal and streptococcal infections refractory to all other therapy. At this stage, the crude, amorphous penicillin was only ~10% pure, and it required nearly 100 L of the broth in which the mold had been grown to obtain enough of the antibiotic to treat one patient for 24 hours. Bedpans actually were used by the Oxford group for growing cultures of Penicillium notatum. Case 1 in the 1941 report from Oxford
was that of a policeman who was suffering from a severe mixed staphylococcal and streptococcal infection. He was treated with penicillin, some of which had been recovered from the urine of other patients who had been given the drug. It is said that an Oxford professor referred to penicillin as a remarkable substance grown in bedpans and purified by passage through the Oxford Police Force.

A vast research program soon was initiated in the U.S. During 1942, 122 million units of penicillin were made available, and the first clinical trials were conducted at Yale University and the Mayo Clinic, with dramatic results. By the spring of 1943, 200 patients had been treated with the drug. The results were so impressive that the surgeon general of the U.S. Army authorized a trial of the antibiotic in a military hospital. Soon thereafter, penicillin was adopted throughout the medical services of the U.S. Armed Forces.

The deep-fermentation procedure for the biosynthesis of penicillin marked a crucial advance in the large-scale production of the antibiotic. From a total production of a few hundred million units a month in the early days, the quantity manufactured rose to over 200 trillion units (nearly 150 tons) by 1950. The first marketable penicillin cost several dollars per 100,000 units; today, the same dose costs only a few cents.

Chemistry. The basic structure of the penicillins, as shown in Figure 53–1, consists of a thiazolidine ring (A) connected to a β-lactam ring (B) to which is attached a side chain (R). The penicillin nucleus itself is the chief structural requirement for biological activity: metabolic transformation or chemical alteration of this portion of the molecule causes loss of all significant antibacterial activity. The side chain (Table 53–1) determines many of the antibacterial and pharmacological characteristics of a particular type of penicillin. Several natural penicillins can be produced depending on the chemical composition of the fermentation medium used to culture Penicillium. Penicillin G (benzylpenicillin) has the greatest antimicrobial activity of these and is the only natural penicillin used clinically. For penicillin G, the side chain (R in Figure 53–1) is a phenyl-methyl substituent (Table 53–1).

Semisynthetic Penicillins. The discovery that 6-aminopenicillanic acid could be obtained from cultures of P. chrysogenum that were depleted of side-chain precursors led to the development of the semisynthetic penicillins. Side chains can be added that alter the susceptibility of the resulting compounds to inactivating enzymes (β-lactamases) and that change the antibacterial activity and the pharmacological properties of the drug. 6-Aminopenicillanic acid is now produced in large quantities with the aid of an amidase from P. chrysogenum (Figure 53–1). This enzyme splits the peptide linkage by which the side chain of penicillin is joined to 6-aminopenicillanic acid. Table 53–1 shows the variety of side chains that have been added to 6-aminopenicillanic acid to produce the medicinal penicillins in current use; the table also summarizes their major therapeutic properties (e.g., absorption following oral administration, resistance to penicillinase, and antimicrobial spectrum).

Unitage of Penicillin. The international unit of penicillin is the specific penicillin activity contained in 0.6 μg of the crystalline sodium salt of penicillin G. One milligram of pure penicillin G sodium thus equals 1667 units; 1.0 mg of pure penicillin G potassium represents 1595 units. The dosage and the antibacterial potency of the semisynthetic penicillins are expressed in terms of weight.

Mechanism of Action of the Penicillins and Cephalosporins. The β-lactam antibiotics can kill susceptible bacteria. Although knowledge of the mechanism of this action is incomplete, numerous researchers have supplied information that allows understanding of the basic phenomenon (Bayles, 2000; Ghuysen, 1991).

The cell walls of bacteria are essential for their normal growth and development. Peptidoglycan is a heteropolymeric component of the cell wall that provides rigid mechanical stability by virtue of its highly cross-linked latticework structure (Figure 53–2). In gram-positive microorganisms, the cell wall is 50-100 molecules thick, but it is only 1 or 2 molecules thick in gram-negative bacteria (Figure 53–3A). The peptidoglycan is composed of glycan chains, which are linear strands of two alternating amino sugars (N-acetylmuramic acid and N-acetylmuramic acid) that are cross-linked by peptide chains.

The biosynthesis of the peptidoglycan involves ~30 bacterial enzymes and may be considered in three stages. The first stage, precursor formation, takes place in the cytoplasm. The product, uridine
The bacterial cell wall consists of glycopeptide polymers (a NAM-NAG amino-hexose backbone) linked via bridges between amino acid side chains. In *S. aureus*, the bridge is (Gly)_5-D-Ala between lysines. The cross-linking is catalyzed by a transpeptidase, the enzyme that penicillins and cephalosporins inhibit. NAM, N-acetyl-muramic acid; NAG, N-acetyl-glucosamine.

During reactions of the second stage, UDP-acetylmuramyl-pentapeptide and UDP-acetylglucosamine are linked (with the release of the uridine nucleotides) to form a long polymer. The third and final stage involves completion of the cross-link. This is accomplished by peptidoglycan glycosyltransferases outside the cell membrane of gram-positive and within the periplasmic space of gram-negative bacteria (Figure 53–3B). The terminal glycosyl residue of the pentaglycine bridge is linked to the fourth residue of the pentapeptide (D-alanine), releasing the fifth residue (also D-alanine) (Figure 53–2). It is this last step in peptidoglycan synthesis that is inhibited by the β-lactam antibiotics and glycopeptide antibiotics such as vancomycin (by a different mechanism than the β-lactams; Chapter 54). Stereo models reveal that the conformation of penicillin is very similar to that of D-alanyl-D-alanine. The transpeptidase probably is acylated by penicillin; i.e., penicilloyl enzyme apparently is formed, with cleavage of the —CO—N— bond of the β-lactam ring. Although the transpeptidase activity has been targeted with the β-lactams and vancomycin, the glycosyltransferase is a relatively unexplored target for antibiotics (Lovering et al., 2007).

Although inhibition of the transpeptidase just described is demonstrably important, there are additional, related targets for the actions of penicillins and cephalosporins; these are collectively termed penicillin-binding proteins (PBPs). All bacteria have several such entities; e.g., *S. aureus* has four PBPs, whereas *Escherichia coli* has at least seven. The PBPs vary in their affinities for different β-lactam antibiotics, although the interactions eventually become covalent. The higher molecular weight PBPs of *E. coli* (PBPs 1a and 1b) include the transpeptidases responsible for synthesis of the peptidoglycan. Other PBPs in *E. coli* include those that are necessary for maintenance of the rod-like shape of the bacterium and for septum formation at division. Inhibition of the transpeptidases causes spheroplast formation and rapid lysis. However, inhibition of the activities of other PBPs may cause delayed lysis (PBP 2) or the production of long filamentous forms of the bacterium (PBP 3). The lethality of penicillin for bacteria appears to involve both lytic and nonlytic mechanisms. Penicillin’s disruption of the balance between PBP-mediated peptidoglycan assembly and murein hydrolase activity results in autolysis. Non-lytic killing by penicillin may involve holin-like proteins in the bacterial membrane that collapse the membrane potential (Bayles, 2000).

**Mechanisms of Bacterial Resistance to Penicillins and Cephalosporins.** Although all bacteria with cell walls contain PBPs, β-lactam antibiotics cannot kill or even inhibit all bacteria because bacteria can be resistant to these agents by myriad mechanisms. The microorganism may be intrinsically resistant because of structural differences in the PBPs that are the targets of these drugs. Furthermore, a sensitive strain may acquire resistance of this type by the development of high-molecular-weight PBPs that have decreased affinity for the antibiotic. Because the β-lactam antibiotics inhibit many different PBPs in a single bacterium, the affinity for β-lactam antibiotics of several PBPs must decrease for the organism to be resistant. Altered PBPs with decreased affinity for β-lactam antibiotics are acquired by homologous recombination between PBP genes of different bacterial species. Four of the five high-molecular-weight PBPs of the most highly penicillin-resistant *Streptococcus pneumoniae* isolates have decreased affinity for β-lactam antibiotics as a result of interspecies homologous recombination events (Figure 53–4). In contrast, isolates with high-level resistance to third-generation cephalosporins contain alterations of only two of the five high-molecular-weight PBPs because the other PBPs have inherently low affinity for the third-generation cephalosporins. Penicillin resistance in *Streptococcus san- guis* and other *viridans* streptococci apparently emerged as a result of replacement of its PBPs with resistant PBPs from *S. pneumoniae* (Carratalá et al., 1995; Spratt, 1994). Methicillin-resistant *S. aureus* are resistant via acquisition of an additional high-molecular-weight PBP (via a transposon from an unknown organism) with a very low affinity for all β-lactam antibiotics. The gene (MecA) encoding this new PBP also is present in and responsible for methicillin resistance in the coagulase-negative staphylococci (Moran et al., 2006).

Other instances of bacterial resistance to the β-lactam antibiotics are caused by the inability of the agent to penetrate to its site of action (Jacoby and Munoz-Price, 2005) (Figure 53–5). In gram-positive bacteria, the peptidoglycan polymer is very near the cell surface (Figure 53–3). Some gram-positive bacteria have polysaccharide capsules that are external to the cell wall, but these structures are not a barrier to the diffusion of the β-lactams; the small
β-lactam antibiotic molecules can penetrate easily to the outer layer of the cytoplasmic membrane and the PBPs, where the final stages of the synthesis of the peptidoglycan take place. The situation is different with gram-negative bacteria. Their surface structure is more complex, and their inner membrane, which is analogous to the cytoplasmic membrane of gram-positive bacteria, is covered by the outer membrane, lipopolysaccharide, and capsule (Figure 53–3). The outer membrane functions as an impenetrable barrier for some antibiotics (Nakae, 1986). Some small hydrophilic antibiotics, however, diffuse through aqueous channels in the outer membrane that are formed by proteins called porins. Broader-spectrum penicillins, such as ampicillin and amoxicillin, and most of the cephalosporins diffuse through the pores in the E. coli outer membrane significantly more rapidly than can penicillin G. The number and size of pores in the outer membrane vary among different gram-negative bacteria. An extreme example is P. aeruginosa, which is intrinsically resistant to a wide variety of antibiotics because it lacks the classical high-permeability porins (Nikaido, 1994). Active efflux pumps serve as another mechanism of resistance, removing the antibiotic from its site of action before it can act (Nikaido, 1998) (Figure 53–5). This is an important mechanism of β-lactam resistance in P. aeruginosa, E. coli, and Neisseria gonorrhoeae.
Different microorganisms elaborate a number of distinct and may be present in large quantities (Figures 53–1 and 53–3). β-lactam resistance caused by gram-negative multidrug efflux pumps. (From Spratt BG. Resistance to antibiotics mediated by target alterations. Science, 1994, 264:388–393. Reprinted with permission from AAAS.)

Bacteria also can destroy β-lactam antibiotics enzymatically. β-Lactamases are capable of inactivating certain of these antibiotics and may be present in large quantities (Figures 53–1 and 53–3). Different microorganisms elaborate a number of distinct β-lactamases, although most bacteria produce only one form of the enzyme. The substrate specificities of some of these enzymes are relatively narrow, and these often are described as either penicillinases or cephalosporinases. Other “extended-spectrum” enzymes are less discriminant and can hydrolyze a variety of β-lactam antibiotics. β-Lactamases are grouped into four classes: A through D. Class A β-lactamases include the extended-spectrum β-lactamases (ESBLs) that degrade penicillins, some cephalosporins, and, in some instances, carbapenems. Perhaps most worrisome of the class A enzymes is the KPC carbapenemase that is rapidly emerging in the Enterobacteriaceae. This enzyme confers resistance to carbapenems, penicillins, and all of the extended-spectrum cephalosporins (Jones et al., 2008). Some class A and D enzymes are inhibited by the commercially available β-lactamase inhibitors, such as clavulanate and tazobactam. Class B β-lactamases are Zn²⁺-dependent enzymes that destroy all β-lactams except aztreonam, whereas class C β-lactamases are active against cephalosporins. Class D includes cloxacillin-degrading enzymes (Bush, 2001; Jacoby and Munoz-Price, 2005; Walsh, 2008).

In general, gram-positive bacteria produce and secrete a large amount of β-lactamase (Figure 53–3A). Most of these enzymes are penicillinases. The information for staphylococcal penicillinase is encoded in a plasmid, and this may be transferred by bacteriophage to other bacteria. The enzyme is inducible by substrates, and 1% of the dry weight of the bacterium can be penicillinase. In gram-negative bacteria, β-lactamases are found in relatively small amounts but are located in the periplasmic space between the inner and outer cell membranes (Figure 53–3A). Because the enzymes of cell wall synthesis are on the outer surface of the inner membrane, these β-lactamases are strategically located for maximal protection of the microbe. β-Lactamases of gram-negative bacteria are encoded either in chromosomes or in plasmids, and they may be constitutive or inducible. The plasmids can be transferred between bacteria by conjugation. These enzymes can hydrolyze penicillins, cephalosporins, or both (Bush, 2001; Jacoby and Munoz-Price, 2005; Walsh, 2008). However, there is an inconsistent correlation between the susceptibility of an antibiotic to inactivation by β-lactamase and the ability of that antibiotic to kill the microorganism.

Other Factors That Influence the Activity of β-Lactam Antibiotics. Microorganisms adhering to implanted prosthetic devices (e.g., catheters, artificial joints, prosthetic heart valves, etc.) produce biofilms. Bacteria in biofilms produce extracellular polysaccharides and, in part owing to decreased growth rates, are much less sensitive to antibiotic therapy (Donlan, 2001). The density of the bacterial population and the age of an infection influence the activity of β-lactam antibiotics. The drugs may be several thousand times more potent when tested against small bacterial inocula than when tested against a dense culture. Many factors are involved. Among these are the greater number of relatively resistant microorganisms in a large population, the amount of β-lactamase produced, and the phase of growth of the culture. The clinical significance of this effect of inoculum size is uncertain. The intensity and duration of penicillin therapy needed to abort or cure experimental infections in animals increase with the duration of the infection. The primary reason is that the bacteria are no longer multiplying as rapidly as they do in a fresh infection. These antibiotics are most active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase, when there is no need to synthesize components of the cell wall.

The presence of proteins or other constituents of pus, low pH, or low O₂ tension does not appreciably decrease the ability of β-lactam antibiotics to kill bacteria. However, bacteria that survive inside viable cells of the host generally are protected from the action of the β-lactam antibiotics.
Classification of the Penicillins and Summary of Their Pharmacological Properties

It is useful to classify the penicillins according to their spectra of antimicrobial activity (Table 53–1) (Chambers, 2005).

- **Penicillin G** and its close congener **penicillin V** are highly active against sensitive strains of gram-positive cocci, but they are readily hydrolyzed by penicillinase. Thus they are ineffective against most strains of *S. aureus*.
- The penicillinase-resistant penicillins (methicillin, discontinued in U.S.), nafcillin, oxacillin, cloxacillin (not currently marketed in the United States), and dicloxacillin have less potent antimicrobial activity against microorganisms that are sensitive to penicillin G, but they are the agents of first choice for treatment of penicillinase-producing *S. aureus* and *S. epidermidis* that are not methicillin resistant.
- Ampicillin, amoxicillin, and others make up a group of penicillins whose antimicrobial activity is extended to include such gram-negative microorganisms as *Haemophilus influenzae*, *E. coli*, and *Proteus mirabilis*. Frequently these drugs are administered with a β-lactamase inhibitor such as clavulanate or sulbactam to prevent hydrolysis by class A β-lactamases.
- The antimicrobial activity of carbenicillin (discontinued in the U.S.), its indanyl ester (carbenicillin indanyl), and ticarcillin (marketed only in combination with clavulanate in the U.S.) is extended to include *Pseudomonas*, *Enterobacter*, and *Proteus* spp. These agents are inferior to ampicillin against gram-positive cocci and *Listeria monocytogenes* and are less active than piperacillin against *Pseudomonas*.
- Mezlocillin, azlocillin (both discontinued in the U.S.), and piperacillin have excellent antimicrobial activity against many isolates of *Pseudomonas*, *Klebsiella*, and certain other gram-negative microorganisms. However, the emergence of broad-spectrum beta-lactamases is threatening the utility of these agents (Jacoby and Munoz-Price, 2005; Walsh, 2008). Piperacillin retains the activity of ampicillin against gram-positive cocci and *L. monocytogenes*.

Although the pharmacological properties of the individual drugs are discussed in detail later in this chapter, certain generalizations are useful. Following absorption of orally administered penicillins, these agents are distributed widely throughout the body. Therapeutic concentrations of penicillins are achieved readily in tissues and in secretions such as joint fluid, pleural fluid, pericardial fluid, and bile. Penicillins do not penetrate living phagocytic cells to a significant extent, and only low concentrations of these drugs are found in prostatic secretions, brain tissue, and intraocular fluid. Concentrations of penicillins in cerebrospinal fluid (CSF) are variable but are <1% of those in plasma when the meninges are normal. When there is inflammation, concentrations in CSF may increase to as much as 5% of the plasma value. Penicillins are eliminated rapidly, particularly by glomerular filtration and renal tubular secretion, such that their half-lives in the body are short, typically 30–90 minutes. As a consequence, concentrations of these drugs in urine are high.

**Penicillin G and Penicillin V**

**Antimicrobial Activity.** The antimicrobial spectra of penicillin G (benzylpenicillin) and penicillin V (the phenoxy methyl derivative) are very similar for aerobic gram-positive microorganisms. However, penicillin G is 5-10 times more active than penicillin V against *Neisseria* spp. that are sensitive to penicillins and against certain anaerobes.

Penicillin G has activity against a variety of species of gram-positive and gram-negative cocci, although many bacteria previously sensitive to the agent are now resistant. Most streptococci (but not enterococci) are very susceptible to the drug; concentrations of <0.01 μg/mL usually are effective. However, penicillin-resistant *viridans* streptococci (Carratalá et al., 1995) and *S. pneumoniae* are becoming more common. Penicillin-resistant pneumococci are especially common in pediatric populations, such as children attending daycare centers. Many penicillin-resistant pneumococci also are resistant to third-generation cephalosporins.

Whereas most strains of *S. aureus* were highly sensitive to penicillin G when this agent was first employed therapeutically, >90% of strains of staphylococci isolated from individuals inside or outside of hospitals are now resistant to penicillin G (and nearly half are meticillin-resistant). Most strains of *S. epidermidis* also are resistant to penicillin. Unfortunately, penicillinase-producing strains of gonococci that are highly resistant to penicillin G have become widespread. With rare exceptions, meningococci are quite sensitive to penicillin G.

Although the vast majority of strains of *Corynebacterium diphtheriae* are sensitive to penicillin G, some are highly resistant. The presence of chromosomally encoded β-lactamase in *Bacillus anthracis* is the reason that penicillin was not used for prophylaxis of anthrax exposure, although most isolates are susceptible. Most anaerobic
microorganisms, including *Clostridium* spp., are highly sensitive. *Bacteroides fragilis* is an exception, displaying resistance to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. Some strains of *Prevotella melanogenes* also have acquired this trait. *Actinomyces israeli*, *Streptobacillus moniliformis*, *Pasteurella multocida*, and *L. monocytogenes* are inhibited by penicillin G. Most species of *Leptospira* are moderately susceptible to the drug. One of the most exquisitely sensitive microorganisms is *Treponema pallidum*. *Borrelia burgdorferi*, the organism responsible for Lyme disease, also is susceptible. None of the penicillins is effective against amebae, plasmodia, rickettsiae, fungi, or viruses.

**Absorption**

**Oral Administration of Penicillin G.** About one-third of an orally administered dose of penicillin G is absorbed from the intestinal tract under favorable conditions. Gastric juice at pH 2 rapidly destroys the antibiotic. The decrease in gastric acid production with aging accounts for better absorption of penicillin G from the gastrointestinal (GI) tract of older individuals. Absorption is rapid, and maximal concentrations in blood are attained in 30-60 minutes. The peak value is ~0.5 unit/mL (0.3 μg/mL) after an oral dose of 400,000 units (~250 mg) in an adult. Ingestion of food may interfere with enteric absorption of all penicillins, perhaps by adsorption of the antibiotic onto food particles. Thus, oral penicillin G should be administered at least 30 minutes before a meal or 2 hours after. Despite the convenience of oral administration of penicillin G, this route should be used only in infections in which clinical experience has proven its efficacy.

**Oral Administration of Penicillin V.** The virtue of penicillin V in comparison with penicillin G is that it is more stable in an acidic medium and therefore is better absorbed from the GI tract. On an equivalent oral-dose basis, penicillin V (K+ salt) yields plasma concentrations two to five times greater than those provided by penicillin G. The peak concentration in the blood of an adult after an oral dose of 500 mg is nearly 3 μg/mL. Once absorbed, penicillin V is distributed in the body and excreted by the kidney in a manner similar to that of penicillin G.

**Parenteral Administration of Penicillin G.** After intramuscular injection, peak concentrations in plasma are reached within 15-30 minutes. This value declines rapidly because the $t_{1/2}$ of penicillin G is 30 minutes.

Many means for prolonging the sojourn of the antibiotic in the body and thereby reducing the frequency of injections have been explored. *Probenecid* blocks renal tubular secretion of penicillin, but it is used rarely for this purpose. More commonly, repository preparations of penicillin G are employed. The compound currently favored is penicillin G benzathine (*Bicillin L-A, Permapen*), which releases penicillin G slowly from the area in which it is injected and produces relatively low but persistent concentrations of antibiotic in the blood. Penicillin G benzathine suspension is the aqueous suspension of the salt obtained by the combination of 1 mol of an ammonium base and 2 mol of penicillin G to yield $N,N'$-dibenzylethylenediamine dipenicillin G. The salt itself is only 0.02% soluble in water. The long persistence of penicillin in the blood after a suitable intramuscular dose reduces cost, need for repeated injections, and local trauma. The local anesthetic effect of penicillin G benzathine is comparable with that of penicillin G procaine.

Penicillin G benzathine is absorbed very slowly from intramuscular depots and produces the longest duration of detectable antibiotic of all the available repository penicillins. For example, in adults, a dose of 1.2 million units given intramuscularly produces a concentration in plasma of 0.09 μg/mL on the first, 0.02 μg/mL on the fourteenth, and 0.002 μg/mL on the thirty-second day after injection. The average duration of demonstrable antimicrobial activity in the plasma is ~26 days. It is administered once monthly for rheumatic fever prophylaxis and can be given in a single injection to treat streptococcal pharyngitis.

**Distribution.** Penicillin G is distributed widely throughout the body, but the concentrations in various fluids and tissues differ widely. Its apparent volume of distribution is ~0.35 L/kg. Approximately 60% of the penicillin G in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, lymph, and intestine.

Although probenecid markedly decreases the tubular secretion of the penicillins, this is not the only factor responsible for the elevated plasma concentrations of the antibiotic that follow its administration. Probenecid also produces a significant decrease in the apparent volume of distribution of the penicillins.

**Penetration into Cerebrospinal Fluid.** Penicillin does not readily enter the CSF when the meninges are normal. However, when the meninges are acutely inflamed, penicillin penetrates into the CSF more easily. Although the concentrations attained vary and are unpredictable, they are usually in the range of 5% of the value in plasma and are therapeutically effective against susceptible microorganisms.

Penicillin and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. Probenecid competitively inhibits this transport and thus elevates the concentration of penicillin in CSF. In uremia, other organic acids accumulate in the CSF and compete with penicillin for secretion; the drug occasionally reaches toxic concentrations in the brain and can produce convulsions.

**Excretion.** Under normal conditions, penicillin G is eliminated rapidly from the body mainly by the kidney but in small part in the bile and by other routes. Approximately 60-90% of an intramuscular dose of penicillin G in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid. The $t_{1/2}$ for elimination of penicillin G is ~30 minutes in normal adults. Approximately 10% of the drug is eliminated by glomerular filtration and 90% by tubular secretion. Renal clearance approximates the total renal plasma flow. The maximal tubular secretory capacity for penicillin in the normal adult male is ~3 million units (1.8 g) per hour.

Clearance values are considerably lower in neonates and infants because of incomplete development of renal function; as a result, after doses proportionate to surface area, the persistence of penicillin in the blood is several times as long in premature infants as in children and adults. The $t_{1/2}$ of the antibiotic in children <1 week of age is ~3 hours; by 14 days of age it is 1.4 hours. After renal function is fully established in young children, the rate of renal excretion of penicillin G is considerably more rapid than in adults.

Anuria increases the $t_{1/2}$ of penicillin G from a normal value of 0.5 hour to ~10 hours. When renal function is impaired, 7-10% of the antibiotic may be inactivated each hour by the liver. Patients with renal shutdown who require high-dose therapy with penicillin can be treated adequately with 3 million units of aqueous penicillin G followed by
CHEMOTHERAPY OF MICROBIAL DISEASES

SECTION VII

These are nongroupable countries, including the U.S. (Fiore et al., 2000).

CHEMOTHERAPY OF MICROBIAL DISEASES

Pneumococcal Infections. Penicillin G remains the agent of choice for the management of infections caused by sensitive strains of S. pneumoniae. However, strains of pneumococci resistant to usual doses of penicillin G are being isolated more frequently in several countries, including the U.S. (Fiore et al., 2000).

Pneumococcal Pneumonia. Until it is highly likely or established that the infecting isolate of pneumococcus is penicillin-sensitive, pneumococcal pneumonia should be treated with a third-generation cephalosporin or with 20-24 million units of penicillin G daily by constant intravenous infusion. If the organism is sensitive to penicillin, then the dose can be reduced (Medical Letter, 2007). For parenteral therapy of sensitive isolates of pneumococci, penicillin G is favored. Although oral treatment with 500 mg penicillin V given every 6 hours for treatment of pneumonia owing to penicillin-sensitive isolates has been used with success in this disease, it cannot be recommended for routine initial use because of the existence of resistance. Therapy should be continued for 7-10 days, including 3-5 days after the patient’s temperature has returned to normal.

Pneumococcal Meningitis. Until it is established that the infecting pneumococcus is sensitive to penicillin, pneumococcal meningitis should be treated with a combination of vancomycin and a third-generation cephalosporin (Catalan et al., 1994; John, 1994). Dexamethasone given at the same time as antibiotics was associated with an improved outcome (de Gans and van de Beek, 2002). Prior to the appearance of penicillin resistance, penicillin treatment reduced the death rate in this disease from nearly 100% to ~25%. The recommended therapy is 20-24 million units of penicillin G daily by constant intravenous infusion or divided into boluses given every 2-3 hours. The usual duration of therapy is 14 days.

Streptococcal Infections. Streptococcal Pharyngitis (Including Scarlet Fever). This is the most common disease produced by S. pyogenes (group A β-hemolytic streptococcus). Penicillin-resistant isolates have yet to be observed for S. pyogenes. The preferred oral therapy is with penicillin V, 500 mg every 6 hours for 10 days. Penicillin therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever; however, current evidence suggests that the incidence of glomerulonephritis that follows streptococcal infections is not reduced to a significant degree by treatment with penicillin.

Streptococcal Toxic Shock and Necrotizing Fascitis. These are life-threatening infections associated with toxin production and are treated optimally with penicillin plus clindamycin (to decrease toxin synthesis) (Bisno and Stevens, 1996; Brown, 2004).

Streptococcal Pneumonia, Arthritis, Meningitis, and Endocarditis. Although uncommon, these conditions should be treated with penicillin G when they are caused by S. pyogenes; daily doses of 12-20 million units are administered intravenously for 2-4 weeks. Such treatment of endocarditis should be continued for a full 4 weeks.

Infections Caused by Other Streptococci. The viridans group of streptococci are the most common cause of infectious endocarditis. These are nongroupable α-hemolytic microorganisms that are increasingly resistant to penicillin G (minimum inhibitory concentration [MIC] >0.1 μg/mL). Because enterococci also may be α-hemolytic, and certain other α-hemolytic strains may be relatively resistant to penicillin, it is important to determine quantitative microbial sensitivities to penicillin G in patients with endocarditis. Patients with penicillin-sensitive viridans group streptococcal endocarditis can be treated successfully with daily doses of 12-20 million units of intravenous penicillin G for 2 weeks in combination with gentamicin 1 mg/kg every 8 hours. Some physicians prefer a 4-week course of treatment with penicillin G alone.

Enterococcal endocarditis is one of the few diseases treated optimally with two antibiotics. The recommended therapy for penicillin- and aminoglycoside-sensitive enterococcal endocarditis is 20 million units of penicillin G or 12 g ampicillin daily administered intravenously in combination with a low dose of gentamicin. Therapy usually should be continued for 6 weeks, but selected patients with a short duration of illness (<3 months) have been treated successfully in 4 weeks (Wilson et al., 1984).

Infections with Anaerobes. Many anaerobic infections are caused by mixtures of microorganisms. Most are sensitive to penicillin G. An exception is the B. fragilis group, in which up to 75% of strains may be resistant to high concentrations of this antibiotic. Pulmonary and periodontal infections (with the exception of β-lactamase-producing Prevotella melaninogenica usually respond well to penicillin G, although a multicenter study indicated that clindamycin is more effective than penicillin for therapy of lung abscesses (Levison et al., 1983). Mild-to-moderate infections at these sites may be treated with oral medication (either penicillin G or penicillin V 400,000 units [250 mg] four times daily). More severe infections should be treated with 12-20 million units of penicillin G intravenously. Brain abscesses also frequently contain several species of anaerobes, and most authorities prefer to treat such disease with high doses of penicillin G (20 million units per day) plus metronidazole or chloramphenicol. Some physicians add a third-generation cephalosporin for activity against aerobic gram-negative bacilli.

Staphylococcal Infections. The vast majority of staphylococcal infections are caused by microorganisms that produce penicillinase (Swartz, 2004). Hospital-acquired methicillin-resistant staphylococci are resistant to penicillin G, all the penicillinase-resistant penicillins, and the cephalosporins. Isolates occasionally may appear to be sensitive to various cephalosporins in vitro, but resistant populations arise during therapy and lead to failure. Vancomycin, linezolid, quinupristin-dalfopristin, and daptomycin are active for infections caused by these bacteria, although reduced susceptibility to vancomycin has been observed. Community-acquired methicillin-resistant S. aureus (MRSA) in many cases retains susceptibility to trimethoprim-sulfamethoxazole, doxycycline, and clindamycin (Medical Letter, 2007).

Meningococcal Infections. Penicillin G remains the drug of choice for meningococcal disease. Patients should be treated with high doses of penicillin given intravenously, as described for pneumococcal meningitis. Penicillin-resistant strains of N. meningitides have been reported in Britain and Spain but are infrequent at present. The occurrence of penicillin-resistant strains should be considered in patients who are slow to respond to treatment. Penicillin G does not eliminate the meningococcal carrier state, and its administration thus is ineffective as a prophylactic measure.
Gonococcal Infections. Gonococci gradually have become more resistant to penicillin G, and penicillins are no longer the therapy of choice, unless it is known that gonococcal strains in a particular geographic area are susceptible. Uncomplicated gonococcal urethritis is the most common infection, and a single intramuscular injection of 250 mg ceftriaxone is the recommended treatment (Handsfield and Sparling, 2005).

Gonococcal arthritis, disseminated gonococcal infections with skin lesions, and gonococcemia should be treated with ceftriaxone 1 g daily given either intramuscularly or intravenously for 7-10 days. Ophthalmitis neonatorum also should be treated with ceftriaxone for 7-10 days (25-50 mg/kg per day intramuscularly or intravenously).

Syphilis. Therapy of syphilis with penicillin G is highly effective. Primary, secondary, and latent syphilis of <1-year duration may be treated with penicillin G procaine (2.4 million units per day intramuscularly) plus probenecid (1.0 g/day orally) for 10 days or with 1-3 weekly intramuscular doses of 2.4 million units of penicillin G benzathine (three doses in patients with HIV infection). Patients with late latent syphilis, neurosyphilis, or cardiovascular syphilis may be treated with a variety of regimens. Because the latter two conditions are potentially lethal and their progression can be halted (but not reversed), intensive therapy with 20 million units of penicillin G daily for 10 days is recommended. There are no proven alternatives for treating syphilis in pregnant women, so penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis (Centers for Disease Control and Prevention, 2006).

Infants with congenital syphilis discovered at birth or during the postnatal period should be treated for at least 10 days with 50,000 units/kg daily of aqueous penicillin G in two divided doses or 50,000 units/kg of procaine penicillin G in a single daily dose (Tramont, 2005).

Most patients (70-90%) with secondary syphilis develop the Jarisch-Herxheimer reaction. This also may be seen in patients with other forms of syphilis. Several hours after the first injection of penicillin, chills, fever, headache, myalgias, and arthralgias may develop. The syphilitic cutaneous lesions may become more prominent, edematous, and brilliant in color. Manifestations usually persist for a few hours, and the rash begins to fade within 48 hours. It does not recur with the second or subsequent injections of penicillin. This reaction is thought to be due to release of spirochetal antigens with subsequent host reactions to the products. Aspirin gives symptomatic relief, and therapy with penicillin should not be discontinued.

Actinomycosis. Penicillin G is the agent of choice for the treatment of all forms of actinomycosis. The dose should be 10-20 million units of penicillin G intravenously per day for 6 weeks. Some physicians continue therapy for 2-3 months with oral penicillin V (500 mg four times daily). Surgical drainage or excision of the lesion may be necessary before cure is accomplished.

Diphtheria. There is no evidence that penicillin or any other antibiotic alters the incidence of complications or the outcome of diphtheria; specific antitoxin is the only effective treatment. However, penicillin G eliminates the carrier state. The parenteral administration of 2-3 million units per day in divided doses for 10-12 days eliminates the diphtheria bacilli from the pharynx and other sites in practically 100% of patients. A single daily injection of penicillin G procaine for the same period produces comparable results.

Anthrax. Strains of *Bacillus anthracis* resistant to penicillin have been recovered from human infections. When penicillin G is used, the dose should be 12-20 million units per day.

Clostridial Infections. Penicillin G is the agent of choice for gas gangrene; the dose is in the range of 12-20 million units per day given parenterally as an adjunct to the antitoxin. Adequate debridement of the infected areas is essential. Antimicrobial drugs probably have no effect on the ultimate outcome of tetanus. Débridement and administration of human tetanus immune globulin may be indicated. Penicillin is administered, however, to eradicate the vegetative forms of the bacteria that may persist.

Fusospirochetal Infections. Gingivostomatitis, produced by the synergistic action of *Leptotrichia buccalis* and spirochetes that are present in the mouth, is readily treatable with penicillin. For simple “trench mouth,” 500 mg penicillin V given every 6 hours for several days is usually sufficient to clear the disease.

*Pasteurella multocida*. The causative agent of this disease, *Pasteurella multocida*, is the cause of wound infections after a cat or dog bite. It is uniformly susceptible to penicillin G and amoxicillin and resistant to penicillinase-resistant penicillins and first-generation cephalosporins (Goldstein et al., 1988). When the infection causes meningitis, a third-generation cephalosporin is preferred because the MICs are slightly lower than for penicillin.

Prophylactic Uses of the Penicillins. The demonstrated effectiveness of penicillin in eradicating microorganisms was followed quickly and quite naturally by attempts to prove that it also was effective in preventing infection in susceptible hosts. As a result, the antibiotic has been administered in almost every situation in which a risk of bacterial invasion has been present. As prophylaxis has been investigated.
under controlled conditions, it has become clear that penicillin is highly effective in some situations, useless and potentially dangerous in others, and of questionable value in still others (Chapter 48).

**Streptococcal Infections.** The administration of penicillin to individuals exposed to *S. pyogenes* affords protection from infection. The oral ingestion of 200,000 units of penicillin G or penicillin V twice a day or a single injection of 1.2 million units of penicillin G benzathine is effective. Indications for this type of prophylaxis include outbreaks of streptococcal disease in closed populations, such as boarding schools or military bases. Patients with extensive deep burns are at high risk of severe wound infections with *S. pyogenes*; “low-dose” prophylaxis for several days appears to be effective in reducing the incidence of this complication.

**Recurrences of Rheumatic Fever.** The oral administration of 200,000 units of penicillin G or penicillin V every 12 hours produces a striking decrease in the incidence of recurrences of rheumatic fever in susceptible individuals. Because of the difficulties of compliance, parenteral administration is preferable, especially in children. The intramuscular injection of 1.2 million units of penicillin G benzathine once a month yields excellent results. In cases of hypersensitivity to penicillin, sulfisoxazole or sulfadiazine, 1 g twice a day for adults, also is effective; for children weighing <27 kg, the dose is halved. Prophylaxis must be continued throughout the year. The duration of such treatment is an unsettled question. It has been suggested that prophylaxis should be continued for life because instances of acute rheumatic fever have been observed in the fifth and sixth decades. However, the necessity for such prolonged prophylaxis has not been established and may be unnecessary for young adults judged to be at low risk for recurrence (Berrios et al., 1993).

**Syphilis.** Prophylaxis for a contact with syphilis consists of a course of therapy as described for primary syphilis. A serological test for syphilis should be performed at monthly intervals for at least 4 months thereafter.

**Surgical Procedures in Patients with Valvular Heart Disease.** About 25% of cases of subacute bacterial endocarditis follow dental extractions. This observation, together with the fact that up to 80% of persons who have teeth removed experience a transient bacteremia, emphasizes the potential importance of chemoprophylaxis for those who have congenital or acquired valvular heart disease of any type and need to undergo dental procedures. Since transient bacterial invasion of the bloodstream occurs occasionally after surgical procedures (e.g., tonsillectomy and genitourinary and GI procedures) and during childbirth, these, too, are indications for prophylaxis in patients with valvular heart disease. Whether the incidence of bacterial endocarditis actually is altered by this type of chemoprophylaxis remains to be determined.

Detailed recommendations for adults and children with valvular heart disease have been formulated (Wilson et al., 2007).

**The Penicillinase-Resistant Penicillins**

The penicillins described in this section are resistant to hydrolysis by staphylococcal penicillinase. Their appropriate use should be restricted to the treatment of infections that are known or suspected to be caused by staphylococci that elaborate the enzyme, which now includes the vast majority of strains of this bacterium that are encountered clinically. These drugs are much less active than penicillin G against other penicillin-sensitive microorganisms, including non-penicillinase-producing staphylococci.

The role of the penicillinase-resistant penicillins as the agents of choice for most staphylococcal disease is changing with the increasing incidence of isolates of so-called *methicillin-resistant microorganisms*. As commonly used, this term denotes resistance of these bacteria to all the penicillinase-resistant penicillins and cephalosporins. Hospital-acquired strains usually are resistant to the aminoglycosides, tetracyclines, erythromycin, and clindamycin as well. Vancomycin is considered the drug of choice for such infections, although intermediate-level resistance is emerging (Centers for Disease Control and Prevention, 2004). Some physicians use a combination of vancomycin and rifampin, especially for life-threatening infections and those involving foreign bodies. Community-acquired methicillin-resistant strains are less likely to be resistant to other classes of antibiotics with the exception of macrolides (Okuma et al., 2002). MRSA contains an additional high-molecular-weight PBP with a very low affinity for β-lactam antibiotics (Spratt, 1994). From 40-60% of strains of *S. epidermidis* also are resistant to the penicillinase-resistant penicillins by the same mechanism. As with MRSA, these strains may appear to be susceptible to cephalosporins on disk-sensitivity testing, but there usually is a significant population of microbes that is resistant to cephalosporins and emerges during such therapy. Vancomycin also is the drug of choice for serious infection caused by methicillin-resistant *S. epidermidis*; rifampin is given concurrently when a foreign body is involved.

**The Isoxazolyl Penicillins: Oxacillin, Cloxacillin, and Dicloxacillin.** These three congeneric semisynthetic penicillins are similar pharmacologically and thus conveniently are considered together. Their structural formulas are shown in Table 53–1. All are relatively stable in an acidic medium and absorbed adequately after oral administration. All are markedly resistant to cleavage by penicillinase. These drugs are not substitutes for penicillin G in the treatment of diseases amenable to it, and they are not active against enterococci or *Listeria*. Furthermore, because of variability in intestinal absorption, oral administration is not a substitute for the parenteral route in the treatment of serious staphylococcal infections that require a penicillin unaffected by penicillinase.

**Pharmacological Properties.** The isoxazolyl penicillins are potent inhibitors of the growth of most penicillinase-producing staphylococci.
Aminopenicillins are bactericidal for both gram-positive and gram-negative bacteria. The structural formula is shown in Table 53–1.

Antimicrobial Activity. Ampicillin and the related aminopenicillins are bactericidal for both gram-positive and gram-negative bacteria. The meningococci and L. monocytogenes are sensitive to this class of drugs.

Many pneumococcal isolates have varying levels of resistance to ampicillin. Penicillin-resistant strains should be considered ampicillin/amoxicillin-resistant. H. influenzae and the viridans group of streptococci exhibit varying degrees of resistance. Enterococci are about twice as sensitive to amoxicillin as to penicillin G (MIC for ampicillin averages 1.5 μg/mL).

Although most strains of N. gonorrhoeae, E. coli, P. mirabilis, Salmonella, and Shigella were highly susceptible when ampicillin was first used in the early 1960s, an increasing percentage of these species now is resistant. From 30% to 50% of E. coli, a significant number of P. mirabilis, and practically all species of Enterobacter presently are insensitive. Resistant strains of Salmonella (plasmid mediated) have been recovered with increasing frequency in various parts of the world. Most strains of Shigella now are resistant. Most strains of Pseudomonas, Klebsiella, Serratia, Acinetobacter, and indole-positive Proteus also are resistant to this group of penicillins; these antibiotics are less active against B. fragilis than penicillin G. However, concurrent administration of a β-lactamase inhibitor such as clavulanate or sulbactam markedly expands the spectrum of activity of these drugs.

**Ampicillin.** This drug is the prototype of the group. Its structural formula is shown in Table 53–1.

**Pharmacological Properties.** Ampicillin (PRINCIPEN, others) is stable in acid and is well absorbed after oral administration. An oral dose of 0.5 g produces peak concentrations in plasma of ~3 μg/mL at 2 hours. Intake of food prior to ingestion of ampicillin diminishes absorption. Intramuscular injection of 0.5 or 1 g sodium ampicillin yields peak plasma concentrations of ~7 or 10 μg/mL, respectively, at 1 hour; these decline exponentially, with a 1/2 of ~80 minutes. Severe renal impairment markedly prolongs the persistence of ampicillin in the plasma. Peritoneal dialysis is ineffective in removing the drug from the blood, but hemodialysis removes ~40% of the body store in ~7 hours. Adjustment of the dose of ampicillin is required in the presence of renal dysfunction. Ampicillin appears in the bile, undergoes enterohepatic circulation, and is excreted in appreciable quantities in the feces.

**Amoxicillin.** This drug, a penicillinase-susceptible semi-synthetic penicillin, is close chemical and pharmacological relative of ampicillin (Table 53–1). The drug is stable in acid and designed for oral use. It is absorbed more rapidly and completely from the GI tract than ampicillin, which is the major difference between the two. The antimicrobial spectrum of amoxicillin is essentially identical to that of ampicillin, with the important exception that amoxicillin appears to be less effective than ampicillin for shigellosis.

Peak plasma concentrations of amoxicillin (AMOXIL, others) are 2-2.5 times greater for amoxicillin than for ampicillin after oral administration.

(Continued)
administration of the same dose; they are reached at 2 hours and average ~4 μg/mL when 250 mg is administered. Food does not interfere with absorption. Perhaps because of more complete absorption of this congener, the incidence of diarrhea with amoxicillin is less than that following administration of ampicillin. The incidence of other adverse effects appears to be similar. Although the t₁/₂ of amoxicillin is similar to that for ampicillin, effective concentrations of orally administered amoxicillin are detectable in the plasma for twice as long as with ampicillin, again because of the more complete absorption. About 20% of amoxicillin is protein bound in plasma, a value similar to that for ampicillin. Most of a dose of the antibiotic is excreted in an active form in the urine. Probenecid delays excretion of the drug.

The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of all the oral β-lactam antibiotics against both penicillin-sensitive and penicillin-resistant S. pneumoniae. Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase in dose of oral amoxicillin (from 40-45 up to 80-90 mg/kg per day) for empirical treatment of acute otitis media in children is recommended (Dowell et al., 1999). Ampicillin-resistant H. influenzae may be a problem in many areas. The addition of a β-lactamase inhibitor (amoxicillin-clavulanate or amoxicillin-sulbactam) extends the spectrum to β-lactamase-producing H. influenzae and Enterobacteriaceae. Bacterial pharyngitis should be treated with penicillin G or penicillin V because S. pyogenes is the major pathogen.

**Therapeutic Indications for the Aminopenicillins**

**Upper Respiratory Infections.** Ampicillin and amoxicillin are active against S. pyogenes and many strains of S. pneumoniae and H. influenzae, which are major upper respiratory bacterial pathogens.

**Urinary Tract Infections.** Most uncomplicated urinary tract infections are caused by Enterobacteriaceae, and E. coli is the most common species; ampicillin often is an effective agent, although resistance is
increasingly common. Enterococcal urinary tract infections are treated effectively with ampicillin alone.

Meningitis. Acute bacterial meningitis in children is most frequently due to S. pneumoniae or N. meningitidis. Because 20–30% of strains of S. pneumoniae now may be resistant to this antibiotic, ampicillin is not indicated for single-agent treatment of meningitis. Ampicillin has excellent activity against L. monocytogenes, a cause of meningitis in immunocompromised persons. Thus, the combination of ampicillin and vancomycin plus a third-generation cephalosporin is a rational regimen for empirical treatment of suspected bacterial meningitis.

Salmonella Infections. Disease associated with bacteremia, disease with metastatic foci, and the enteric fever syndrome (including typhoid fever) respond favorably to antibiotics. A fluoroquinolone or ceftriaxone is considered by some to be the drug of choice, but the administration of trimethoprim-sulfamethoxazole or high doses of ampicillin (12 g/day for adults) also is effective. In some geographic areas, resistance to ampicillin is common. The typhoid carrier state has been eliminated successfully in patients without gallbladder disease with ampicillin, trimethoprim-sulfamethoxazole, or ciprofloxacin.

Anti-Pseudomonal Penicillins: The Carboxypenicillins and the Ureidopenicillins

The carboxypenicillins, carbenicillin (discontinued in the U.S.) and ticarcillin (marketed in combination with clavulanate in the U.S.) and their close relatives, are active against some isolates of P. aeruginosa and certain indole-positive Proteus spp. that are resistant to ampicillin and its congeners. They are ineffective against most strains of S. aureus, Enterococcus faecalis, Klebsiella, and L. monocytogenes. B. fragilis is susceptible to high concentrations of these drugs, but penicillin G is actually more active on the basis of weight. The ureidopenicillins, mezlocillin (discontinued in the U.S.) and piperacillin, have superior activity against P. aeruginosa compared with carbenicillin and ticarcillin. In addition, mezlocillin and piperacillin are useful for treatment of infections with Klebsiella. The carboxypenicillins and the ureidopenicillins are sensitive to destruction by β-lactamases.

Carbenicillin. This drug is a penicillinase-susceptible derivative of 6-aminopenicillanic acid. Its structural formula is shown in Table 53–1. Carbenicillin was the first penicillin with activity against P. aeruginosa and some Proteus strains that are resistant to ampicillin. Because carbenicillin is supplied as a disodium salt, it contains ~5 mEq Na+ per gram of drug, and this results in the administration of >100 mEq Na+ to patients treated for P. aeruginosa infections. In the U.S., carbenicillin has been superseded by piperacillin.

Preparations of carbenicillin may cause adverse effects in addition to those that follow the use of other penicillins. Congestive heart failure may result from the administration of excessive Na+. Hypokalemia may occur because of obligatory excretion of cation with the large amount of nonreabsorbable anion (carbenicillin) presented to the distal renal tubule. The drug interferes with platelet function, and bleeding may occur because of abnormal aggregation of platelets.

Carbenicillin Indanyl Sodium. This congener is the indanyl ester of carbenicillin; it is acid stable and is suitable for oral administration. After absorption, the ester is converted rapidly to carbenicillin by hydrolysis of the ester linkage. The antimicrobial spectrum of the drug is therefore that of carbenicillin. Although the concentration of carbenicillin reached in the serum is not high enough to treat a systemic Pseudomonas infection, the active moiety is excreted rapidly in the urine, where it achieves effective concentrations. Thus, the only use of this drug is for the management of urinary tract infections caused by Proteus spp. other than P. mirabilis and by P. aeruginosa.

Piperacillin. Piperacillin extends the spectrum of ampicillin to include most strains of P. aeruginosa, Enterobacteriaceae (non-β-lactamase-producing), many Bacteroides spp., and E. faecalis. In combination with a β-lactamase inhibitor (piperacillin-tazobactam, ZOSYN) it has the broadest antibacterial spectrum of the penicillins. Pharmacokinetic properties are reminiscent of the other ureidopenicillins. High biliary concentrations are achieved.

Therapeutic Indications. Piperacillin and related agents are important agents for the treatment of patients with serious infections caused by gram-negative bacteria. Such patients frequently have impaired immunological defenses, and their infections often are acquired in the hospital. Therefore, these penicillins find their greatest use in treating bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to penicillin G and ampicillin; the bacteria especially responsible include P. aeruginosa, indole-positive strains of Proteus, and Enterobacter spp. Because Pseudomonas infections are common in neutropenic patients, therapy for severe bacterial infections in such individuals should include a β-lactam antibiotic such as piperacillin with good activity against these microorganisms.

Ticarcillin. This semisynthetic penicillin (Table 53–1) is very similar to carbenicillin, but it is two to four times more active against P. aeruginosa. Ticarcillin is inferior to piperacillin for the treatment of serious infections caused by Pseudomonas. Ticarcillin is only marketed in combination with clavulanate (Timentin) in the U.S.

Mezlocillin. This ureidopenicillin is more active against Klebsiella than is carbenicillin; its activity against Pseudomonas in vitro is similar to that of ticarcillin. It is more active than ticarcillin against E. faecalis. Mezlocillin sodium has been discontinued in the U.S.
Untoward Reactions to Penicillins

Hypersensitivity Reactions. Hypersensitivity reactions are by far the most common adverse effects noted with the penicillins, and these agents probably are the most common cause of drug allergy. Allergic reactions complicate 0.7–4% of all treatment courses. There is no convincing evidence that any single penicillin differs from the group in its potential for causing true allergic reactions. In approximate order of decreasing frequency, the group in its potential for causing true allergic reactions is the penicillins, and these agents probably are the most sensitizing. The reported overall incidence of such reactions to the penicillins is 0.7–10%. Hypersensitivity to penicillins generally extends to the other β-lactams (e.g., cephalosporins, some carbapenems).

Hypersensitivity reactions may occur with any dosage form of penicillin; allergy to one penicillin exposes the patient to a greater risk of reaction if another is given. But the occurrence of an untoward effect does not necessarily imply repetition on subsequent exposures. Hypersensitivity reactions may appear in the absence of a previous known exposure to the drug. This may be caused by unrecognized prior exposure to penicillin in the environment (e.g., in foods of animal origin or from the fungus-producing penicillin). Although elimination of the antibiotic usually results in rapid clearing of the allergic manifestations, they may persist for 1–2 weeks or longer after therapy has been stopped. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin treatment is required. In a few instances, it is necessary to interdict the future use of penicillin because of the risk of death, and the patient should be so warned. It must be stressed that fatal episodes of anaphylaxis have followed the ingestion of very small doses of this antibiotic or skin testing with minute quantities of the drug.

Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl moiety (major determinant moiety [MDM]), which is formed when the β-lactam ring is opened. A large percentage of immunoglobulin (Ig)E-mediated reactions are to the MDM, but at least 25% of reactions are to other breakdown products, and the severities of the reactions to the various components are comparable. These products are formed in vivo and can be found in solutions of penicillin prepared for administration. The terms major and minor determinants refer to the frequency with which antibodies to these haptens appear to be formed. They do not describe the severity of the reaction that may result. In fact, anaphylactic reactions to penicillin usually are mediated by IgE antibodies against the minor determinants.

Antipenicillin antibodies are detectable in virtually all patients who have received the drug and in many who have never knowingly been exposed to it. Recent treatment with the antibiotic induces an increase in major-determinant–specific antibodies that are skin sensitizing. The incidence of positive skin reactors is three to four times higher in atopic than in nonatopic individuals. Clinical and immunological studies suggest that immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major-determinant–specific skin-sensitizing antibodies. The recurrent-arthralgia syndrome appears to be related to the presence of skin-sensitizing antibodies of minor-determinant specificities. Some maculopapular and erythematous reactions may be due to toxic antigen-antibody complexes of major-determinant-specific IgM antibodies. Accelerated and late urticarial reactions to penicillin may terminate spontaneously because of the development of blocking antibodies.

Skin rashes of all types may be caused by allergy to penicillin. Scleratiniform, morbilliform, urticarial, vesicular, and bullous eruptions may develop. Purpuric lesions are uncommon and usually are the result of a vasculitis; thrombocytopenic purpura may occur very rarely. Henoch–Schönlein purpura with renal involvement has been a rare complication. Contact dermatitis is observed occasionally in pharmacists, nurses, and physicians who prepare penicillin solutions. Fixed-drug reactions also have occurred. More severe reactions involving the skin are exfoliative dermatitis and exudative erythema multiforme of either the erythematopapular or vesiculobullous type; these lesions may be very severe and atypical in distribution and constitute the characteristic Stevens–Johnson syndrome. The incidence of skin rashes appears to be highest following the use of ampicillin, at ~9%; rashes follow the administration of ampicillin in nearly all patients with infectious mononucleosis. When allopurinol and ampicillin are administered concurrently, the incidence of rash also increases. Ampicillin-induced skin eruptions in such patients may represent a “toxic” rather than a truly allergic reaction. Positive skin reactions to the major and minor determinants of penicillin sensitization may be absent. The rash may clear even while administration of the drug is continued.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Angioedema, with marked swelling of the lips, tongue, face, and periorbital tissues, frequently accompanied by asthmatic breathing and “giant hives,” has been observed after topical, oral, or systemic administration of penicillins of various types.

Acute anaphylactic or anaphylactoid reactions induced by various preparations of penicillin constitute the most important immediate danger connected with their use. Among all drugs, the penicillins are most often responsible for this type of untoward effect. Anaphylactoid reactions may occur at any age. Their incidence is thought to be 0.004–0.04% in persons treated with penicillins (Kucers and Bennett, 1987). About 0.001% of patients treated with these agents die from anaphylaxis. It has been estimated that at least 300 deaths per year are due to this complication of therapy. About 70% have had penicillin previously, and one-third of these reacted to it on a prior occasion. Anaphylaxis most often has followed the injection of penicillin, although it also has been observed after oral ingestion of the drug and even has resulted from the intra-dermal instillation of a very small quantity for the purpose of testing for the presence of hypersensitivity. The clinical pictures that develop vary in severity. The most dramatic is sudden, severe hypotension and rapid death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness and a fall in blood pressure; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes.
Serum sickness varies from mild fever, rash, and leukopenia to severe arthralgia or arthritis, purpura, lymphadenopathy, splenomegaly, mental changes, electrocardiographic abnormalities suggestive of myocarditis, generalized edema, albuminuria, and hematuria. It is mediated by IgG antibodies. This reaction is rare, but when it occurs, it appears after penicillin treatment has been continued for 1 week or more; it may be delayed, however, until 1 or 2 weeks after the drug has been stopped. Serum sickness caused by penicillin may persist for a week or longer.

Vasculitis of the skin or other organs may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy with a penicillin or cephalosporin, but hemolytic anemia is rare. Reversible neutropenia may occur. It is not known if this is truly a hypersensitivity reaction; it has been noted with all the penicillins and has been seen in up to 30% of patients treated with 8-12 g nafcillin for >21 days. The bone marrow shows an arrest of maturation.

Fever may be the only evidence of a hypersensitivity reaction to the penicillins. It may reach high levels and be maintained, remittent, or intermitten; chills occur occasionally. The febrile reaction usually disappears within 24-36 hours after administration of the drug is stopped but may persist for days.

Eosinophilia is an occasional accompaniment of other allergic reactions to penicillin. At times, it may be the sole abnormality, and eosinophils may reach levels of ≥10-20% of the total number of circulating white blood cells.

Penicillins rarely cause interstitial nephritis; methicillin has been implicated most frequently. Hematuria, albuminuria, pyuria, renal cell and other casts in the urine, elevation of serum creatinine, and even oliguria have been noted. Biopsy shows a mononuclear infiltrate with eosinophilia and tubular damage. IgG is present in the interstitium. This reaction usually is reversible.

Management of the Patient Potentially Allergic to Penicillin. Evaluation of the patient’s history is the most practical way to avoid the use of penicillin in patients who are at the greatest risk of adverse reaction. Most patients who give a history of allergy to penicillin should be treated with a different type of antibiotic. Unfortunately, there is no totally reliable means to confirm a history of penicillin allergy (Romano et al., 2003). Skin testing for IgE-mediated immediate-type responses is compromised by the lack of a commercially available minor-determinant mixture. A National Institute of Allergy and Infectious Diseases (NIAID) multicenter study used major and minor determinants for skin testing. Of 726 patients with a history of penicillin allergy, 566 had negative skin tests. Of those, only 7 of 566 (1.2%) had possibly IgE-mediated or accelerated penicillin allergy when given penicillin (Sogn et al., 1992). Radioallergosorbent tests (RASTs) for IgE antipenicillloyl determinants suffer from the same limitations as skin tests (Weiss and Adkinson, 2005).

Occasionally, desensitization is recommended for penicillin-allergic patients who must receive the drug. This procedure consists of administering gradually increasing doses of penicillin in the hope of avoiding a severe reaction and should be performed only in an intensive care setting. This may result in a subclinical anaphylactic discharge and the binding of all IgE before full doses are administered. Penicillin may be given in doses of 1, 5, 10, 100, and 1000 units intradermally in the lower arm, with 60-minute intervals between doses. If this is well tolerated, then 10,000 and 50,000 units may be given subcutaneously. Desensitization also may be accomplished by the oral administration of penicillin. When full doses are reached, penicillin should not be discontinued and then restarted because immediate reactions may recur (see Weiss and Adkinson, 2005, for details). The patient should be observed constantly during the desensitizing procedure, an intravenous line must be in place, and epinephrine and equipment and expertise for artificial ventilation must be on hand. It must be emphasized that this procedure may be dangerous, and its efficacy is unproven.

Patients with life-threatening infections (e.g., endocarditis or meningitis) may be continued on penicillin despite the development of a maculopapular rash, although alternative antimicrobial agents should be used whenever possible. The rash often resolves as therapy is continued, perhaps owing to the development of blocking antibodies of the IgG class. The rash may be treated with antihistamines or glucocorticoids, although there is no evidence that this therapy is efficacious. Rarely, exfoliative dermatitis with or without vasculitis develops in these patients if therapy with penicillin is continued.

Other Adverse Reactions. The penicillins have minimal direct toxicity. Apparent toxic effects that have been reported include bone marrow depression, granulocytopenia, and hepatitis. The last-named effect is rare but is seen most commonly following the administration of oxacillin and nafcillin. The administration of penicillin G, carbenicillin, piperacillin, or ticarcillin has been associated with a potentially significant defect of hemostasis that appears to be due to an impairment of platelet aggregation; this may be caused by interference with the binding of aggregating agents to platelet receptors (Fass et al., 1987).

Most common among the irritative responses to penicillin are pain and sterile inflammatory reactions at the sites of intramuscular injections—reactions that are related to concentration. Serum transaminases and lactic dehydrogenase may be elevated as a result of local damage to muscle. In some individuals who receive penicillin intravenously, phlebitis or thrombophlebitis develops. Many persons who take various penicillin preparations by mouth experience nausea, with or without vomiting, and some have mild to severe diarrhea. These manifestations often are related to the dose of the drug.

When penicillin is injected accidentally into the sciatic nerve, severe pain occurs and dysfunction in the area of distribution of this nerve develops and persists for weeks. Intrathecal injection of penicillin G may produce arachnoiditis or severe and fatal encephalopathy. Because of this, intrathecal or intraventricular administration of penicillins should be avoided. The parenteral administration of large doses of penicillin G (>20 million units per day, or less with renal insufficiency) may produce lethargy, confusion, twitching, multifocal myoclonus, or localized or generalized epileptiform seizures. These are most apt to occur in the presence of renal insufficiency, localized lesions of the central nervous system (CNS), or hyponatremia. When the concentration of penicillin G in CSF exceeds 10 μg/mL, significant dysfunction of the CNS is frequent. The rapid intravenous administration of 20 million units of penicillin G potassium, which contains 34 mEq of K⁺, may lead to severe or even fatal hyperkalemia in persons with renal dysfunction.

Injection of penicillin G procaine may result in an immediate reaction, characterized by dizziness, tinnitus, headache, hallucinations, and sometimes seizures. This is due to the rapid liberation of
toxic concentrations of procaine. It has been reported to occur in 1 of 200 patients receiving 4.8 million units of penicillin G procaine to treat venereal disease.

Reactions Unrelated to Hypersensitivity or Toxicity. Regardless of the route by which the drug is administered, but most strikingly when it is given by mouth, penicillin changes the composition of the microflora in the GI tract by eliminating sensitive microorganisms. This phenomenon is usually of no clinical significance, and normal microflora are typically reestablished shortly after therapy is stopped. In some persons, however, superinfection results from pathological changes to the flora. Pseudomembranous colitis, related to overgrowth and production of a toxin by Clostridium difficile, has followed oral and, less commonly, parenteral administration of penicillins.

THE CEPHALOSPORINS

Cephalosporium acremonium, the first source of the cephalosporins, was isolated in 1948 by Brotzu from the sea near a sewer outlet off the Sardinian coast. Crude filtrates from cultures of this fungus were found to inhibit the in vitro growth of S. aureus and to cure staphylococcal infections and typhoid fever in humans. Culture fluids in which the Sardinian fungus was cultivated were found to contain three distinct antibiotics, which were named cephalosporin P, N, and C. With isolation of the active nucleus of cephalosporin C, 7-aminoccephalosporanic acid, and with the addition of side chains, it became possible to produce semisynthetic compounds with antibacterial activity very much greater than that of the parent substance.

Chemistry. Cephalosporin C contains a side chain derived from d-α-amino adipic acid, which is condensed with a dihydrothiazine β-lactam ring system (7-aminoccephalosporanic acid). Compounds containing 7-aminoccephalosporanic acid are relatively stable in dilute acid and highly resistant to penicillinase regardless of the nature of their side chains and their affinity for the enzyme.

Cephalosporin C can be hydrolyzed by acid to 7-aminoccephalosporanic acid. This compound subsequently has been modified by the addition of different side chains to create a whole family of cephalosporin antibiotics. It appears that modifications at position 7 of the β-lactam ring are associated with alteration in antibacterial activity and that substitutions at position 3 of the dihydrothiazine ring are associated with changes in the metabolism and pharmacokinetic properties of the drugs.

The cephamycins are similar to the cephalosporins but have a methoxy group at position 7 of the β-lactam ring of the 7-aminoccephalosporanic acid nucleus. The structural formulas of representative cephalosporins and cephamycins are shown in Table 53–2, along with dosages schedules and half-lives.

Mechanism of Action. Cephalosporins and cephamycins inhibit bacterial cell wall synthesis in a manner similar to that of penicillin.

Classification. The large number of cephalosporins makes a system of classification most desirable. Although cephalosporins may be classified by their chemical structure, clinical pharmacology, resistance to β-lactamase, or antimicrobial spectrum, the well-accepted system of classification by “generations” is very useful, although admittedly somewhat arbitrary (Table 53–3). It is important to remember that none of the cephalosporins has activity against MRSA, listeria, or enterococci.

Classification by generations is based on general features of antimicrobial activity (Andes and Craig, 2005). The first-generation cephalosporins, epitomized by cephalothin (discontinued in the U.S.) and cefazolin, have good activity against gram-positive bacteria and relatively modest activity against gram-negative microorganisms. Most gram-positive cocci (with the exception of enterococci, methicillin-resistant S. aureus, and S. epidermidis) are susceptible. Most oral cavity anaerobes are sensitive, but the B. fragilis group is resistant. Activity against Moraxella catarrhalis, E. coli, K. pneumoniae, and P. mirabilis is good. The second-generation cephalosporins have somewhat increased activity against gram-negative microorganisms but are much less active than the third-generation agents. A subset of second-generation agents (cefotaxime, cefoxitin, and cefotetan, and cefametazole, which have been discontinued in the U.S.) also is active against the B. fragilis group. Third-generation cephalosporins generally are less active than first-generation agents against gram-positive cocci; these agents are much more active against the Enterobacteriaceae, although resistance is dramatically increasing due to β-lactamase-producing strains. A subset of third-generation agents (ceftazidime and cefotaxime, which are discontinued in the U.S.) also is active against P. aeruginosa but less active than other third-generation agents against gram-positive cocci. Fourth-generation cephalosporins, such as cefepime, have an extended spectrum of activity compared with the third generation and have increased stability from hydrolysis by plasmid and chromosomally mediated β-lactamases (but not the KPC class A β-lactamases). Fourth-generation agents are useful in the empirical treatment of serious infections in hospitalized patients when gram-positive microorganisms, Enterobacteriaceae, and Pseudomonas all are potential etiologies. It is important to remember that none of the cephalosporins has reliable activity against the following bacteria: penicillin-resistant S. pneumoniae, MRSA, methicillin-resistant S. epidermidis and other coagulase-negative staphylococci, Enterococcus, L. monocytogenes, Legionella pneumophila, L. micdadei, C. difficile, Xanthomonas maltophilia, Campylobacter jejuni, KPC-producing Enterobacteriaceae, and Acinetobacter spp.

Mechanisms of Bacterial Resistance to the Cephalosporins. Resistance to the cephalosporins may be related to the inability of the antibiotic to reach its sites of action or to alterations in the penicillin-binding proteins (PBPs) that are targets of the cephalosporins such that the antibiotics bind to bacterial enzymes (β-lactamases) that can hydrolyze the β-lactam ring and inactivate the cephalosporin. Alterations in two PBPs (1A and 2X) that decrease their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other three high-molecular-weight PBPs have inherently low affinity (Spratt, 1994).

The most prevalent mechanism of resistance to cephalosporins is destruction of the cephalosporins by hydrolysis of the β-lactam ring.

</table>

*T, tablet; C, capsule; O, oral suspension; I, injection

* Cefoxitin, a cephapirin, has a –OCH₃ group at position 7 of cepham nucleus.
* Cefuroxime axetil is the acetyloxyethyl ester of cefuroxime.
* Cefpodoxime proxetil has a –COO(CH₃)OCOOCH(CH₃)₂ group at position 4 of cepham nucleus.
Many gram-positive microorganisms release relatively large amounts of β-lactamase into the surrounding medium. Although gram-negative bacteria seem to produce less β-lactamase, the location of their enzyme in the periplasmic space may make it more effective in destroying cephalosporins because they diffuse to their targets on the inner membrane, as is the case for the penicillins. The cephalosporins have variable susceptibility to β-lactamase. For example, of the first-generation agents, cefazolin is more susceptible to hydrolysis by β-lactamase from *S. aureus* than is cephalothin (no longer marketed). Cefoxitin, cefuroxime, and the third-generation cephalosporins are more resistant to hydrolysis by the β-lactamases produced by gram-negative bacteria than first-generation cephalosporins. Third-generation cephalosporins are susceptible to hydrolysis by inducible, chromosomally encoded (type I) β-lactamases. Induction of type I β-lactamases by treatment of infections owing to aerobic gram-negative bacilli (especially *Enterobacter* spp., *Citrobacter freundii*, *Morganella*, *Serratia*, *Providencia*, and *P. aeruginosa*) with second- or third-generation cephalosporins and/or imipenem may result in resistance to all third-generation cephalosporins. The fourth-generation cephalosporins, such as cefepime, are poor inducers of type I β-lactamases and are less susceptible to hydrolysis by type I β-lactamases than are the third-generation agents. They are, however, susceptible to degradation by KPC and metallo-β-lactamases (Jacoby and Munoz-Price, 2005; Jones et al., 2008; Walsh, 2008).

**General Features of the Cephalosporins.** Cephalexin, cephradine, cefaclor, cefadroxil, loracarbef, cefprozil, cefpodoxime proxetil, ceftibuten, and cefuroxime axetil are absorbed readily after oral administration. Cefdinir and cefditoren are also effective orally. The other cephalosporins can be administered intramuscularly or intravenously. Cephalexin and cefdinir are added activity against *Bacteroides fragilis* and other *Bacteroides* spp. Ceftriaxone (ROCEPHIN) is active against *Bacteroides* spp. inferior to that of cefoxitin and cefotetan.

*All cephalosporins lack activity against enterococci, *Listeria monocytogenes*, *Legionella* spp., methicillin-resistant *S. aureus*, *Xanthomonas maltophilia*, and *Acinetobacter* species. *Except for penicillin-resistant strains. *Except for methicillin-resistant strains. *Resistance to cephalosporins may be induced rapidly during therapy by de-repression of bacterial chromosomal β-lactamases, which destroy the cephalosporins. *Ceftazidime only. *Ceftazidime lacks significant gram-positive activity. Cefotaxime is most active in class against *S. aureus* and *S. pyogenes*. |
the bile (neither is available in the U.S.). Cefotaxime is deacetylated in vivo. The metabolite has less antimicrobial activity than the parent compound and is excreted by the kidneys. None of the other cephalosporins appears to undergo appreciable metabolism.

Several cephalosporins penetrate into the CSF in sufficient concentration to be useful for the treatment of meningitis. These include cefotaxime, ceftriaxone, and cefepime (see “Therapeutic Uses” section). Cefazolin also crosses the placenta, and they are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor. Some evidence indicates that concentrations sufficient for therapy of ocular infections owing to gram-positive and certain gram-negative microorganisms can be achieved after systemic administration. Concentrations in bile usually are high, with those achieved after administration of cefoperazone and cefpiramide the highest.

Specific Agents

First-Generation Cephalosporins. Cefazolin has an antibacterial spectrum that is typical of other first-generation cephalosporins except that it also has activity against some Enterobacter spp. Cefazolin is relatively well tolerated after either intramuscular or intravenous administration, and concentrations of the drug in plasma after a 1-g intramuscular injection reach 64 μg/mL. Cefazolin is excreted by glomerular filtration and is bound to plasma proteins to a great extent (~85%). Cefazolin usually is preferred among the first-generation cephalosporins because it can be administered less frequently owing to its longer t1/2.

Cephalixin is available for oral administration, and it has the same antibacterial spectrum as the other first-generation cephalosporins. However, it is somewhat less active against penicillinase-producing staphylococci. Oral therapy with cephalixin results in peak concentrations in plasma of 16 μg/mL after a dose of 0.5 g; this is adequate for the inhibition of many gram-positive and gram-negative pathogens. The drug is not metabolized, and 70-100% is excreted in the urine.

Cephadrine is similar in structure to cephalixin, and its activity in vitro is almost identical. Cephadrine is not metabolized and, after rapid absorption from the GI tract, is excreted unchanged in the urine. Cephadrine can be administered orally, intramuscularly, or intravenously. When administered orally, it is difficult to distinguish cephadrine from cephalixin; some authorities believe these two drugs can be used interchangeably. Because cephadrine is so well absorbed, the concentrations in plasma are nearly equivalent after oral or intramuscular administration.

Cefadroxil is the para-hydroxy analog of cephalexin. Concentrations of cefadroxil in plasma and urine are at somewhat higher levels than those of cephalixin. The drug may be administered orally once or twice a day for the treatment of urinary tract infections. Its activity in vitro is similar to that of cephalixin.

Second-Generation Cephalosporins. Second-generation cephalosporins have a broader spectrum than do the first-generation agents and are active against sensitive strains of Enterobacter spp., indole-positive Proteus spp., and Klebsiella spp.

Cefoxitin is a cephamycin produced by Streptomyces lactam durans. It is resistant to some β-lactamases produced by gram-negative rods. This antibiotic is less active than the first-generation cephalosporins against gram-positive bacteria. Cefotixin is more active than other first- or second-generation agents (except cefotetan) against anaerobes, especially B. fragilis. After an intramuscular dose of 1 g, concentrations in plasma are ~22 μg/mL. The t1/2 is ~40 minutes. Cefoxitin’s special role seems to be for treatment of certain anaerobic and mixed aerobic-anaerobic infections, such as pelvic inflammatory disease and lung abscess.

Cefaclor is used orally. The concentration in plasma after oral administration is ~50% of that achieved after an equivalent oral dose of cephalixin. However, cefaclor is more active against H. influenzae and Moraxella catarrhalis, although some β-lactamase-producing strains of these organisms may be resistant.

Loracarbef is an orally administered carbapenem, similar in activity to cefaclor, that is more stable against some β-lactamases. The serum t1/2 is 1.1 hours.

Cefuroxime is similar to loracarbef with broader gram-negative activity against some Citrobacter and Enterobacter spp. Unlike cefoxitin, cefmetazole (discontinued in the U.S.), and cefotetan, cefuroxime lacks activity against B. fragilis. The t1/2 is 1.7 hours, and the drug can be given every 8 hours. Concentrations in CSF are ~10% of those in plasma, and the drug is effective (but inferior to ceftriaxone) for treatment of meningitis owing to H. influenzae (including strains resistant to ampicillin), N. meningitidis, and S. pneumoniae (Schaad et al., 1990).

Cefuroxime axetil is the 1-acetyloxyethyl ester of cefuroxime. Between 30% and 50% of an oral dose is absorbed, and the drug then is hydrolyzed to cefuroxime; resulting concentrations in plasma are variable.

Cefprozil is an orally administered agent that is more active than first-generation cephalosporins against penicillin-sensitive streptococci, E. coli, P. mirabilis, Klebsiella spp., and Citrobacter spp. It has a serum t1/2 of ~1.3 hours.

Third-Generation Cephalosporins. Cefotaxime is highly resistant to many (but not the extended-spectrum product) of the bacterial β-lactamases and has good activity against many gram-positive and gram-negative aerobic bacteria. However, activity against B. fragilis is poor compared with agents such as clindamycin and metronidazole. Cefotaxime has a t1/2 in plasma of ~1 hour and should be administered every 4–8 hours for serious infections. The drug is metabolized in vivo to desacetylcefotaxime, which is less active against most
microorganisms than is the parent compound. However, the metabolite acts synergistically with the parent compound against certain microbes. Cefotaxime has been used effectively for meningitis caused by *H. influenzae*, penicillin-sensitive *S. pneumoniae*, and *N. meningitides*.

Ceftizoxime has a spectrum of activity in vitro that is very similar to that of cefotaxime, except that it is less active against *S. pneumoniae* and more active against *B. fragilis* (Haas et al., 1995). The t1/2 is somewhat longer, 1.8 hours, and the drug thus can be administered every 8-12 hours for serious infections. Ceftizoxime is not metabolized, and 90% is recovered in urine.

Ceftriaxone has activity in vitro very similar to that of ceftizoxime and cefotaxime. A t1/2 of ~8 hours is the outstanding feature. Administration of the drug once or twice daily has been effective for patients with meningitis, whereas dosage once a day has been effective for other infections. About half the drug can be recovered from the urine; the remainder appears to be eliminated by biliary secretion. A single dose of ceftriaxone (125-250 mg) is effective in the treatment of urethral, cervical, rectal, or pharyngeal gonorrhea, including disease caused by penicillinase-producing microorganisms.

Cefpodoxime proxetil is an orally administered third-generation agent that is very similar in activity to the fourth-generation agent cefepime except that it is not more active against *Enterobacter* or *Pseudomonas* spp. It has a serum t1/2 of 2.2 hours.

Cefditoren pivoxil is a prodrug that is hydrolyzed by esterases during absorption to the active drug, cefditoren. Cefditoren has a t1/2 of ~1.6 hours and is eliminated unchanged in the urine. The drug is active against methicillin-susceptible strains of *S. aureus*, penicillin-susceptible strains of *S. pneumoniae*, *S. pyogenes*, *H. influenzae*, *H. parainfluenzae*, and *Moraxella catarrhalis*. Cefditoren pivoxil is only indicated for the treatment of mild-to-moderate pharyngitis, tonsillitis, uncomplicated skin and skin structure infections, and acute exacerbations of chronic bronchitis.

Cefixime is an oral third-generation cephalosporin with clinical efficacy against urinary tract infections caused by *E. coli* and *P. mirabilis*, otitis media caused by *H. influenzae* and *S. pyogenes*, pharyngitis due to *S. pyogenes*, and uncomplicated gonorrhea. It is available as an oral suspension (Suprex, others). Cefixime has a plasma t1/2 of 3–4 hours and is both excreted in the urine and eliminated in the bile. The standard dose for adults is 400 mg/day for 5-7 days, and for a longer interval in patients with *S. pyogenes*. Doses must be reduced in patients with renal impairment (300 mg/day for creatinine clearance between 20 and 60 mL/minute, and 200 mg/day for <20 mL/minute). Pediatric dosing varies with patient weight.

Cefditoren is an orally effective cephalosporin with a t1/2 of 2.4 hours. It is less active against gram-positive and gram-negative organisms than cefixime, with activity limited to *S. pneumonia* and *S. pyogenes*, *H. influenzae*, and *M. catarrhalis*. Cefditoren is only indicated for acute bacterial exacerbations of chronic bronchitis, acute bacterial otitis media, pharyngitis, and tonsillitis. It lacks useful activity against *S. aureus*.

Cefdinir is effective orally, with a t1/2 of ~1.7 hours; it is eliminated primarily unchanged in the urine. Cefdinir has greater activity than the second-generation agents for facultative gram-negative bacteria but lacks anaerobic activity. It is also inactive against *Pseudomonas* and *Enterobacter* spp.

**Third-Generation Cephalosporins with Good Activity Against Pseudomonas**

Ceftazidime is one-quarter to one-half as active by weight against gram-positive microorganisms as is cefotaxime. Its activity against the Enterobacteriaceae is very similar, but its major distinguishing feature is excellent activity against *Pseudomonas* and other gram-negative bacteria. Ceftazidime has poor activity against *B. fragilis*. Its t1/2 in plasma is ~1.5 hours, and the drug is not metabolized. Ceftazidime is more active in vitro against *Pseudomonas* than piperacillin is (Edmond et al., 1999).

**Fourth-Generation Cephalosporins.** Cefepime and cefpirome are fourth-generation cephalosporins. Only cefepime is available for use in the U.S. Cefepime is stable to hydrolysis by many of the previously identified plasmid-encoded β-lactamases (called TEM-1, TEM-2, and SHV-1). It is a poor inducer of, and is relatively resistant to, the type I chromosomally encoded and some extended-spectrum β-lactamases. Thus, it is active against many Enterobacteriaceae that are resistant to other cephalosporins via induction of type I β-lactamases but remains susceptible to many bacteria expressing extended-spectrum plasmid-mediated β-lactamases (such as KPC, TEM-3, and TEM-10).

Against the fastidious gram-negative bacteria (*H. influenzae*, *N. gonorrhoeae*, and *N. meningitidis*), cefepime has comparable or greater in vitro activity than cefotaxime. For *P. aeruginosa*, cefepime has comparable activity to ceftazidime, although it is less active than ceftazidime for other *Pseudomonas* spp. and *X. maltophilia*. Cefepime has higher activity than ceftazidime and comparable activity to cefotaxime for streptococci and methicillin-sensitive *S. aureus*. It is not active against methicillin-resistant *S. aureus*, penicillin-resistant pneumococci, enterococci, *B. fragilis*, *L. monocytogenes*, *Mycobacterium avium* complex, or *M. tuberculosis*. Cefepime is excreted almost 100% renally, and doses should be adjusted for renal failure. Cefepime has excellent penetration into the CSF in animal models of meningitis. When given at the recommended dosage for adults of 2 g intravenously every 12 hours, peak serum concentrations in humans range from 126 to 193 μg/mL. The serum t1/2 is 2 hours.

**Adverse Reactions.** Hypersensitivity reactions to the cephalosporins are the most common side effects, and there is no evidence that any single cephalosporin is more or less likely to cause such sensitization. The reactions appear to be identical to those caused by the penicillins, perhaps related to the shared β-lactam structure of both groups of antibiotics. Immediate reactions such as anaphylaxis, bronchospasm, and urticaria are observed. More commonly, maculopapular rash develops, usually after several days of therapy; this may or may not be accompanied by fever and eosinophilia.

Because of the similar structures of the penicillins and cephalosporins, patients who are allergic to one class of agents may...
manifest cross-reactivity to a member of the other class. Immunological studies have demonstrated cross-reactivity in as many as 20% of patients who are allergic to penicillin, but clinical studies indicate a much lower frequency (~1%) of such reactions. There are no skin tests that can reliably predict whether a patient will manifest an allergic reaction to the cephalosporins.

Patients with a history of a mild or a temporally distant reaction to penicillin appear to be at low risk of rash or other allergic reaction following the administration of a cephalosporin. However, patients who have had a recent severe, immediate reaction to a penicillin should be given a cephalosporin with great caution, if at all. A positive Coombs reaction appears frequently in patients who receive large doses of a cephalosporin. Hemolysis usually is not associated with this phenomenon, although it has been reported and has been associated with fatalities. Cephalosporins have produced rare instances of bone marrow depression, characterized by granulocytopenia.

The cephalosporins have been implicated as potentially nephrotoxic agents, although they are not nearly as toxic to the kidney as the aminoglycosides or the polymyxins. Renal tubular necrosis has followed the administration of cephaloridine in doses >4 g/day; this agent is no longer available in the U.S. Other cephalosporins are much less toxic and, when used by themselves in recommended doses, rarely produce significant renal toxicity. High doses of cephalothin (no longer available in the U.S.) have produced acute tubular necrosis in certain instances, and usual doses (8-12 g/day) have caused nephrotoxicity in patients with pre-existing renal disease. There is good evidence that the concurrent administration of cephapirin and gentamicin or tobramycin act synergistically to cause nephrotoxicity, especially in patients >60 years of age. Diarrhea can result from the administration of cephalosporins and may be more frequent with cefoperazone, perhaps because of its greater biliary excretion. Intolerance to alcohol (a disulfiram-like reaction) has been noted with cephalosporins that contain the methylthiotetrazole (MTT) group, including cefotetan, cefamandole, moxalactam, and cefoperazone (the latter three are no longer available in the U.S.). Serious bleeding related either to hypoprothrombinemia owing to the MTT group, thrombocytopenia, and/or platelet dysfunction has been reported with several β-lactam antibiotics.

**Therapeutic Uses.** The cephalosporins are used widely and are therapeutically important antibiotics. Clinical studies have shown cephalosporins to be effective as both therapeutic and prophylactic agents. Unfortunately, a wide array of bacteria is resistant to their activity.

The first-generation cephalosporins are excellent agents for skin and soft tissue infections owing to *S. pyogenes* and methicillin-susceptible *S. aureus*. A single dose of cefazolin just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens (Medical Letter, 2006). For colorectal surgery, where prophylaxis for intestinal anaerobes is desired, the second-generation agent cefoxitin is preferred.

The second-generation cephalosporins generally have been displaced by third-generation agents. They have inferior activity against penicillin-resistant *S. pneumoniae* compared with either the third-generation agents or ampicillin and therefore should not be used for empirical treatment of meningitis or pneumonia. The oral second-generation cephalosporins can be used to treat respiratory tract infections, although they are suboptimal (compared with oral amoxicillin) for treatment of penicillin-resistant *S. pneumoniae* pneumonia and otitis media. In situations where facultative gram-negative bacteria and anaerobes are involved, such as intra-abdominal infections, pelvic inflammatory disease, and diabetic foot infection, cefoxitin and cefetetan both are effective.

The third-generation cephalosporins, with or without aminoglycosides, have been considered to be the drugs of choice for serious infections caused by *Klebsiella, Enterobacter, Proteus, Providencia, Serratia*, and *Haemophilus* spp. Ceftriaxone is the therapy of choice for all forms of gonorrhea and for severe forms of Lyme disease. The third-generation cephalosporins cefotaxime or ceftriaxone are used for the initial treatment of meningitis in nonimmunocompromised adults and children >3 months of age (in combination with vancomycin and ampicillin pending identification of the causative agent) because of their antimicrobial activity, good penetration into CSF, and record of clinical success. They are the drugs of choice for the treatment of meningitis caused by *H. influenzae*, sensitive *S. pneumoniae*, *N. meningitidis*, and gram-negative enteric bacteria. Cefotaxime has failed in the treatment of meningitis owing to resistant *S. pneumoniae*; thus vancomycin should be added (Quagliarello and Scheld, 1997). Ceftazidime plus an aminoglycoside is the treatment of choice for *Pseudomonas* meningitis. Third-generation cephalosporins, however, lack activity against *L. monocytogenes* and penicillin-resistant pneumococci, which may cause meningitis. The antimicrobial spectra of cefotaxime and ceftriaxone are excellent for the treatment of community-acquired pneumonia, i.e., pneumonia caused by some pneumococci (achievable serum concentrations exceed MICs for many or most penicillin-resistant isolates), *H. influenzae*, or *S. aureus*.

The fourth-generation cephalosporins are indicated for the empirical treatment of nosocomial infections where antibiotic resistance owing to extended-spectrum β-lactamases or chromosomally induced β-lactamases are anticipated. For example, cefepime has superior activity against nosocomial isolates of *Enterobacter, Citrobacter*, and *Serratia* spp. compared with ceftazidime and piperacillin. However KPC- or metallo-β-lactamase expressing strains are resistant to cefepime.

**OTHER β-LACTAM ANTIBIOTICS**

Important therapeutic agents with a β-lactam structure that are neither penicillins nor cephalosporins have been developed.

**Carbapenems**

Carbapenems are β-lactams that contain a fused β-lactam ring and a five-member ring system that differs from the penicillins because it is unsaturated and contains a carbon atom instead of the sulfur atom. This class of antibiotics has a broader spectrum of activity than most other β-lactam antibiotics.
**Imipenem.** Imipenem is marketed in combination with cilastatin, a drug that inhibits the degradation of imipenem by a renal tubular dipeptidase.

![IMIPENEM](image)

Imipenem is derived from a compound produced by *Streptomyces cattleya.* The compound thienamycin is unstable, but imipenem, the N-formimidoyl derivative, is stable.

**Antimicrobial Activity.** Imipenem, like other β-lactam antibiotics, binds to penicillin-binding proteins, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is very resistant to hydrolysis by most β-lactamases.

The activity of imipenem is excellent in vitro for a wide variety of aerobic and anaerobic microorganisms. Streptococci (including penicillin-resistant *S. pneumoniae*), enterococci (excluding *E. fae-
cium* and non-β-lactamase-producing penicillin-resistant strains), staphylococci (including penicillinase-producing strains), and *Listeria* all are susceptible. Although some strains of methicillin-resistant staphylococci are susceptible, many strains are not. Activity was excellent against the Enterobacteriaceae until the emergence of KPC carbapenemase-producing strains (Jones et al., 2008; Walsh, 2008). Most strains of *Pseudomonas* and *Acinetobacter* are inhibited. *S. maltophilia* is resistant. Anaerobes, including *B. fragilis*, are highly susceptible.

**Pharmacokinetics and Adverse Reactions.** Imipenem is not absorbed orally. The drug is hydrolyzed rapidly by a dipeptidase found in the brush border of the proximal renal tubule. Because concentrations of active drug in urine were low, cilastatin, an inhibitor of the dehydropeptidase, was synthesized. A preparation has been developed that contains equal amounts of imipenem and cilastatin (PRIMAXIN).

After the intravenous administration of 500 mg imipenem and cilastatin, peak concentrations in plasma average 33 μg/mL. Both imipenem and cilastatin have a t½ of ~1 hour. When administered concurrently with cilastatin, ~70% of administered imipenem is recovered in the urine as the active drug. Dosage should be modified for patients with renal insufficiency.

Nausea and vomiting are the most common adverse reactions (1-20%). Seizures also have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions and to those with renal insufficiency. Patients who are allergic to other β-lactam antibiotics may have hypersensitivity reactions when given imipenem.

**Therapeutic Uses.** Imipenem–cilastatin is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft tissue, bone, and joint infections. The drug combination appears to be especially useful for the treatment of infections caused by cephalosporin-resistant nosocomial bacteria, such as *Citrobacter freundii* and *Enterobacter* spp. (with the exception of the increasingly common KPC-producing strains). It would be prudent to use imipenem for empirical treatment of serious infections in hospitalized patients who have recently received other β-lactam antibiotics because of the increased risk of infection with cephalosporin- and/or penicillin-resistant bacteria. Imipenem should not be used as monotherapy for infections owing to *P. aeruginosa* because of the risk of resistance developing during therapy.

**Meropenem.** Meropenem (MERREM iv) is a dimethylcarbamoyl pyro-

lindinyl derivative of thienamycin. It does not require co-administra-
tion with cilastatin because it is not sensitive to renal dipeptidase. Its toxicity is similar to that of imipenem except that it may be less likely to cause seizures (0.5% for meropenem; 1.5% for imipenem). Its in vitro activity is similar to that of imipenem, with activity against some imipenem-resistant *P. aeruginosa* but less activity against gram-positive cocci. Clinical experience with meropenem demonstrates therapeutic equivalence with imipenem.

**Doripenem.** Doripenem (DORIBAX) has a spectrum of activity that is similar to that of imipenem and meropenem, with greater activity against some resistant isolates of *Pseudomonas* (Medical Letter, 2008).

**Ertapenem.** Ertapenem (INVANZ) differs from imipenem and meropenem by having a longer t½ that allows once-daily dosing and by having inferior activity against *P. aeruginosa* and *Acinetobacter* spp. Its spectrum of activity against gram-positive organisms, Enterobacteriaceae, and anaerobes makes it attractive for use in intra-abdominal and pelvic infections (Solomkin et al., 2003).

**Aztreonam.** Aztreonam (AZACTAM) is a monocyclic β-lactam compound (a monobactam) isolated from *Chromobacterium violaceum* (Sykes et al., 1981).

![AZTREONAM](image)

Aztreonam interacts with penicillin-binding proteins of susceptible microorganisms and induces the formation of long filamentous bacterial structures. The compound is resistant to many of the β-lactamases that are elaborated by most gram-negative bacteria, including the metallo-β-lactamases but not the KPC β-lactamases (Jones et al., 2008; Walsh, 2008).

The antimicrobial activity of aztreonam differs from those of other β-lactam antibiotics and more closely resembles that of an aminoglycoside. Aztreonam has activity only against gram-negative bacteria; it has no activity against gram-positive bacteria and anaerobic organisms. However, activity against Enterobacteriaceae is excellent, as is that against *P. aeruginosa.* It is also highly active in vitro against *H. influenzae* and gonococci.

Aztreonam is administered either intramuscularly or intra-

venously. Peak concentrations of aztreonam in plasma average nearly 50 μg/mL after a 1-g intramuscular dose. The t½ for elimination is 1.7 hours, and most of the drug is recovered unaltered in the urine. The t½ is prolonged to ~6 hours in anephric patients.
Aaztreonam generally is well tolerated. Interestingly, patients who are allergic to penicillins or cephalosporins appear not to react to aztreonam, with the exception of ceftazidime.

The usual dose of aztreonam for severe infections is 2 g every 6-8 hours. This should be reduced in patients with renal insufficiency. Aztreonam has been used successfully for the therapy of a variety of infections. One of its notable features is little allergic cross-reactivity with β-lactam antibiotics, with the possible exception of ceftazidime (Perez Pimiento et al., 1998), with which it has considerable structural similarity. Aztreonam is therefore quite useful for treating gram-negative infections that normally would be treated with a β-lactam antibiotic were it not for the history of a prior allergic reaction.

**β-LACTAMASE INHIBITORS**

Certain molecules can inactivate β-lactamases, thereby preventing the destruction of β-lactam antibiotics that are substrates for these enzymes. β-Lactamase inhibitors are most active against plasmid-encoded β-lactamases (including the enzymes that hydrolyze ceftazidime and cefotaxime), but they are inactive at clinically achievable concentrations against the type I chromosomal β-lactamases induced in gram-negative bacilli (such as Enterobacter, Acinetobacter, and Citrobacter) by treatment with second- and third-generation cephalosporins.

Clavulanic acid is produced by Streptomyces clavuligerus; its structural formula is:

![Clavulanic Acid](image)

It has poor intrinsic antimicrobial activity, but it is a “suicide” inhibitor that irreversibly binds β-lactamases produced by a wide range of gram-positive and gram-negative microorganisms. Clavulanic acid is well absorbed by mouth and also can be given parenterally. It has been combined with amoxicillin as an oral preparation (AUGMENTIN, others) and with ticarcillin as a parenteral preparation (TIMENTIN).

Amoxicillin plus clavulanate is effective in vitro and in vivo for β-lactamase-producing strains of staphylococci, H. influenzae, gonococci, and E. coli. Amoxicillin-clavulanate plus ciprofloxacin has been shown to be an effective oral treatment for low-risk febrile patients with neutropenia from cancer chemotherapy (Freifeld et al., 1999; Kern et al., 1999). It also is effective in the treatment of acute otitis media in children, sinusitis, animal or human bite wounds, cellulitis, and diabetic foot infections. The addition of clavulanate to ticarcillin (timentin) extends its spectrum such that it resembles imipenem to include aerobic gram-negative bacilli, S. aureus, and Bacteroides spp. There is no increased activity against Pseudomonas spp. The dosage should be adjusted for patients with renal insufficiency. The combination is especially useful for mixed nosocomial infections and is used often with an aminoglycoside.

Sulbactam is another β-lactamase inhibitor similar in structure to clavulanic acid. It may be given orally or parenterally along with a β-lactam antibiotic. It is available for intravenous or intra-muscular use combined with ampicillin (UNASYN, others). Dosage must be adjusted for patients with impaired renal function. The combination has good activity against gram-positive cocci, including β-lactamase-producing strains of S. aureus, gram-negative aerobes (but not resistant strains of E. coli or Pseudomonas), and anaerobes; it also has been used effectively for the treatment of mixed intra-abdominal and pelvic infections.

Tazobactam is a penicillanic acid sulfone β-lactamase inhibitor.

In comparison with the other available inhibitors, it has poor activity against the inducible chromosomal β-lactamases of Enterobacteriaceae but has good activity against many of the plasmid β-lactamases, including some of the extended-spectrum class. It has been combined with piperacillin as a parenteral preparation (ZOSYN).

The combination of piperacillin and tazobactam does not increase the activity of piperacillin against P. aeruginosa because resistance is due to either chromosomal β-lactamases or decreased permeability of piperacillin into the periplasmic space. Because the currently recommended dose (3 g piperacillin per 375 mg tazobactam every 4-8 hours) is less than the recommended dose of piperacillin when used alone for serious infections (3-4 g every 4-6 hours), concern has been raised that piperacillin-tazobactam may prove ineffective in the treatment of some P. aeruginosa infections that would have responded to piperacillin. The combination of piperacillin plus tazobactam should be equivalent in antimicrobial spectrum to ticarcillin plus clavulanate.

**BIBLIOGRAPHY**

This page intentionally left blank
The aminoglycoside group includes gentamicin, tobramycin, amikacin, netilmicin (not available in the U.S.), kanamycin, streptomycin, paromomycin, and neomycin. These drugs are used primarily to treat infections caused by aerobic gram-negative bacteria; streptomycin is an important agent for the treatment of tuberculosis, and paromomycin is used orally for intestinal amebiasis and in the management of hepatic coma. In contrast to most inhibitors of microbial protein synthesis, which are bacteriostatic, the aminoglycosides are bactericidal inhibitors of protein synthesis. Mutations affecting proteins in the bacterial ribosome, the target for these drugs, can confer marked resistance to their action. However, most commonly resistance is due to acquisition of plasmids or transposon-encoding genes for aminoglycoside-metabolizing enzymes or from impaired transport of drug into the cell. Thus, there can be cross-resistance between members of the class.

These agents contain amino sugars linked to an aminocyclitol ring by glycosidic bonds (Figure 54–1). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in cerebrospinal fluid (CSF), and all are excreted relatively rapidly by the normal kidney. Although aminoglycosides are widely used and important agents, serious toxicity limits their utility. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve.

**History and Source.** Aminoglycosides are natural products or semisynthetic derivatives of compounds produced by a variety of soil actinomycetes. Streptomycin was first isolated from a strain of *Streptomyces griseus*. Gentamicin and netilmicin are derived from species of the actinomycete *Micromonospora*. The difference in spelling (-micin) compared with the other aminoglycoside antibiotics (-mycin) reflects this difference in origin. Tobramycin is one of several components of an aminoglycoside complex (nebramycin) that is produced by *S. tenebrarius*. It is most similar in antimicrobial activity and toxicity to gentamicin. In contrast to the other aminoglycosides, amikacin, a derivative of kanamycin, and netilmicin, a derivative of sisomicin, are semisynthetic products. Other aminoglycoside antibiotics have been developed (e.g., arbekacin, isepamicin, and sisomicin), but they have not been introduced into clinical practice in the U.S. because numerous potent, less toxic alternatives (e.g., broad-spectrum β-lactam antibiotics and quinolones) are available.

**Chemistry.** The aminoglycosides consist of two or more amino sugars joined in glycosidic linkage to a hexose nucleus, which usually is in a central position (Figure 54–1). This hexose, or aminocyclitol, is either streptidine (found in streptomycin) or 2-deoxystreptamine (found in all other available aminoglycosides). These compounds thus are aminoglycosidic aminocyclitols, although the simpler term aminoglycoside is used commonly. A related compound, spectinomycin, is an aminocyclitol that does not contain amino sugars (Chapter 55).

The aminoglycoside families are distinguished by the amino sugars attached to the aminocyclitol ring by glycosidic bonds (Figure 54–1). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in cerebrospinal fluid (CSF), and all are excreted relatively rapidly by the normal kidney. Although aminoglycosides are widely used and important agents, serious toxicity limits their utility. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve.
Figure 54–1. Sites of activity of various plasmid-mediated enzymes capable of inactivating aminoglycosides. The red X indicates regions of the molecules that are protected from the designated enzyme. In gentamicin C1, R1=R2=CH3; in gentamicin C2, R1=CH3, R2=H; in gentamicin C1a, R1=R2=H. The Medical Journal of Australia.)
Mechanism of Action. The aminoglycoside antibiotics are rapidly bactericidal. Bacterial killing is concentration dependent: the higher the concentration, the greater is the rate at which bacteria are killed. A post-antibiotic effect, that is, residual bactericidal activity persisting after the serum concentration has fallen below the minimum inhibitory concentration (MIC), also is characteristic of aminoglycoside antibiotics; the duration of this effect also is concentration dependent. These properties probably account for the efficacy of high-dose, extended-interval dosing regimens of aminoglycosides.

Aminoglycosides diffuse through aqueous channels formed by porin proteins in the outer membrane of gram-negative bacteria to enter the periplasmic space. Transport of aminoglycosides across the cytoplasmic (inner) membrane depends on electron transport, in part because of a requirement for a membrane electrical potential (interior negative) to drive permeation of these antibiotics. This phase of transport has been termed energy-dependent phase I (EDP$_1$). It is rate limiting and can be blocked or inhibited by divalent cations (e.g., Ca$^{2+}$ and Mg$^{2+}$), hyperosmolarity, a reduction in pH, and anaerobic conditions. The last two conditions impair the ability of the bacteria to maintain the membrane potential, which is the driving force for transport. Thus, the antimicrobial activity of aminoglycosides is reduced markedly in the anaerobic environment of an abscess, in hyperosmolar acidic urine, and in other conditions that limit EDP$_1$ (Mingeot-Leclercq et al., 1999).

Once inside the cell, aminoglycosides bind to polysomes and interfere with protein synthesis by causing misreading and premature termination of mRNA translation (Figure 54–2).

The primary intracellular site of action of the aminoglycosides is the 30S ribosomal subunit, which consists of 21 proteins and a single 16S molecule of RNA. At least three of these ribosomal proteins, and perhaps the 16S ribosomal RNA as well, contribute to the streptomycin-binding site, and alterations of these molecules markedly affect the binding and subsequent action of streptomycin. For example, a single amino acid substitution of asparagine for lysine at position 42 of the S$_{12}$ ribosomal protein prevents binding of the drug; the resulting mutant is totally resistant to streptomycin. Substitution of glutamine for lysine creates a mutant that actually requires streptomycin for survival. The other aminoglycosides also bind to the 30S ribosomal subunit; however, they also appear to bind to several sites on the 50S ribosomal subunit (Davis, 1988).

Aminoglycosides disrupt the normal cycle of ribosomal function by interfering, at least in part, with the initiation of protein synthesis, leading to the accumulation of abnormal initiation complexes, or streptomycin monosomes, shown schematically in Figure 54–2B (Luzzatto et al., 1969). Aminoglycosides also cause misreading of the mRNA template and incorporation of incorrect amino acids into the growing polypeptide chains. Aminoglycosides vary in their
Similarly, facultative bacteria are resistant when they are grown under anaerobic conditions.

Clinically, drug inactivation is the most common mechanism for acquired microbial resistance to aminoglycosides. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conjugation and transfer of resistance plasmids (Davies, 1994) (Chapter 48). These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (Figure 54–1). Amikacin is a suitable substrate for only a few of these inactivating enzymes (Figure 54–1); thus, strains that are resistant to multiple other aminoglycosides tend to be susceptible to amikacin. The metabolites of the aminoglycosides may compete with the unaltered drug for transport across the inner membrane, but they are incapable of binding effectively to ribosomes and interfering with protein synthesis. A significant percentage of clinical isolates of Enterococcus faecalis and E. faecium are highly resistant to all aminoglycosides. Infections caused by aminoglycoside-resistant strains of enterococci can be especially difficult to treat because of the loss of the synergistic bactericidal activity between a penicillin or vancomycin and an aminoglycoside (Spera and Farber, 1992; Vemuri and Zervos, 1993). Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because the inactivating enzyme is bifunctional and can modify all these aminoglycosides. Owing to differences in the chemical structures of streptomycin and other aminoglycosides, this enzyme does not modify streptomycin, which is inactivated by another enzyme.

Microbial Resistance to the Aminoglycosides. Bacteria may be resistant to aminoglycosides because of failure of the antibiotic to penetrate intracellularly, inactivation of the drug by microbial enzymes, or low affinity of the drug for the bacterial ribosome. Intrinsic resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Penetration of drug across the outer membrane of gram-negative microorganisms into the periplasmic space can be slow, but resistance on this basis is unimportant clinically. Transport of aminoglycosides across the cytoplasmic membrane is an oxygen-dependent active process. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system.

The resulting aberrant proteins may be inserted into the cell membrane, leading to altered permeability and further stimulation of aminoglycoside transport (Busse et al., 1992). This phase of aminoglycoside transport, termed energy-dependent phase II (EDP₂), is poorly understood; however, EDP₂ may link to disruption of the structure of the cytoplasmic membrane, perhaps by the aberrant proteins. This concept is consistent with the observed progression of the leakage of small ions, followed by larger molecules and, eventually, by proteins from the bacterial cell prior to aminoglycoside-induced death. This progressive disruption of the cell envelope, as well as other vital cell processes, may help to explain the lethal action of aminoglycosides (Bryan, 1989).

**Microbial Resistance to the Aminoglycosides.** Bacteria may be resistant to aminoglycosides because of failure of the antibiotic to penetrate intracellularly, inactivation of the drug by microbial enzymes, or low affinity of the drug for the bacterial ribosome. Intrinsic resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Penetration of drug across the outer membrane of gram-negative microorganisms into the periplasmic space can be slow, but resistance on this basis is unimportant clinically. Transport of aminoglycosides across the cytoplasmic membrane is an oxygen-dependent active process. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system.

Similarly, facultative bacteria are resistant when they are grown under anaerobic conditions.

Clinically, drug inactivation is the most common mechanism for acquired microbial resistance to aminoglycosides. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conjugation and transfer of resistance plasmids (Davies, 1994) (Chapter 48). These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (Figure 54–1). Amikacin is a suitable substrate for only a few of these inactivating enzymes (Figure 54–1); thus, strains that are resistant to multiple other aminoglycosides tend to be susceptible to amikacin. The metabolites of the aminoglycosides may compete with the unaltered drug for transport across the inner membrane, but they are incapable of binding effectively to ribosomes and interfering with protein synthesis. A significant percentage of clinical isolates of *Enterococcus faecalis* and *E. faecium* are highly resistant to all aminoglycosides. Infections caused by aminoglycoside-resistant strains of enterococci can be especially difficult to treat because of the loss of the synergistic bactericidal activity between a penicillin or vancomycin and an aminoglycoside (Spera and Farber, 1992; Vemuri and Zervos, 1993). Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because the inactivating enzyme is bifunctional and can modify all these aminoglycosides. Owing to differences in the chemical structures of streptomycin and other aminoglycosides, this enzyme does not modify streptomycin, which is inactivated by another enzyme;
consequently, gentamicin-resistant strains of enterococci may be susceptible to streptomycin.

Resistance owing to mutations that alter ribosomal structure and reduce aminoglycoside binding is relatively uncommon. Missense mutations in *Escherichia coli* that substitute a single amino acid in a crucial ribosomal protein may prevent binding of streptomycin. Although highly resistant to streptomycin, these strains are not widespread in nature. Similarly, only 5% of strains of *Pseudomonas aeruginosa* exhibit such ribosomal resistance to streptomycin. Resistance in ~50% of streptomycin-resistant strains of enterococci is attributable to ribosomal mutations (Eliopoulos et al., 1984). Because ribosomal resistance usually is specific for streptomycin, these strains of enterococci remain sensitive to a combination of penicillin and gentamicin *in vitro*.

**Antibacterial Spectrum of the Aminoglycosides.** The antibacterial activity of gentamicin, tobramycin, kanamycin, netilmicin, and amikacin is directed primarily against aerobic gram-negative bacilli. Kanamycin, like streptomycin, has a more limited spectrum compared with other aminoglycosides; in particular, it should not be used to treat infections caused by *Serratia* or *P. aeruginosa*. The aerobic gram-negative bacilli vary in their susceptibility to the aminoglycosides (Table 54–1). Tobramycin and gentamicin exhibit similar activity against most gram-negative bacilli, although tobramycin usually is more active against *P. aeruginosa* and some *Proteus* spp., whereas gentamicin is usually more active against *Serratia*. Many gram-negative bacilli that are resistant to gentamicin because of plasmid-mediated inactivating enzymes also are resistant to tobramycin. Amikacin and, in some instances, netilmicin retain their activity against gentamicin-resistant strains because they are a poor substrate for many of the aminoglycoside-inactivating enzymes.

Aminoglycosides have little activity against anaerobic microorganisms or facultative bacteria under anaerobic conditions. Their action against most gram-positive bacteria is limited, and they should not be used as single agents to treat infections caused by gram-positive bacteria. In combination with a cell wall–active agent, such as a penicillin or vancomycin, an aminoglycoside produces a synergistic bactericidal effect *in vitro*. Clinically, the superiority of aminoglycoside combination regimens over β-lactams alone is not proven except in relatively few infections (discussed later).

**Absorption, Distribution, Dosing, and Elimination of the Aminoglycosides**

**Absorption.** The aminoglycosides are highly polar cations and therefore are very poorly absorbed from the GI tract. Less than 1% of a dose is absorbed after either oral or rectal administration. The drugs are not inactivated in the intestine and are eliminated quantitatively in the feces. Long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment. Absorption of gentamicin from the GI tract may be increased by GI disease (e.g., ulcers or inflammatory bowel disease). Instillation of these drugs into body cavities with serosal surfaces also may result in rapid absorption and unexpected toxicity (i.e., neuromuscular blockade). Similarly, intoxication may occur when aminoglycosides are applied topically for long periods to large

wounds, burns, or cutaneous ulcers, particularly if there is renal insufficiency.

All the aminoglycosides are absorbed rapidly from intramuscular sites of injection. Peak concentrations in plasma occur after 30-90 minutes and are similar to those observed 30 minutes after completion of an intravenous infusion of an equal dose over a 30-minute period. These concentrations typically range from 4-12 μg/mL following a 1.5-2 mg/kg dose of gentamicin, tobramycin, or netilmicin and from 20 to 35 μg/mL following a 7.5 mg/kg dose of amikacin or kanamycin. In critically ill patients, especially those in shock, absorption of drug may be reduced from intramuscular sites because of poor perfusion.

There is increasing use of aminoglycosides administered via inhalation, primarily for the management of patients with cystic fibrosis who have chronic *Pseudomonas aeruginosa* pulmonary infections. Amikacin and tobramycin solutions for injection have been used, as well as a commercial formulation of tobramycin designed for inhalation (TOBI, others). Studies of this formulation indicate that high sputum concentrations are obtained (mean of 1200 μg/mL), but serum concentrations remain low (mean peak concentration of 0.95 μg/mL) (Geller et al., 2002).

**Distribution.** Because of their polar nature, the aminoglycosides do not penetrate into most cells, the CNS, or the eye. Except for streptomycin, there is negligible binding of aminoglycosides to plasma albumin. The apparent volume of distribution of these drugs is 25% of lean body weight and approximates the volume of extracellular fluid. The aminoglycosides distribute poorly into adipose tissue, which must be considered when using weight-based dosing regimens in obese patients. Approaches using ideal or adjusted body weight are recommended in conjunction with drug-level monitoring to avoid excessive serum concentrations.

Concentrations of aminoglycosides in secretions and tissues are low. High concentrations are found only in the renal cortex and the endolymph and perilymph of the inner ear; the high concentration in these sites likely contribute to the nephrotoxicity and ototoxicity caused by these drugs. As a result of active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route for the aminoglycosides. Penetration into respiratory secretions is poor (Panidis et al., 2005). Diffusion into pleural and synovial fluid is relatively slow, but concentrations that approximate those in the plasma may be achieved after repeated administration. Inflammation increases the penetration of aminoglycosides into peritoneal and pericardial cavities.

Concentrations of aminoglycosides achieved in CSF with parenteral administration usually are subtherapeutic. In patients, concentrations in CSF in the absence of inflammation are <10% of those in plasma; this value may approach 25% when there is meningitis (Kearney and Aweeka, 1999). Given the limit on dosage escalation due to the toxicity of aminoglycosides, treatment of meningitis with intravenous administration is generally suboptimal. Intrathecal and intraventricular administration of aminoglycosides has been used to achieve therapeutic levels, but the availability of third- and fourth-generation cephalosporins has made this unnecessary in most cases. Penetration of aminoglycosides into ocular fluids is so poor that effective therapy of bacterial endophthalmitis requires periocular and intraocular injections of the drugs.

Administration of aminoglycosides to women late in pregnancy may result in accumulation of drug in fetal plasma and amniotic fluid. Streptomycin and tobramycin can cause hearing loss in children born to women who receive the drug during pregnancy. Insufficient data are available regarding the other aminoglycosides; it is therefore recommended that they be used with caution during pregnancy and only for strong clinical indications in the absence of suitable alternatives.

**Elimination.** The aminoglycosides are excreted almost entirely by glomerular filtration, and urine concentrations of 50-200 μg/mL are achieved. A large fraction of a parenterally administered dose is excreted unchanged during the first 24 hours, with most of this appearing in the first 12 hours. The half-lives of the aminoglycosides in plasma are similar, 2-3 hours in patients with normal renal function. Renal clearance of aminoglycosides is approximately two-thirds of the simultaneous creatinine clearance; this observation suggests some tubular reabsorption of these drugs.

After a single dose of an aminoglycoside, disappearance from the plasma exceeds renal excretion by 10-20%; however, after 1-2 days of therapy, nearly 100% of subsequent doses eventually is recovered in the urine. This lag period probably represents saturation of binding sites in tissues. The rate of elimination of drug from these sites is considerably longer than from plasma; the t1/2 for tissue-bound aminoglycoside has been estimated to range from 30 to 700 hours. For this reason, small amounts of aminoglycosides can be detected in the urine for 10-20 days after drug administration is discontinued. Aminoglycoside bound to renal tissue exhibits antibacterial activity and protects experimental animals against bacterial infections of the kidney even when the drug no longer can be detected in serum (Bergeron et al., 1982).

The concentration of aminoglycoside in plasma produced by the initial dose depends only on the volume of distribution of the drug. Because the elimination of aminoglycosides depends almost entirely on the kidney, a linear relationship exists between the concentration of creatinine in plasma and the t1/2 of all aminoglycosides in patients with moderately compromised renal function. In anephric patients, the t1/2 varies from 20-40 times that is determined in normal individuals. Because the incidence of nephrotoxicity and ototoxicity is likely related to the overall drug exposure to aminoglycosides, it is critical to reduce the maintenance dosage of these drugs in patients with impaired renal function.

Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis. Approximately 50% of the administered dose is removed in 12 hours by hemodialysis, which has been used for the treatment of overdosage. As a general rule, a dose equal to half the loading dose administered after each hemodialysis should maintain the plasma concentration in the desired range; however, a number of variables make this a rough approximation at best. Continuous arteriovenous hemofiltration (CAVH) and continuous venovenous hemofiltration (CVVH) will result in aminoglycoside clearances approximately equivalent to 15 and 15-30 mL/min of creatinine clearance, respectively, depending on the flow rate. The amount of aminoglycoside removed can be replaced by administering ~15-30% of the maximum daily dose (Table 54–2) each day. Frequent monitoring of plasma drug concentrations is again crucial.

Peritoneal dialysis is less effective than hemodialysis in removing aminoglycosides. Clearance rates are ~5-10 mL/min for the various drugs but are highly variable. If a patient who requires
dialysis has bacterial peritonitis, a therapeutic concentration of the aminoglycoside probably will not be achieved in the peritoneal fluid because the ratio of the concentration in plasma to that in peritoneal fluid may be 10:1 (Smithivas et al., 1971). Thus, it is recommended that antibiotic be added to the dialysate to achieve concentrations equal to those desired in plasma.

Aminoglycosides can be inactivated by various penicillins in vitro and thus should not be admixed in solution. Some reports indicate that this inactivation may occur in vivo in patients with end-stage renal failure (Blair et al., 1982), thus making monitoring of aminoglycoside plasma concentrations even more necessary in such patients. Amikacin appears to be the aminoglycoside least affected by this interaction, and penicillins with more nonrenal elimination (such as piperacillin) may be less prone to cause this interaction.

Although excretion of aminoglycosides is similar in adults and children >6 months of age, half-lives of the drugs may be prolonged significantly in the newborn: 8-11 hours in the first week of life in newborns weighing <2 kg and ~5 hours in those weighing >2 kg (Yow, 1977). Thus, it is critically important to monitor plasma concentrations of aminoglycosides during treatment of neonates (Philips et al., 1982). For unknown reasons, aminoglycoside clearances are increased and half-lives are reduced in patients with cystic fibrosis compared to subjects without cystic fibrosis, after controlling for age and weight (Mann et al., 1985). Larger doses of aminoglycosides may likewise be required in burn patients because of more rapid drug clearance, possibly because of drug loss through burn tissue.

**Dosing.** Recommended doses of individual aminoglycosides in the treatment of specific infections are given in later sections of this chapter. Historically, aminoglycosides have been administered as two or three equally divided doses, based on the short $t_{1/2}$ of the drugs. However, studies of the pharmacokinetic/pharmacodynamic properties of aminoglycosides demonstrate that administering higher doses at extended intervals (typically once daily in patients with normal renal function) is likely to be at least equally efficacious and potentially less toxic than administration of divided doses.

A comparison of this high-dose, extended-interval dosing method to traditional divided-dose methods is illustrated in Figure 54–3. Because of the post-antibiotic effect of aminoglycosides, good therapeutic response can be attained even when concentrations of aminoglycosides fall below inhibitory concentrations for a substantial fraction of the dosing interval. High-dose, extended-interval dosing schemes for aminoglycosides may also reduce the characteristic ototoxic and nephrotoxicity of these drugs. This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. More drug accumulates with higher plasma concentrations, particularly at trough, and with prolonged periods of exposure. Net elimination of aminoglycoside from these organs occurs more slowly when plasma concentrations are relatively high. High-dose, extended-interval regimens, despite the higher peak concentration, provide a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (12 hours versus <3 hours total in the example shown in Figure 54–3), potentially accounting for the lower toxicity of this approach.

Numerous studies and meta-analyses demonstrate that administration of the total dose once daily is associated with less nephrotoxicity and is just as effective as multiple-dose regimens (Bailey et al., 1997; Buijk et al., 2002). Extended-interval dosing also costs less and is administered more easily. For these reasons, high-dose, extended-interval administration of aminoglycosides is the preferred means of administering aminoglycosides for most indications and patient populations. Although the use of extended-interval dosing has been controversial in pregnancy, neonatal, and pediatric infections

*The maximum adult daily dose for amikacin, kanamycin, and streptomycin is 15 mg/kg; for gentamicin and tobramycin, 5.5 mg/kg; and for netilmicin, 6.5 mg/kg.

**Figure 54–3.** Plasma concentrations (µg/mL) after administration of 5.1 mg/kg of gentamicin intravenously to a hypothetical patient either as a single dose (every 24h) or as three divided doses (every 8h). The threshold for toxicity has been chosen to correspond to a plasma concentration of 2 µg/mL, the maximum recommended. The high-dose, extended-interval (once-daily) regimen produces a 3-fold higher plasma concentration, which enhances efficacy that otherwise might be compromised due to prolonged sub-MIC concentrations later in the dosing interval compared with the every-8-hours regimen. The once-daily regimen provides a 12-hour period during which plasma concentrations are below the threshold for toxicity, thereby minimizing the toxicity that otherwise might result from the high plasma concentrations early on. The every-8-hours regimen, in contrast, provides only a brief period during which plasma concentrations are below the threshold for toxicity.
(Knoderer et al., 2003; Rastogi et al., 2002), data from meta-analyses now support this mode of administration in appropriately selected patients from these populations (Contopoulos-Ioannidis et al., 2004; Nestaas et al., 2005; Ward and Theiler, 2008). One key exception to the use of extended-interval dosing is for aminoglycoside use as combination therapy with a cell wall–active agent in the treatment of gram-positive infections, such as endocarditis. In these infections, administration of multiple daily doses (with a lower total daily dose) is preferred because data documenting equivalent safety and efficacy of extended-interval dosing are inadequate. Although schemes exist for adjusting dosages of aminoglycosides dosed by extended-interval methods in patients with significant renal dysfunction (i.e., creatinine clearance <25 mL/minute), some clinicians prefer to use the traditional multiple-dose regimen in such patients.

Nomograms may be helpful in selecting initial doses, but variability in aminoglycoside clearance among patients is too great for these to be relied on for more than a few days (Bartal et al., 2003). If it is anticipated that the patient will be treated with an aminoglycoside for >3-4 days, then plasma concentrations should be monitored to avoid drug accumulation. Whether extended-interval or multiple-daily dosing is chosen, the dose must be adjusted for patients with creatinine clearances of <80-100 mL/minute (Table 54–2), and plasma concentrations must be monitored. Determination of the concentration of drug in plasma is an essential guide to the proper administration of aminoglycosides. In patients with life-threatening systemic infections, aminoglycoside concentrations should be determined several times per week (more frequently if renal function is changing) and should be determined within 24-48 hours of a change in dosage. The size of the individual dose, the interval between doses, or both can be altered based on the results of monitoring of drug levels in plasma. Methods for calculation of dosage are described in Appendix II. There are obvious difficulties in using any of these approaches for ill patients with rapidly changing renal function. In addition, even when known factors are taken into consideration, concentrations of aminoglycosides achieved in plasma after a given dose vary widely among patients. If the extracellular volume is expanded, the volume of distribution is increased, and concentrations will be reduced.

For twice- or thrice-daily dosing regimens, both peak and trough plasma concentrations are determined. The trough sample is obtained just before a dose, and the peak sample is obtained 60 minutes after intramuscular injection or 30 minutes after an intravenous infusion given over 30 minutes. The peak concentration documents that the dose is being cleared and not accumulating. Although schemes exist for those with clearances <50 mL/min and 1-2.5 μg/mL for those with clearances <50 mL/min also have been used. This method also tends to be inaccurate, particularly when conditions that alter aminoglycoside clearance are present (Bartal et al., 2003; Toschlog et al., 2003).

The simplest method is to obtain a trough sample 24 hours after dosing and adjust the dose to achieve the recommended plasma concentration, (e.g., <1-2 μg/mL in the case of gentamicin or tobramycin). This approach probably is the least desirable. An undetectable trough concentration could reflect grossly inadequate dosing in patients who clear the drug rapidly with prolonged periods (perhaps well over half the dosing interval) during which concentrations are subtherapeutic. In contrast, a 24-hour trough concentration target of 1-2 μg/mL actually would increase aminoglycoside exposure compared with a multiple-daily-dosing regimen (Barclay et al., 1999), which defeats the goal of providing a washout with concentrations of 0-1 μg/mL between 18 and 24 hours after a dose.

Untoward Effects

All aminoglycosides have the potential to produce reversible and irreversible vestibular, cochlear, and renal toxicity. These side effects complicate the use of these compounds and make their proper administration difficult.

Otoxicity. Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides, and otoxicity may become a dose-limiting adverse effect. Aminoglycoside induced ototoxicity results in irreversible, bilateral high-frequency hearing loss and temporary vestibular hypofunction. Degeneration of hair cells and neurons in the cochlea correlates with the loss of hearing. With increasing dosage and prolonged exposure, damage progresses from the base of the cochlea, where high-frequency sounds are processed, to the apex, which is necessary for the perception of low frequencies. Although these histological changes correlate with the ability of the cochlea to generate an action potential in response to sound, the biochemical mechanism for otoxicity is poorly understood. Early changes induced by aminoglycosides in experimental otoxicity are reversible by Ca2+. Once sensory cells are lost, however, regeneration does not occur; retrograde degeneration of the auditory nerve follows, resulting in irreversible hearing loss.

Aminoglycosides may interfere with the active transport system essential for the maintenance of the
ionic balance of the endolymph (Neu and Bendush, 1976). Ototoxicity is largely irreversible and results from progressive destruction of vestibular or cochlear sensory cells, which are highly sensitive to damage by aminoglycosides. The degree of permanent dysfunction correlates with the number of destroyed or altered sensory hair cells and is related to sustained exposure to the drug. An iron-aminoglycoside complex is postulated to potentiate reactive oxygen species–induced cellular degeneration in the cochlea (Guthrie, 2008).

Accumulation within the perilymph and endolymph occurs predominantly when aminoglycoside concentrations in plasma are high. Diffusion back into the bloodstream is slow; the half-lives of the aminoglycosides are five to six times longer in the otic fluids than in plasma. Back diffusion is concentration dependent and facilitated at the trough concentration of drug in plasma. Thus, it is generally thought that ototoxicity is more likely to occur in patients with persistently elevated concentrations of drug in plasma. However, studies have not consistently shown an association between ototoxicity and putative risk factors such as aminoglycoside serum levels, total dose and duration of aminoglycoside exposure, and renal dysfunction (including aminoglycoside–induced nephrotoxicity) (de Jager and van Altena, 2002; Peloquin et al., 2004). Drugs such as ethacrynic acid and furosemide potentiate the ototoxic effects of the aminoglycosides in animals, but data from humans implicating furosemide are less convincing (Moore et al., 1984). Hearing loss following exposure to these agents also is more likely to develop in patients with pre-existing auditory impairment.

The description of families where several members experienced profound deafness from as little as a single dose of aminoglycoside led to the investigation of a potential genetic predisposition for this toxicity. Subsequent studies have identified several predisposing mutations in mitochondrial ribosomal RNA genes (Fischel-Ghodsian, 2005). The contribution of genetic susceptibility to the overall incidence of aminoglycoside–induced ototoxicity is unclear, but surveys of subjects of European origin put the prevalence of one of these mutations at 1 in 500 (Vandebona et al., 2009). Although all aminoglycosides can affect cochlear and vestibular function, there is some preferential toxicity. Streptomycin and gentamicin produce predominantly vestibular effects, whereas amikacin, kanamycin, and neomycin primarily affect auditory function; tobramycin affects both equally. The incidence of ototoxicity is difficult to determine. Audiometric data suggest that the incidence may be as high as 25% (de Jager and van Altena, 2002); however, these data need to be interpreted in the context of the limitations of audiometric testing in acutely ill patients and day-to-day variability of audiometric testing (Brummett and Morrison, 1990). The relative incidence appears to be equal for tobramycin, gentamicin, and amikacin. Initial studies suggested that netilmicin is less ototoxic than other aminoglycosides (Lerner et al., 1983); however, the incidence of ototoxicity from netilmicin is not negligible—such complications developed in 10% of patients in one clinical trial of netilmicin. The incidence of vestibular toxicity is particularly high in patients receiving streptomycin; nearly 20% of individuals who received 500 mg twice daily for 4 weeks for enterococcal endocarditis developed clinically detectable irreversible vestibular damage (Wilson et al., 1984).

In addition, up to 75% of patients who received 2 g streptomycin for >60 days showed evidence of nystagmus or postural imbalance. Because the initial symptoms may be reversible, patients receiving high doses and/or prolonged courses of aminoglycosides should be monitored carefully for ototoxicity; however, deafness may occur several weeks after therapy is discontinued. Screening patients for a family history of aminoglycoside–induced deafness seems reasonable, but the cost effectiveness of genetic screening for mutations predisposing to aminoglycoside ototoxicity is not yet clear.

**Clinical Symptoms of Cochlear Toxicity.** A high-pitched tinnitus often is the first symptom of toxicity. If the drug is not discontinued, auditory impairment may develop after a few days. The tinnitus may persist for several days to 2 weeks after therapy is stopped. Because perception of sound in the high-frequency range (outside the conversational range) is lost first, the affected individual is not always aware of the difficulty, and it will not be detected except by careful audiometric examination. If the hearing loss progresses, the lower sound ranges are affected, and conversation becomes difficult.

**Clinical Symptoms of Vestibular Toxicity.** Moderately intense headache lasting 1–2 days may precede the onset of labyrinthine dysfunction. This is followed immediately by an acute stage in which nausea, vomiting, and difficulty with equilibrium develop and persist for 1–2 weeks. Prominent symptoms include vertigo in the upright position, inability to perceive termination of movement (“mental past-pointing”), and difficulty in sitting or standing without visual cues. Drifting of the eyes at the end of a movement so that both focusing and reading are difficult, a positive Romberg test, and rarely, pendular trunk movement and spontaneous nystagmus, are prominent signs. The acute stage ends suddenly and is followed by the appearance of manifestations of chronic labyrinthitis, in which, although symptomless while in bed, the patient has difficulty when attempting to walk or make sudden movements; ataxia is the most prominent feature. The chronic phase persists for ~2 months; it is gradually superseded by a compensatory stage in which symptoms are latent and appear only when the eyes are closed. Adaptation to the impairment of labyrinthine function is accomplished by the use of visual cues and deep proprioceptive sensation for determining movement and position. It is more adequate in the young than in the old but may not be sufficient to permit the high degree of coordination required in many special trades. Recovery from this phase may require 12–18 months, and most patients have some permanent residual damage. Although there is no specific treatment for the vestibular deficiency, early discontinuation of the drug may permit recovery before irreversible damage of the hair cells.

**Nephrotoxicity.** Approximately 8–26% of patients who receive an aminoglycoside for several days develop mild renal impairment that is almost always reversible. The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells (Lietman and Smith, 1983). The initial manifestation of damage at this site is excretion of enzymes of the renal tubular brush border (Banday et al., 2008). After several days, there is a defect in renal concentrating ability, mild proteinuria, and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days (Schentag et al., 1979). The non-oliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron with a reduced sensitivity.
of the collecting-duct epithelium to endogenous antidiuretic hormone (Appel, 1982). Although severe acute tubular necrosis may occur rarely, the most common significant finding is a mild rise in plasma creatinine (5-20 μg/mL; 40-175 μM). Hypokalemia, hypocalcemia, and hypophosphatemia are seen very infrequently. The impairment in renal function is almost always reversible because the proximal tubular cells have the capacity to regenerate.

The biochemical events leading to tubular cell damage and glomerular dysfunction are poorly understood but may involve perturbations of the structure of cellular membranes. Aminoglycosides inhibit various phospholipases, sphingomyelinases, and ATPases, and they alter the function of mitochondria and ribosomes (Humes et al., 1984; Queener et al., 1983). Because of the ability of cationic aminoglycosides to interact with anionic phospholipids, these drugs may impair the synthesis of membrane-derived autacoids and intracellular second messengers such as prostaglandins, inositol phosphates, and diacylglycerol.

Several variables appear to influence nephrotoxicity from aminoglycosides. Toxicity correlates with the total amount of drug administered. Consequently, toxicity is more likely to be encountered with longer courses of therapy. Continuous infusion is more nephrotoxic in animals than intermittent dosing (Powell et al., 1983). High-dose, extended-interval dosing approaches lead to less nephrotoxicity at the same level of total drug exposure (as measured by area under the curve) than divided-dose approaches (Figure 54-3). Advanced age, liver disease, diabetes mellitus, and septic shock have been suggested as risk factors for the development of nephrotoxicity from aminoglycosides, but data are not convincing. Note, however, that renal function in the elderly patient is overestimated by measurement of creatinine concentration in plasma, and overdosing will occur if this value is used as the only guide in this patient population (Baciewicz et al., 2003).

The nephrotoxic potential varies among individual aminoglycosides. The relative toxicity correlates with the concentration of drug found in the renal cortex in experimental animals. Neomycin, which concentrates to the greatest degree, is highly nephrotoxic in human beings and should not be administered systemically. Streptomycin does not concentrate in the renal cortex and is the least nephrotoxic. Most of the controversy has concerned the relative toxicities of gentamicin and tobramycin. If differences between the renal toxicity of these two aminoglycosides do exist in human beings, they appear to be slight. Comparative studies with amikacin, sisomicin, and netilmicin are not conclusive. Other drugs, such as amphotericin B, vancomycin, angiotensin-converting enzyme inhibitors, cisplatin, and cyclosporine, may potentiate aminoglycoside-induced nephrotoxicity (Wood et al., 1986). Clinical studies have not proven conclusively that furosemide potentiates aminoglycoside nephrotoxicity (Smith and Lietman, 1983), but volume depletion and wasting of K+ that accompany the use of furosemide may predispose to aminoglycoside toxicity.

**Neuromuscular Blockade.** An unusual toxic reaction of acute neuromuscular blockade and apnea has been attributed to the aminoglycosides. The order of decreasing potency for blockade is neomycin, kanamycin, amikacin, gentamicin, and tobramycin. In humans, neuromuscular blockade generally has occurred after intrapleural or intraperitoneal instillation of large doses of an aminoglycoside; however, the reaction can follow intravenous, intramuscular, and even oral administration of these agents. Most episodes have occurred in association with anesthesia or the administration of other neuromuscular blocking agents. Patients with myasthenia gravis are particularly susceptible to neuromuscular blockade by aminoglycosides (Chapter 11).

Aminoglycosides may inhibit prejunctional release of acetylcholine while also reducing postsynaptic sensitivity to the transmitter, but Ca2+ can overcome this effect, and the intravenous administration of a calcium salt is the preferred treatment for this toxicity (Sarkar et al., 1992). Inhibitors of acetylcholinesterase (e.g., edrophonium and neostigmine) also have been used with varying degrees of success.

**Other Untoward Effects.** In general, the aminoglycosides have little allergenic potential; anaphylaxis and rash are unusual. Rare hypersensitivity reactions—including skin rashes, eosinophilia, fever, blood dyscrasias, angioedema, exfoliative dermatitis, stomatitis, and anaphylactic shock—have been reported as cross-hypersensitivity among drugs in this class. Parenterally administered aminoglycosides are not associated with pseudomembranous colitis, probably because they do not disrupt the normal anaerobic flora. Other reactions that have been attributed to individual drugs are discussed next.

**Therapeutic Uses of Gentamicin and Other Aminoglycosides**

Gentamicin is an important agent for the treatment of many serious gram-negative bacillary infections. It is the aminoglycoside of first choice because of its lower cost and reliable activity against all but the most resistant gram-negative aerobes. Gentamicin preparations are available for parenteral, ophthalmic, and topical administration.

Gentamicin, tobramycin, amikacin, and netilmicin can be used interchangeably for the treatment of most of the following infections and therefore are discussed together. For most indications, gentamicin is the preferred agent because of long experience with its use and its lower cost. Many different types of infections can be treated successfully with these aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to the therapy of life-threatening infections and those for which a less toxic agent is contraindicated or less effective.

Aminoglycosides frequently are used in combination with a cell wall–active agent (β-lactam or glycopeptide) for the therapy of serious proven or suspected bacterial infections. Three rationales exist for this approach:

- To expand the empiric spectrum of activity of the antimicrobial regimen to ensure the presence of at least one drug active against a suspected pathogen.
• To provide synergistic bacterial killing.
• To prevent the emergence of resistance to the individual agents.

The first rationale is the most common justification for the use of combination therapy in infections such as healthcare-associated pneumonia or sepsis, where multidrug-resistant gram-negative organisms such as *P. aeruginosa*, *Enterobacter*, *Klebsiella*, and *Serratia* may be causative and the consequences of failing to provide initially active therapy are dire (Dupont et al., 2001). This approach leverages the high levels of coverage that aminoglycosides continue to provide against this organism. The use of aminoglycosides to achieve synergistic bacterial killing and improve microbiological eradication and clinical response is most well established for the treatment of endocarditis due to gram-positive organisms, most importantly *Enterococcus*. Clinical data do not support the use of combination therapy for synergistic killing of gram-negative organisms, with the possible exceptions of serious *P. aeruginosa* infections (Paul et al., 2003, 2004; Safdar et al., 2004). With the exception of mycobacterial infections, the use of aminoglycosides to prevent the emergence of resistance is not supported by clinical data, despite establishment as an *in vitro* phenomenon (Bliziotis et al., 2005).

**Gentamicin**

The typical recommended intramuscular or intravenous dose of gentamicin sulfate when used for the treatment of known or suspected gram-negative organisms as a single agent or in combination therapy for adults with normal renal function is 5-7 mg/kg daily given over 30-60 minutes. For patients with renal dysfunction, the interval may be extended. For patients who are not candidates for extended-interval dosing, a typical dosing regimen for gram-negative coverage is a loading dose of 2 mg/kg and then 3-5 mg/kg per day, one-third given every 8 hours when administered as a multiple-daily-dosing regimen. Dosages at the upper end of this range may be required to achieve therapeutic levels for trauma or burn patients, those with septic shock, patients with cystic fibrosis, and others in whom drug clearance is more rapid or volume of distribution is larger than normal. Several dosage schedules have been suggested for newborns and infants: 3 mg/kg once daily for preterm newborns <35 weeks of gestation (Hansen et al., 2003; Rastogi et al., 2002); 4 mg/kg once daily for newborns >35 weeks of gestation; 5 mg/kg daily in two divided doses for neonates with severe infections; and 2-2.5 mg/kg every 8 hours for children up to 2 years of age. Peak plasma concentrations range from 4-10 mg/mL (dosing: 1.7 mg/kg every 8 hours) and 16-24 mg/mL (dosing: 5.1 mg/kg once daily). It should be emphasized that the recommended doses of gentamicin do not always yield desired concentrations. Periodic determinations of the plasma concentration of aminoglycosides are recommended strongly, especially in seriously ill patients, to confirm that drug concentrations are in the desired range (see earlier sections on dosing for more details).

**Urinary Tract Infections.** Aminoglycosides usually are not indicated for the treatment of uncomplicated urinary tract infections, although a single intramuscular dose of gentamicin (5 mg/kg) has been effective in uncomplicated infections of the lower urinary tract. However, as strains of *E. coli* have acquired resistance to β-lactams, trimethoprim-sulfamethoxazole, and fluoroquinolones, use of aminoglycosides may increase. In the seriously ill patient with pyelonephritis, an aminoglycoside alone or in combination with a β-lactam antibiotic offers broad and effective initial coverage. Once the microorganism is isolated and its sensitivities to antibiotics are determined, the aminoglycoside should be discontinued if the infecting microorganism is sensitive to less toxic antibiotics.

**Pneumonia.** The organisms that cause community-acquired pneumonia are susceptible to broad-spectrum β-lactam antibiotics, macrolides, or a fluoroquinolone, and usually it is not necessary to add an aminoglycoside. Therapy with an aminoglycoside alone is likely to be ineffective; therapeutic concentrations are difficult to achieve owing to relatively poor penetration of drug into inflamed tissues and the associated conditions of low O₂ tension and low pH—both of which interfere with aminoglycoside antibacterial activity. Aminoglycosides are ineffective for the treatment of pneumonia due to anaerobes or *S. pneumoniae*, which are common causes of community-acquired pneumonia. They should not be considered as effective single-drug therapy for any aerobic gram-positive cocci (including *S. aureus* or streptococci), the microorganisms commonly responsible for suppurative pneumonia or lung abscess. An aminoglycoside in combination with a β-lactam antibiotic is recommended as standard therapy for hospital-acquired pneumonia in which a multiple-drug-resistant gram-negative aerobe is a likely causative agent (American Thoracic Society, 2005). Once it is established that the β-lactam is active against the causative agent, there is generally no benefit from continuing the aminoglycoside. Patients presenting with pulmonary exacerbations of cystic fibrosis often receive aminoglycosides as a component of therapy. Due to the altered pharmacokinetics of aminoglycosides in cystic fibrosis patients, higher daily doses (up to 10 mg/kg/day) may be necessary.

**Meningitis.** Availability of third-generation cephalosporins, especially cefotaxime and ceftriaxone, has reduced the need for treatment with aminoglycosides in most cases of meningitis, except for infections caused by gram-negative organisms resistant to β-lactam antibiotics (e.g., species of *Pseudomonas* and *Acinetobacter*). If therapy with an aminoglycoside is necessary, in adults, 5 mg of a preservative-free formulation of gentamicin (or equivalent dose of another aminoglycoside) is administered directly intrathecally or intraventricularly once daily (Barnes et al., 2003).

**Peritonitis Associated with Peritoneal Dialysis.** Patients who develop peritonitis as a result of peritoneal dialysis may be treated with aminoglycoside diluted into the dialysis fluid to a concentration of 4-8 mg/L for gentamicin, netilmicin, or tobramycin or 6-12 mg/L for amikacin. Intravenous or intramuscular administration of drug is unnecessary because serum and peritoneal fluid will equilibrate rapidly.

**Bacterial Endocarditis.** “Synergistic” or low-dose gentamicin (3 mg/kg per day in three divided doses) in combination with a penicillin or
vancomycin has been recommended in certain circumstances for treatment of infections due to gram-positive organisms, primarily bacterial endocarditis. Penicillin and gentamicin in combination are effective as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal endocarditis. In cases of enterococcal endocarditis, concomitant administration of penicillin and gentamicin for 4-6 weeks has been recommended because of an unacceptably high relapse rate with penicillin alone. A large case series from Sweden, however, found that cure rates were not substantially affected by shortening the duration of aminoglycoside therapy to a median of 15 days (Olaision and Schadewitz, 2002). A 2-week regimen of gentamicin or tobramycin in combination with nafcillin is effective for the treatment of selected cases of staphylococcal tricuspid native-valve endocarditis in intravenous drug users (Chambers et al., 1988), although the need to include the aminoglycoside is not established (Le and Bayer, 2003). For patients with native mitral or aortic valve staphylococcal endocarditis, the risks of aminoglycoside administration likely outweigh the benefits (Cosgrove et al., 2009). Administration of an aminoglycoside in combination with a cell wall–active agent and rifampin is recommended for treatment of staphylococcal prosthetic valve endocarditis, but clinical studies supporting this practice are limited.

Sepsis. Inclusion of an aminoglycoside in an empirical regimen is commonly recommended for the febrile patient with granulocytopenia and for sepsis when *P. aeruginosa* is a potential pathogen. Most studies that demonstrate a benefit for combination aminoglycoside therapy in these infections compared weak β-lactams (e.g., carbenicillin, no longer marketed in the U.S.) alone versus these agents plus an aminoglycoside (Paul et al., 2003, 2004). More recent studies using potent broad-spectrum β-lactams (e.g., carbapenems and anti-pseudomonal cephalosporins) have demonstrated no benefit from adding an aminoglycoside to the regimen. If there is concern that an infection may be caused by a multiple-drug-resistant organism that may be susceptible only to an aminoglycoside, then adding this antibiotic to the regimen is reasonable. Evidence that aminoglycosides are beneficial for other gram-negative infections is weak if the isolate is susceptible to other antibiotics. To avoid toxicity, aminoglycosides should be used briefly and sparingly as long as other alternatives are available.

Topical Applications. Gentamicin is absorbed slowly when it is applied topically in an ointment and somewhat more rapidly when it is applied as a cream. When the antibiotic is applied to large areas of denuded body surface, as may be the case in burned patients, plasma concentrations can reach 4 μg/mL, and 2-5% of the drug used may appear in the urine.

Untoward Effects. Like other aminoglycosides, the most important and serious side effects of the use of gentamicin are nephrotoxicity and irreversible otoxicity. Intrathecal or intraventricular administration is used rarely because it may cause local inflammation and can result in radiculitis and other complications.

**Tobramycin**

The antimicrobial activity, pharmacokinetic properties, and toxicity profile of tobramycin are very similar to those of gentamicin. Tobramycin may be given either intramuscularly, intravenously, or by inhalation. Tobramycin (TOBREX, others) also is available in ophthalmic ointments and solutions.

**Therapeutic Uses.** Indications for the use of tobramycin are the same as those for gentamicin. The superior activity of tobramycin against *P. aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections known or suspected to be caused by this organism; the drug has been usefully administered by inhalation to combat *P. aeruginosa* infections (LoBue, 2005). Tobramycin usually is used with an anti-pseudomonal β-lactam antibiotic. In contrast to gentamicin, tobramycin shows poor activity in combination with penicillin against many strains of enterococci. Most strains of *E. faecium* are highly resistant. Tobramycin is ineffective against mycobacteria. Dosages and serum concentrations are identical with those for gentamicin.

**Amikacin**

The spectrum of antimicrobial activity of amikacin is the broadest of the group. Because of its resistance to many of the aminoglycoside-inactivating enzymes, it has a special role in hospitals where gentamicin- and tobramycin-resistant microorganisms are prevalent.

**Therapeutic Uses.** Amikacin is the preferred agent for the initial treatment of serious nosocomial gram-negative bacillary infections in hospitals where resistance to gentamicin and tobramycin has become a significant problem. Amikacin is active against the vast majority of aerobic gram-negative bacilli in the community and the hospital. This includes most strains of *Serratia, Proteus,* and *P. aeruginosa.* It is active against nearly all strains of *Klebsiella, Enterobacter,* and *E. coli* that are resistant to gentamicin and tobramycin. Most resistance to amikacin is found among strains of *Actinobacter, Providencia,* and *Flavobacter* and strains of *Pseudomonas* other than *P. aeruginosa,* these all are unusual pathogens. Like tobramycin, amikacin is less active than gentamicin against enterococci and should not be used for this organism. Amikacin is not active against the majority of gram-positive anaerobic bacteria. It is active against *M. tuberculosis* (99% of strains inhibited by 4 μg/mL), including streptomycin-resistant strains and atypical mycobacteria. It has been used in the treatment of disseminated atypical mycobacterial infections in patients with acquired immunodeficiency syndrome (AIDS).

The recommended dose of amikacin is 15 mg/kg per day as a single daily dose or divided into two or three equal portions, which must be reduced for patients with renal failure. The drug is absorbed rapidly after intramuscular injection, and peak concentrations in plasma approximate 20 μg/mL after injection of 7.5 mg/kg. An intravenous infusion of the same dose over a 30-minute period produces a peak concentration in plasma of nearly 40 μg/mL at the end of
the infusion, which falls to ~20 μg/mL 30 minutes later. The concentration 12 hours after a 7.5 mg/kg dose typically is 5-10 μg/mL. A 15 mg/kg once-daily dose produces peak concentrations 50-60 μg/mL and a trough of <1 μg/mL. For treatment of mycobacterial infections, thrice-weekly dosing schedules of amikacin are often used, with doses up to 25 mg/kg.

Untoward Effects. As with the other aminoglycosides, amikacin causes ototoxicity, hearing loss, and nephrotoxicity.

Netilmicin
Netilmicin is the latest of the aminoglycosides to be marketed. It is similar to gentamicin and tobramycin in its pharmacokinetic properties and dosage. Its antibacterial activity is broad against aerobic gram-negative bacilli. Like amikacin, it is not metabolized by most of the aminoglycoside-inactivating enzymes, and it therefore may be active against certain bacteria that are resistant to gentamicin.

Therapeutic Uses. Netilmicin is useful for the treatment of serious infections owing to susceptible Enterobacteriaceae and other aerobic gram-negative bacilli. It is effective against certain gentamicin-resistant pathogens, with the exception of enterococci (Panwalker et al., 1978).

The recommended dose of netilmicin for complicated urinary tract infections in adults is 1.5-2 mg/kg every 12 hours. For other serious systemic infections, a total daily dose of 4-7 mg/kg is administered as a single dose or two to three divided doses. Children should receive 3.7 mg/kg per day in two to three divided doses; neonates receive 3.5-5 mg/kg per day as a single daily dose (Gosden et al., 2001). The distribution and elimination of netilmicin, gentamicin, and tobramycin are very similar. The \( t_{1/2} \) for elimination is usually 2–2.5 hours in adults and increases with renal insufficiency.

Untoward Effects. As with other aminoglycosides, netilmicin also may produce ototoxicity and nephrotoxicity. Animal models suggest that netilmicin may be less toxic than other aminoglycosides, but this remains to be proven in humans (Tange et al., 1995).

Streptomycin
Streptomycin is used for the treatment of certain unusual infections generally in combination with other antimicrobial agents. Because it generally is less active than other members of the class against aerobic gram-negative rods, it is rarely used.

Therapeutic Uses. Bacterial Endocarditis. Streptomycin and penicillin in combination are synergistically bactericidal in vitro and in animal models of infection against strains of enterococci, group D streptococci, and the various oral streptococci of the viridans group. The combination of penicillin G, which by itself is only bacteriostatic against enterococci, and streptomycin is effective as bactericidal therapy for enterococcal endocarditis. Gentamicin is generally preferred for its lesser toxicity; also, gentamicin should be used when the strain of enterococcus is resistant to streptomycin (MIC >2 mg/mL). Streptomycin should be used instead of gentamicin when the strain is resistant to the latter and susceptibility has been demonstrated to streptomycin, which may occur because the enzymes that inactivate these two aminoglycosides are different.

Streptomycin may be administered by deep intramuscular injection or intravenously. Intramuscular injection may be painful, with a hot tender mass developing at the site of injection. The dose of streptomycin is 15 mg/kg per day for patients with creatinine clearances >80 mL/minute. It typically is administered as a 1000-mg single daily dose for tuberculosis or 500 mg twice daily, resulting in peak serum concentrations of ~50-60 and 15-30 μg/mL and trough concentrations of <1 and 5-10 μg/mL, respectively. The total daily dose should be reduced in direct proportion to the reduction in creatinine clearance for creatinine clearances >30 mL/minute (Table 54–2).

Tularemia. Streptomycin (or gentamicin) is the drug of choice for the treatment of tularemia. Most cases respond to the administration of 1-2 g (15-25 mg/kg) streptomycin per day (in divided doses) for 10-14 days. Fluoroquinolones and tetracyclines also are effective, although the failure rate may be higher with tetracyclines.

Plague. Streptomycin is effective agent for the treatment of all forms of plague. The recommended dose is 2 g/day in two divided doses for 10 days. Gentamicin is probably as efficacious (Boulanger et al., 2004).

Tuberculosis. Streptomycin is a second-line agent for the treatment of active tuberculosis, and streptomycin always should be used in combination with at least one or two other drugs to which the causative strain is susceptible. The dose for patients with normal renal function is 15 mg/kg per day as a single intramuscular injection for 2-3 months and then two or three times a week thereafter.

Untoward Effects. Streptomycin has been replaced by gentamicin for most indications because the toxicity of gentamicin is primarily renal and reversible, whereas that of streptomycin is vestibular and irreversible. The administration of streptomycin may produce dysfunction of the optic nerve, including scotomas, presenting as enlargement of the blind spot. Among the less common toxic reactions to streptomycin is peripheral neuritis. This may be due either to accidental injection of a nerve during the course of parenteral therapy or to toxicity involving nerves remote from the site of antibiotic administration.

Kanamycin
The use of kanamycin has declined markedly because its spectrum of activity is limited compared with other aminoglycosides, and it is among the most toxic aminoglycosides. Kanamycin sulfate is available for injection and oral use. The parenteral dose for adults is 15 mg/kg per day (2-4 equally divided and spaced doses), with a maximum of 1.5 g/day. Children may be given up to 15 mg/kg per day.

Therapeutic Uses. Kanamycin is all but obsolete, and there are few indications for its use. Kanamycin has been employed to treat tuberculosis in combination with other effective drugs. It has no therapeutic advantage over streptomycin or amikacin and probably is more toxic; either should be used instead, depending on susceptibility of the isolate.
Prophylactic Uses. Kanamycin can be administered orally as adjunctive therapy in cases of hepatic encephalopathy. The dose is 4-6 g/day for 36-72 hours; quantities as large as 12 g/day (in divided doses) have been given.

Untoward Effects. Kanamycin is ototoxic and nephrotoxic. Like neomycin, its oral administration can cause malabsorption and superinfection. The untoward effects of the oral administration of aminoglycosides are considered in the section on neomycin.

Neomycin

Neomycin is a broad-spectrum antibiotic. Susceptible microorganisms usually are inhibited by concentrations of ≤10 μg/mL. Gram-negative species that are highly sensitive are E. coli, Enterobacter aerogenes, Klebsiella pneumoniae, and Proteus vulgaris. Gram-positive microorganisms that are inhibited include S. aureus and E. faecalis. M. tuberculosis is sensitive to neomycin. Strains of P. aeruginosa are resistant to neomycin. Neomycin sulfate is available for topical and oral administration. Neomycin currently is available in many brands of creams, ointments, and other products alone and in combination with polymyxin, bacitracin, other antibiotics, and a variety of corticosteroids. There is no evidence that these topical preparations shorten the time required for healing of wounds or that those containing a steroid are more effective.

Therapeutic Uses. Neomycin has been used widely for topical application in a variety of infections of the skin and mucous membranes caused by microorganisms susceptible to the drug. These include infections associated with burns, wounds, ulcers, and infected dermatoses. However, such treatment does not eradicate bacteria from the lesions.

The oral administration of neomycin (usually in combination with erythromycin base) has been employed primarily for “preparation” of the bowel for surgery. For therapy of hepatic encephalopathy, an oral daily dose of 4-12 g (in divided doses) is given, provided that renal function is normal. Because renal insufficiency is a complication of hepatic failure and neomycin is nephrotoxic, it is used rarely for this indication.

Neomycin and polymyxin B have been used for irrigation of the bladder. For this purpose, 1 mL of a preparation (NEOSPORIN G.U., IRRIGANT) containing 40 mg neomycin and 200,000 units polymyxin B per milliliter is diluted in 1 L of 0.9% sodium chloride solution and is used for continuous irrigation of the urinary bladder through appropriate catheter systems. The goal is to prevent bacteriuria and bacteremia associated with indwelling catheters. The bladder is irrigated at the rate of 1 L every 24 hours.

Absorption and Excretion. Neomycin is poorly absorbed from the GI tract and is excreted by the kidney, as are the other aminoglycosides. An oral dose of 3 g produces a peak plasma concentration of 1–4 μg/mL; a total daily intake of 10 g for 3 days yields a blood concentration below that associated with systemic toxicity if renal function is normal. Patients with renal insufficiency may accumulate the drug. About 97% of an oral dose of neomycin is not absorbed and is eliminated unchanged in the feces.

Untoward Effects. Hypersensitivity reactions, primarily skin rashes, occur in 6-8% of patients when neomycin is applied topically. Individuals sensitive to this agent may develop cross-reactions when exposed to other aminoglycosides. The most important toxic effects of neomycin are renal damage and nerve deafness; as a consequence, the drug is no longer available for parenteral administration. Toxicity has been reported in patients with normal renal function after topical application or irrigation of wounds with 0.5% neomycin solution. Neuromuscular blockade with respiratory paralysis also has occurred after irrigation of wounds or serosal cavities. Individuals treated with 4-6 g/day of the drug by mouth sometimes develop a sprue-like syndrome with diarrhea, steatorrhea, and azotorrhea. Overgrowth of yeasts in the intestine also may occur; this is not associated with diarrhea or other symptoms in most cases.

CLINICAL SUMMARY

The role of aminoglycosides in the treatment of bacterial infections has diminished steadily as alternative drugs have become available. The aminoglycosides are narrow-spectrum agents, with their activity limited mainly to gram-negative aerobes. Compared with other antibacterials, aminoglycosides are among the most toxic, particularly if used for prolonged periods of time; serum concentrations must be monitored to avoid drug accumulation. These agents are first-line therapy for only a limited number of very specific, often historically prominent infections, such as plague, tularemia, and tuberculosis. Gentamicin or amikacin may have a role as a backup agent in the treatment of nosocomial infections caused by multidrug-resistant gram-negative pathogens such as Pseudomonas or Acinetobacter. Gentamicin also may be useful for the treatment of serious urinary tract infections caused by enteric organisms that have acquired resistance to sulfa drugs, penicillins, cephalosporins, and fluoroquinolones. Although gentamicin has been recommended for use in combination with vancomycin or a β-lactam to enhance bactericidal effect (i.e., synergism), the clinical benefit of such combinations is unproven for most infections. Because more effective and less toxic alternatives usually are available, aminoglycosides should be used sparingly and reserved for specific indications. If an aminoglycoside must be used, the duration of therapy should be kept to a minimum to avoid toxicity, and serum concentrations should be monitored.

BIBLIOGRAPHY

The antimicrobial agents discussed in this chapter may be assigned to three groups:

- Bacteriostatic, protein-synthesis inhibitors that target the ribosome, such as tetracyclines and glycylcyclines, chloramphenicol, macrolides and ketolides, lincosamides (clindamycin), streptogramins (quinupristin/dalfopristin), oxazolidinones (linezolid), and aminocyclitols (spectinomycin).
- Agents acting on the cell wall or cell membrane such as polymyxins, glycopeptides (vancomycin and teicoplanin), and lipopeptides (daptomycin).
- Miscellaneous compounds acting by diverse mechanisms with limited indications: bacitracin and mupirocin.

**TETRACYCLINES AND GLYCYLCYCLINES**

Sources and Chemistry. The tetracyclines are close congeners of polycyclic naphthacenecarboxamide. Structural formulas of the tetracyclines are shown in Table 55–1.

Chlortetracycline, the prototype of this class, was introduced in 1948 but is no longer marketed in the U.S. Oxytetracycline is a natural product elaborated by *Streptomyces rimosus*. Tetracycline is a semisynthetic derivative of chlortetracycline. Demeclocycline is the product of a mutant strain of *S. aureofaciens*, and methacycline (not available in the U.S.), doxycycline, and minocycline all are semisynthetic derivatives.

Because of their activity against *Rickettsia*, aerobic and anaerobic gram-positive and gram-negative bacteria, and *Chlamydia*, tetracyclines became known as “broad-spectrum” antibiotics. The spread of antimicrobial resistance has eroded the activity of tetracyclines against many gram-positive and gram-negative organisms. A new group of tetracycline derivatives, the glycylcyclines, have regained much of this activity. The glycylcyclines are synthetic analogs of the tetracyclines; the glycylcycline currently approved is tigecycline, the 9-tert-butyl-glycylamido derivative of minocycline.

**Antimicrobial Activity.** Tetracyclines are bacteriostatic antibiotics with activity against a wide range of aerobic and anaerobic gram-positive and gram-negative bacteria.

They also are effective against some microorganisms, such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella* spp., *Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp., that are resistant to cell-wall-active antimicrobial agents. The tetracyclines are active against many spirochetes, including *Borrelia recurrentis*, *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis), and *Treponema pertenue*. Tetracyclines are active against *Chlamydia* and *Mycoplasma*. Some nontuberculosis strains of mycobacteria (e.g., *M. marinum*) also are susceptible. They are not active against fungi. Demeclocycline, tetracycline, minocycline, and doxycycline are available in the U.S. for systemic use. Other derivatives are available in other countries. The more lipophilic drugs, minocycline and doxycycline, usually are the most active by weight, followed by tetracycline. Resistance of a bacterial strain to any one member of the class may or may not result in cross-resistance to other tetracyclines. Tigecycline is generally, although not universally, active against organisms that are susceptible to tetracyclines as well as those with acquired resistance to tetracyclines (Gales et al., 2008).

Bacterial strains with tetracycline minimum inhibitory concentrations (MICs) \( \leq 4 \mu g/mL \) are considered susceptible except for *Haemophilus influenzae* and *Streptococcus pneumoniae*, whose susceptibility breakpoints (defined as the upper limit of the concentration at which bacteria are still considered susceptible to a given drug) are \( \leq 2 \mu g/mL \), and *Neisseria gonorrhoeae*, with a breakpoint of \( \leq 0.25 \mu g/mL \). The MIC breakpoint for susceptible anaerobic bacteria is 8 \( \mu g/mL \). Tetracyclines intrinsically are more active against gram-positive than gram-negative microorganisms, but acquired resistance is common. Recent data from the U.S. on the activity of tetracycline and other agents discussed in this chapter against selected gram-positive aerobes are displayed in Table 55–2. However, prevalence of resistant strains varies in different regions. For example, \( \sim 10\% \) of *S. pneumoniae* isolates in the U.S. are resistant...
Bacillus anthracis and Listeria monocytogenes are susceptible. Of note, the tetracyclines, doxycycline and minocycline in particular, have generally retained excellent levels of activity against staphylococci, including methicillin-resistant Staphylococcus aureus (MRSA). Doxycycline and minocycline can be active against some tetracycline-resistant isolates.

H. influenzae is generally susceptible, but many Enterobacteriaceae have acquired resistance. Although all strains of Pseudomonas aeruginosa are resistant, 90% of strains of Burkholderia pseudomallei (the cause of melioidosis) are sensitive. Most strains of Brucella also are susceptible. Tetracyclines remain useful for infections caused by Haemophilus ducreyi (chancroid), Vibrio cholerae and V. vulnificus, and inhibit the growth of Legionella pneumophila, Campylobacter jejuni, Helicobacter pylori, Yersinia pestis, Yersinia enterocolitica, Francisella tularensis, and Pasteurella multocida. Strains of Neisseria gonorrhoeae no longer are predictably susceptible to tetracycline, which is not recommended for treatment of gonococcal infections. The tetracyclines are active against many anaerobic and facultative microorganisms. A variable number of anaerobes (e.g.,

Entries are drug concentrations, in μg/mL, required to inhibit growth of 90% of isolates of that organism. In parentheses below each drug concentration is the percentage of isolates inhibited at clinically useful drug concentrations. PCN-S = penicillin-susceptible; PCN-R = penicillin-resistant; MSSA = methicillin-susceptible Staphylococcus aureus; MRSA = methicillin-resistant Staphylococcus aureus; NR = not reported; NA = not applicable.

Sources: Gales et al., 2008; Critchley et al., 2003.
**Mechanism of Action.** Tetracyclines and glycylcyclines inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 55–1). These drugs enter gram-negative bacteria by passive diffusion through the hydrophilic channels formed by the porin proteins of the outer cell membrane and by active transport via an energy-dependent system that pumps all tetracyclines across the cytoplasmic membrane. Entry of these drugs into gram-positive bacteria requires metabolic energy, but the process is not as well understood.

**Resistance to Tetracyclines and Glycylcyclines.** Resistance is primarily plasmid mediated and often inducible. The three main resistance mechanisms are (1) decreased accumulation of tetracycline as a result of either decreased antibiotic influx or acquisition of an energy-dependent efflux pathway; (2) production of a ribosomal protection protein that displaces tetracycline from its target, a “protection” that also may occur by mutation; and (3) enzymatic inactivation of tetracyclines. Cross-resistance, or lack thereof, among tetracyclines depends on which mechanism is operative. For example, *S. aureus* strains that are tetracycline resistant on the basis of efflux mediated by tetK still may be susceptible to minocycline. Tetracycline resistance due to a ribosomal protection mechanism (tetM) produces cross-resistance to doxycycline and minocycline because the target site protected is the same for all tetracyclines.

The glycylamido moiety characteristic of tigecycline reduces its affinity for most efflux pumps, restoring activity against many organisms displaying tetracycline resistance due to this mechanism. Binding of glycylcyclines to ribosomes is also enhanced, improving activity against organisms that harbor ribosomal protection proteins that confer resistance to other tetracyclines (Petersen et al., 1999).

**Absorption, Distribution, and Excretion Absorption.** Oral absorption of most tetracyclines is incomplete. The percentage of an oral dose that is absorbed with an empty stomach is modest for demeclocycline and tetracycline (60-80%) and high for doxycycline (95%) and minocycline (100%). The percentage of unabsorbed drug rises as the dose increases. Tigecycline is not appreciably absorbed from the gastrointestinal (GI) tract and is only available for parenteral administration. Absorption of orally administered tetracyclines mostly takes place in the stomach and upper small intestine and is greater in the fasting state. Absorption may be impaired by the concurrent ingestion of divalent and trivalent cations (e.g., Ca\(^{2+}\), Mg\(^{2+}\), Al\(^{3+}\), Fe\(^{3+}\), and Zn\(^{2+}\)). Thus, dairy products, antacids, aluminum hydroxide gels; calcium, magnesium, and iron or zinc salts; bismuth subsalicylate (e.g., PEPTO-BISMOL), and dietary Fe and Zn supplements can interfere with absorption of tetracyclines. The decreased absorption apparently results from chelation with these cations and formation of complexes with poor solubility. Doxycycline and minocycline are less affected than tetracyclines and administration with milk or calcium-containing foods is unlikely to impair absorption substantially, but co-administration of antacids or mineral supplements should be avoided.

Variable absorption of orally administered tetracyclines leads to a wide range of plasma concentrations in different individuals. Tetracycline is incompletely absorbed. After a single oral dose, the peak plasma concentration is attained in 2–4 hours. These drugs have half-lives in the range of 6-12 hours and frequently are administered two to four times daily. The administration of 250 mg tetracycline every 6 hours produces peak plasma concentrations of 2-2.5 μg/mL. Increasing the dosage above 1 g every 6 hours does not further increase plasma concentrations. Demeclocycline, which also is incompletely absorbed, can be administered in lower daily dosages than the congeners just mentioned because its \(t_{1/2}\) of 16 hours provides effective plasma concentrations for 24-48 hours.

---

**Figure 55–1. Inhibition of bacterial protein synthesis by tetracyclines.** Messenger RNA (mRNA) attaches to the 30S subunit of bacterial ribosomal RNA. The P (peptidyl) site of the 50S ribosomal RNA subunit contains the nascent polypeptide chain; normally, the aminoacyl tRNA charged with the next amino acid (aa) to be added to the chain moves into the A (acceptor) site, with complementary base pairing between the anticodon sequence of tRNA and the codon sequence of mRNA. **Tetracyclines** inhibit bacterial protein synthesis by binding to the 30S subunit and blocking tRNA binding to the A site.
Oral doses of doxycycline and minocycline are well absorbed (90-100%) and have half-lives of 16-18 hours; they therefore can be administered less frequently and at lower doses than tetracycline or demeclocycline. After an oral dose of 200 mg of doxycycline, a maximum plasma concentration of 3 μg/mL is achieved at 2 hours, and the plasma concentration remains above 1 μg/mL for 8-12 hours. Plasma concentrations are equivalent whether doxycycline is given orally or parenterally.

**Distribution.** Tetracyclines distribute widely throughout the body and into tissues and secretions, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow, and in bone, dentine, and enamel of unerupted teeth. Tigecycline distributes rapidly and extensively into tissues, with an estimated apparent volume of 7-10 L/kg. Because of this extensive distribution, peak serum levels of tigecycline are relatively low (~1 μg/mL).

Inflammation of the meninges is not required for the passage of tetracyclines into the cerebrospinal fluid (CSF). Penetration of these drugs into most other fluids and tissues is excellent. Concentrations in synovial fluid and the mucosa of the maxillary sinus approach that in plasma. Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relative to the maternal circulation, tetracycline concentrations in umbilical cord plasma and amniotic fluid are 60% and 20%, respectively. Relatively high concentrations of these drugs also are found in breast milk.

**Excretion.** The primary route of elimination of most older tetracyclines (e.g., demeclocycline, tetracycline) is the kidney, although they also are concentrated in the liver and excreted in bile. After biliary excretion, they are partially reabsorbed via enterohepatic recirculation. Elimination via the intestinal tract occurs even when the drugs are given parenterally. Comparable amounts of tetracycline (i.e., 20-60%) are excreted in the urine within 24 hours following oral or intravenous administration.

Doxycycline is largely excreted unchanged both in the bile and urine, tigecycline is mostly excreted unchanged along with a small amount of glucuronidated metabolites, and minocycline is extensively metabolized by the liver before excretion. Doses of these agents do not require adjustment in patients with renal dysfunction. Decreased hepatic function or obstruction of the common bile duct reduces the biliary excretion of these agents, resulting in longer half-lives and higher plasma concentrations. Specific dosage adjustment recommendations in hepatic disease are available only for tigecycline. Because of their enterohepatic circulation, these drugs may remain in the body for a long time after cessation of therapy. There is some evidence for drug interactions between doxycycline and hepatic enzyme-inducing agents such as phenytoin and rifampin, but not for minocycline or tigecycline.

**Therapeutic Uses and Dosage.** The tetracyclines have been used extensively to treat infectious diseases and as an additive to animal feeds to facilitate growth. These uses have increased resistance to tetracyclines among gram-positive and gram-negative organisms, limiting their use for a number of common bacterial infections. However, the drugs remain useful as first-line therapy for infections caused by rickettsiae, mycoplasmas, and chlamydiae. The glycylcyclines have restored much of the antibacterial activity lost to the tetracyclines due to resistance and can be used for a number of infections due to gram-positive and gram-negative organisms.

Children >8 years of age should receive 25-50 mg/kg daily in four divided doses. The total daily dose of intravenous tetracycline (no longer available in the U.S.) for most acute infections is 1 g (or 2 g for severe infection), divided into equal doses and administered at 6- or 12-hour intervals. The low pH of tetracycline, but not doxycycline or minocycline, invariably causes phlebitis if infused into a peripheral vein. The recommended dose of demeclocycline is 150 mg every 6 hours or 300 mg every 12 hours for adults and 6.6-13.2 mg/kg in two to four divided doses for children >8 years of age. Demeclocycline is used rarely as an antimicrobial agent because of its higher risks of photosensitivity reactions and nephrogenic diabetes insipidus. The oral or intravenous dose of doxycycline for adults is 100 mg every 12 hours on the first day and then 50 mg every 12 hours, 100 mg once a day, or 100 mg twice daily when severe infection is present; for children >8 years of age, the dose is 4-5 mg/kg per day in two divided doses the first day, then 2-2.5 mg/kg given once or twice daily. The dose of minocycline for adults is 200 mg orally or intravenously initially, followed by 100 mg every 12 hours; for children, it is 4 mg/kg initially followed by 2 mg/kg every 12 hours. Tigecycline is administered intravenously to adults as a 100-mg loading dose, followed by 50 mg every 12 hours. For patients with severe hepatic impairment, the loading dose should be followed by a reduced maintenance dose of 25 mg every 12 hours. Dosage data are not available for tigecycline in pediatrics.

Tetracyclines should not be administered intramuscularly because of local irritation and poor absorption. GI distress, nausea, and vomiting can be minimized by administration of tetracyclines with food. Generally, oral administration of tetracyclines should occur 2 hours before or 2 hours after co-administration with any of the agents listed. Cholestyramine and colestipol also bind orally administered tetracyclines and interfere with the absorption of the antibiotic.

**Respiratory Tract Infections.** Doxycycline’s good activity against *S. pneumoniae* and *H. influenzae* and excellent activity against atypical pathogens such as *Mycoplasma* and *Chlamydia pneumoniae* make it an effective single agent for empirical therapy of community-acquired pneumonia in the outpatient setting or as an adjunct to cephalosporin-based therapy for inpatients (Mandell et al., 2007). Tigecycline has been demonstrated to be effective for use as a single agent for adults hospitalized with community-acquired bacterial pneumonia (Bergallo et al., 2009).

**Skin and Soft-Tissue Infections.** Community strains of methicillin-resistant *S. aureus* often are susceptible to tetracycline, doxycycline, or minocycline, which appear to be effective for uncomplicated skin and soft-tissue infections, although published data are limited (Cenizal et al., 2007). Tigecycline is approved by the Food and Drug Administration (FDA) for the treatment of complicated skin and soft-tissue infections.

Tetracyclines have been used to treat acne. They may act by inhibiting propionibacteria, which reside in sebaceous follicles and metabolize lipids into irritating free fatty acids. The relatively low doses of tetracycline used for acne (e.g., 250 mg orally twice a day) are associated with few side effects.
**Intra-abdominal Infections.** Increasing resistance among Enterobacteriaceae and gram-negative anaerobes limit the utility of the tetracyclines for intra-abdominal infections. However, tigecycline possesses excellent activity against these pathogens as well as *Enterococcus* and has demonstrated effectiveness in clinical trials for complicated intra-abdominal infections (Oliva et al., 2005).

**GI Infections.** Therapy with the tetracyclines is often ineffective in infections caused by *Shigella, Salmonella,* or other Enterobacteriaceae because of a high prevalence of drug-resistant strains in many areas. Resistance limits the usefulness of tetracyclines for travelers’ diarrhea. Doxycycline (300 mg as a single dose) is effective in reducing stool volume and eradicating *Vibrio cholerae* from the stool within 48 hours. Antimicrobial agents, however, are not substitutes for fluid and electrolyte replacement in this disease. In addition, some strains of *V. cholerae* are resistant to tetracyclines.

**Urinary Tract Infections.** Tetracyclines are no longer recommended for routine treatment of urinary tract infections because many enteric organisms that cause these infections, including *E. coli,* are resistant. There is little experience in using tigecycline for urinary tract infections; based on its *in vitro* activity, it should be adequate.

**Sexually Transmitted Diseases.** Because of resistance, doxycycline no longer is recommended for gonococcal infections. If coinfection with *C. trachomatis* has not been excluded, then either doxycycline or azithromycin should be administered in addition to an agent effective for gonococcal urethritis (Workowski and Berman, 2006).

*C. trachomatis* often is a coexistent pathogen in acute pelvic inflammatory disease, including endometritis, salpingitis, parametritis, and/or peritonitis. Doxycycline, 100 mg intravenously twice daily, is recommended for at least 48 hours after substantial clinical improvement, followed by oral therapy at the same dosage to complete a 14-day course. Doxycycline usually is combined with cefoxitin or cefotetan (Chapter 53) to cover anaerobes and facultative aerobes.

Acute epididymitis is caused by infection with *C. trachomatis* or *N. gonorrhoeae* in men <35 years of age. Effective regimens include a single injection of ceftriaxone (250 mg) plus doxycycline, 100 mg orally twice daily for 10 days. Sexual partners of patients with any of these conditions also should be treated.

Nonspecific urethritis is often due to *Chlamydia trachomatis.* Doxycycline, 100 mg every 12 hours for 7 days, is effective; however, azithromycin is usually preferred because it can be given as a single 1-g dose. Doxycycline (100 mg twice daily for 21 days) is first-line therapy for treatment of lymphogranuloma venereum. The size of buboes decreases within 4 days, and inclusion and elementary bodies entirely disappear from the lymph nodes within 1 week. Rectal pain, discharge, and bleeding of lymphogranulomatous procititis are decreased markedly. When relapses occur, treatment is resumed with full doses and is continued for longer periods.

Nonpregnant penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline regimen such as doxycycline, 100 mg orally twice daily for 2 weeks. Tetracyclines should not be used for treatment of neurosyphilis.

**Rickettsial Infections.** Tetracyclines are effective and may be lifesaving in rickettsial infections, including Rocky Mountain spotted fever, recrudescent epidemic typhus (Brill’s disease), murine typhus, scrub typhus, rickettsialpox, and Q fever. Clinical improvement often is evident within 24 hours after initiation of therapy. Doxycycline is the drug of choice for treatment of suspected or proven Rocky Mountain spotted fever in adults and in children, including those <9 years of age, in whom the risk of staining of permanent teeth is outweighed by the seriousness of this potentially fatal infection (Masters et al., 2003).

**Anthrax.** Doxycycline, 100 mg every 12 hours (2.2 mg/kg every 12 hours for children weighing <45 kg), is indicated for prevention or treatment of anthrax. It should be used in combination with another agent when treating inhalational or GI infection. The recommended duration of therapy is 60 days for exposures occurring as an act of bioterrorism.

**Local Application.** Except for local use in the eye, topical use of the tetracyclines is not recommended. Their use in ophthalmic therapy is discussed in previous versions of this text. Minocycline sustained-release microspheres for subgingival administration are used in dentistry as an adjunct to scaling and root planing procedures to reduce pocket depth in patients with adult periodontitis.

**Other Infections.** Tetracyclines in combination with rifampin or streptomycin are effective for acute and chronic infections caused by *Brucella melitensis,* *Brucella suis,* and *Brucella abortus.* Effective regimens are doxycycline, 200 mg per day, plus rifampin, 600-900 mg daily for 6 weeks, or the usual dose of doxycycline plus streptomycin 1 g daily, intramuscularly. Relapses usually respond to a second course of therapy. Although streptomycin is preferable, tetracyclines also are effective in tularemia (Ellis et al., 2002). Both the ulceroglandular and typhoidal types of the disease respond well. Actinomycosis, although most responsive to penicillin G, may be successfully treated with a tetracycline. Minocycline is an alternative for the treatment of nocardiosis, but a sulfonamide should be used concurrently. Yaws and relapsing fever respond favorably to the tetracyclines. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis (*Leptospira spp.*). *Borrelia spp.,* including *B. recurrentis* (relapsing fever) and *B. burgdorferi* (Lyme disease), respond to therapy with a tetracycline. The tetracyclines have been used to treat susceptible atypical mycobacterial pathogens, including *M. marinum.*

**Untoward Effects**

**Gastrointestinal.** All tetracyclines can produce GI irritation, most commonly after oral administration. GI distress is also characteristic of tigecycline administration. Epigastric burning and distress, abdominal discomfort, nausea, vomiting, and diarrhea may occur. Tolerability can be improved by administering these drugs with food, but tetracyclines should not be taken with dairy products or antacids. Tetracycline has been associated with esophagitis, esophageal ulcers, and pancreatitis.

Many of the tetracyclines are incompletely absorbed from the GI tract, and high concentrations in the bowel can markedly alter enteric flora. Sensitive aerobic and anaerobic coliform microorganisms and gram-positive spore-forming bacteria are suppressed markedly during long-term tetracycline regimens. As the fecal coliform count declines, overgrowth of tetracycline-resistant microorganisms occurs, particularly of yeasts (*Candida* spp.), enterococci, *Proteus,* and *Pseudomonas.* Moniliasis, thrush, or *Candida*-associated esophagitis may arise during therapy with tetracyclines. Tetracyclines and glycylcyclines may occasionally produce pseudomembranous colitis caused by *Clostridium difficile; pseudomembranous colitis caused by overgrowth of* *C. difficile* is a potentially life-threatening complication.
Photosensitivity. Demeclocycline, doxycycline, and other tetracyclines and glycyclines to a lesser extent may produce mild-to-severe photosensitivity reactions in the skin of treated individuals exposed to sunlight. Onycholysis and pigmentation of the nails may develop with or without accompanying photosensitivity.

Hepatic Toxicity. Hepatic toxicity has developed in patients with renal failure receiving ≥2 g of drug per day parenterally, but this effect also may occur when large quantities are administered orally. Cases of hepatotoxicity have been reported rarely with doxycycline, minocycline, and tigecycline administration. Pregnant women are particularly susceptible to tetracycline-induced hepatic damage.

Renal Toxicity. Tetracyclines may aggravate azotemia in patients with renal disease because of their catabolic effects. Doxycycline, minocycline, and tigecycline have fewer renal side effects than other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving demeclocycline, and this phenomenon has been exploited for the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (Chapter 25).

Fanconi syndrome, characterized by nausea, vomiting, polyuria, polydipsia, proteinuria, acidosis, glycosuria, and aminoaciduria, has been observed in patients ingesting outdated and degraded tetracycline. These symptoms presumably result from a toxic effect of the degradational products on proximal renal tubules. Under no circumstances should outdated tetracyclines be administered.

Effects on Teeth. Children receiving long- or short-term therapy with a tetracycline or glycylcycline may develop permanent brown discoloration of the teeth. The larger the drug dose relative to body weight, the more intense the enamel discoloration. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk of this untoward effect is highest when a tetracycline is given to neonates and infants before the first dentition. However, pigmentation of the permanent teeth may develop if the drug is given between the ages of 2 months and 5 years when these teeth are being calcified. The deposition of the drug in the teeth and bones probably is due to its chelating property and the formation of a tetracycline–calcium orthophosphate complex.

Treatment of pregnant patients with tetracyclines may produce discoloration of the teeth in their children. The period of greatest danger to the teeth is from midpregnancy to ~4–6 months of the postnatal period for the deciduous anterior teeth, and from a few months to 5 years of age for the permanent anterior teeth when the crowns are being formed. However, children up to 8 years old may be susceptible to this complication of tetracycline therapy.

Other Toxic and Irritative Effects. Tetracyclines are deposited in the skeleton during gestation and throughout childhood and may depress bone growth in premature infants. This is readily reversible if the period of exposure to the drug is short.

Thrombophlebitis frequently follows intravenous administration. This irritative effect of tetracyclines has been used therapeutically in patients with malignant pleural effusions, where drug is instilled into the pleural space in a procedure called pleurodesis.

Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation of granulocytes, and thrombocytopenic purpura.

The tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even when given in the usual therapeutic doses. Except for the elevated pressure, the spinal fluid is normal. The pressure promptly returns to normal when therapy is discontinued, and this complication rarely occurs in older individuals.

Patients receiving minocycline may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. The symptoms occur soon after the initial dose and generally disappear within 24–48 hours after drug administration is stopped. Long-term use of minocycline can pigment the skin, producing a brownish discoloration. Various skin reactions, including morbilliform rashes, urticaria, fixed drug eruptions, and generalized exfoliative dermatitis, rarely may follow the use of any of the tetracyclines. Among the more severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even after the oral use of these agents. Other hypersensitivity reactions are burning of the eyes, cheilosis, atrophic or hypertrophic glossitis, pruritus ani or vulvae, and vaginitis.

Although the exact cause of these reactions is unknown, they can persist for weeks or months after cessation of tetracycline therapy. Fever of varying degrees and eosinophilia may occur when these agents are administered. Asthma also has been observed. Cross-sensitization among the various tetracyclines is common.

Tetracyclines have a variety of effects on mammalian cells unrelated to their capacity to inhibit bacterial protein synthesis. Doxycycline is being studied as an inhibitor of matrix metalloproteinases (Villareal et al., 2003).

CHLORAMPHENICOL

Chloramphenicol, an antibiotic produced by Streptomyces venezuelae, was introduced into clinical practice in 1948. With the drug’s wide use, it became evident that chloramphenicol could cause serious and fatal blood dyscrasias. For this reason, chloramphenicol is now reserved for treatment of life-threatening infections (e.g., meningitis, rickettsial infections) in patients who cannot take safer alternatives because of resistance or allergies (Wareham and Wilson, 2002).

\[
\text{CHLORAMPHENICOL} \quad \text{O} \quad \text{H}_2\text{O} \quad \text{CHCH} \quad \text{NH} \quad \text{C} \quad \text{Cl}_2
\]

The antibiotic is unique among natural compounds in that it contains a nitrobenzene moiety and is a derivative of dichloroacetic acid. The biologically active form is levorotatory.

Antimicrobial Activity. Chloramphenicol possesses a broad spectrum of antimicrobial activity. Strains are considered sensitive if they are inhibited by concentrations of ≤8 μg/mL, except S. pneumoniae where the breakpoint is 4 μg/mL, and H. influenzae, which has a breakpoint of 2 μg/mL. Chloramphenicol is bacteriostatic against most species, although it may be bactericidal against H. influenzae, Neisseria meningitidis, and S. pneumoniae. More than 95% of strains of the following gram-negative bacteria are inhibited in vitro by 8 μg/mL or less of chloramphenicol: H. influenzae, N. meningitidis, N. gonorrhoeae, Brucella spp., and Bordetella pertussis. Likewise,
most anaerobic bacteria, including gram-positive cocci and Clostridium spp., and gram-negative rods including B. fragilis, are inhibited by this concentration of the drug. Strains of S. aureus tend to be less susceptible, with MICs >8 μg/mL. Chloramphenicol is active against Mycoplasma, Chlamydia, and Rickettsia.

The Enterobacteriaceae are variably sensitive to chloramphenicol. Most strains of Escherichia coli (≥75%) and Klebsiella pneumoniae are susceptible. Proteus mirabilis and indole-positive Proteus spp. are susceptible. P. aeruginosa is resistant to even very high concentrations of chloramphenicol. Strains of V. cholerae have remained largely susceptible to chloramphenicol. Strains of Shigella and Salmonella resistant to multiple drugs, including chloramphenicol, are prevalent. Of special concern is the increasing prevalence of multiple-drug-resistant strains of Salmonella serotype typhi, particularly for strains acquired outside the U.S.

Mechanism of Action. Chloramphenicol inhibits protein synthesis in bacteria, and to a lesser extent, in eukaryotic cells. The drug readily penetrates bacterial cells, probably by facilitated diffusion. Chloramphenicol acts primarily by binding reversibly to the 50S ribosomal subunit (near the binding site for the macrolide antibiotics and clindamycin, which chloramphenicol inhibits competitively). Although binding of tRNA at the codon recognition site on the 30S ribosomal subunit is undisturbed, the drug apparently prevents the binding of the amino acid–containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate cannot occur, and peptide bond formation is inhibited (Figure 55–2).

Chloramphenicol also can inhibit mitochondrial protein synthesis in mammalian cells, perhaps because mitochondrial ribosomes resemble bacterial ribosomes (both are 70S) more than they do the 80S cytoplasmic ribosomes of mammalian cells. The peptidyltransferase of mitochondrial ribosomes, but not of cytoplasmic ribosomes, is inhibited by chloramphenicol. Mammalian erythropoietic cells are particularly sensitive to the drug.

Resistance to Chloramphenicol. Resistance to chloramphenicol usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug. Resistance also can result from decreased permeability and from ribosomal mutation. Acetylated derivatives of chloramphenicol fail to bind to bacterial ribosomes.

Absorption, Distribution, Fate, and Excretion. Chloramphenicol is absorbed rapidly from the GI tract, and peak concentrations of 10–13 μg/mL occur within 2–3 hours after the administration of a 1-g dose. The product for oral administration is no longer available in the U.S. The preparation of chloramphenicol for parenteral use is the water-soluble, inactive prodrug sodium succinate. Similar concentrations of chloramphenicol succinate in plasma are achieved after intravenous and intramuscular administration. Hydrolysis of chloramphenicol succinate by esterases occurs in vivo. Chloramphenicol succinate is rapidly cleared from plasma by the kidneys; this may reduce overall bioavailability of the drug because as much as 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of chloramphenicol succinate. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active chloramphenicol (up to 4 hours) and extending the period over which renal clearance of chloramphenicol succinate can occur.

Chloramphenicol is widely distributed in body fluids and readily reaches therapeutic concentrations in CSF, where values are ~60% of those in plasma (range, 45-99%) in the presence or absence of meningitis. The drug actually may accumulate in the brain. Chloramphenicol is present in bile, milk, and placental fluid. It also is found in the aqueous humor after subconjunctival injection.

Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and chloramphenicol itself are excreted in the urine following filtration and secretion. Patients with cirrhosis or otherwise impaired hepatic function have decreased metabolic clearance, and dosage should be adjusted in these individuals. The t1/2 of chloramphenicol correlates with plasma bilirubin concentrations. About 50% of chloramphenicol is bound to plasma proteins; such binding is reduced in cirrhotic patients and in neonates. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dosage adjustment usually is not required. However, if the dose of chloramphenicol has been reduced because of cirrhosis, clearance by hemodialysis may be significant. This effect can be minimized by administering the drug at the end of hemodialysis. Significant variability in the metabolism and pharmacokinetics of chloramphenicol in neonates, infants, and children necessitates monitoring of drug concentrations in plasma.

Therapeutic Uses and Dosage. Therapy with chloramphenicol must be limited to infections for which the benefits of the drug outweigh the risks of the potential toxicities. When other antimicrobial drugs that are equally effective and potentially less toxic are available, they should be used instead of chloramphenicol (Wareham and Wilson, 2002).

Typhoid Fever. Third-generation cephalosporins and quinolones are drugs of choice for the treatment of typhoid fever because they are
less toxic and because strains of *Salmonella typhi* often are resistant to chloramphenicol (Parry, 2003).

The adult dose of chloramphenicol for typhoid fever is 1 g every 6 hours for 4 weeks. Although intravenous and oral routes have been used, the response is more rapid with oral administration. Provided that the primary isolate is sensitive, relapses respond satisfactorily to retreatment.

**Bacterial Meningitis.** Third-generation cephalosporins have replaced chloramphenicol in the therapy of bacterial meningitis (Quagliarello and Scheld, 1997). Chloramphenicol remains an alternative drug for the treatment of meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* in patients who have severe allergy to β-lactams and in developing countries (Fuller et al., 2003). The total daily dose for children should be 50 mg/kg of body weight, divided into four equal doses given intravenously every 6 hours. Results with chloramphenicol used for pneumococcal meningitis may be unsatisfactory because some strains are inhibited but not killed. Moreover, penicillin-resistant strains frequently also are resistant to chloramphenicol (Hoban et al., 2001). In the rare situation in which chloramphenicol must be used to treat pneumococcal meningitis, lumbar puncture should be repeated 2-3 days after treatment is initiated to ensure that an adequate response has occurred.

**Rickettsial Diseases.** The tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. However, in patients allergic to these drugs, in those with reduced renal function, in pregnant women, and in children <8 years of age who require prolonged or repeated courses of therapy, chloramphenicol may be the drug of choice. Rocky Mountain spotted fever, epidemic, murine, scrub, and recrudescent typhus, and Q fever respond well to chloramphenicol. For adults and children with these diseases, a dosage of 50 mg/kg/day divided into 6-hour intervals is recommended. For severe or resistant infections, doses up to 100 mg/kg/day may be used for short intervals, but the dose be reduced to 50 mg/kg/day as soon as possible. Therapy should be continued until the general condition has improved and the patient is afebrile for 24-48 hours.

**Untoward Effects.** Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. These include subunits of cytochrome c oxidase, ubiquinone-cytochrome c reductase, and the proton-translocating ATPase critical for aerobic metabolism. Much of the toxicity observed with this drug can be attributed to these effects.

**Hypersensitivity Reactions.** Although relatively uncommon, macular or vesicular skin rashes result from hypersensitivity to chloramphenicol. Fever may appear simultaneously or be the sole manifestation. Angioedema is a rare complication. Jarisch-Herxheimer reactions may occur after administration of chloramphenicol therapy for syphilis, brucellosis, and typhoid fever.

**Hematological Toxicity.** The most important adverse effect of chloramphenicol is on the bone marrow. Chloramphenicol affects the hematopoietic system in two ways: a dose-related toxicity that presents as anemia, leukopenia, or thrombocytopenia, and an idiosyncratic response manifested by aplastic anemia, leading in many cases to fatal pancytopenia. Pancytopenia seems to occur more commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on more than one occasion. A genetic predisposition is suggested by the occurrence of pancytopenia in identical twins. Although the incidence of the reaction is low, ~1 in ≥30,000 courses of therapy, the fatality rate is high when bone marrow aplasia is complete, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for ~70% of cases of blood dyscrasias due to chloramphenicol; hypoplastic anemia, agranulocytosis, and thrombocytopenia make up the remainder. The exact biochemical mechanism has not yet been elucidated but is hypothesized to involve conversion of the nitro group to a toxic intermediate by intestinal bacteria.

The risk of aplastic anemia does not contraindicate the use of chloramphenicol in situations in which it may be lifesaving. The drug should never be used, however, in undefined situations or in diseases readily, safely, and effectively treatable with other antimicrobial agents.

Dose-related, reversible erythroid suppression probably reflects an inhibitory action of chloramphenicol on mitochondrial protein synthesis in erythroid precursors, which in turn impairs iron incorporation into heme. Leukopenia and thrombocytopenia also may occur. Bone marrow suppression occurs regularly when plasma concentrations are ≥25 μg/mL and is observed with the use of large doses of chloramphenicol, prolonged treatment, or both. Dose-related suppression of the bone marrow may progress to fatal aplasia if treatment is continued, but most cases of bone marrow aplasia develop suddenly, without prior dose-related marrow suppression. Some patients who developed chronic bone marrow hypoplasia after chloramphenicol treatment subsequently developed acute myeloblastic leukemia. The administration of chloramphenicol in the presence of hepatic disease frequently depresses erythropoiesis. About one-third of patients with severe renal insufficiency exhibit the same reaction.

**Other Toxic and Irritative Effects.** Nausea and vomiting, unpleasant taste, diarrhea, and perineal irritation may follow the oral administration of chloramphenicol. Blurring of vision and digital paresthesias may rarely occur. Tissues that have a high rate of oxygen consumption may be particularly susceptible to chloramphenicol effects on mitochondrial enzyme systems; encephalopathy and cardiomyopathy have been reported.

Neonates, especially if premature, may develop a serious illness termed gray baby syndrome if exposed to excessive doses of chloramphenicol. This syndrome usually begins 2-9 days (average of 4 days) after treatment is started. Within the first 24 hours, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose green stools occur. The children all are severely ill by the end of the first day, and in the next 24 hours turn an ashen-gray color and become flaccid and hypothermic. A similar “gray syndrome” has been reported in adults who were accidentally overdosed with the drug. Death occurs in ~40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae.

Two mechanisms apparently are responsible for chloramphenicol toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes chloramphenicol, in the first 3-4 weeks of life; and (2) inadequate renal excretion of unconjugated drug. At the onset of the clinical syndrome, chloramphenicol concentrations in plasma usually exceed 100 μg/mL, although they may be as low as 75 μg/mL. Children ≤2 weeks of age should receive chloramphenicol in a daily dose no larger than 25 mg/kg of body weight; after this age, full-term infants may be given daily quantities up to 50 mg/kg. Toxic effects have not been observed in the newborns when as much as 1 g of the antibiotic has been given every 2 hours to the mothers during labor.
**Drug Interactions.** Chloramphenicol inhibits hepatic CYPs and thereby prolongs the half-lives of drugs that are metabolized by this system, including warfarin, dicumarol, phenytoin, chlorpropamide, antiretroviral protease inhibitors, rifabutin, and tolbutamide. Severe toxicity and death have occurred because of failure to recognize such effects. Conversely, other drugs may alter the elimination of chloramphenicol. Concurrent administration of phenobarbital or rifampin, which potently induce CYPs, shortens the $t_{1/2}$ of the antibiotic and may result in subtherapeutic drug concentrations.

**MACROLIDES AND KETOLIDES**

Erythromycin was discovered in 1952 by McGuire and coworkers in the metabolic products of a strain of *Streptomyces erythreus*. Clarithromycin (BIAXIN, others) and azithromycin (ZITHROMAX, others) are semisynthetic derivatives of erythromycin. Ketolides are semisynthetic derivatives of erythromycin with activity against some macrolide-resistant strains. Telithromycin (KETEK) is the only ketolide currently approved in the U.S. Although the ketolides are promising agents against drug-resistant organisms, substantial hepatotoxicity seen with telithromycin has limited their use.

Macrolide antibiotics contain a many-membered lactone ring (14-membered rings for erythromycin and clarithromycin and a 15-membered ring for azithromycin) to which are attached one or more deoxy sugars. Clarithromycin differs from erythromycin only by methylation of the hydroxyl group at the 6 position, and azithromycin differs by the addition of a methyl-substituted nitrogen atom into the lactone ring. These structural modifications improve acid stability and tissue penetration and broaden the spectrum of activity.

**Antimicrobial Activity.** Erythromycin usually is bacteriostatic but may be bactericidal in high concentrations against susceptible organisms. The antibiotic is most active in vitro against aerobic gram-positive cocci and bacilli (Table 55–2). Staphylococci are considered susceptible at $\leq 0.5 \, \mu g/mL$ and streptococci at $\leq 0.25 \, \mu g/mL$. Macrolide resistance among *S. pneumoniae* often co-exists with penicillin resistance. Staphylococci are not reliably sensitive to erythromycin, especially methicillin-resistant strains. Macrolide-resistant strains of *S. aureus* are potentially cross-resistant to clindamycin and streptogramin B (quinupristin). Gram-positive bacilli also are sensitive to erythromycin; typical MICs are 1 $\mu g/mL$ for *Clostridium perfringens*, from 0.2 to 3 $\mu g/mL$ for *Corynebacterium diphtheriae*, and from 0.25 to 4 $\mu g/mL$ for *Listeria monocytogenes*.

Erythromycin is inactive against most aerobic enteric gram-negative bacilli. It has modest activity in vitro against other gram-negative organisms, including *H. influenzae* (MIC, 1-32 $\mu g/mL$) and *N. meningitidis* (MIC, 0.4-1.6 $\mu g/mL$), and good activity against most strains of *N. gonorrhoeae* (MIC, 0.12-2 $\mu g/mL$). Useful antibacterial activity also is observed against *Pasteurella multocida*, *Borrelia* spp., and *Bordetella pertussis*. Resistance is common for *B. fragilis* (the MIC ranging from 2-32 $\mu g/mL$). Macrolides are usually active against *Campylobacter jejuni* (MIC, 0.5-4 $\mu g/mL$). Erythromycin is active against *M. pneumoniae* (MIC, 0.004-0.02 $\mu g/mL$) and *Legionella pneumophila* (MIC, 0.01-2 $\mu g/mL$). Most strains of *C. trachomatis* are inhibited by 0.06-2 $\mu g/mL$ of erythromycin. Some of the atypical mycobacteria, including *M. scrofulaceum*, are sensitive to erythromycin in vitro; *M. kansasi* and *M. avium-intracellulare* vary in sensitivity. *M. fortuitum* is resistant. Macrolides have no effect on viruses, yeasts, or fungi.
In general, organisms are considered susceptible to clarithromycin and azithromycin at MICs ≤ 2 μg/mL.

Clarithromycin and azithromycin have some activity against *H. influenzae*, with MIC breakpoints of ≤8 μg/mL and ≤4 μg/mL, respectively. However, these agents are not drugs of choice for documented *H. influenzae* infections because of their lesser activity compared to β-lactams or fluoroquinolones. Clarithromycin is slightly more potent than erythromycin against sensitive strains of streptococci and staphylococci, and has modest activity against *H. influenzae* and *N. gonorrhoeae*. Azithromycin generally is less active than erythromycin against gram-positive organisms and slightly more active than either erythromycin or clarithromycin against *H. influenzae* and *Campylobacter* spp. Clarithromycin and azithromycin have good activity against *M. catarrhalis*, *Chlamydia* spp., *L. pneumophila*, *B. burgdorferi*, *Mycoplasma pneumoniae*, and *H. pylori*. Azithromycin and clarithromycin have enhanced activity against *M. avium-intracellulare*, as well as against some protozoa (e.g., *Toxoplasma gondii*, *Cryptosporidium*, and *Plasmodium* spp.). Clarithromycin has good activity against *Mycobacterium leprae*.

Telithromycin’s spectrum of activity is similar to clarithromycin and azithromycin. MIC breakpoints for telithromycin are ≤0.25 μg/mL for *S. aureus*, ≤1 μg/mL for *S. pneumoniae*, and ≤4 μg/mL for *H. influenzae*. Telithromycin’s ability to withstand many macrolide resistance mechanisms increases its activity against macrolide-resistant *S. pneumoniae* and *S. aureus*.

**Mechanism of Action.** Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms (Figure 55–3), at or very near the site that binds chloramphenicol (Figure 55–2). Erythromycin does not inhibit peptide bond formation per se but rather inhibits the translocation step wherein a newly synthesized peptidyl-tRNA molecule moves from the acceptor site on the ribosome to the peptidyl donor site. Gram-positive bacteria accumulate ~100 times more erythromycin than do gram-negative bacteria. Cells are considerably donor site. Gram-positive bacteria accumulate ~100 times more erythromycin than do gram-negative bacteria.

**Resistance to Macrolides and Ketolides.** Resistance to macrolides usually results from one of four mechanisms:

- drug efflux by an active pump mechanism (encoded by *mrsA*, *mefA*, or *mefE* in staphylococci, group A streptococci, or *S. pneumoniae*, respectively)
- ribosomal protection by inducible or constitutive production of methylase enzymes, mediated by expression of *ermA*, *ermB*, and *ermC*, which modify the ribosomal target and decrease drug binding
- macrolide hydrolysis by esterases produced by Enterobacteriaceae (Lina et al., 1999; Nakajima, 1999)
- chromosomal mutations that alter a 50S ribosomal protein (found in *B. subtilis*, *Campylobacter* spp., mycobacteria, and gram-positive cocci)

The MLSB (macrolide-lincosamide-streptogramin B) phenotype is conferred by *erm* genes, which encode methylases that modify the macrolide binding of the ribosome. Because macrolides, lincosamides, and type B streptogramins share the same ribosomal binding site, constitutive expression of *erm* confers cross-resistance to all three drug classes. If resistance is due to inducible expression of *erm*, there is resistance to the macrolides, which are inducers of *erm*, but not to lincosamides and streptogramin B, which are not inducers. Cross-resistance can still occur if constitutive mutants are selected by exposure to lincosamides or streptogramin B. Efflux-mediated resistance to macrolides may not result in cross-resistance to lincosamides or streptogramin B because they are structurally dissimilar to macrolides and are not substrates of the macrolide pump.

Introduction of the 3-keto function converts a methylase-inducing macrolide into a noninducing ketolide. This moiety also prevents drug efflux, probably because it generates a less-desirable substrate. The carbamate substitution at C11-C12 enhances binding to the ribosomal target site, even when the site is methylated, by introducing an extra interaction of the ketolide with the ribosome. Inducible and constitutive methylase-producing strains of *S. pneumoniae* are therefore susceptible to telithromycin. However, constitutive methylase-producing strains of *S. aureus* and *S. pyogenes* are telithromycin resistant because the strength of the ketolide interaction...
with the fully methylated ribosomal binding site is insufficient to overcome resistance. Constitutive methylase producers can be selected from strains with the inducible \textit{erm} phenotype.

\textbf{Absorption, Distribution, and Excretion.}

\textit{Absorption.} Erythromycin base is incompletely but adequately absorbed from the upper small intestine. Because it is inactivated by gastric acid, the drug is administered as enteric-coated tablets, as capsules containing enteric-coated pellets that dissolve in the duodenum, or as an ester. Food, which increases gastric acidity, may delay absorption.

Peak serum concentrations are 0.3-0.5 \(\mu\)g/mL, 4 hours after oral administration of 250 mg of the base, and 0.3-1.9 \(\mu\)g/mL after a single dose of 500 mg. Esters of erythromycin base (e.g., stearyl, estolate, and ethylsuccinate) have improved acid stability, and their absorption is less altered by food. A single oral 250-mg dose of erythromycin estolate produces peak serum concentrations of \(\sim\)1.5 \(\mu\)g/mL after 2 hours, and a 500-mg dose produces peak concentrations of 4 \(\mu\)g/mL. Peak serum concentrations of erythromycin ethylsuccinate are 1.5 \(\mu\)g/mL (0.5 \(\mu\)g/mL of base) 1-2 hours after administration of a 500-mg dose. These peak values include the inactive ester and the free base, the latter of which comprises 20-35\% of the total. The concentration of microbiologically active erythromycin base in serum therefore is similar for the various preparations. Higher concentrations of erythromycin can be achieved by intravenous administration. Values are \(\sim\)10 \(\mu\)g/mL 1 hour after intravenous administration of 500-1000 mg of erythromycin lactobionate.

Clarithromycin is absorbed rapidly from the GI tract after oral administration, but first-pass metabolism reduces its bioavailability to 50-55\%. Peak concentrations occur \(\sim\)2 hours after drug administration. Clarithromycin may be given with or without food, but the extended-release form, typically given once daily as a 1-g dose, should be administered with food to improve bioavailability. Steady-state peak concentrations in plasma of 2-3 \(\mu\)g/mL are achieved after 2 hours with a regimen of 500 mg every 12 hours, or after 2-4 hours with two 500-mg extended-release tablets given once daily.

Azithromycin administered orally is absorbed rapidly and distributes widely throughout the body, except to the brain and CSF. Concomitant administration of aluminum and magnesium hydroxide antacids decreases the peak serum drug concentrations but not overall bioavailability. Azithromycin should not be administered with food. A 500-mg loading dose will produce a peak plasma drug concentration of \(\sim\)0.4 \(\mu\)g/mL. When this loading dose is followed by 250 mg once daily for 4 days, the steady-state peak drug concentration is 0.24 \(\mu\)g/mL. Azithromycin also can be administered intravenously, producing plasma concentrations of 3-4 \(\mu\)g/mL after a 1-hour infusion of 500 mg.

Telithromycin is formulated as a 400-mg tablet for oral administration. There is no parenteral form. It is well absorbed with \(\sim\)60\% bioavailability. Peak serum concentrations, averaging 2 \(\mu\)g/mL following a single 800-mg oral dose, are achieved within 30 minutes to 4 hours.

\textit{Distribution.} Erythromycin diffuses readily into intracellular fluids, achieving antibacterial activity in essentially all sites except the brain and CSF. Erythromycin penetrates into prostatic fluid, achieving concentrations \(\sim\)40\% of those in plasma. Concentrations in middle ear exudate reach only 50\% of serum concentrations and thus may be inadequate for the treatment of otitis media caused by \textit{H. influenzae}.

Protein binding is \(\sim\)70-80\% for erythromycin base and even higher, 96\%, for the estolate. Erythromycin traverses the placenta, and drug concentrations in fetal plasma are \(\sim\)5-20\% of those in the maternal circulation. Concentrations in breast milk are 50\% of those in serum.

Clarithromycin and its active metabolite, 14-hydroxyclarithromycin, distribute widely and achieve high intracellular concentrations throughout the body. Tissue concentrations generally exceed serum concentrations. Concentrations in middle-ear fluid are 50\% higher than simultaneous serum concentrations for clarithromycin and the active metabolite. Protein binding of clarithromycin ranges from 40\% to 70\% and is concentration dependent.

Azithromycin’s unique pharmacokinetic properties include extensive tissue distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. Tissue fibroblasts act as the natural reservoir for the drug \textit{in vivo}. Protein binding is 50\% at very low plasma concentrations and less at higher concentrations.

Telithromycin is 60-70\% bound by serum protein, principally albumin. It penetrates well into most tissues, exceeding plasma concentrations by \(\sim\)2-fold to \(\geq\)10-fold. Telithromycin is concentrated in macrophages and white blood cells, where concentrations of 40 \(\mu\)g/mL (500 times the simultaneous plasma concentration) are maintained 24 hours after dosing.

\textit{Elimination.} Only 2-5\% of orally administered erythromycin is excreted in active form in the urine; this value is from 12-15\% after intravenous infusion. The antibiotic is concentrated in the liver and excreted in the bile, which may contain as much as 250 \(\mu\)g/mL when serum concentrations are very high. The serum elimination \(t_{1/2}\) of erythromycin is \(\sim\)1.6 hours. Although the \(t_{1/2}\) may be prolonged in patients with anuria, dosage reduction is not routinely recommended in renal failure patients. The drug is not removed significantly by either peritoneal dialysis or hemodialysis.

Clarithromycin is eliminated by renal and nonrenal mechanisms. It is metabolized in the liver to several metabolites; the active 14-hydroxy metabolite is the most significant. Primary metabolic pathways are oxidative N-demethylation and hydroxylation at the 14 position. The elimination half-lives are 3-7 hours for clarithromycin and 5-9 hours for 14-hydroxyclarithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics with higher dosages; longer half-lives are observed after larger doses. The amount of clarithromycin excreted unchanged in the urine ranges from 20\% to 40\%, depending on the dose administered and the formulation (tablet versus oral suspension). An additional 10-15\% of a dose is excreted in the urine as 14-hydroxyclarithromycin. Although the pharmacokinetics of clarithromycin are altered in patients with either hepatic or renal dysfunction, dose adjustment is not necessary unless the creatinine clearance is <30 mL/minute.

Azithromycin undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12\% of drug is excreted unchanged in the urine. The elimination \(t_{1/2}\), 40-68 hours, is prolonged because of extensive tissue sequestration and binding.

With a \(t_{1/2}\) of 9.8 hours, telithromycin can be given once daily. The drug is cleared primarily by hepatic metabolism, 50\% by CYP3A4 and 50\% by CYP-independent metabolism. No adjustment of the dose is required for hepatic failure or mild-to-moderate renal
failure. No dose has been established for patients in whom creatinine clearance is <30 mL/minute, although a reduction in dosage probably is advisable (Shi et al., 2004).

**Therapeutic Uses and Dosage.** Depending on the nature and severity of the infection, the usual oral dose of erythromycin (erythromycin base) for adults ranges from 1-2 g per day, in equally divided and spaced amounts, usually given every 6 hours. Erythromycin base is available as immediate release (film-coated) and delayed-release (enteric-coated) tablets. Daily doses of erythromycin as large as 8 g orally, given for 3 months, have been well tolerated. Food should not be taken concurrently, if possible, with erythromycin base or the stearate formulations, but this is not necessary with erythromycin estolate. The oral dose of erythromycin for children is 30-50 mg/kg per day, divided into four portions; this dose may be doubled for severe infections. Intramuscular administration of erythromycin is not recommended because of pain upon injection. Intravenous administration is generally reserved for the therapy of severe infections, such as legionellosis. The usual dose is 0.5-1 g every 6 hours; 1 g of erythromycin gluceptate (not available in the U.S.) has been given intravenously every 6 hours for as long as 4 weeks with no adverse effects except for thrombophlebitis at the site of injection. Erythromycin lactobionate is available for intravenous injection. The combination of erythromycin and sulfisoxazole appears to have synergistic antibacterial activity; it is available as a suspension used primarily for treatment of otitis media in children.

Clarithromycin (BIAXIN, others) usually is given twice daily at a dose of 250 mg for children >12 years and adults with mild to moderate infection. Larger doses (e.g., 500 mg twice daily) are indicated for more severe infection such as pneumonia or when infection is caused by more resistant organisms such as *H. influenzae*. Children <12 years old have received 7.5 mg/kg twice daily in clinical studies. The 500-mg extended-release formulation is given as two tablets once daily. Clarithromycin (500 mg) is also packaged with lansoprazole (30 mg) and amoxicillin (1 g) as a combination regimen (PREVPAC) that is administered twice daily for 10 or 14 days to eradicate *H. pylori* and to reduce the associated risk of duodenal ulcer recurrence (Chapter 45).

Azithromycin (ZITHROMAX, other) should be given 1 hour before or 2 hours after meals when administered orally. For outpatient therapy of community-acquired pneumonia, pharyngitis, or skin and skin-structure infections, a loading dose of 500 mg is given on the first day, and then 250 mg per day is given for days 2 through 5. A single 2-g dose of extended-release microspheres is an alternative regimen for treatment of community-acquired pneumonia or acute exacerbations of chronic bronchitis. Treatment or prophylaxis of *M. avium-intracellulare* infection in AIDS patients requires higher doses: 600 mg daily in combination with one or more other agents for treatment, or 1200 mg once weekly for primary prevention (Kovacs and Masur, 2000). Azithromycin is useful in treatment of sexually transmitted diseases, especially during pregnancy when tetracyclines are contraindicated. The treatment of uncomplicated nongonococcal urethritis presumed to be caused by *C. trachomatis* consists of a single 1-g dose of azithromycin. This dose also is effective for chancroid. Azithromycin (1 g per week for 3 weeks) is an alternative regimen for treatment of granuloma inguinale or lymphogranuloma venereum.

In children, the recommended dose of azithromycin oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum: 500 mg) and 5 mg/kg (maximum: 250 mg per day) on days 2 through 5. A single 30 mg/kg dose is approved as an alternative for otitis media. The dose for tonsillitis or pharyngitis is 12 mg/kg per day, up to 500 mg total, for 5 days.

**Respiratory Tract Infections.** Macrolides and ketolides are suitable drugs for the treatment of a number of respiratory tract infections due to their activity against *Streptococcus pneumoniae*, *Haemophilus influenzae*, and atypical pathogens (*Mycoplasma, Chlamydophilia, Legionella*). Azithromycin and clarithromycin are suitable choices for treatment of mild to moderate community-acquired pneumonia among ambulatory patients. In hospitalized patients, a macrolide is commonly added to a cephalosporin for coverage of atypical respiratory pathogens. Macrolides, fluoroquinolones, and tetracyclines are drugs of choice for treatment of pneumonia caused by *Chlamydia pneumoniae* or *Mycoplasma pneumoniae*. Erythromycin has been considered as the drug of choice for treatment of pneumonia caused by *L. pneumophila, L. micdadei,* or other *Legionella* spp. Because of excellent in vitro activity, superior tissue concentration, the ease of administration as a single daily dose, and better tolerability compared to erythromycin, azithromycin (or a fluoroquinolone) has supplanted erythromycin as the first-line agent for treatment of legionellosis (Garey and Amsden, 1999). The recommended dose is 500 mg daily, intravenously or orally, for a total of 10-14 days.

Macrolides are also appropriate alternative agents for the treatment of acute exacerbations of chronic bronchitis, acute otitis media, acute streptococcal pharyngitis, and acute bacterial sinusitis. Azithromycin or clarithromycin are generally preferred to erythromycin for these indications due to their broader spectrum and superior tolerability.

Telithromycin has shown to be effective in the treatment of community-acquired pneumonia, acute exacerbations of chronic bronchitis, and acute bacterial sinusitis, and has a potential advantage over macrolides in regions where macrolide-resistant strains are common. However, due to a number of cases of severe hepatotoxicity due to telithromycin, telithromycin’s U.S. FDA approval for treatment
of acute exacerbations of chronic bronchitis and sinusitis have been resceded, leaving only its indication for community-acquired pneumonia. Because of the substantial risk of serious hepatotoxicity, telithromycin should be used only in circumstances where it provides a substantial advantage over less toxic therapies.

**Skin and Soft-Tissue Infections.** Macrolides are alternatives for treatment of erysipelas and cellulitis among patients who have a serious allergy to penicillin. Unfortunately, macrolide-resistant strains of staphylococci and streptococci are increasingly encountered. Erythromycin has been an alternative agent for the treatment of relatively minor skin and soft-tissue infections caused by either penicillin-sensitive or penicillin-resistant *S. aureus*. However, many strains of *S. aureus* are resistant to macrolides, and they no longer can be relied on unless *in vitro* susceptibility has been documented.

**Chlamydial Infections.** Chlamydial infections can be treated effectively with any of the macrolides. A single 1-g dose of azithromycin is recommended for patients with uncomplicated urethral, endocervical, rectal, or epididymal infections because of the ease of compliance. During pregnancy, erythromycin base, 500 mg four times daily for 7 days, is recommended as first-line therapy for chlamydial urogenital infections. Azithromycin, 1 g orally as a single dose, is a suitable alternative. Erythromycin base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg per day in four divided doses for 10-14 days). Azithromycin, 1 g/week for 3 weeks, may be effective for lymphogranuloma venereum.

**Diphtheria.** Erythromycin, 250 mg four times daily for 7 days, is very effective for acute infections or for eradicating the carrier state. The other macrolides also are likely to be effective; because clinical experience with them is lacking, they are not FDA-approved for this indication. The presence of an antibiotic does not alter the course of an acute infection with the diphtheria bacillus or the risk of complications. Antitoxin is indicated in the treatment of acute infection.

**Pertussis.** Erythromycin is the drug of choice for treating persons with *B. pertussis* disease and for postexposure prophylaxis of household members and close contacts. A 7-day regimen of erythromycin estolate (40 mg/kg per day; maximum: 1 g/day; not available in U.S) is as effective as the 14-day regimens traditionally recommended (Halperin et al., 1997). Clarithromycin and azithromycin also are effective (Bace et al., 1999). If administered early in the course of whooping cough, erythromycin may shorten the duration of illness; it has little influence on the disease once the paroxysmal stage is reached, although it may eliminate the microorganisms from the nasopharynx. Nasopharyngeal cultures should be obtained from people with pertussis who do not improve with erythromycin therapy because resistance has been reported.

**Campylobacter Infections.** The treatment of gastroenteritis caused by *C. jejuni* with erythromycin (250-500 mg orally four times a day for 7 days) hastens eradication of the microorganism from the stools and reduces the duration of symptoms. Availability of fluoroquinolones, which are highly active against *Campylobacter* species and other enteric pathogens, largely has replaced the use of erythromycin for this disease in adults. Erythromycin remains useful for treatment of *Campylobacter* gastroenteritis in children.

**Helicobacter pylori Infection.** Clarithromycin, 500 mg, in combination with omeprazole, 20 mg, and amoxicillin, 1 g (PREVPAC), each administered twice daily for 10-14 days, is effective for treatment of peptic ulcer disease caused by *H. pylori* (Peterson et al., 2000). Numerous other regimens, some effective as 7-day treatments, have been studied and also are effective. The more effective regimens generally include three agents, one of which usually is clarithromycin (Chapter 45).

**Mycobacterial Infections.** Clarithromycin or azithromycin is recommended as first-line therapy for prophylaxis and treatment of disseminated infection caused by *M. avium-intracellulare* in AIDS patients and for treatment of pulmonary disease in patients not infected with HIV (Kovacs and Masur, 2000). Azithromycin (1.2 g once weekly) or clarithromycin (500 mg twice daily) is recommended for primary prevention for AIDS patients with <50 CD4 cells/mm³. Single-agent therapy should not be used for treatment of active disease or for secondary prevention in AIDS patients. Clarithromycin (500 mg twice daily) plus ethambutol (15 mg/kg once daily) with or without rifabutin is an effective combination regimen. Azithromycin (500 mg once daily) may be used instead of clarithromycin, but clarithromycin appears to be slightly more efficacious (Ward et al., 1998). Clarithromycin also has been used with minocycline for the treatment of *Mycobacterium leprae* in lepromatous leprosy.

**Prophylactic Uses.** Penicillin is the drug of choice for the prophylaxis of recurrences of rheumatic fever. Erythromycin is an effective alternative for individuals who are allergic to penicillin. Clarithromycin or azithromycin (or clindamycin) are recommended alternatives for the prevention of bacterial endocarditis in patients undergoing dental procedures who are at high risk for endocarditis (Wilson et al., 2007).

**Untoward Effects.**

- **Hepatotoxicity.** Cholestatic hepatitis is the most striking side effect. It is caused primarily by erythromycin estolate and rarely by the ethylsuccinate or the stearate. The illness starts after 10-20 days of treatment and is characterized initially by nausea, vomiting, and abdominal cramps. The pain often mimics that of acute cholecystitis. These symptoms are followed shortly thereafter by jaundice, which may be accompanied by fever, leukocytosis, eosinophilia, and elevated transaminases in plasma. Biopsy of the liver reveals cholestasis, periporal infiltration by neutrophils, lymphocytes, and eosinophils, and occasionally, necrosis of neighboring parenchymal cells. Findings usually resolve within a few days after cessation of drug therapy and rarely are prolonged. The syndrome may represent a hypersensitivity reaction to the estolate ester.

  Hepatotoxicity has also been observed with clarithromycin and azithromycin, although at a lower rate than with erythromycin. After its regulatory approval and widespread use, a number of postmarketing reports of severe telithromycin-induced hepatotoxicity emerged. These cases tended to have a short latency between drug initiation and manifestation of hepatotoxicity, with some leading to death or liver transplantation (Brinker et al., 2009). Because of this toxicity, telithromycin should only be used in circumstances where it represents a clear advantage over alternative agents.

- **GI Toxicity.** Oral administration of erythromycin, especially of large doses, frequently is accompanied by epigastric distress, which may be quite severe. Intravenous administration of erythromycin may cause similar symptoms, with abdominal cramps, nausea, vomiting, and diarrhea. Erythromycin stimulates GI motility by acting on motilin receptors. Because of this property, erythromycin is used postoperatively to promote peristalsis; it has been exploited to speed
gastric emptying in patients with gastroparesis (Chapter 46). The GI symptoms are dose related and occur more commonly in children and young adults; they may be reduced by prolonging the infusion time to 1 hour or by pretreatment with glycopyrrolate (Bowler et al., 1992). Intravenous infusion of 1-g doses, even when dissolved in a large volume, often is followed by thrombophlebitis. This can be minimized by slow rates of infusion. Clarithromycin, azithromycin, and telithromycin also may cause GI distress, but typically to a lesser degree than that seen with erythromycin.

**Cardiac toxicity.** Erythromycin, clarithromycin, and telithromycin have been reported to cause cardiac arrhythmias, including QT prolongation with ventricular tachycardia. Most patients have had underlying risk factors, such as prolonged QT syndrome, uncorrected hypokalemia or hypomagnesemia, profound bradycardia, or in patients receiving certain antiarrhythmics (e.g., quinidine, procaainamide, amiodarone) or other agents that prolong QTc (e.g., cisapride, pimozide).

Other Toxic and Irritative Effects. Among the allergic reactions observed are fever, eosinophilia, and skin eruptions, which may occur alone or in combination; each disappears shortly after therapy is stopped. Transient auditory impairment is a potential complication of treatment with erythromycin; it has been observed to follow intravenous administration of large doses of the glucuronide or lactobionate (4 g per day) or oral ingestion of large doses of the esolate. Visual disturbances due to slowed accommodation have been reported to occur in ~1% of treatment courses with telithromycin, and they include blurred vision, difficulty focusing, and diplopia. Telithromycin is contraindicated in patients with myasthenia gravis due to reports of exacerbation of neurological symptoms by the antibiotic in these patients. Loss of consciousness and visual disturbances are associated with telithromycin.

**Drug Interactions.** Erythromycin, clarithromycin, and telithromycin inhibit CYP3A4 and are associated with clinically significant drug interactions (Periti et al., 1992). Erythromycin potentiates the effects of carbamazepine, corticosteroids, cyclosporine, digoxin, ergot alkaloids, theophylline, triazolam, valproate, and warfarin, probably by interfering with CYP-mediated metabolism of these drugs (Chapter 6). Clarithromycin, which is structurally related to erythromycin, has a similar drug interaction profile. Telithromycin is both a substrate and a strong inhibitor of CYP3A4. Co-administration of rifampin, a potent inducer of CYP, decreases the serum concentrations of telithromycin by 80%. CYP3A4 inhibitors (e.g., itraconazole) increase peak serum concentrations of telithromycin. Azithromycin, which differs from erythromycin and clarithromycin because of its 15-membered lactone ring structure, and dirithromycin, which is a longer-acting 14-membered lactone ring analog of erythromycin, appear to be free of these drug interactions. Caution is advised, nevertheless, when using azithromycin in conjunction with drugs known to interact with erythromycin.

**LINCOSAMIDES (CLINDAMYCIN)**

Clindamycin is a lincomamide, a derivative of the amino acid trans-L-4-n-proplyhygrinic acid, attached to a sulfur-containing derivative of an octose. It is a congener of lincomycin:

**Antimicrobial Activity.** Bacterial strains are susceptible to clindamycin at MICs of ≤0.5 μg/mL. Clindamycin generally is similar to erythromycin in its in vitro activity against susceptible strains of pneumococci, S. pyogenes, and viridans streptococci (Table 55–2). Methicillin-resistant strains of S. aureus usually are susceptible to clindamycin, but methicillin-resistant strains of S. aureus and coagulase-negative staphylococci frequently are resistant.

Clindamycin is more active than erythromycin or clarithromycin against anaerobic bacteria, especially B. fragilis; some strains are inhibited by <0.1 μg/mL, and most are inhibited by 2 μg/mL. The MICs for other anaerobes are as follows: *Bacteroides melaninogenicus*, 0.1 to 1 μg/mL; *Fusobacterium*, <0.5 μg/mL (although most strains of *Fusobacterium varium* are resistant); Peptostreptococcus, <0.1-0.5 μg/mL; Peptococcus, 1-100 μg/mL (with 10% of strains resistant); and *C. perfringens*, <0.1-8 μg/mL. From 10-20% of clostridial species other than *C. perfringens* are resistant. Resistance to clindamycin in *Bacteroides* spp. increasingly is encountered (Hedberg and Nord, 2003). Strains of *Actinomyces israeli* and *Nocardia asteroides* are sensitive. Essentially all aerobic gram-negative bacilli are resistant.

With regard to atypical organisms and parasites, *M. pneumoniae* is resistant. *Chlamydia* spp. are variably sensitive, although the clinical relevance is not established. Clindamycin plus primaquine and clindamycin plus pyrimethamine are second-line regimens for *Pneumocystis jiroveci* pneumonia and T. gondii encephalitis, respectively. Clindamycin has been used for treatment of babesiosis.

**Mechanism of Action.** Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although clindamycin, erythromycin, and chloramphenicol are not structurally related, they act at sites in close proximity (Figures 55–2 and 55–3), and binding by one of these antibiotics to the ribosome may inhibit the interaction of the others. There are no clinical indications for the concurrent use of these antibiotics.

**Resistance to Clindamycin.** Macrolide resistance due to ribosomal methylation by *erm*-encoded enzymes also may produce resistance to clindamycin. Because clindamycin does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. However, strains with inducible resistance may develop constitutive production of the methylase during therapy. Thus, many clinicians avoid use of clindamycin in the treatment of deep-seated infections due to organisms displaying an inducible resistance phenotype. Detection of this phenotype can be accomplished by approximating erythromycin and clindamycin on an agar plate with a lawn of the organism; a blunting of the zone of inhibition between clindamycin and erythromycin suggests inducible resistance (this is known as the “D-test”) (Lewis & Jorgensen, 2005). Clindamycin is not a substrate for macrolide efflux pumps; thus strains that are resistant to macrolides by this mechanism are susceptible to clindamycin.
These strains would not display a blunting of inhibition on a D-test, and clindamycin use would be appropriate. Altered metabolism occasionally causes clindamycin resistance (Bozdogan et al., 1999).

Absorption, Distribution, and Excretion

Absorption. Clindamycin is nearly completely absorbed following oral administration. Peak plasma concentrations of 2-3 μg/mL are attained within 1 hour after the ingestion of 150 mg. The presence of food in the stomach does not reduce absorption significantly. The \( t_{1/2} \) of the antibiotic is ~2.9 hours, and modest accumulation of drug is thus expected if it is given every 6 hours.

Clindamycin palmitate, an oral preparation for pediatric use, is an inactive prodrug that is hydrolyzed rapidly \( \textit{in vivo} \). Its rate and extent of absorption are similar to those of clindamycin. After several oral doses at 6-hour intervals, children attain plasma concentrations of 2-4 μg/mL with the administration of 8-16 μg/kg.

The phosphate ester of clindamycin, which is given parenterally, also is rapidly hydrolyzed \( \textit{in vivo} \) to the active parent compound. After intramuscular injection, peak concentrations in plasma are not attained until 3 hours in adults and 1 hour in children; these values approximate 6 μg/mL after a 300-mg dose and 9 μg/mL after a 600-mg dose in adults.

Distribution. Clindamycin is widely distributed in many fluids and tissues, including bone. Significant concentrations are not attained in CSF, even when the meninges are inflamed. Concentrations sufficient to treat cerebral toxoplasmosis are achievable (Gatti et al., 1998). The drug readily crosses the placental barrier. Ninety percent or more of clindamycin is bound to plasma proteins. Clindamycin accumulates in polymorphonuclear leukocytes, alveolar macrophages, and in abscesses.

Excretion. Only ~10% of the clindamycin administered is excreted unaltered in the urine, and small quantities are found in the feces. However, antimicrobial activity persists in feces for ≥5 days after parenteral therapy with clindamycin is stopped; growth of clindamycin-sensitive microorganisms in colonic contents may be suppressed for up to 2 weeks.

Clindamycin is inactivated by metabolism to N-demethylclindamycin and clindamycin sulfoxide, which are excreted in the urine and bile. Accumulation of clindamycin can occur in patients with severe hepatic failure, and dosage adjustments thus may be required.

Therapeutic Uses and Dosage. The oral dose of clindamycin (clindamycin hydrochloride; CLEOCIN, others) for adults is 150-300 mg every 6 hours; for severe infections, it is 300-600 mg every 6 hours. Children should receive 8-12 mg/kg per day of clindamycin palmitate hydrochloride (CLEOCIN PEDIATRIC) in three or four divided doses (some physicians recommend 10-30 mg/kg per day in six divided doses) or for severe infections, 13-25 mg/kg per day. However, children weighing ≤10 kg should receive 1/2 teaspoonful of clindamycin palmitate hydrochloride (37.5 mg) every 8 hours as a minimal dose. Clindamycin phosphate (CLEOCIN PHOSPHATE, others) is available for intramuscular or intravenous use. For serious infections, intravenous or intramuscular administration is recommended in dosages of 1200-2400 mg per day, divided into three or four equal doses for adults. Daily doses as high as 4.8 g have been given intravenously to adults. Children should receive 15-40 mg/kg per day in three or four divided doses; in severe infections, a minimal daily dose of 300 mg is recommended, regardless of body weight.

Skin and Soft-Tissue Infections. Because of clindamycin’s good activity against aerobic and anaerobic gram-positive cocci and good oral bioavailability, it is an alternative agent for the treatment of skin and soft-tissue infections, especially in patients with β-lactam allergies. However, the high incidence of diarrhea and the occurrence of pseudomembranous colitis should limit its use to infections where it represents a clear therapeutic advantage. Clindamycin has been employed in the treatment of necrotizing skin and soft-tissue infections based on its potential to reduce toxin expression.

Respiratory Tract Infections. On the basis of one clinical trial which found that clindamycin (600 mg intravenously every 8 hours) was superior to penicillin (1 million units intravaneously every 4 hours; Levison et al., 1983), clindamycin has replaced penicillin as the drug of choice for treatment of lung abscess and anaerobic lung and pleural space infections. Clindamycin (600 mg intravenously every 8 hours, or 300-450 mg orally every 6 hours for less severe disease) in combination with primaquine (15 mg of base once daily) is useful for the treatment of mild to moderate cases of \( P. jiroveci \) pneumonia in AIDS patients.

Other Infections. Clindamycin (600-1200 mg given intravenously every 6 hours) in combination with pyrimethamine (a 200-mg loading dose followed by 75 mg orally each day) and leucovorin (folinic acid, 10 mg/day) is effective for acute treatment of encephalitis caused by \( T. gondii \) in patients with AIDS. Clindamycin also is available as a topical solution, gel, or lotion (CLEOCIN T, others) and as a vaginal cream (CLEOCIN, others). It is effective topically (or orally) for acne vulgaris and bacterial vaginosis. Clindamycin is not predictably useful for the treatment of bacterial brain abscesses because penetration into the CSF is poor; metronidazole, in combination with penicillin or a third-generation cephalosporin, is preferred.

Untoward Effects.

Gastrointestinal Effects. The reported incidence of diarrhea associated with the administration of clindamycin ranges from 2% to 20%. A number of patients (variously reported as 0.01-10%) have developed pseudomembranous colitis caused by the toxin from the organism \( C. difficile \). This colitis is characterized by watery diarrhea, fever, and elevated peripheral white blood cell counts. Proctoscopic examination reveals white to yellow plaques on the mucosa of the colon. \textit{This syndrome may be lethal.} Discontinuation of the drug, combined with administration of metronidazole or oral vancomycin usually is curative, but relapses occur in up to 20% of cases. Agents that inhibit peristalsis, such as opioids, may prolong and worsen the condition.

Other Toxic and Irritative Effects. Skin rashes occur in ~10% of patients treated with clindamycin and may be more common in patients with HIV infection. Other reactions, which are uncommon, include exudative erythema multiforme (Stevens-Johnson syndrome), reversible elevation of aspartate aminotransferase and alanine aminotransferase, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration of the drug. Clindamycin can inhibit neuromuscular transmission and may potentiate the effect of a neuromuscular blocking agent administered concurrently.

STREPTOGRAMINS (QUINUPRISTIN/ DALFOPRISTIN)

Quinupristin/dalfopristin (SYNERCID) is a combination of quinupristin, a streptogramin B, with dalfopristin, a
streptogramin A, in a 30:70 ratio. These compounds are semisynthetic derivatives of naturally occurring pristinamycins, produced by *Streptomyces pristinaespiralis*. Pristinamycin has been available in France for >30 years for oral treatment of staphylococcal infections. Quinupristin and dalfopristin are more soluble derivatives of pristinamycin IA and pristinamycin IIA, respectively, and therefore are suitable for intravenous administration.

**Antimicrobial Activity.** Quinupristin/dalfopristin is active against gram-positive cocci, including *S. pneumoniae*, beta- and alphahemolytic strains of streptococci, *E. faecium* (but not *E. faecalis*), and coagulase-positive and coagulase-negative strains of staphylococci (Table 55–2). Strains are considered sensitive if they are inhibited by concentrations of ≤1 μg/mL. The combination is largely inactive against gram-negative organisms, although *Moraxella catarrhalis* and *Neisseria* spp. are susceptible. It also is active against organisms responsible for atypical pneumonia, *M. pneumoniae*, *Legionella* spp., and *Chlamydia pneumoniae*. The combination is bactericidal against streptococci and many strains of staphylococci but bacteriostatic against *E. faecium*.

**Mechanism of Action.** Quinupristin and dalfopristin are protein synthesis inhibitors that bind the 50S ribosomal subunit. Quinupristin binds at the same site as macrolides and has a similar effect, with inhibition of peptidyl-tRNA translocation and early termination of protein synthesis. Dalfopristin binds at a site nearby, resulting in a conformational change in the 50S ribosome, synergistically enhancing the binding of quinupristin at its target site. Dalfopristin directly interferes with peptidyl-tRNA chain formation. In many bacterial species, the net result of the cooperative and synergistic binding of these two molecules to the ribosome is bactericidal activity.

**Resistance to Streptogramins.** Resistance to quinupristin is mediated by MLS type B resistance determinants (e.g., *erm*A and *erm*C in staphylococci and *erm*B in enterococci), encoding a ribosomal methylase that prevents binding of drug to its target; or *vga* or *vgb*, which encode lactonases that inactivate type B streptogramins (Allignet et al., 1998; Bozdogan and Leclercq, 1999). Resistance to dalfopristin is mediated by *vat*, *vat*B, *vat*C, *vat*D, and *vat*A, which encode acetyltransferases that inactivate type A streptogramins (Soltani et al., 2000); or staphylococcal genes *vga* and *vgb*, which encode ATP-binding efflux proteins that pump type A streptogramins out of the cell (Bozdogan and Leclercq, 1999). These resistance determinants are located on plasmids that may be transferable by conjugal mobilization. Resistance to quinupristin/dalfopristin always is associated with a resistance gene for type A streptogramins. Genes encoding resistance to type B streptogramins also may be present but are not sufficient by themselves to produce resistance. Methylase-encoding *erm* genes, however, can render the combination bacteriostatic instead of bactericidal, making it ineffective in certain infections in which bactericidal activity is necessary for cure, such as endocarditis.

**Absorption, Distribution, and Excretion.** The combination of quinupristin/dalfopristin is administered only by intravenous infusion over at least 1 hour. It is incompatible with saline and heparin and should be dissolved in 5% dextrose in water. Steady-state peak serum concentrations in healthy male volunteers are ~3 μg/mL of quinupristin and 7 μg/mL of dalfopristin with a 7.5-mg/kg dose administered every 8 hours. The *t*1/2 is 0.85 hour for quinupristin and 0.7 hour for dalfopristin. The volume of distribution is 0.87 L/kg for quinupristin and 0.71 L/kg for dalfopristin. Hepatic metabolism by conjugation is the principal means of clearance for both compounds, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder.

No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. The area under the plasma concentration curve of active component and its metabolites is increased by 180% for quinupristin and 50% for dalfopristin by hepatic insufficiency. No adjustment is recommended unless the patient is unable to tolerate the drug, in which case the dosing frequency should be reduced from 8 to 12 hours.

**Therapeutic Uses and Dosage.** Quinupristin/dalfopristin is approved in the U.S. for treatment of infections caused by vancomycin-resistant strains of *E. faecium* and complicated skin and skin-structure infections caused by methicillin-susceptible strains of *S. aureus* or *S. pyogenes* (Nichols et al., 1999). In Europe it also is approved for treatment of nosocomial pneumonia and infections caused by methicillin-resistant strains of *S. aureus* (Fagon et al., 2000). In open-label, nonrandomized studies, clinical and microbiological cure rates for a variety of infections caused by vancomycin-resistant *E. faecium* were ~70% with quinupristin/dalfopristin at a dose of 7.5 mg/kg every 8–12 hours (Moellering et al., 1999). Quinupristin/dalfopristin should be reserved for treatment of serious infections caused by multiple-drug-resistant gram-positive organisms such as vancomycin-resistant *E. faecium*.

**Untoward Effects.** The most common side effects are infusion-related events, such as pain and phlebitis at the infusion site and arthralgias and myalgias. Phlebitis and pain can be minimized by infusion of drug through a central venous catheter. Arthralgias and myalgias,
which are more likely to be a problem in patients with hepatic insufficiency and may be due to accumulation of metabolites, are managed by reducing the infusion frequency to every 12 hours.

**Drug Interactions.** Quinupristin/dalfopristin inhibits CYP3A4. The concomitant administration of other CYP3A4 substrates (Chapter 6) with quinupristin/dalfopristin may raise blood pressure and/or result in significant toxicity. Examples include antihistamines (e.g., azelastine and clemastine); some anticonvulsants (e.g., fosphenytoin and felbamate), macrolide antibiotics; some fluoroquinolones (e.g., moxifloxacin) and ketoconazole; some antimalarials (e.g., chloroquine, mefloquine, and quinine); some antidepressants (e.g., fluoxetine, imipramine, venlafaxine); some antipsychotics (e.g., haloperidol, risperidone, and quetiapine); tacrolimus; and doxepin. Appropriate caution and monitoring are recommended for drugs in which the toxic therapeutic window is narrow or for drugs that prolong the QTc interval.

### OXAZOLIDINONES (LINEZOLID)

Linezolid (ZYVOX) is a synthetic antimicrobial agent of the oxazolidinone class (Clemett and Markham, 2000; Diekema and Jones, 2000; Hamel et al., 2000). Several other oxazolidinones are in clinical development.

![Linezolid](image)

**Antimicrobial Activity.** Linezolid is active against gram-positive organisms including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as Corynebacterium spp. and Listeria monocytogenes (Table 55–2). It has poor activity against most gram-negative aerobic or anaerobic bacteria. It is bacteriostatic against enterococci and staphylococci and bactericidal against streptococci. Breakpoints for susceptibility are ≤4 μg/mL for staphylococci and ≤2 μg/mL for enterococci and streptococci. Mycobacterium tuberculosis is moderately susceptible, with MICs of 2 μg/mL.

**Mechanism of Action and Resistance to Oxazolidinones.** Linezolid inhibits protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal 23S rRNA complex that initiates protein synthesis. Because of its unique mechanism of action, linezolid is active against strains that are resistant to multiple other agents, including penicillin-resistant strains of S. pneumoniae; methicillin-resistant, vancomycin-intermediate, and vancomycin-resistant strains of staphylococci; and vancomycin-resistant strains of enterococci. Resistance in enterococci and staphylococci is due to point mutations of the 23S rRNA (Wilson et al., 2003). Because multiple copies of 23S rRNA genes are present in bacteria, resistance generally requires mutations in two or more copies.

**Absorption, Distribution, and Excretion.** Linezolid is well absorbed after oral administration and may be administered without regard to food. With oral bioavailability approaching 100%, dosing for oral and intravenous preparations is the same. Peak serum concentrations average 13 μg/mL 1-2 hours after a single 600-mg dose in adults and ~20 μg/mL at steady state with dosing every 12 hours. The t1/2 is ~4-6 hours. Linezolid is 30% protein-bound and distributes widely to well-perfused tissues, with a 0.6-0.7 L/kg volume of distribution.

Linezolid is broken down by nonenzymatic oxidation to aminooxyacetic acid and hydroxyethyl glycine derivatives. Approximately 80% of the dose of linezolid appears in the urine, 30% as active compound and 50% as the two primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. Although serum concentrations and t1/2 of the parent compound are not appreciably altered by renal insufficiency, oxidation products accumulate in renal insufficiency, with half-lives increasing by ~50-100%. The clinical significance of this is unknown, and no dose adjustment in renal insufficiency is currently recommended. Linezolid and its breakdown products are eliminated by dialysis; therefore the drug should be administered after hemodialysis. One case report noted sustained therapeutic concentrations of linezolid in peritoneal dialysis fluid with oral administration of 600 mg of linezolid twice daily (DePestel et al., 2003).

**Therapeutic Uses and Dosage.** Linezolid is FDA approved for treatment of infections caused by vancomycin-resistant E. faecium; nosocomial pneumonia caused by methicillin-susceptible and resistant strains of S. aureus; community-acquired pneumonia caused by penicillin-susceptible strains of S. pneumoniae; complicated skin and skin structure infections caused by streptococci and methicillin-susceptible and -resistant strains of S. aureus; and uncomplicated skin and skin-structure infections (Clemett and Markham, 2000). Linezolid is bacteriostatic for staphylococci and enterococci; it should not be first-line therapy for treatment of suspected endocarditis, although there are reports of cure of endocarditis with linezolid in salvage situations (Falagas et al., 2006).

**Infections Due to Vancomycin-resistant E. faecium.** In noncomparative studies, linezolid (600 mg twice daily) has had clinical and microbiological cure rates in the range of 85-90% in treatment of a variety of infections (soft tissue, urinary tract, and bacteremia) caused by vancomycin-resistant E. faecium.

**Skin and Soft-Tissue Infections.** Efficacy of linezolid was similar to that of either oxacillin or vancomycin for complicated and uncomplicated skin and skin-structure infections, most microbiologically documented cases are caused by S. aureus. Linezolid, 600 mg twice daily (with or without aztreonam), was as effective as ampicillin/sulbactam (with or without vancomycin or aztreonam) for the management of diabetic foot infections. A 400-mg twice-daily dosage regimen is recommended only for treatment of uncomplicated skin and skin-structure infections.

**Respiratory Tract Infections.** In randomized, comparative studies, cure rates with linezolid (~60%) were similar to those with vancomycin for nosocomial pneumonia caused by methicillin-resistant or methicillin-susceptible S. aureus (Rubinstein et al., 2001; Wunderink et al., 2003a). A post hoc analysis suggested that linezolid may be superior to vancomycin for nosocomial pneumonia caused by methicillin-resistant S. aureus, but this needs to be confirmed in a prospective randomized trial (Wunderink et al., 2003b). Linezolid also may be an effective alternative for patients with MRSA infections who are failing vancomycin therapy or whose isolates have reduced susceptibility to vancomycin (Howden et al., 2004).

**Linezolid should be reserved as an alternative agent for treatment of infections caused by multiple-drug-resistant strains. It should not be used when other agents are likely to be effective (e.g., community-acquired pneumonia, even though it has the indication).**
Indiscriminant use and overuse will hasten selection of resistant strains and the eventual loss of this valuable newer agent.

Untoward Effects

Hematological Toxicity. Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported in patients receiving linezolid. Thrombocytopenia or a significant reduction in platelet count has been associated with linezolid in 2.4% of treated patients, and its occurrence is related to duration of therapy. Platelet counts should be monitored in patients with risk of bleeding, preexisting thrombocytopenia, or intrinsic or acquired disorders of platelet function (including those potentially caused by concomitant medication) and in patients receiving courses of therapy lasting beyond 2 weeks.

Other Toxic and Irritative Effects. The drug seems to be well tolerated, with generally minor side effects (e.g., GI complaints, headache, rash). Patients receiving concomitant therapy with an adrenergic or serotoninergic agent (including selective serotonin reuptake inhibitors [SSRIs]) or consuming >100 mg of tyramine a day may experience serotonin syndrome, characterized by palpitations, headache, or hypertensive crisis. Co-administration of these agents is best avoided if possible. However, in patients receiving SSRIs who acutely require linezolid therapy for short-term (10-14 days) treatment, co-administration with careful monitoring is reasonable because SSRIs generally require tapering to avoid discontinuation syndrome. Linezolid is neither a substrate nor an inhibitor of CYPs.

Drug Interactions. Linezolid is a weak nonspecific inhibitor of monoamine oxidase. Patients receiving concomitant therapy with an adrenergic or serotoninergic agent (including selective serotonin reuptake inhibitors [SSRIs]) or consuming >100 mg of tyramine a day may experience serotonin syndrome, characterized by palpititations, headache, or hypertensive crisis. Co-administration of these agents is best avoided if possible. However, in patients receiving SSRIs who acutely require linezolid therapy for short-term (10-14 days) treatment, co-administration with careful monitoring is reasonable because SSRIs generally require tapering to avoid discontinuation syndrome. Linezolid is neither a substrate nor an inhibitor of CYPs.

AMINOACYCLITOLS (SPECTINOMYCIN)

Spectinomycin is an antibiotic produced by Streptomyces spectabilis. The drug is an aminocyclitol:

\[
\text{SPECTINOMYCIN} \quad \text{(CH}_3\text{O)}_3\text{HNO}_2\text{OCH}_3\text{OCH}_3\text{NHCHOCH}_3
\]

Antimicrobial Activity, Mechanism of Action, and Resistance to Spectinomycin. Spectinomycin is active against a number of gram-negative bacterial species, but it is inferior to other drugs to which such microorganisms are susceptible. Its only therapeutic use is in the treatment of gonorrhea caused by strains resistant to first-line drugs or if there are contraindications to the use of these drugs. Spectinomycin selectively inhibits protein synthesis in gram-negative bacteria. The antibiotic binds to and acts on the 30S ribosomal subunit. Its action is similar to that of the aminoglycosides, but spectinomycin is not bactericidal and does not cause misreading of messenger RNA. Bacterial resistance may be mediated by mutations in the 16S ribosomal RNA or by modification of the drug by adenylyltransferase (Clark et al., 1999).

Absorption, Distribution, and Excretion. Spectinomycin is rapidly absorbed after intramuscular injection. A single dose of 2 g produces peak serum concentrations of 100 μg/mL at 1 hour. Eight hours after injection, the concentration is ~15 μg/mL. The drug is not significantly bound to plasma protein, and all of an administered dose is recovered in the urine within 48 hours.

Therapeutic Uses and Dosage. The Centers for Disease Control and Prevention recommends ceftriaxone or cefixime for the treatment of uncomplicated gonococcal infection (Workowski and Berman, 2006). Fluoroquinolones are no longer recommended because of increasing resistance. Spectinomycin is recommended as an alternative regimen in patients who are intolerant or allergic to β-lactam antibiotics; however, the drug is not currently available in the U.S. Spectinomycin also is useful in pregnancy when patients are intolerant of β-lactams. The recommended dose for men and women is a single deep intramuscular injection of 2 g. One of the disadvantages of this regimen is that spectinomycin has no effect on incubating or established syphilis, and it is not active against Chlamydia spp. It also is less effective for pharyngeal infections, and follow-up cultures to document cure should be obtained.

Untoward Effects. Spectinomycin, when given as a single intramuscular injection, produces few significant untoward effects. Urticaria, chills, and fever have been noted after single doses, as have dizziness, nausea, and insomnia. The injection may be painful.

POLYMIXINS

The polymyxins, discovered in 1947, are a group of closely related antibiotics elaborated by various strains of Bacillus polymyxa. Colistin (polymyxin E) is produced by Bacillus (Aerobacillus) colistinus. These drugs, which are cationic detergents, are relatively simple basic peptides with molecular masses of ~1000 Da. Polymyxin B is a mixture of polymyxins B₁ and B₂:

\[
\text{Polymyxin B}_{1,2}: R_{1} = (+)-\text{methyloctanoyl} \quad \text{Polymyxin B}_{2}: R_{2} = 6\text{-methylheptanoyl} \\
\text{DAB} = \alpha,\gamma\text{-diaminobutyric acid}
\]

Colistin has a similar structure.

Antimicrobial Activity, Mechanism of Action, and Resistance to Polymyxins. The antimicrobial activities of polymyxin B and colistin are similar and restricted to gram-negative bacteria, including Enterobacter, E. coli, Klebsiella, Salmonella, Pasteurella, Bordetella, and Shigella, which usually are sensitive to concentrations of 0.05-2 μg/mL. Most strains of P. aeruginosa and Acinetobacter are inhibited by <8 μg/mL in vitro. Proteus and Serratia spp. are intrinsically resistant.

Polymyxins are surface-active amphipathic agents. They interact strongly with phospholipids and disrupt the structure of cell
membranes. The permeability of the bacterial membrane changes immediately on contact with the drug. Sensitivity to polymyxin B apparently is related to the phospholipid content of the cell wall–membrane complex. The cell walls of certain resistant bacteria may prevent access of the drug to the cell membrane. Polymyxin B binds to the lipid A portion of endotoxin (the lipopolysaccharide of the outer membrane of gram-negative bacteria) and inactivates this molecule. Polymyxin B attenuates pathophysiological consequences of the release of endotoxin in several experimental systems, but the clinical utility of polymyxin B for this indication has not yet been established.

Although resistance to polymyxins among normally susceptible species is rare (likely owing to the minimal systemic use of this agent for many years), emergence of resistance while on treatment has been documented. Dosing regimens, including combination therapies, able to suppress the emergence of resistance are currently being studied.

Absorption, Distribution, and Excretion. Polymyxin B and colistin are not absorbed when given orally and are poorly absorbed from mucous membranes and the surfaces of large burns. They are cleared renally, and modification of the dose is required in patients with impaired renal function.

Therapeutic Uses and Dosage

Topical Uses. Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. Colistin is available as otic drops. Infections of the skin, mucous membranes, eye, and ear due to polymyxin B–sensitive microorganisms respond to local application of the antibiotics in solution or ointment. External otitis, frequently due to Pseudomonas, may be cured by the topical use of the drug. P. aeruginosa is a common cause of infection of corneal ulcers; local application or subconjunctival injection of polymyxin B often is curative. Polymyxin B, in combination with neomycin (NEOSPORIN G.U. IRRIGANT), is administered as a urinary bladder irritant in conjunction with the use of indwelling catheters.

Systemic Uses. Colistin is available as colistin sulfate for oral use and as colistimethate sodium for parenteral administration. Due to the emergence of multidrug-resistant gram-negative organisms (especially Stenotrophomonas maltophilia, Acinetobacter spp., P. aeruginosa, and Klebsiella spp.), there has been a resurgence in the systemic use of polymyxins, despite their toxicity when administered via this route. There are no prospective clinical trials of polymyxin use for systemic infections; however, a number of studies have described their use as salvage therapy for treatment of infections caused by multidrug-resistant organisms (Linden et al., 2003; San Gabriel et al., 2004). Because dosing of these agents varies by drug (polymyxin B or colistin), by the particular commercial preparation, and by the patient’s degree of renal dysfunction, expert consultation is recommended before using these agents.

Untoward Effects. Polymyxin B applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption from these sites. Hypersensitization is uncommon with topical application. Polymyxins are nephrotoxic, and administration with aminoglycosides or other nephrotoxins should be avoided if possible. Polymyxins interfere with neurotransmission at the neuromuscular junction, resulting in muscle weakness and apnea. Other neurological reactions include paresthesias, vertigo, and slurred speech.

GLYCOPEPTIDES (VANCOMYCIN AND TEICOPLANIN)

Vancomycin. Vancomycin is a tricyclic glycopeptide antibiotic produced by Streptococcus orientalis. Teicoplanin, a glycopeptide antibiotic produced by Actinoplanes teichomycetius, is available in Europe (Biavasco et al., 1997). A number of derivatives, the lipoglycopeptides (including telavancin, oritavancin, and dalbavancin), are in late-stage development.

Teicoplanin. This agent is a mixture of six closely related compounds: One compound has a terminal hydrogen at the oxygen indicated by an asterisk; five compounds have an R substituent of either a decanoic acid [n-, 8-methyl-1, 9-methyl (Z)-4-] or of a nonanoic acid [8-methyl]. Although not FDA approved for use in the U.S., it is available in Europe. It is similar to vancomycin in chemical structure, mechanism of action, spectrum of activity, and route of elimination (i.e., primarily renal).
**Antimicrobial Activity.** Vancomycin possesses activity against a broad spectrum of gram-positive bacteria (Table 55–2). Strains are considered susceptible at MICs of ≤2 μg/mL for *S. aureus*, ≤4 μg/mL for *S. epidermidis*, and ≤1 μg/mL for streptococci. Bacillus spp., including *B. anthracis*, are inhibited by ≤2 μg/mL. *Corynebacterium* spp. (diphtheroids) are inhibited by <0.04-3.1 μg/mL of vancomycin; most species of *Actinomyces*, by 5-10 μg/mL; and *Clostridium* spp., by 0.39-6 μg/mL. Essentially all species of gram-negative bacilli and mycobacteria are resistant to vancomycin.

Teicoplanin is active against methicillin-susceptible and methicillin-resistant staphylococci, which typically have MICs of <4 μg/mL. The MICs for *Listeria monocytogenes*, *Corynebacterium* spp., *Clostridium* spp., and anaerobic gram-positive cocci range from 0.25-2 μg/mL. Nonviridans and viridans streptococci, *S. pneumoniae*, and enterococci are inhibited by concentrations ranging from 0.01-1 μg/mL. Some strains of staphylococci, coagulase positive and coagulase negative, as well as enterococci and other organisms that are intrinsically resistant to vancomycin (i.e., *Lactobacillus* spp. and *Leuconostoc* spp.), are resistant to teicoplanin.

**Mechanism of Action.** Vancomycin and teicoplanin inhibit the synthesis of the cell wall in sensitive bacteria by binding with high affinity to the d-alanyl-d-alanine terminus of cell wall precursor units (Figure 55–4). Because of their large molecular size, they are unable to penetrate the outer membrane of gram-negative bacteria.

Glycopeptides are generally bactericidal against susceptible strains, except for enterococci. The activity of glycopeptides is best predicted by the ratio of the total drug exposure (area under the curve [AUC]) of glycopeptide to minimum inhibitory concentration (MIC) of the infecting organism. This AUC-to-MIC ratio is established as being predictive of organism killing and cure in *in vitro* and animal models, and in some limited clinical data (Rybak, 2006). An AUC-to-MIC ratio of 400 was predictive of efficacy in patients with MRSA pneumonia (Moise-Broder et al., 2004). One implication of the potential importance of this parameter is that increases in organism MIC, even below the cutoff for susceptibility, can make achieving this target ratio difficult without substantial dosage increases. Thus, although an isolate of *S. aureus* with an MIC of 2 μg/mL would be considered susceptible, it would be difficult to achieve an AUC-to-MIC ratio of 400 at standard doses. The validity and target value of this parameter requires confirmation in further clinical studies with a variety of organisms and infections. The potential contribution to toxicity of using higher doses to achieve these target values also requires consideration (see later in the chapter).

**Resistance to Glycopeptides.** Strains of enterococci once were uniformly susceptible to glycopeptides. Glycopeptide-resistant strains

---

**Figure 55–4. Inhibition of bacterial cell wall synthesis: vancomycin and β-lactam agents.** Vancomycin inhibits the polymerization or transglycosylase reaction (A) by binding to the d-alanyl-d-alanine terminus of the cell wall precursor unit attached to its lipid carrier and blocks linkage to the glycopeptide polymer (indicated by the subscript n). These (NAM–NAG)_n peptidoglycan polymers are located within the cell wall. Van A-type resistance is due to expression of enzymes that modify cell wall precursor by substituting a terminal d-lactate for d-alanine, reducing vancomycin binding affinity by 1000 times. β-Lactam antibiotics inhibit the cross-linking or transpeptidase reaction (B) that links glycopeptide polymer chains by formation of a cross-bridge with the stem peptide (the five glycines in this example) of one chain, displacing the terminal d-alanine of an adjacent chain. See also Figure 53–3.
of enterococci, primarily Enterococcus faecium, have emerged as major nosocomial pathogens in hospitals in the U.S. Vancomycin resistance determinants in E. faecium and E. faecalis are located on a transposon that is part of a conjugative plasmid, rendering it readily transferable among enterococci and, potentially, other gram-positive bacteria. These strains typically are resistant to multiple antibiotics, including streptomycin, gentamicin, and ampicillin, effectively eliminating these as alternative therapeutic agents. Resistance to streptomycin and gentamicin is of special concern because the combination of an aminoglycoside with a cell-wall synthesis inhibitor is the only reliably bactericidal regimen for treatment of enterococcal endocarditis.

Enterococcal resistance to glycopeptides is the result of alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate or D-alanyl-D-serine (Arias et al., 2000), which bind glycopeptides poorly, due to the lack of a critical site for hydrogen bonding. Several enzymes within the van gene cluster are required for this target alteration to occur. Several phenotypes of resistance to glycopeptides have been described. The Van A phenotype confers inducible resistance to teicoplanin and vancomycin in E. faecium and E. faecalis. The Van B phenotype, which tends to be a lower level of resistance, also has been identified in E. faecium and E. faecalis. The Van C phenotype, the least important clinically and least well characterized, confers resistance only to vancomycin, is constitutive, and is present in no species of enterococci other than E. faecalis and E. faecium. Van D and Van E gene clusters also have been identified, and presumably others will follow.

S. aureus and coagulase-negative staphylococci may express reduced or “intermediate” susceptibility to vancomycin (MIC, 4-8 μg/mL) (Garrett et al., 1999; Hiramatsu et al., 1997; Smith et al., 1999) or high-level resistance (MIC ≥16 μg/mL). Intermediate resistance is associated with (and may be preceded by) a heterogeneous phenotype in which a small proportion of cells within the population (1 in 10^6 to 1 in 10^9) will grow in the presence of vancomycin concentrations >4 μg/mL. The genetic and biochemical basis of the intermediate phenotype is unknown. Intermediate strains produce an abnormally thick cell wall, and resistance may be due to false targets for vancomycin. Several genetic elements and multiple mutations are involved, and many of the genes that have been implicated encode enzymes of the cell-wall biosynthetic pathway (Sieradzki and Tomasz, 1999; Sieradzki et al., 1999). Infections caused by vancomycin-intermediate strains have failed to respond to vancomycin clinically and in animal models (Climo et al., 1999; Moore et al., 2003). Prior treatment courses and low vancomycin levels may predispose patients to infection and treatment failure with vancomycin-intermediate strains. These strains typically are resistant to methicillin and multiple other antibiotics; their emergence is a major concern because until recently vancomycin has been the only antibiotic to which staphylococci were reliably susceptible.

The first high-level vancomycin-resistant S. aureus strain (MIC ≥32 μg/mL) was isolated in June 2002 (Weigel et al., 2003). This strain, like others that have subsequently been isolated, harbored a conjugative plasmid into which the Van A transposon, Tn1546, was integrated as a consequence of an interspecies horizontal gene transfer from E. faecalis to a methicillin-resistant strain of S. aureus. These isolates have been variably susceptible to teicoplanin and the investigational lipoglycopeptides.

**Absorption, Distribution, and Excretion**

**Absorption.** Vancomycin is poorly absorbed after oral administration. For parenteral therapy, the drug should be administered intravenously, never intramuscularly. Teicoplanin can be administered safely by intramuscular injection as well as intravenous administration.

**Distribution.** A single intravenous dose of 1 g in adults produces plasma concentrations of 15-30 μg/mL 1 hour after a 1- to 2-hour infusion. Approximately 30% of vancomycin is bound to plasma protein. Vancomycin appears in various body fluids, including the CSF when the meninges are inflamed (7-30%); bile; and pleural, pericardial, synovial, and ascitic fluids. Teicoplanin is highly bound by plasma proteins (90-95%).

**Elimination.** About 90% of an injected dose of vancomycin is excreted by glomerular filtration. The drug has a serum elimination t1/2 of ~6 hours. The drug accumulates if renal function is impaired, and dosage adjustments must be made under these circumstances. The drug can be cleared rapidly from plasma with high-flux hemodialysis. In contrast to vancomycin, teicoplanin has an extremely long serum elimination t1/2 (up to 100 hours in patients with normal renal function).

**Therapeutic Uses and Dosage.** Teicoplanin and teicoplanin have been used to treat a wide variety of infections, including osteomyelitis and endocarditis, caused by methicillin-resistant and methicillin-susceptible staphylococci, streptococci, and enterococci. Teicoplanin has been found to be comparable to vancomycin in efficacy, except for treatment failures from low doses used for serious infections as endocarditis. In general, recommendations for teicoplanin follow those of vancomycin, except where noted later. Although extensively studied for >10 years, teicoplanin has not yet been licensed for use in the U.S.

Vancomycin hydrochloride (VANCOCIN, others) is marketed for intravenous use as a sterile powder for solution. It should be diluted and infused over at least a 60-minute period to avoid infusion-related adverse reactions. The recommended dose of vancomycin for adults is 30-45 mg/kg per day in 2-3 divided doses. The “therapeutic range” for this agent is somewhat controversial. Current recommendations call for monitoring serum trough concentrations (within 30 minutes prior to a dose) at steady state, typically before the fourth dose of a given dosage regimen. A minimum target trough serum concentration of 10 μg/mL is recommended in the most recent consensus guidelines (Rybak et al., 2009). For patients with more serious infections (including endocarditis, osteomyelitis, meningitis, and MRSA pneumonia), trough levels of 15-20 μg/mL are recommended.

General pediatric dosage ranges for vancomycin are as follows: for newborns during the first week of life, 15 mg/kg initially, followed by 10 mg/kg every 12 hours; for infants 8-30 days old, 15 mg/kg followed by 10 mg/kg every 8 hours; for older infants (30 days) and children, 10-15 mg/kg every 6 hours (Prymoyer et al, 2009).

Alteration of dosage is required for patients with impaired renal function. Serum drug concentrations may help guide dose adjustment, but caution should be used in interpreting concentrations in patients with rapidly changing renal function. In functionally anephric patients and patients receiving dialysis with non-high-flux membranes, administration of 1 g (~15 mg/kg) every 5-7 days typically achieves adequate serum levels. In patients receiving intermittent high-efficiency or high-flux dialysis, maintenance doses administered after each dialysis session are typically required.
because these modalities clear vancomycin efficiently. Because there is so much variation in how well vancomycin is dialyzed with different membranes, it is recommended that blood levels be monitored to decide how frequently the drug needs to be administered to maintain therapeutic concentrations.

**Skin/Soft-Tissue and Bone/Joint Infections.** Vancomycin is frequently used in the empirical and definitive treatment of skin/soft-tissue and bone/joint infections, where gram-positive organisms including MRSA are the leading pathogens.

**Respiratory Tract Infections.** Vancomycin is employed for the treatment of pneumonia when MRSA is suspected, either because of healthcare-associated acquisition or in patients with community-acquired pneumonia with risk factors for staphylococcal infection (e.g., influenza). Because vancomycin penetration into lung tissue is relatively low, aggressive dosing (targeting trough levels of 15-20 μg/mL) is generally recommended.

**CNS Infections.** Because of vancomycin’s excellent activity against Streptococcus pneumoniae, it is a key component in the initial empirical treatment of community-acquired bacterial meningitis in locations where penicillin-resistant Streptococcus pneumoniae is common (Tunkel et al., 2004). Penetration of vancomycin across inflamed meninges is modest to poor; thus aggressive dosing is typically warranted. Vancomycin is also used to treat nosocomial meningitis, usually associated with neurosurgical procedures and often caused by staphylococci. Intraventricular administration of vancomycin (via a shunt or reservoir) has been necessary in a few cases of CNS infections due to susceptible microorganisms that did not respond to intravenous therapy alone.

**Endocarditis and Vascular Catheter Infections.** Vancomycin is standard therapy for staphylococcal endocarditis when the isolate is methicillin resistant or patients have a severe penicillin allergy (Baddour et al., 2005). Administration of an adjunctive aminoglycoside is no longer recommended unless there is a prosthetic valve. Vancomycin is an effective alternative for the treatment of endocarditis caused by viridans streptococci in patients who are allergic to penicillin. In combination with an aminoglycoside, it may be used for enterococcal endocarditis in patients with serious penicillin allergy or for isolates that are not susceptible to penicillins.

Vancomycin is commonly used for the treatment of vascular catheter infections due to gram-positive organisms, such as staphylococci, viridans streptococci, Corynebacterium spp, and Bacillus spp. In situations when removal of the catheter is not desired, adjunctive treatment with vancomycin as an “antibiotic lock” may aid in salvaging the catheter. In this procedure, a concentrated solution of vancomycin is instilled into the catheter hub and allowed to dwell for variable amounts of time when the catheter is not in use (Carratala, 2002).

**Other Infections.** Vancomycin can be administered orally to patients with pseudomembranous colitis due to *C. difficile*, and it may be more efficacious than metronidazole in patients with severe disease. The dose for adults is 125-250 mg every 6 hours; the total daily dose for children is 40 mg/kg, given in three to four divided doses. Commercially available capsules can be used for this purpose, or the intravenous formulation can be administered orally with or without compounding into a more palatable oral solution.

The standard dose of teicoplanin in adults is 3-6 mg/kg per day, with higher dosages possible for treatment of serious staphylococcal infections. Once-daily dosing is possible for the treatment of most infections because of the prolonged serum elimination half-life. As with vancomycin, teicoplanin doses must be adjusted in patients with renal insufficiency. For functionally anephric patients, administration once weekly has been appropriate, but serum drug concentrations should be monitored to determine that the therapeutic range has been maintained (e.g., trough concentration of 15-20 μg/mL). Oral teicoplanin has also been studied for the treatment of *C. difficile* disease, at a dose of 100 mg twice daily.

**Untoward Effects.** Among the hypersensitivity reactions produced by vancomycin and teicoplanin are macular skin rashes and anaphylaxis. Phlebitis and pain at the site of intravenous injection are relatively uncommon. Chills, rash, and fever may occur. Rapid intravenous infusion of vancomycin may cause erythematous or urticarial reactions, flushing, tachycardia, and hypotension. The extreme flushing that can occur is sometimes called “red-neck” or “red-man” syndrome. This is not an allergic reaction but a direct toxic effect of vancomycin on mast cells, causing them to release histamine. This reaction is generally not observed with teicoplanin.

Auditory impairment, sometimes permanent, may follow the use of vancomycin or teicoplanin. Otoxicity is associated with excessively high concentrations of these drugs in plasma (60-100 μg/mL of vancomycin). Nephrotoxicity, formerly very problematic due to the impurities in earlier formulations of vancomycin, has become less common with modern formulations at standard dosages. However, the more aggressive dosing regimens recently advocated have been demonstrated to increase nephrotoxicity risk. In a recent observational study, nephrotoxicity occurred in 33% of patients with initial vancomycin trough concentrations of >20 μg/mL, compared to 5% among patients with trough concentrations of <10 μg/mL (Lodise et al., 2009). Thus, careful dosing and monitoring of vancomycin is necessary to balance the risks and benefits. Additionally, caution should be exercised when ototoxic or nephrotoxic drugs, such as aminoglycosides, are administered concurrently with vancomycin.

**LIPOPEPTIDES (DAPTOMYCIN)**

Daptomycin (CUBICIN) is a cyclic lipopeptide antibiotic derived from *Streptomyces roseosporus*. Discovered 25 years ago, its clinical development has been resumed in response to increasing need for bactericidal antibiotics effective against vancomycin-resistant gram-positive bacteria (Carpenter and Chambers, 2004; Eisenstein and Tally, 2006).
Daptomycin binds to bacterial membranes resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity. During initial clinical trials for treatment of skin and soft-tissue infections, resistance was rarely observed. Subsequently, during clinical use, daptomycin resistance has been reported to emerge while on therapy, typically during treatment of deep-seated infections (e.g., osteomyelitis, endocarditis, infections of prosthetic material). In a trial of daptomycin for staphylococcal bacteremia and right-sided endocarditis, increases in daptomycin-susceptible counterparts. MICs of *Corynebacterium spp.*, *Peptostreptococcus*, propionibacteria, and *Clostridium perfringens* are generally inhibited by ≤0.5-1 μg/mL (Goldstein et al., 2004). *Actinomyces* spp. are inhibited over the concentration range of 4-32 μg/mL. In vitro activity of daptomycin is Ca²⁺ dependent, and MIC tests should be performed in medium containing 50 mg/L calcium.

**Mechanisms of Action and Resistance to Daptomycin.**

Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-positive bacteria (Table 55-2) (Jevitt et al., 2003; Streit et al., 2004). The MIC susceptibility breakpoint for staphylococci and streptococci is ≤1 μg/mL: for enterococci it is ≤4 μg/mL. Daptomycin may be active against vancomycin-resistant strains, although MICs tend to be higher for these organisms than for their vancomycin-susceptible counterparts. MICs of *Corynebacterium spp.*, *Peptostreptococcus*, propionibacteria, and *Clostridium perfringens* are generally inhibited by ≤0.5-1 μg/mL (Goldstein et al., 2004). *Actinomyces* spp. are inhibited over the concentration range of 4-32 μg/mL. In vitro activity of daptomycin is Ca²⁺ dependent, and MIC tests should be performed in medium containing 50 mg/L calcium.

**Daptomycin** binds to bacterial membranes resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity. dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive bacteria. Unlike several other antibiotics used topically, bacitracin rarely produces hypersensitivity. Suppurative conjunctivitis and infected corneal ulcer respond well to the topical use of bacitracin when caused by susceptible bacteria. Bacitracin has been used with limited success for eradication of nasal carriage of staphylococci. Oral bacitracin has been used with some success for the treatment of antibiotic-associated diarrhea caused by *C. difficile*. Bacitracin is used by neurosurgeons to irrigate the meninges intraoperatively as an alternative to vancomycin. It has no direct toxicity on neurons.

**Untoward Effects.** Serious nephrotoxicity results from the parenteral use of this antibiotic. Hypersensitivity reactions rarely result from topical application.

**MUPIROCIN**

Mupirocin (BACTROBAN) is derived from a fermentation product of *Pseudomonas fluorescens*. It is for topical use only.

![Mupirocin](image)

**Antimicrobial Activity.** Mupirocin is active against many gram-positive and selected gram-negative bacteria. It has good activity with MICs \(\leq 1\, \mu g/mL\) against *Streptococcus pyogenes* and methicillin-susceptible and methicillin-resistant strains of *S. aureus*. It is bactericidal at concentrations achieved with topical application.

**Mechanism of Action and Mupirocin Resistance.** Mupirocin inhibits bacterial protein synthesis by reversible binding and inhibition of isoleucyl transfer-RNA synthetase. There is no cross-resistance with other classes of antibiotics. Low-level resistance, which is not clinically significant, is due to mutations of the host gene encoding isoleucyl transfer-RNA synthetase or an extra chromosomal copy of a gene encoding a modified isoleucyl transfer-RNA synthetase (Ramsey et al., 1996; Udo et al., 2001). High-level resistance (MIC \(>1\, mg/mL\)) is mediated by a plasmid or chromosomal copy of *mupA*, which encodes a “bypass” synthetase that binds mupirocin poorly (Udo et al., 2001).

**Absorption, Fate, and Excretion.** Systemic absorption through intact skin or skin lesions is minimal. Any mupirocin that is absorbed is rapidly metabolized to inactive monic acid.

**Therapeutic Uses and Dosage.** Mupirocin is available as a 2% cream and a 2% ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatologic preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*.

The nasal ointment is approved for eradication of *S. aureus* nasal carriage. Mupirocin is highly effective in eradicating *S. aureus* carriage (Laupland and Conly, 2003). Because *S. aureus* colonization often precedes infection, eradication of carriage by intranasal application of mupirocin might reduce the risk of later infection. However, two clinical trials failed to demonstrate that mupirocin prophylaxis reduces nosocomial *S. aureus* infections (Kalmeijer et al., 2002; Wertheim et al., 2004). A third large study found that *S. aureus* nasal carriers had fewer *S. aureus* nosocomial infections of any site, but it failed to show a reduction in *S. aureus* surgical site infections, the primary end point of the study (Perl et al., 2002). The accumulated evidence indicates that patients who stand to benefit from mupirocin prophylaxis are those with proven carriage (Laupland and Conly, 2003). Because mupirocin causes tearing, burning, and irritation that may take several days to resolve. Systemic reactions to mupirocin occur rarely, if at all. Polyethylene glycol present in the ointment can be absorbed from damaged skin. Application of the ointment to large surface areas should be avoided in patients with moderate to severe renal failure to avoid accumulation of polyethylene glycol.

**CLINICAL SUMMARY**

Doxycycline, the most important member of the tetracyclines, is a drug of choice for sexually transmitted diseases, rickettsial infections, plague, brucellosis, tularemia, and spirochetal infections. It is also an important agent for treatment of respiratory tract infections, given its activity against *S. pneumoniae, Haemophilus spp.*, and atypical pneumonia pathogens; and for skin and soft-tissue infections caused by community strains of methicillin-resistant *S. aureus*, for which minocycline also is particularly active. Glycylcyclines, beginning with tigecycline, have restored much of the activity of the tetracyclines against bacteria that have become refractory to first- and second-generation tetracyclines, including aerobic and anaerobic gram-negative organisms as well as refractory gram-positive organisms.

Macrolides and ketolides are effective for treatment of respiratory tract infections caused by the common pathogens of community-acquired pneumonia, including *S. pneumoniae, Haemophilus spp.*, *Chlamydia*, mycoplasma, and *Legionella*. They generally are well-tolerated, orally bioavailable, and except for erythromycin, effective in once or twice-daily dosing. All except azithromycin have important drug interactions because they inhibit hepatic CYPs.

Chloramphenicol is rarely indicated in the U.S. and Europe because it can cause irreversible bone marrow toxicity and because less toxic drugs are readily available. However, it continues to be an important
antibiotic in developing nations because it is inexpensive and highly effective for a broad range of infections.

Spectinomycin is indicated only for the treatment of gonococcal infection when a β-lactam or fluoroquinolone cannot be given. Clindamycin has excellent activity against gram-positive cocci but principally is used to treat anaerobic infections. Vancomycin, daptomycin, quinupristin/dalfopristin, and linezolid are indicated for the treatment of gram-positive infections caused by drug-resistant organisms such as penicillin-resistant pneumococci and methicillin-resistant staphylococci. Quinupristin/dalfopristin and linezolid are indicated for the treatment of vancomycin-resistant E. faecium infections. These drugs, along with daptomycin, also are active against vancomycin-insensitive strains of S. aureus, although clinical trials have not established their clear clinical efficacy to date.

Polymyxins, bacitracin, and mupirocin are effective for the topical treatment of minor skin infections. Colistin (polymyxin E) can be administered systemically and is active against drug-resistant gram-negative bacteria, including Pseudomonas, Stenotrophomonas, and Acinetobacter; its significant toxicity makes it an agent of last resort. Mupirocin is effective for eradication of S. aureus nasal colonization.

**BIBLIOGRAPHY**

This page intentionally left blank
Mycobacteria have caused epic diseases: Tuberculosis (TB) and leprosy have terrorized humankind since antiquity. Although the burden of leprosy has decreased, TB is still the most important infectious killer of humans. *Mycobacterium avium-intracellulare* (or *Mycobacterium avium* complex; MAC) infection continues to be difficult to treat.

*Mycobacterium*, from the Greek “mycos,” refers to Mycobacteria’s waxy appearance, which is due to the composition of their cell walls. More than 60% of the cell wall is lipid, mainly mycolic acids composed of 2-branched, 3-hydroxy fatty acids with chains made of 76-90 carbon atoms! This extraordinary shield prevents many pharmacological compounds from getting to the bacterial cell membrane or inside the cytosol.

A second layer of defense comes from an abundance of efflux pumps in the cell membrane. These transport proteins pump out potentially harmful chemicals from the bacterial cytoplasm back into the extracellular space and are responsible for the native resistance of mycobacteria to many standard antibiotics (Morris et al., 2005). As an example, ATP binding cassette (ABC) permeases comprise a full 2.5% of the genome of *Mycobacterium tuberculosis*.

A third barrier is the propensity of some of the bacilli to hide inside the patient’s cells, thereby surrounding themselves with an extra physicochemical barrier that antimicrobial agents must cross to be effective.

Mycobacteria are separated into two groups, defined by their rate of growth on agar. A list of pathogenic *rapid* and *slow* growers is shown in Table 56–1. Rapid growers are visible to the naked eye within 7 days; slow growers are visible later. Slow growers tend to be susceptible to antibiotics specifically developed for Mycobacteria, whereas rapid growers tend to be also susceptible to antibiotics used against many other bacteria. The pharmacology of drugs developed against slow growers is discussed in this chapter.

The mechanisms of action of the anti-mycobacterial drugs are summarized in Figure 56–1. The mycobacterial mechanisms of resistance to these drugs are summarized in Figure 56–2. Pharmacokinetic parameters are presented in terms of Figure 48–1 and Equation 48–1.

**History.** The first successful drug for treating TB was para-amino salicylic acid (PAS), developed by Lehman in 1943. A more dramatic success came when Waksman and Schatz developed streptomycin. Further efforts led to development of thiacetazone by Domagk in 1946, isoniazid at Squibb, Hoffman La Roche, and Bayer in 1952, pyrazinamide by Kushner and colleagues in 1952, and rifamycins by Sensi and Margalith in 1957. Ethambutol was discovered at Lederle Laboratories in 1961. As might be anticipated, the use of all of these drugs presents problems of drug resistance, adverse events, and drug interactions. Therefore, newer classes of agents are being developed. Moxifloxacin, PA-824, and TMC-207 have reached advanced clinical testing.

**ANTI-MYCOBACTERIAL DRUGS**

**Rifamycins: Rifampin, Rifapentine, and Rifabutin**

Rifampin or rifampicin (RIFADIN; RIMACTANE, others), rifapentine (PRIFTIN), and rifabutin (MYCOBUTIN) are important in treatment of mycobacterial diseases.

**Chemistry.** Rifamycins are macrocyclic antibiotics characterized by a chromophoric naphthohydroquinone group that is spanned by a...
long aliphatic bridge, with an acetyl group at C25. Rifapentine and rifabutin are derivatives of rifampin, whose structure is:

Mechanism of Action. The mechanism of action for rifamycins is typified by rifampin’s action against *M. tuberculosis*. Rifampin enters bacilli in a concentration dependent manner, achieving steady-state concentrations within 15 minutes (Gumbo et al., 2007a). Rifampin binds to the β subunit of DNA-dependent RNA polymerase (*rpoB*) to form a stable drug–enzyme complex. Drug binding suppresses chain formation in RNA synthesis.

Antibacterial Activity. Rifampin inhibits the growth of most gram-positive bacteria as well as many gram-negative microorganisms such as *Escherichia coli*, *Pseudomonas*, indole-positive and indole-negative *Proteus*, and *Klebsiella*. Rifampin is very active against *Staphylococcus aureus* and coagulase-negative staphylococci. The drug also is highly active against *Neisseria meningitidis* and *Haemophilus influenzae*. Rifampin inhibits the growth of *Legionella* species in cell culture and in animal models.

Rifampin inhibits the growth of many *M. tuberculosis* clinical isolates in vitro at concentrations of 0.06-0.25 mg/L (Heifets, 1991). Rifampin is also bactericidal against *M. leprae*. *M. kansasi* is inhibited by 0.25-1 mg/L. Most strains of *Mycobacterium scrofulaceum*, *Mycobacterium intracellulare*, and *M. avium* are suppressed by concentrations of 4 mg/L. *Mycobacterium fortuitum* is highly resistant to the drug. Rifapentine minimum inhibitory concentrations (MICs) are similar to those of rifampin. Rifabutin inhibits the growth of most MAC isolates at concentrations ranging from 0.25-1 mg/L. Rifabutin also inhibits the growth of many strains of *M. tuberculosis* at concentrations of ≤0.125 mg/L and in vitro has better MICs than rifampin.

Bacterial Resistance. The prevalence of rifampin-resistant isolates are 1 in every 107 to 108 bacilli. Microbial resistance to rifampin is due to an alteration of the target of this drug, *rpoB*, with resistance in 86% of cases due to mutations at codons 526 and 531 of the *rpoB* gene (Somoskovi et al., 2001). Rifamycin monoresistance occurs at higher rates when patients with AIDS and multi-cavitary TB are treated with either rifapentine or rifabutin (Burman et al., 2006a).

Mutations in genes involved in DNA repair mechanisms will impair the repair of multiple genes, which may lead to hyper-mutable strains (Chapter 48). *M. tuberculosis* Beijing genotype clinical isolates have been associated with higher rates of simultaneous rifampin and isoniazid resistance associated with mutations in the repair genes *mut* and *ogt* (Nouvel et al., 2006; Rad et al., 2003). Inducible or environment-dependent mutators may be a more common phenomenon than these stable mutator phenotypes (Warner and Mizrahi, 2006). Antibiotics, endogenous oxidative and metabolic stressors lead to DNA damage, which induces *dnaE2*. The induction is associated with error-prone DNA repair. This leads to higher rates of rifampin resistance (Boshoff et al., 2003).

Absorption, Distribution, and Excretion. After oral administration, the rifamycins are absorbed to variable extents (Table 56–2) (Burman et al., 2001). Food decreases the rifampin Cmax by one third; a high-fat meal increases the area under the curve (AUC) of rifampine by 50%. Food has no effect on rifabutin absorption. Thus rifapentine should be taken on an empty stomach, whereas rifampin should be taken with food, if possible.

Rifamycins are metabolized by microsomal B-esterases and cholinesterases that remove the acetyl group at position 25, resulting in 25-O-desacetyl rifamycins. Rifampin is also metabolized by hydrolysis to 3-formyl rifampin, whereas rifapentine is metabolized to 3-formyl rifapentine and 3-formyl-25-O-desacetyl-rifapentine. A major pathway for rifabutin elimination is CYP3A. Due to autoinduction, all three rifamycins reduce their own area...
under the concentration-time curves (AUC) with repeated administration (Table 56–3). They have good penetration into many tissues, but levels in the CNS reach only ~5% of those in plasma, likely due to the activity of P-glycoprotein. The drugs and metabolites are excreted by bile and eliminated via feces, with urine elimination accounting for only one-third and less of metabolites.

The population pharmacokinetics (PK) of rifampin are best described using a one-compartment model with transit compartment absorption (Wilkins et al., 2008), using the PK parameters in Table 56–2. Single-drug formulations increase mean transit time during absorption by ~100% and systemic clearance (SCL) by 24% in comparison to fixed-dose combinations of rifampin and other anti-TB drugs. Thus the absorption of rifampin will be slower, and the peak concentration (CPmax) of rifampin lower, with some formulations compared to others (Wilkins et al., 2008).

Rifapentine pharmacokinetics are likewise best described using a one-compartment open model with first-order absorption and elimination (Langdon et al., 2005). The PK parameters are summarized in Table 56–2. However, for each 1-kg weight increase above 50 kg, SCL increases by 0.05 L/hour and Vₐ by 0.69 L. Thus, CPmax and AUC decrease with increasing patient weight above 50 kg.

Rifabutin pharmacokinetics are best described by a two-compartment open model with first-order absorption and elimination. Rifabutin disposition is biexponential. Rifabutin concentrations are substantially higher in tissue than in plasma due to its lipophilic properties, leading to the very high apparent volumes of distribution (Table 56–2). The consequence is that CPmax values for rifabutin are lower than one would predict by comparison with other rifamycins. The volume of peripheral compartment decreases by 27% with concomitant azithromycin administration; tobacco smoking increases the volume by 39%.

Pharmacokinetics-Pharmacodynamics. Rifampin’s bactericidal activity is best optimized by a high AUC/MIC ratio (Gumbo et al., 2007a). However, resistance suppression and rifampin’s enduring post-antibiotic effect are best optimized by high Cmax/MIC. Therefore, the duration of time that the rifampin concentration persists above the MIC is of less importance.

These results predict that the t½ of a rifamycin is less of an issue in optimizing therapy, and that if patients could tolerate it, higher doses

Figure 56–1. Mechanisms of action of established and experimental drugs used for the chemotherapy of mycobacterial infections. Shown at the top are the sites of action of approved drugs for the chemotherapy of mycobacterial diseases. Rifamycin is used as a generic term for several drugs, of which rifampin is used most frequently. Also included are two experimental drugs now under investigation: TMC-207 and PA-824. Clofazimine, whose mode of action is not understood, is omitted.
especially those caused by staphylococci “tolerant” to penicillin. Rifampin may also be indicated for the eradication of the staphylococcal nasal carrier state in patients with chronic furunculosis.

Untoward Effects. Rifampin is generally well tolerated in patients. Usual doses result in <4% of patients with TB developing significant adverse reactions; the most common are rash (0.8%), fever (0.5%), and nausea and vomiting (1.5%). Rarely, hepatitis and deaths due to liver failure have been observed in patients who received other hepatotoxic agents in addition to rifampin or who had preexisting liver disease. Chronic liver disease, alcoholism, and old age appear to increase the incidence of severe hepatic problems. GI disturbances have occasionally required discontinuation of the drug. Various nonspecific symptoms related to the nervous system also have been noted. Hypersensitivity reactions may be encountered. Hemolysis, hemoglobinuria, hematuria, renal insufficiency, and acute renal failure have been observed rarely; these also are thought to be hypersensitivity reactions. High-dose rifampin should not be administered on a dosing schedule of less than twice weekly because this is associated with a flu-like syndrome of fever, chills, and myalgias in 20% of patients so treated. The syndrome also may include eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock. Light chain proteinuria has also been documented with rifampin use. Thrombocytopenia, transient leukopenia, and anemia have occurred during therapy. Because the potential teratogenicity of rifampin is unknown and the drug is known to cross the placenta, it is best to avoid the use of this agent during pregnancy.

Rifabutin is generally well tolerated; primary reasons for discontinuation of therapy include rash (4%), GI intolerance (3%), and neutropenia (2%) (Nightingale et al., 1993). Neutropenia occurred in

AUC, area under the curve.

25% of patients with severe HIV infection who received rifabutin. Uveitis and arthralgias have occurred in patients receiving rifabutin doses >450 mg daily in combination with clarithromycin or fluconazole. Patients should be cautioned to discontinue the drug if visual symptoms (pain or blurred vision) occur. Rifabutin causes an orange-tan discoloration of skin, urine, feces, saliva, tears, and contact lenses, like rifampin. Rarely, thrombocytopenia, a flu-like syndrome, hemolysis, myositis, chest pain, and hepatitis develop in patients treated with rifabutin. Unique side effects include polymyalgia, pseudojaundice, and anterior uveitis.
**Pyrazinamide**

Pyrazinamide is the synthetic pyrazine analog of nicotinamide. Pyrazinamide is also known as pyrazinoic acid amide, pyrazine carboxylamide, and pyrazincarboxamide.

**Mechanism of Action.** Pyrazinamide is “activated” by acidic conditions. Initially it was assumed that the acidic conditions under which pyrazinamide works were inside macrophage phagosomes. However, pyrazinamide may not be very effective within macrophages; rather, the acidic conditions for activation may be at the edges of necrotic TB cavities where inflammatory cells produce lactic acid (Blumberg et al., 2003). *Mycobacterium tuberculosis* nicotineamidase, or pyrazinamidase deaminates pyrazinamide to pyrazinoic acid (POA), which is then transported to the extracellular milieu by an efflux pump (Zhang et al., 1999). In an acid extracellular milieu, a fraction of POA is protonated to POAH, a more lipid-soluble form that enters the bacillus. The Henderson-Hasselbalch equilibrium (Chapter 2) progressively favors the formation of POAH and its equilibrium across membranes as the pH of the extracellular medium declines toward the pKa of pyrazinoic acid, 2.9, a condition that also enhances microbial killing (Zhang et al., 2002). Although the actual mechanism of microbial kill is still unclear, three mechanisms have been proposed (Zhang et al., 2003; Zimhony et al., 2000):

- inhibition of fatty acid synthase type I leading to interference with mycolic acid synthesis
- reduction of intracellular pH
- disruption of membrane transport by HPOA

**Antibacterial Activity.** Pyrazinamide exhibits antimicrobial activity in vitro only at acidic pH. At pH of 5.8-5.95, 80-90% of clinical isolates have an MIC of ≤100 mg/L (Salfinger and Heifets, 1988).

**Mechanisms of Resistance.** Pyrazinamide-resistant *M. tuberculosis* have pyrazinamidase with reduced affinity for pyrazinamide. This reduced affinity decreases the conversion of pyrazinamide to POA. Single point mutations in the *pncA* gene are encountered in up to 70% of resistant clinical isolates. The mechanisms contributing to resistance in 30% of resistant clinical isolates is unclear.

**Absorption, Distribution, and Excretion.** Pyrazinamide oral bioavailability is >90%. Pharmacokinetics are best described by a one-compartment model. GI absorption segregates patients into two groups: fast absorbers (56%) with an absorption rate constant of 3.56/hour and slow absorbers (44%) with an absorption rate of 1.25/hour (Wilkins et al., 2006). The drug is concentrated 20-fold in lung epithelial lining fluid (Conte et al., 2000). Pyrazinamide is metabolized by microsomal deamidase to POA and subsequently hydroxylated to 5-hydroxy-POA, which is then excreted by the kidneys. CL (clearance) and Vd (volume of distribution) increase with patient mass (0.5 L/hour and 4.3 L for every 10 kg above 50 kg), and Vd is larger in males (by 4.5 L) (see Table 56–2). This has several implications: The t1/2 of pyrazinamide will vary considerably based on weight and gender, and the AUC0-24 will decrease with increase in weight for the same dose (same mg drug/kg body weight). Pyrazinamide clearance is reduced in renal failure; therefore, the dosing frequency is reduced to three times a week at low glomerular filtration rates. Hemodialysis removes pyrazinamide; therefore, the drug needs to be re-dosed after each session of hemodialysis (Malone et al., 1999b).

**Microbial Pharmacokinetics-Pharmacodynamics.** Pyrazinamide’s sterilizing effect is closely linked to AUC0-24/MIC (Gumbo et al., 2008). However, resistance suppression is linked to the fraction of time that C_P persists above MIC (T > MIC). Because patient weight impacts both SCL and volume, both AUC and t1/2 will be impacted by high weight. Clinical trial simulations that account for patient weight reveal that optimal AUC0-24/MIC and T > MIC are likely to be achieved only by doses much higher than the currently recommended 15-30 mg/kg/day (Gumbo et al., 2008). The safety of such higher doses in actual patients is unclear.

**Therapeutic Uses.** The co-administration of pyrazinamide with isoniazid or rifampin has led to a one-third reduction in the duration of anti-TB therapy, and a two-thirds reduction in TB relapse. This led to reduction in length of therapy to 6 months, producing the current “short course” chemotherapy. Pyrazinamide is administered at an oral dose of 15-30 mg/kg/day.

**Untoward Effects.** Injury to the liver is the most serious side effect of pyrazinamide. When a dose of 40-50 mg/kg is administered orally, signs and symptoms of hepatic disease appear in ~15% of patients, with jaundice in 2-3% and death due to hepatic necrosis in rare instances. However, these rates were determined in an era when
Pyrazinamide was administered for durations much longer than the current 2 months. Elevations of plasma alanine/aspartate aminotransferases are the earliest abnormalities produced by the drug. Regimens employed currently (15-30 mg/kg/day) are much safer. Prior to pyrazinamide administration, all patients should undergo studies of hepatic function, and these studies should be repeated at frequent intervals during the entire period of treatment. If evidence of significant hepatic damage becomes apparent, therapy must be stopped. Pyrazinamide should not be given to individuals with hepatic dysfunction unless this is absolutely unavoidable.

Pyrazinamide inhibits excretion of urate, resulting in hyperuricemia in nearly all patients, and may cause acute episodes of gout. Other untoward effects observed with pyrazinamide include arthralgias, anorexia, nausea and vomiting, dysuria, malaise, and fever. In the U.S., the use of pyrazinamide is not approved during pregnancy because of inadequate data on teratogenicity.

There are minimal data on pyrazinamide overdose, and no antidote has been studied.

**Isoniazid**

Isoniazid (NYDRAZID, others) is a primary drug for the chemotherapy of tuberculosis. All patients infected with isoniazid-sensitive strains of the tubercle bacillus should receive the drug if they can tolerate it. The use of combination therapy (isoniazid + pyrazinamide + rifampin) provides the basis for “short-course” therapy and improved remission rates.

**Chemistry.** Isoniazid (isonicotinic acid hydrazide), also called INH, is a small water-soluble molecule (MW = 137) that is structurally related to pyrazinamide (see Figure 56–3).

**Mechanism of Action.** Isoniazid enters bacilli by passive diffusion. The drug is not directly toxic to the bacillus but must be activated to its toxic form within the bacillus by KatG, a multifunctional catalase-peroxidase. KatG catalyzes the production from isoniazid of an isonicotinoyl radical that subsequently interacts with mycobacterial NAD and NADP to produce a dozen adducts (Argyrou et al., 2007). One of these, a nicotinoyl-NAD isomer, inhibits the activities of enoyl acyl carrier protein reductase (InhA) and β-ketoacyl acyl carrier protein synthase (KasA). Inhibition of these enzymes inhibits synthesis of mycolic acid, an essential component of the mycobacterial cell wall, leading to bacterial cell death. Another adduct, a nicotinoyl-NADP isomer, potently inhibits \( K_i < 1 \text{nM} \) mycobacterial dihydrofolate reductase, thereby interfering with nucleic acid synthesis (Argyrou et al., 2006). See Figure 56–3.

![Figure 56–3](image)

*Figure 56–3. Metabolism and activation of isoniazid.* The pro-drug isoniazid is metabolized in humans by NAT2 isoforms to its principal metabolite, N-acetyl isoniazid, which is excreted by the kidney. Isoniazid diffuses into mycoplasma where it is “activated” by KatG (oxidase/peroxidase) to the nicotinoyl radical, which reacts spontaneously with NAD\(^+\) or NADP\(^+\) to produce adducts that inhibit important enzymes in cell-wall and nucleic acid synthesis. DHFR, dihydrofolate reductase.
Other products of KatG activation of INH include superoxide, \( \text{H}_2\text{O}_2 \), alkyl hydroperoxides, and the NO radical, which may also contribute to the mycobactericidal effects of INH (Timmins and Deretic, 2006). \( M. \text{tuberculosis} \) could be especially sensitive to damage from these radicals because the bacilli have a defect in the central regulator of the oxidative stress response, \( \text{oxyR} \). Backup defense against radicals is provided by alkyl hydroperoxide reductase (encoded by \( \text{ahpC} \)), which detoxifies organic peroxides. Increased expression of \( \text{ahpC} \) reduces isoniazid effectiveness.

**Antibacterial Activity.** The isoniazid MICs with clinical \( M. \text{tuberculosis} \) strains vary from country to country. In the U.S., e.g., the MICs are 0.025-0.05 mg/L (Heifets, 1991). Activity against \( M. \text{bovis} \) and \( M. \text{kansasii} \) is moderate. Isoniazid has poor activity against MAC. It has no activity against any other microbial genus.

**Mechanisms of Resistance.** The prevalence of drug-resistant mutants is ~1 in 10^6 bacilli. Because TB cavities may contain as many as 10^7 to 10^8 microorganisms, preexistent resistance can be expected in pulmonary TB cavities of untreated patients. These spontaneous mutants can be selected by monotherapy; indeed, strains resistant to isoniazid will be selected and amplified by isoniazid monotherapy. Thus two or more agents are usually used. Because the mutations resulting in drug resistance are independent events, the probability of resistance to two antimycobacterial agents is small, ~1 in 10^{12} (1 \times 10^6 \times 10^6), a low probability considering the number of bacilli involved.

Resistance to INH is associated with mutation or deletion of katG, overexpression of the genes for inhA (confers low-level resistance to INH and some cross-resistance to ethionamide), and \( \text{ahpC} \) and mutations in the \( \text{kasA} \) and \( \text{katG} \) genes. KatG mutants exhibit a high level of resistance to isoniazid (Zhang and Yew, 2009). The most common mechanism of isoniazid resistance in clinical isolates is due to single point mutations in the heme binding catalytic domain of KatG, especially a serine to asparagine change at position 315. Although isolates with this mutation completely lose the ability to form nicotinoyl-NAD+/NADP+ adducts, they retain good catalase activity and maintain good biofitness. Compensatory mutations in the \( \text{ahpC} \) promoter occur and increase survival of \( \text{katG} \) mutant strains under oxidative stress.

\( \text{KatG} \) 315 mutants have a high probability of co-occurrence with ethambutol resistance (Hazbón et al., 2006; Parsons et al., 2005). Mutations in \( \text{katG} \), \( \text{ahpC} \), and \( \text{inhA} \) have also been associated with \( \text{rpoB} \) mutations (Habzón et al., 2006). This suggests that mutations at different loci associated with resistance to different drugs may somehow interact to make multiple drug resistance more likely. In the laboratory, efflux pump induction by isoniazid has been demonstrated, and it also confers resistance to ethambutol (Colangeli et al., 2005). In an in vitro pharmacodynamic model, efflux pump-induced resistance developed within 3 days and was followed by development of \( \text{katG} \) mutations (Gumbo et al., 2007b).

**Absorption, Distribution, and Excretion.** The bioavailability of orally administered isoniazid is ~100% for the 300 mg dose. The pharmacokinetics of isoniazid are best described by a one-compartment model, with the pharmacokinetic parameters in Table 56–2 (Kinzig-Schippers et al., 2005). The ratio of isoniazid in the epithelial lining fluid to that in plasma is 1-2 and for CSF is 0.9 (Conte et al., 2002). Approximately 10% of drug is bound to protein. From 75-95% of a dose of isoniazid is excreted in the urine within 24 hours, mostly as acetylisoniazid and isonicotinic acid.

Isoniazid is metabolized by hepatic arylamine \( N \)-acetyltransferase type 2 (\( \text{ NAT2}^* \)), encoded by a variety of \( \text{ NAT2}^* \) alleles (Figure 56–3). The drug is \( N \)-acetylated to \( N \)-acetylisoniazid in a reaction that uses acetyl-coA. Isoniazid clearance in patients has been traditionally classified as one of two phenotypic groups: “slow” and “fast” acetylators, as seen in Figure 56–4. Recently, the phenotypic groups have been expanded to fast, intermediate, and slow acetylators, and population pharmacokinetic parameters of isoniazid have been estimated and related to \( \text{ NAT2} \) genotype; the number of \( \text{ NAT2}^*4 \) alleles account for 88% of the variability of INH clearance (Kinzig-Schippers et al., 2005).

The frequency of each acetylation phenotype depends on race but is not influenced by sex or age. Fast acetylation is found in Inuit and Japanese. Slow acetylation is the predominant phenotype in most Scandinavians, Jews, and North African whites. The incidence of “slow acetylators” among various racial types in the U.S. is ~50%. Because high acetyltransferase activity (fast acetylation) is inherited as an autosomal dominant trait, “fast acetylators” of isoniazid are either heterozygous or homozygous. Although it has been useful to categorize different “racial” groups dominated by one or the other of these phenotypes, the more precise approach will be to determine the \( \text{ NAT2}^*4 \) alleles for each patient to guide therapy for that patient in the future.

**Microbial Pharmacokinetics-Pharmacodynamics.** Isoniazid’s microbial kill is best explained by the AUC_{0-24h} to MIC ratio (Gumbo et al., 2007c). Resistance emergence is closely related to both AUC/MIC and \( C_{\text{max}}/\text{MIC} \) (Gumbo et al., 2007c). Because AUC is proportional to dose/CL, this means that efficacy is most dependent on drug dose and CL, and thus on the activity of \( \text{ NAT-2} \) polymorphic forms. This also suggests that dividing the isoniazid dose into more frequent doses may be detrimental in terms of resistance emergence, and more intermittent dosing would be better (Chapter 48).

**Therapeutic Uses.** Isoniazid is available as a pill, as an elixir, and for parenteral administration. The commonly used total daily dose of isoniazid is 5 mg/kg, with a maximum of 300 mg; oral and intramuscular doses are identical. Children should receive 10-15 mg/kg/day (300 mg maximum). Dosing information in the treatment of \( M. \text{tuberculosis} \) and \( M. \text{kansasii} \) infections is given in section II and VI.

**Untoward Effects.** After \( \text{ NAT2} \) converts isoniazid to acetylsisoniazid, which is excreted by the kidney; acetylsisoniazid can also be converted to acetylhydrazine (Roy et al., 2008), and then to hepatotoxic metabolites by CYP2E1. Alternatively, acetylhydrazine may be further acetylated by \( \text{ NAT-2} \) to diacetylhydrazine, which is nontoxic. In this scenario, rapid acetylators will rapidly remove acetylhydrazine while slower acetylators or induction of CYP2E1 will lead to more toxic metabolites. Rifampin is a potent inducer of CYP2E1, which is why it potentiates isoniazid hepatotoxicity.

Elevated serum aspartate and alanine transaminases are encountered commonly in patients on isoniazid. However, the enzyme levels often normalize even when isoniazid therapy is continued (Blumberg et al., 2003). Severe hepatic injury occurs in ~0.1% of all patients taking the drug. Hepatic damage is rare in patients <20 years old but the incidence increases with age to 1.2%
between 35 and 49 years and to 2.3% over 50 years of age. Overall risk is increased by co-administration with rifampin to ~3%. Fatal hepatitis is even rarer (0.02%). Most cases of hepatitis occur 4-8 weeks after the start of therapy.

If pyridoxine is not given concurrently, peripheral neuritis (most commonly paresthesias of feet and hands) is encountered in ~2% of patients receiving isoniazid 5 mg/kg of the drug daily. Neuropathy is more frequent in “slow” acetylators and in individuals with diabetes mellitus, poor nutrition, or anemia. Other neurological toxicities include convulsions in patients with seizure disorders, optic neuritis and atrophy, muscle twitching, dizziness, ataxia, paresthesias, stupor, and toxic encephalopathy. Mental abnormalities may

**Figure 56–4. Multi-modal distribution of INH clearance due to NAT2 polymorphisms.** Twenty-four male volunteers were given INH (250 mg orally [3.3 ± 0.5 mg/kg; all subjects within 10% of estimated lean body mass]) and the time courses of plasma levels (Cₚ) were assessed. (Modified with permission from Peloquin CA et al. Population pharmacokinetic modeling of isoniazid, rifampin, and pyrazinamide. *Antimicrob Agents Chemother*; 1997, 41:2670. With permission from American Society for Microbiology.)

**A. Frequency distribution of elimination half-times.** Plotting elimination half-times (t₁/₂) as a frequency distribution demonstrates a group of 8 subjects with t₁/₂ values < 1.5 hours (mean = 1.2 hours), the *fast acetylators*, and a group of 16 with t₁/₂ values > 2 hours (mean = 3.3 hours), the *slow acetylators*. **B. Time course of plasma levels.** The mean data (Cₚ vs time after administration) fall into two major groups (see panel A). Both groups reached Cₚmax at 1 hour. One group (red line) achieved a higher Cₚ (3.6 μg/mL) with a mean elimination t₁/₂ = 3.3 hours (*slow acetylators*); the other group (green line) reached a lower maximal Cₚ (2.3 μg/mL) with a mean elimination t₁/₂ = 1.2 hours (*fast acetylators*).

Variation in expression of active and defective polymorphic forms of NAT2 characterize the fast and slow acetylators. Slow acetylators may be a greater risk for adverse effects from INH, sulfonamides, and procainamide, whereas fast acetylators may have diminished responses to standard doses of these agents but greater risk from bioactivation by NAT2 of arylamine/hydrazine carcinogens. Recently, researchers have identified three elimination subgroups for INH metabolism, *fast*, *slow*, and *intermediate* (codominant fast and slow alleles).
appear during the use of this drug, including euphoria, transient impairment of memory, separation of ideas and reality, loss of self-control, and florid psychoses. The prophylactic administration of pyridoxine prevents the development not only of peripheral neuritis, as well as most other nervous system disorders in practically all instances, even when therapy lasts as long as 2 years.

Patients may develop hypersensitivity to isoniazid. Hematological reactions also may occur. Vasculitis associated with antinuclear antibodies may appear during treatment but disappears when the drug is stopped. Arthritic symptoms (back pain; bilateral proximal interphalangeal joint involvement; arthralgia of the knees, elbows, and wrists; and the “shoulder-hand” syndrome) have been attributed to this agent.

Miscellaneous reactions associated with isoniazid therapy include dryness of the mouth, epigastric distress, methemoglobinemia, tinnitus, and urinary retention. In persons predisposed to pyridoxine-deficiency anemia, the administration of isoniazid may result in dramatic anemia. Treatment of the anemia with large doses of vitamin B₆ gradually returns the blood count to normal. A drug-induced syndrome resembling systemic lupus erythematosus has also been reported.

**Isoniazid Overdose.** Intentional isoniazid overdose occurs most often in young women with concomitant psychiatric problems prescribed isoniazid for latent TB (Sullivan et al., 1998). As little as 1.5 g can be toxic. Isoniazid overdose has been associated with the clinical triad of:

- seizures refractory to treatment with phenytoin and barbiturates
- metabolic acidosis with an anion gap that is resistant to treatment with sodium bicarbonate
- coma

The common early symptoms appear within 0.5-3 hours of ingestion and include ataxia, peripheral neuropathy, dizziness, and slurred speech. The most dangerous are grand mal seizures and coma, encountered when patients ingest ≥30 mg/kg of the drug. Mortality in these circumstances is as high as 20%. Intravenous pyridoxine is administered over 5-15 minutes on a gram-to-gram basis with the ingested isoniazid. If the dose of ingested isoniazid is unknown, then a pyridoxine dose of 70 mg/kg should be used. In patients with seizures, benzodiazepines are utilized.

Isoniazid’s toxicity may be interpreted in terms of effects on pyridoxine metabolism. Isoniazid binds to pyridoxal 5’-phosphate to form isoniazid-pyridoxal hydrazones, thereby depleting neuronal pyridoxal 5’-phosphate and interfering with pyridoxal phosphate-requiring reactions, including the synthesis of the inhibitory neurotransmitter, GABA. Decreased levels of GABA lead to cerebral overexcitability and lowered seizure threshold. The antidote is replenishment of pyridoxal 5’-phosphate.

**Drug Interactions.** Isoniazid is a potent inhibitor of CYP2C19, CYP3A, and a weak inhibitor of CYP2D6 (Desta et al., 2001). However, isoniazid induces CYP2E1. Drugs that are metabolized by these enzymes will potentially be affected. Table 56–4, based on work by Desta et al. (2001), is a summary of drugs that interact with isoniazid via these mechanisms.

**Ethambutol**

Ethambutol hydrochloride (MYAMBUTOL) is a water-soluble and heat-stable compound:

![Ethambutol](image)

**Mechanism of Action.** Ethambutol inhibits arabinosyl transferase III, thereby disrupting the transfer of arabinose into arabinogalactan biosynthesis, which in turn disrupts the assembly of mycobacterial cell wall (Lewis, 1999). The arabinosyl transferases are encoded by embAB genes.

**Antibacterial Activity.** Ethambutol has activity against a wide range of mycobacteria but has no activity against any other genus. Ethambutol MICs are 0.5-2 mg/L in clinical isolates of *M. tuberculosis*, ~0.8 mg/L for *M. kansasii*, and 2-7.5 mg/L for *M. avium* (Heifets, 1991; 1993).

</table>
and children. Ethambutol is administered at 15-25 mg/kg per day for both adults and children. However, the majority of M. gordonae, M. marinum, M. scrofulaceum, M. szulgai. However, the majority of M. xenopi, M. fortuitum, and M. chelonea have been reported as resistant (Lewis, 1999).

Mechanisms of Resistance. In vitro, mycobacterial resistance to the drug develops via mutations in the embB gene. In 30-70% of clinical isolates that are resistant to ethambutol, mutations are encountered at codon 306 of the embB gene. However, mutations in this codon are also encountered in ethambutol-susceptible mycobacteria, as though this mutation is necessary, but not sufficient, to confer ethambutol resistance (Safi et al., 2008). In addition, enhanced efflux pump activity may induce resistance to both isoniazid and ethambutol in the laboratory.

Absorption, Distribution, Metabolism, and Excretion. The oral bioavailability of ethambutol is ~80%. Approximately 10-40% of the drug is bound to plasma protein. Ethambutol drug concentrations have been modeled using a two-compartment open model, with first-order absorption and elimination (Peloquin et al., 1999; Zhu et al., 2004). The decline in ethambutol is biexponential, with a t1/2 of 3 hours in the first 12 hours, and a t1/2 of 9 hours between 12 and 24 hours, due to redistribution of drug. Clearance and Vd are greater in children than in adults on a per kilogram basis. Slow and incomplete absorption is common in children, so that good peak concentrations of drug are often not achieved with standard dosing (Zhu et al., 2004). In addition, these Cmax values are not very impressive given the typical MIC values for most clinical isolates of mycobacteria. See Table 56–2 for PK data on this drug.

Alcohol dehydrogenase oxidizes ethambutol to an aldehyde, which is then oxidized by aldehyde dehydrogenase to dicarboxylic acid. However, 80% of the drug is not metabolized at all and is renally excreted. Therefore, in renal failure ethambutol should be dosed at 15-25 mg/kg, three times a week instead of daily, even in patients receiving hemodialysis.

Microbial pharmacokinetics-pharmacodynamics. Ethambutol’s microbial kill of M. tuberculosis is optimized by AUC/MIC, while that against disseminated MAC is optimized by Cmax/MIC (Srivastava et al., 2010; Deshpande et al., 2010). Thus, to optimize microbial kill, high intermittent doses such as 25 mg/kg every other day to 50 mg/kg twice a week may be superior to daily doses of 15 mg/kg.

Therapeutic Uses. Ethambutol is available for oral administration in tablets containing the D-isomer. It is used for the treatment of TB, disseminated MAC, and in M. kansasi infection. Ethambutol is administered at 15-25 mg/kg per day for both adults and children.

Untoward Effects. Ethambutol produces very few serious untoward reactions. Fewer than 2% of patients who receive daily doses of 15 mg/kg of ethambutol have adverse reactions: ~1% experience diminished visual acuity, 0.5% a rash, and 0.3% drug fever. Other side effects that have been observed are pruritus, joint pain, GI upset, abdominal pain, malaise, headache, dizziness, mental confusion, disorientation, and possible hallucinations. Numbness and tingling of the fingers owing to peripheral neuritis are infrequent. Anaphylaxis and leukopenia are rare. Therapy with ethambutol results in an increased concentration of urate in the blood in ~50% of patients, owing to decreased renal excretion of uric acid.

The most important side effect is optic neuritis, resulting in decreased visual acuity and loss of ability to differentiate red from green. The incidence of this reaction is proportional to the dose of ethambutol and is observed in 15% of patients receiving 50 mg/kg/day, in 5% of patients receiving 25 mg/kg/day, and in <1% of patients receiving daily doses of 15 mg/kg. The intensity of the visual difficulty is related to the duration of therapy after the decreased visual acuity first becomes apparent and may be unilateral or bilateral. Tests of visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter are thus recommended. Recovery usually occurs when ethambutol is withdrawn; the time required is a function of the degree of visual impairment.

Cases of ethambutol overdose are rare; drug interactions involving ethambutol are not significant.

Aminoglycosides: Streptomycin, Amikacin, and Kanamycin

The aminoglycosides streptomycin, amikacin, and kanamycin are used for the treatment of mycobacterial diseases. The MICs for M. tuberculosis in Middlebrook broth are 0.25-3.0 mg/L for all three aminoglycosides (Heifets, 1991). For M. avium streptomycin and amikacin, MICs are 1-8 mg/L; those of kanamycin are 3-12 mg/L. M. kansasi is frequently susceptible to these agents, but other nontuberculous mycobacteria are only occasionally susceptible. The pharmacological properties and therapeutic uses of aminoglycosides are discussed in full in Chapter 54.

Bacterial Resistance. Primary resistance to streptomycin is found in 2-3% of M. tuberculosis clinical isolates. Streptomycin and the two other aminoglycosides inhibit protein synthesis by binding to the 30S ribosomal subunit and causing misreading of the genetic code during translation. The 30S ribosomal unit is made of the 16S mRNA (encoded by rpsL), which binds to the ribosomal protein S12 (encoded by rrs) to optimize tRNA binding and mRNA decoding. Mutations in rpsL and rrs are associated with high-level aminoglycoside resistance in mycobacteria. However, mutations in these genes are only encountered in half of clinical isolates with aminoglycoside resistance. GidB is an rRNA methyltransferase for 16S rRNA, and mutations in gidB gene are associated with low-level streptomycin resistance (Okamoto et al., 2007). The gidB mutations lead to high-level streptomycin resistant mutants at a rate 2000 times that in wild type. Mutations in gidB are encountered in 33% of streptomycin-resistant clinical isolates of M. tuberculosis. Finally, efflux pump–mediated resistance was recently demonstrated in clinical isolates with low-level streptomycin-resistant M. tuberculosis and interacted with chromosomal mutations in gidB (Spies et al., 2008). Thus resistance to aminoglycosides involves several genetic loci, as well as efflux pumps.

Therapeutic Uses. Therapeutic uses of aminoglycosides in treatment of mycobacterial infections are discussed later.
**Mechanism of Action.** The biochemical basis for the antimicrobial actions of clofazimine remains to be established (Anonymous, 2008a). Possible mechanisms of action include:

- membrane disruption
- inhibition of mycobacterial phospholipase A$_2$
- inhibition of microbial K$^+$ transport
- generation of hydrogen peroxide
- interference with the bacterial electron transport chain

However, it is known that clofazimine has both antibacterial activity as well as anti-inflammatory effects via inhibition of macrophages, T cells, neutrophils, and complement.

**Antibacterial Activity.** The MICs for *M. avium* clinical isolates are 1-5 mg/L. The MICs for *M. tuberculosis* are ~1.0 mg/L. The compound also is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*. It has activity against many gram-positive bacteria with an MIC ≤1.0 mg/L against *S. aureus*, coagulase-negative *Staphylococci*, *Streptococcus pyogenes*, and *Listeria monocytogenes*. Gram-negative bacteria have MICs >32 mg/L.

**Bacterial Resistance.** Mechanisms of resistance are unknown.

**Absorption, Distribution, and Excretion.** Clofazimine’s oral bioavailability is highly variable, 45-60%; bioavailability is increased 2-fold by high-fat meals and decreased 30% by antacids (Nix et al., 2004). After a single dose, clofazimine is best modeled using a one-compartment model and has a prolonged absorption phase; after 200 mg of clofazimine, the $t_{max}$ is 5.3-7.8 hours. After prolonged repeated dosing, the $t_{1/2}$ is ~70 days. For PK data, see Table 56–2 and Nix et al. (2004). As a result of the good penetration into many tissues, a reddish black discoloration of skin and body secretions may occur and take a long time to resolve. Crystalline deposits of the drug have been encountered in many tissues at autopsy (Anonymous, 2008a). Clofazimine is metabolized in the liver in four steps: hydrolytic dehalogenation, hydrolytic deamination, glucuronidation, and hydroxylation.

**Dosing.** Clofazimine is administered orally at doses up to 300 mg a day.

**Untoward Effects.** GI problems are encountered in 40-50% of patients and include abdominal pain, diarrhea, nausea, and vomiting. In patients who have died following the abdominal pain, crystal deposition in intestinal mucosa, liver, spleen, and abdominal lymph nodes has been demonstrated (Anonymous, 2008a). Body secretion discoloration, eye discoloration, and skin discoloration occur in most patients and can lead to depression in some patients.

**Drug interactions.** Anti-inflammatory effects may be inhibited by dapsone.

**Fluoroquinolones**

Fluoroquinolones are DNA gyrase inhibitors. Their chemistry, spectrum of activity, pharmacology, and adverse events are discussed in greater detail in Chapter 52. Drugs such as ofloxacin and ciprofloxacin have been second-line anti-TB agents for many years, but they are limited by the rapid development of resistance. Adding C8 halogen and C8 methoxy groups markedly reduces the propensity for drug resistance. Of the C8 methoxy quinolones, moxifloxacin (approved by the Food and Drug Administration for nontubercular infections) is furthest along in clinical testing as an anti-TB agent. Moxifloxacin is being studied to replace either isoniazid or ethambutol.

**Microbial Pharmacokinetics-Pharmacodynamics Relevant to TB.** Fluoroquinolone microbial kill is best explained by AUC$_{0-24}$/MIC ratio. In preclinical models, moxifloxacin AUC$_{0-24}$/MIC exposures equivalent to those from the standard 400-mg dose were associated with good microbial kill but amplified the drug-resistant subpopulation, so that resistance emerged in 7-13 days with monotherapy (Gumbo et al., 2004). This time to emergence of resistance harmonizes well with speed of resistance emergence in patients (Ginsburg et al., 2003). Moxifloxacin exposure best associated with minimizing emergence of resistance was an AUC$_{0-24}$/MIC of 53. Clinical trial simulations revealed that doses >400 mg a day might better achieve this AUC/MIC, which experiments in mice substantiate (Almeida et al., 2007). Given that rifamycins reduce moxifloxacin AUC, these results point to a potential concern of quinolone resistance. Unfortunately, the safety of moxifloxacin doses >400 mg has not been established.

**Therapeutic Uses in Treatment of TB.** In TB patients, moxifloxacin (400 mg/day) has bactericidal effects similar to that of standard doses of isoniazid (Johnson et al., 2006). When replacing ethambutol in the standard multi-drug regimen, 400 mg/day of moxifloxacin produces faster sputum conversion at 4 weeks than ethambutol (Burman et al., 2006b). In a comparison study of moxifloxacin, gatifloxacin, ofloxacin, and ethambutol as the fourth drug administered concurrently with isoniazid, rifampin, and pyrazinamide (Rustomjee et al., 2008b), moxifloxacin led to faster rates of bacterial kill during the early phases, gatifloxacin was equivalent by the eighth week, and ofloxacin was no better than ethambutol. Moxifloxacin is currently being studied in a phase 3 trial that may eventually lead to 4-month duration of anti-TB therapy compared to the current 6 months.

**Drug Interactions Relevant to TB.** In a study of volunteers treated with rifampin, moxifloxacin, or both drugs, rifampin reduced the moxifloxacin AUC$_{0-24}$ by 27% via induction of sulfate conjugation (Weiner et al., 2007). In another study, rifapentine reduced moxifloxacin AUC$_{0-24}$ by 17% (Dooley et al., 2008). These studies suggest that the most important cause of pharmacokinetic variability for moxifloxacin is concomitantly administered drugs for tuberculosis.
TMC-207 (R207910)

TMC-207 is a diarylquinone discovered by Andries et al. in 2005.

Mechanism of Action. TMC-207 acts by targeting subunit c of the ATP synthase of M. tuberculosis, leading to inhibition of the proton pump activity of the ATP synthase (Andries et al., 2005; Koul et al., 2007). Thus, the compound targets bacillary energy metabolism.

Antibacterial Activity. The TMC-207 MIC for M. tuberculosis is 0.03-0.12 mg/L. It has good activity against MAC, M. leprae, M. bovis, M. marinum, M. kansasii, M. ulcera, M. fortuitum, M. szulgai, and M. abscessus (Andries et al., 2005; Huitric et al., 2007).

Bacterial Resistance. The proportion of M. tuberculosis mutants resistant to four times the MIC is 5 × 10^{-7} to 2 × 10^{-8}. Resistance is associated with two point mutations: D32V and A63P. This region of the gene encodes the membrane-spanning domain of the ATP synthase c subunit.

Absorption, Distribution, and Excretion. After oral ingestion of 400 mg of TMC-207, the t max was 4 hours, the C max was 5.5 mg/L after 400 mg/day, and the AUC0-24 was 65 mg·h/L. Based on these data, the CL is ~6.2 L/h, although systemic clearance reportedly is “triexponential.” Population pharmacokinetic studies have not been published.

Pharmacokinetics, Efficacy, and Therapeutic Use. The anti-TB activity of TMC-207 is correlated with time above MIC. In murine TB, TMC-207 had superior bactericidal activity compared to isoniazid and rifampin, and accelerated sterilization when combined with rifampin, isoniazid, and pyrazinamide (Andries et al., 2005). In patients with drug-susceptible TB, the rate of sputum bacillary decline was similar to rifampin and isoniazid (Rustomjee et al., 2008a). A regimen of TMC207 400 mg daily for 2 weeks followed by 200 mg three times day thereafter was added to a background second-line regimen of either kanamycin or amikacin, ofloxacin with or without ethambutol in patients with TB resistant to both isoniazid and rifampin (MDR-TB), and led to an 8-week sputum conversion of ~50% with TMC207 compared to 9% without (Diacon et al., 2009).

Untoward Effects. The adverse events encountered with TMC207 are mild and include nausea in 26% of patients and diarrhea in 13% of patients, with others such as arthralgia, pain in extremities, and hyperuricemia in a small proportion of patients (Diacon et al., 2009). However, only a limited number of patients have been exposed to this drug, so that the full side-effect profile is unclear.

PA-824

PA-824 is a nitroimidazopyran discovered by Stover et al. in 2000.

Mechanism of Action. PA-824 inhibits M. tuberculosis mycolic acid and protein synthesis at the step between hydroxymycolate and ketomycolate (Stover et al., 2000). Similar to the structurally related metronidazole, PA-824 is a pro-drug that requires activation by the bacteria via a nitro-reduction step that requires, among other factors, a specific glucose-6-phosphate dehydrogenase, FGD1, and the reduced deazaflavin co-factor F_{420} (Bashiri et al., 2008). Another mechanism involves generation of reactive nitrogen species such as NO by PA-824’s des-nitro metabolite, which then augment the kill of intracellular nonreplicating persistent bacilli by the innate immune system (Singh et al., 2008).

Antibacterial Activity. In vitro, the drug kills both nonreplicating M. tuberculosis that are under anaerobic conditions as well as replicating bacteria in ambient air. The MICs of PA-824 against M. tuberculosis range from 0.015–0.25 mg/L, but the drug lacks activity against other mycobacteria.

Bacterial Resistance. The proportion of mutants resistant to 5 mg/L of PA-824 is 10^{-6}. Resistance arises due to changes in structure of FGD, which is due to a variety of point mutations in fgd gene. However, resistant isolates have also been identified that lack fgd mutations, so that resistance may also be due to other mechanisms (Stover et al., 2000).

Pharmacokinetics and Efficacy. In murine and guinea pig TB, PA-824 was equivalent to standard doses of isoniazid (Stover et al., 2000). In a recent murine TB study, 100 mg/kg/day of PA-824 with pyrazinamide and rifampin showed total sterilization at 2 months and no relapse, versus 15% relapse with the standard isoniazid, rifampin, and pyrazinamide regimen (Tasneen et al., 2008). Phase 1 studies have been performed, but the pharmacokinetic data have not been published. Phase 2 studies are in progress.

Ethionamide

Ethionamide (TRECATOR) is a congener of thioisonicotinamide.

Mechanism of Action. Mycobacterial EthA, an NADPH-specific, FAD-containing monoxygenase, converts ethionamide to a sulfoxide, and then to 2-ethyl-4-aminopyridine (Vannelli et al., 2002). Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. Ethionamide inhibits mycobacterial growth by inhibiting the activity of the inhA gene product, the enoyl-ACP reductase of fatty
Para-Aminosalicylic Acid

Para-amnosalicylic acid (PAS), discovered by Lehman in 1943, was the first effective treatment for TB.

Mechanism of Action. PAS is a structural analog of para-aminobenzoic acid, the substrate of dihydropteroate synthase (folP1/P2). As a result, PAS is thought to be a competitive inhibitor folP1. However, in vitro the inhibitory activity against folP1 is very poor. However, mutation of the thymidylate synthase gene (thyA) results in resistance to PAS, but only 37% of the PAS-resistant clinical isolates or spontaneous mutants encode a mutation in thyA gene, or in any genes encoding enzymes in the folate pathway or biosynthesis of thymine nucleotides (Mathys et al., 2009). Unidentified actions of PAS likely play more important roles in its anti-TB effects.

Antibacterial Activity. PAS is bacteriostatic. In vitro, most strains of M. tuberculosis are sensitive to a concentration of 1 mg/L. It has no activity against other bacteria.

Bacterial Resistance. Mutations in thyA gene lead to drug resistance in a minority of drug-resistant isolates.

Absorption, Distribution, and Excretion. The oral bioavailability of ethionamide approaches 100%. The pharmacokinetics are adequately explained by a one-compartment model with first-order absorption and elimination (Zhu et al., 2002); see PK values in Table 56–2. After oral administration of 500 mg of ethionamide, a C_max of 1.4 mg/L is achieved in 2 hours. The t_1/2 is ~2 hours. The concentrations in the blood and various organs are approximately equal. Ethionamide is cleared by hepatic metabolism; six metabolites have been identified. Metabolites are eliminated in the urine, with <1% of ethionamide excreted in an active form.

Therapeutic Uses. Ethionamide is administered orally. The initial dosage for adults is 250 mg twice daily; it is increased by 125 mg/day every 5 days until a dose of 15-20 mg/kg/day is achieved. The maximal dose is 1 g daily. The drug is best taken with meals in divided doses to minimize gastric irritation. Children should receive 10-20 mg/kg/day in two divided doses, not to exceed 1 g/day.

Untoward Effects. Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI upset. The most common reactions are anorexia, nausea and vomiting, gastric irritation, and a variety of neurologic symptoms. Severe postural hypotension, mental depression, drowsiness, and asthenia are common. Convulsions and peripheral neuropathy are rare. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restless-
Mechanisms of Resistance. Mutations involved in cycloserine resistance to pathogenic Mycobacteria are currently unknown. However, resistance in clinical isolates of M. tuberculosis has been detected in 10–82% of isolates (Anonymous, 2008b).

Absorption, Distribution, and Excretion. Oral cycloserine is almost completely absorbed. The population pharmacokinetics are best described using a one-compartment model with first-order absorption and elimination (Zhu et al., 2001). The drug’s $t_{1/2}$ is 9 hours. $C_{max}$ in plasma is reached in 45 minutes in fasting subjects, but is delayed for up to 3.5 hours with a high-fat meal. See Table 56–2 for PK values. Cycloserine is well distributed throughout the body. There is no appreciable barrier to CNS entry for cycloserine, and cerebrospinal fluid (CSF) concentrations are approximately the same as those in plasma. About 50% of cycloserine is excreted unchanged in the urine in the first 12 hours; a total of 70% is recoverable in the active form over a period of 24 hours. The drug may accumulate to toxic concentrations in patients with renal failure. About 60% of it is removed by hemodialysis, and the drug must be re-dosed after each hemodialysis session (Malone et al., 1999a).

Therapeutic Uses. Cycloserine is available for oral administration. The usual dose for adults is 250-500 mg twice daily.

Untoward Effects. Neuropsychiatric symptoms are common and occur in 50% of patients on 1 g/day, so much so that the drug has earned the nickname “psych-serine.” Symptoms range from headache and somnolence to severe psychosis, seizures, and suicidal ideas. Large doses of cycloserine or the concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

Capreomycin

Capreomycin (CAPASTAT) is an antimycobacterial cyclic peptide. It consists of four active components: capreomycins IA, IB, IIA, and IIB. The agent used clinically contains primarily IA and IB. Antimycobacterial activity is similar to that of aminoglycosides as are adverse effects, and capreomycin should not be administered with other drugs that damage cranial nerve VIII.

Bacterial resistance to capreomycin develops when it is given alone; such microorganisms show cross-resistance with kanamycin and neomycin. The adverse reactions associated with the use of capreomycin are hearing loss, tinnitus, transient proteinuria, cylinduria, and nitrogen retention. Severe renal failure is rare. Eosinophilia is common. Leukocytosis, leukopenia, rashes, and fever have also been observed. Injections of the drug may be painful. Capreomycin is a second-line antituberculosis agent. The recommended daily dose is 1 g (no more than 20 mg/kg) per day for 60-120 days, followed by 1 g two to three times a week.

Macrolides

The pharmacology, bacterial activity, resistance mechanisms of macrolides are discussed in Chapter 55. Azithromycin and clarithromycin are used for the treatment of MAC.

Dapsone

Dapsone (DD, diamino-diphenylsulfone) or 4’-diaminodiphenylsulfone, was synthesized by Fromm and Wittman in 1908, and its similarity to sulphonamides led to the establishment of anti-streptococcal effects by Butt et al. and Forneau et al. in 1937.

Mechanism of Action. Dapsone is a structural analog of para-aminobenzoic acid (PABA) and a competitive inhibitor of dihydropteroate synthase (folP1/P2) in the folate pathway, shown in Figure 56–5. The effect on this evolutionarily conserved pathway also explains why dapsone is a broad-spectrum agent with antibacterial, anti-protozoal, and antifungal effects.

The anti-inflammatory effects of dapsone occur via inhibition of tissue damage by neutrophils (summarized by Wolf et al., 2002). First, dapsone inhibits neutrophil myeloperoxidase activity and respiratory burst. Second, it inhibits activity of neutrophil lysosomal enzymes. Third, it may also act as a free radical scavenger, counteracting the effect of free radicals generated by neutrophils. Fourth, dapsone may also inhibit migration of neutrophils to inflammatory lesions (Wolf et al., 2002). Dapsone is extensively used for acne, but this therapy is not recommended.

Antimicrobial Effects. Antibacterial. Dapsone is bacteriostatic against M. leprae at concentrations of 1-10 mg/L. More than 90% of clinical isolates of MAC and M. kansasii have an MIC of ≤8 mg/L, but the MICs for M. tuberculosis isolates are high. It has little activity against other bacteria.
**Anti-parasitic.** Dapsone is also highly effective against *Plasmodium falciparum* with IC$_{50}$ of 0.006-0.013 mg/mL (0.6-1.3 mg/L) even in sulfadoxine-pyrimethamine–resistant strains. Dapsone has an IC$_{50}$ of 0.55 mg/L against Toxoplasma gondii tachyzoites.

**Antifungal.** Dapsone is effective at concentrations of 0.1/mg/L against the fungus *Pneumocystis jiroveci*.

**Drug Resistance.** Resistance to dapsone in *P. falciparum, P. jiroveci,* and *M. leprae* results primarily from mutations in genes encoding dihydropteroate synthase (Figure 56–5). In *P. falciparum* mutations occur at several positions such as 436, 437, 540, 58, and 613. In *P. jiroveci* isolates, mutations are often amino acid substitutions at positions 55 and 57. In *M. leprae,* mutations are encountered at codons 53 and 55.

**Absorption, Distribution, and Excretion.** After oral administration, absorption is complete; the elimination $t_{1/2}$ is 20–30 hours. The population pharmacokinetics of dapsone are shown in Table 56–2 (Simpson et al., 2006). CL increases 0.03 L/hour and $V_d$ 0.7 L for each 1-kg increase in body weight above 62.3 kg. Dapsone undergoes N-acetylation by NAT2. Oxidation to dapsone hydroxylamine is via CYP2E1, and to a lesser extent by CYP2C. Dapsone hydroxylamine enters red blood cells, leading to methemoglobin formation. Sulfones tend to be retained for up to 3 weeks in skin and muscle and especially in liver and kidney. Intestinal reabsorption of sulfones excreted in the bile contributes to long-term retention in the bloodstream; periodic interruption of treatment is advisable for this reason. Epithelial lining fluid to plasma ratio is between 0.76 and 2.91; CSF-to-plasma ratio is 0.21–2.01 (Gatti et al., 1997). Approximately 70–80% of a dose of dapsone is excreted in the urine as an acid-labile mono-$N$-sulfamate and mono-$N$-sulfamate.

**Therapeutic Uses.** Dapsone is administered as an oral agent. Therapeutic uses of dapsone in the treatment of leprosy are described later. Dapsone is combined with chlorproguanil for the treatment of malaria. Dapsone is also used for *P. jiroveci* infection and prophylaxis, and for the prophylaxis for *T. gondii,* as discussed in chapters devoted to these infections. The anti-inflammatory effects are the basis for therapy for pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, relapsing chondritis, and ulcers caused by the brown recluse spider (Wolf et al., 2002).

**Dapsone and Glucose-6-Phosphate Dehydrogenase Deficiency.** Glucose-6-phosphate dehydrogenase (G6PD) protects red cells against oxidative damage. However, G6PD deficiency is encountered in nearly half a billion people worldwide, the most common of 100 variants being G6PD-A. Dapsone, an oxidant, causes severe hemolysis in patients with G6PD deficiency. Thus, G6PD deficiency testing should be performed prior to use of dapsone wherever possible.

**Other Untoward Effects.** Hemolysis develops in almost every individual treated with 200-300 mg of dapsone per day. Doses of ≤100 mg in healthy persons and ≤50 mg in healthy individuals with a G6PD deficiency do not cause hemolysis. Methemoglobinemia also is common. A genetic deficiency in the NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of dapsone. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy (thought to be due to axonal degeneration), drug fever, hematuria, pruritus, psychosis, and a variety of skin rashes have been reported. An infectious mononucleosis-like syndrome, which may be fatal, occurs occasionally.

**PRINCIPLES OF ANTITUBERCULOSIS CHEMOTHERAPY**

**Evolution and Pharmacology.** *Mycobacterium tuberculosis* is not a single species, but a complex of species with 99.9% similarity at nucleotide level. The complex includes *M. tuberculosis* (typus humanus), *M. canetti,* *M. africanum, M. bovis,* and *M. microti.* They all cause tuberculosis (TB), with *M. microti* responsible for only a handful of human cases.

**Antituberculosis Therapy.** Isoniazid, pyrazinamide, rifampin, ethambutol, and streptomycin are currently considered first-line anti-TB agents. Moxifloxacin is being studied as a first-line agent. First-line agents are more efficacious and better tolerated, relative to second-line agents. Second-line agents are used in case of poor tolerance or resistance to first-line agents. Second-line drugs include ethionamide, PAS, cycloserine, amikacin, kanamycin, and capreomycin.

When anti-TB drug monotherapy was administered to TB patients, resistance emergence terminated the effectiveness of these drugs. The mutation rates to first-line anti-TB drugs are between 10$^{-7}$ and 10$^{-10}$, so that the likelihood of resistance is high to any single anti-TB drugs in patients with cavitary TB who have ~10$^9$ CFU of bacilli in a 3-cm pulmonary lesion. However, the likelihood that bacilli would develop mutations to two or more different drugs is the product of two mutation rates (between 1 in 10$^{14}$ and 1 in 10$^{20}$), which makes the probability of resistance emergence to more than two drugs acceptably small. Thus, only combination therapy anti-TB therapy is currently recommended for treatment of TB. Multidrug therapy has led to a reduction in length of therapy.

**Types of Antituberculosis Therapy**

**Prophylaxis.** After infection with *M. tuberculosis,* ~10% of people will develop active disease over a lifetime. The highest risk of reactivation TB is in patients with Mantoux tuberculin skin test reaction ≥5 mm who also fall into one of the following categories: recently exposed to TB, have HIV co-infection, have fibrotic changes on chest radiograms, or are immunosuppressed due to HIV infection, post-transplantation, or are taking immunosuppressive medications for any reason. If the tuberculin skin test is ≥10 mm, high risk of TB is encountered in recent (≤5 years) immigrants from areas of high TB prevalence, children <4 years of age, children exposed to adults with TB, intravenous drug users, as well as residents and...
employees of high-risk congregate settings. Any person with a skin test >15 mm is also at high risk of disease. In these patients at high risk of active TB, prophylaxis is recommended to prevent active disease. Prophylaxis consists of oral isoniazid, 300 mg daily or twice weekly, for 6 months in adults. Those who cannot take isoniazid should be given rifampin, 10 mg/kg daily, for 4 months. In children, isoniazid 10-15 mg/kg daily (maximum 300 mg) is administered, or 20-30 mg/kg two times a week directly observed, for 9 months. In children who cannot tolerate isoniazid, rifampin 10-20 mg/kg daily for 6 months is recommended.

**Definitive Therapy.** All active TB cases should be confirmed by culture and have antimicrobial susceptibilities determined. The current standard regimen for drug-susceptible TB consists of isoniazid (5 mg/kg, maximum 300 mg/day), rifampin (10 mg/kg, maximum 600 mg/day), and pyrazinamide (15-30 mg/kg, maximum of 2 g/day) for 2 months, followed by intermittent 10 mg/kg rifampin and 15 mg/kg isoniazid two or three times a week for 4 months. Children should receive 10-20 mg/kg isoniazid per day (300 mg maximum). Rifabutin 5 mg/kg/day can be used for the entire 6 months of therapy in adult HIV-infected patients because rifampin can adversely interact with some antiretroviral agents to reduce their effectiveness. In case there is resistance to isoniazid, initial therapy also may include ethambutol (15-20 mg/kg/day) or streptomycin (1 g/day) until isoniazid susceptibility is documented. Ethambutol doses in children are 15-20 mg/kg/day (maximum 1 g) or 50 mg/kg twice weekly (2.5 g). Because monitoring of visual acuity is difficult in children <5 years old, caution should be exercised in using ethambutol in these children.

The first 2 months of the four-drug regimen is termed the initial phase of therapy, and the last 4 months the continuation phase of therapy. Rifapentine (10 mg/kg once a week) may be substituted for rifampin in the continuation phase in patients with no evidence of HIV infection or cavitary TB. Pyridoxine, vitamin B6 (10-50 mg/day) should be administered with isoniazid to minimize the risks of neurological toxicity in patients predisposed to neuropathy (e.g., the malnourished, elderly, pregnant women, HIV-infected individuals, diabetic patients, alcoholic patients, and uremic patients). To ensure compliance, therapy is administered as directly observed therapy (DOT). Although DOT is the standard of care, an analysis of a series of 11 randomized clinical trials found no difference in outcome between DOT and self-administered therapy (Volmink and Garner, 2007).

The duration of therapy for drug-susceptible pulmonary TB is 6 months. A 9-month duration should be used for patients with cavitary disease who are still spumtal culture positive at 2 months. HIV-infected patients with CD4+ lymphocyte cell counts <100/mm³ are at increased risk of developing rifamycin resistance. Therefore, daily therapy is recommended during the continuation phase. Most cases of extrapulmonary TB are treated for 6 months. TB meningitis is an exception that requires a 9- to 12-month duration. In addition, corticosteroids are recommended for TB pericarditis, and results of a meta-analysis suggest they should also be used in TB meningitis (Prasad and Singh, 2008).

**Drug-Resistant TB.** According to the fourth global report of the World Health Organization (WHO), from 2002 to 2006, the proportion of new TB cases resistant to at least one anti-TB drug was 17%; isoniazid resistance was 10%, and MDR (multidrug resistant) was 3%. MDR-TB is said to be present if an isolate is resistant simultaneously to isoniazid and rifampin. According to the CDC, in the U.S., resistance to isoniazid was 8% and MDR was 1%. In previously treated patients, resistance to at least one drug was 35%, isoniazid resistance was 28%, and MDR was 15%; resistance to isoniazid in previously treated cases was 13%, and MDR was 4%; of the MDR, only 3% was extensively drug resistant TB [XDR]. XDR-TB is MDR-TB that is also resistant to fluoroquinolones and at least one of three injectable second-line drugs (i.e., amikacin, kanamycin, or capreomycin).

In documented drug resistance, therapy should be based on evidence of susceptibility and should include:

- at least three drugs to which the pathogen is susceptible, with at least one of the injectable anti-TB agents
- in the case of MDR-TB, use of four to six medications for better outcomes
- at least 18 months of therapy (Blumberg et al., 2003; Orenstein et al., 2009)

The addition to the regimen of a fluoroquinolone and surgical resection of the main lesions have been associated with improved outcome (Chan et al., 2004). There are currently no data to support intermittent therapy.

**PRINCIPLES OF THERAPY AGAINST MYCOBACTERIUM AVIUM COMPLEX**

The Mycobacterium avium complex (MAC) is made up of at least two species: *M. intracellulare* and *M. avium*. *M. intracellulare* causes pulmonary disease often in immunocompetent individuals. *M. avium* is further divided into a number of subspecies: *M. avium* subsp. *hominissuis* causes disseminated disease in immunocompromised patients, *M. avium* subsp. *paratuberculosis* has been implicated in the etiology of Crohn’s disease, and *M. avium* subsp. *avium* causes TB of birds. These bacteria are ubiquitous in the environment and can be encountered in water, food, and soil. Therefore, when MAC bacteria are isolated from a nonsterile site in patient’s body, one cannot assume they are causing an infection.
Therapy of MAC Pulmonary Infection

*M. intracellulare* often infects immunocompetent patients. The first decision after isolating MAC from pulmonary specimens is to determine whether disease is actually present or if the organism is merely part of environmental contamination. Criteria in favor of therapy include bacteriological evidence, which consists of positive cultures from at least two sputums, or one positive culture from bronchoalveolar lavage or pulmonary biopsy with a positive culture or histopathological features, and clinical evidence of infection, and radiological evidence of infection such as pulmonary cavitation, nodular lesions, and/or bronchiectasis (Griffith et al., 2007).

In newly diagnosed patients with MAC pneumonia, triple drug therapy is recommended. These include a rifamycin, ethambutol, and a macrolide (Griffith et al., 2007; Kasperbauer and Daley, 2008). For the macrolides, either oral clarithromycin or azithromycin may be used. Clarithromycin, 1000 mg, or azithromycin, 500 mg, are combined with ethambutol, 25 mg/kg, and rifampin, 600 mg, and administered three times a week for nodular and bronchiectatic disease. Therapy is continued for 12 months after the last negative culture. The same drugs are administered for patients with cavitary disease, but the dosing regimens are azithromycin 250 mg, ethambutol 15 mg/kg, and rifampin 600 mg. Parenteral streptomycin or amikacin at 15 mg/kg are recommended as a fourth drug. The effect of the aminoglycosides on clinical outcomes is unclear. Duration of therapy is as for nodular disease. In advanced pulmonary disease or during re-treatment, rifabutin 300 mg daily may replace rifampin. Because clarithromycin susceptibility correlates with outcome, risk of failure is high when high clarithromycin MICs are documented. Patients at risk for failure also include those with cavitary disease, presumably due to higher bacillary load. Even with these therapies, long-term success is still fairly limited. Only half of patients have successful outcomes as defined by both culture conversion and clinical outcomes.

Therapy for Disseminated M. Avium Complex

Disseminated MAC disease is caused by *M. avium* in 95% of patients. This is a disease of the immunocompromised patient, especially with reduced cell-mediated immunity. MAC usually occurs in patients whose CD4 cell count is <50/mm³. Patients at risk for infection are those who have had other opportunistic infections, are colonized with MAC, or have an HIV RNA burden >5 log copies/mm³.

The symptoms and laboratory findings of disseminated disease are nonspecific and include fever, night sweats, weight loss, elevated serum alkaline phosphates, and anemia at the time of diagnosis. However, when disease occurs in patients already on antiretroviral therapy, it may manifest as a focal disease of the lymph nodes, osteomyelitis, pneumonitis, pericarditis, skin or soft-tissue abscesses, genital ulcers, or CNS infection (DHHS Panel, 2008). In addition to a compatible clinical picture, isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids is required for diagnosis.

**Definitive and Suppressive Therapy.** In patients with disease due to MAC, the goals of therapy include suppression of symptoms and conversion to negative blood cultures. The infection itself is not completely eradicated until immune reconstitution. Therapy is divided into initial therapy and chronic suppressive therapy. Recommended therapy consists of a combination of clarithromycin 500 mg twice a day with ethambutol 15 mg/kg daily, administered orally (DHHS Panel, 2008). Azithromycin 500-600 mg daily is an acceptable alternative to clarithromycin, especially in those patients in whom clarithromycin would adversely interact with other drugs. The addition of rifabutin 300 mg a day may improve outcomes. Mortality in disseminated MAC is high in patients with either a CD4 cell count <50/mm³ or a MAC burden of >2 log₁₀ CFU/mm³ of blood, or in the absence of effective antiretroviral therapy. In these patients, a fourth drug may be added, based on susceptibility testing. Potential fourth agents include amikacin, 10-15 mg/kg intravenously daily; streptomycin, 1 g intravenously or intramuscularly daily; ciprofloxacin, 500-750 mg orally twice daily; levofloxacin, 500 mg orally daily; or moxifloxacin, 400 mg orally daily. Patients should be continued on suppressive therapy until all three of the following criteria are met:

- therapy duration of at least 12 months
- CD4 count >100/mm³ for at least 6 months
- asymptomatic for MAC infection

**PRINCIPLES OF ANTI-LEPROSY THERAPY**

The global prevalence of leprosy has markedly declined, largely due to the global initiative of the WHO to eliminate leprosy (Hansen’s disease) as a public health problem by providing multidrug therapy (rifampin, clofazimine, and dapsone) free of charge. Prevalence of the disease has dropped by ~90% since 1985. Nevertheless, there are pockets of disease around the world, especially in Africa, Asia, and South America. In the U.S., <200 new cases were reported in 2005, mainly among immigrants.

Four major clinical types of leprosy impact therapy. At one end of the spectrum is *tuberculoid leprosy*, also termed paucibacillary leprosy because the bacterial burden is low and *M. leprae* is rarely found in smears. On the other end of the spectrum is the *lepromatous* form of the disease (Levis and Ernst, 2005). This is characterized by a disseminated infection and a high bacillary burden. Two major intermediate forms of the disease are recognized: borderline (dimorphous) tuberculoid disease, which has features of both tuberculoid and lepromatous leprosy, and indeterminate...
A disease, which has early hypopigmented lesions without features of the lepromatous and tuberculoid leprosy. 

Mycobacterium leprae was discovered by Armauer Hansen in 1873. The M. leprae genome has undergone reductive evolution and has radically downsized its genome (Cole et al., 2001). As a result, M. leprae cannot produce ATP from NADH or utilize acetate or galactose as carbon sources; moreover, it has lost the anaerobic electron transfer system and cannot survive under hypoxic conditions. It has a long doubling time (14 days) and is an obligate intracellular pathogen. As a result, M. leprae is difficult to culture on synthetic media, an impediment to basic research on the disease.

Types of Anti-Leprosy Therapy

Therapy for leprosy is based on multi-drug regimens using rifampin, clofazimine, and dapsone. The reasons for using combinations of agents include reduction in the development of resistance, the need for adequate therapy when primary resistance already exists, and reduction in the duration of therapy. The most bactericidal drug in current regimens is rifampin. Because of high kill rates and massive release of bacterial antigens, rifampin is not often given during a “reversal” reaction (see below) or in patients with erythema nodosum leprosum. Clofazimine is only bacteriostatic against M. leprae. However, it also has anti-inflammatory effects and can treat reversal reactions and erythema nodosum leprosum. The third major agent in the regimen is dapsone. The objective of administering these drugs is total cure.

Definitive Therapy; Standard Therapy

Pauci-Bacillary Leprosy. The WHO regimen consists of a single dose of oral rifampin, 600 mg, combined with dapsone, 100 mg, administered under direct supervision once every month for 6 months, and dapsone, 100 mg a day, in between for 6 months. In the U.S., the regimen consists of dapsone, 100 mg, and rifampin, 600 mg, daily for 6 months, followed by dapsone monotherapy for 3-5 years.

Multibacillary Therapy. The WHO recommends the same regimen as for paucibacillary leprosy, with two major changes. First, clofazimine, 300 mg a day, is added for the entirety of therapy. Second, the regimen lasts 1 year instead of 6 months. In the U.S., the regimen is also the same as for paucibacillary, but dual therapy continues for 3 years, followed by dapsone monotherapy for 10 years. Clofazimine (an orphan drug) is added when there is dapsone resistance or chronically reactional patients.

The duration of therapy for multi-bacillary leprosy is a drawback. Studies in murine leprosy, and in patients, have demonstrated that viable bacilli are killed within 3 months of therapy (Ji et al., 1996) suggesting that the length of current therapy for multibacillary leprosy may be unnecessarily long. Recently, the WHO proposed that all forms of leprosy be treated with the same dose as for paucibacillary leprosy; a clinical trial was promising (Kroger et al., 2008). This new shorter regimen promises to reduce duration of therapy radically.

Treatment of Reactions in Leprosy. Patients with tuberculoid leprosy may develop “reversal reactions,” manifestations of delayed

<sup>a</sup>In HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and non-nucleoside reverse transcriptase inhibitors. <sup>b</sup>Based on animal models. <sup>c</sup>For Mycobacterium ulcerans, surgery is the primary therapy.
hypersensitivity to antigens of *M. leprae*. Cutaneous ulcerations and deficits of peripheral nerve function may occur. Early therapy with corticosteroids or clofazimine is effective. Reactions in the lepromatous form of the disease (erythema nodosum leprosum) are characterized by the appearance of raised, tender, intracutaneous nodules, severe constitutional symptoms, and high fever. This reaction may be triggered by several conditions but is often associated with therapy. It is thought to be an Arthus-type reaction related to release of microbial antigens in patients harboring large numbers of bacilli. Treatment with clofazimine or thalidomide is effective.

**Therapy for Other Nontuberculous Mycobacteria**

Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity *in vitro* and drug therapy selected on this basis. Therapy for infections from these organisms is summarized in Table 56–5. In some instances, surgical removal of the infected tissue followed by long-term treatment with effective agents is necessary. *M. kansasii* causes disease similar to that caused by *M. tuberculosis*, but it may be milder. The microorganisms may be resistant to isoniazid. Therapy with isoniazid, rifampin, and ethambutol has been successful.

**CLINICAL SUMMARY**

Combination therapy is almost always the desirable approach for mycobacterial disease, to ensure effective eradication and to prevent the emergence of resistance. Isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide are first-line agents for the treatment of tuberculosis. Moxifloxacin promises to replace either isoniazid or ethambutol and shorten therapy. Antimicrobial agents with excellent activity against *Mycobacterium avium* complex include rifabutin, clarithromycin, azithromycin, and fluoroquinolones. Clinical monitoring of patients with mycobacterial infections is important because drug interactions and adverse drug reactions are common with the multiple-drug regimens used. Considerable progress has been achieved in eliminating leprosy through the use of multiple-drug chemotherapy including dapsone, rifampin, and clofazimine.

**BIBLIOGRAPHY**

There are 200,000 known species of fungi, and estimates of the total size of Kingdom Fungi range to well over a million. Residents of the kingdom are quite diverse and include yeasts, molds, mushrooms, smuts, the pathogens Aspergillus fumigatus and Candida albicans, and the source of penicillin, Penicillium chrysogenum. Fortunately, only ~400 fungi cause disease in animals, and even fewer cause significant human disease. However, fungal infections are becoming more common: Patients with AIDS and patients whose immune systems are compromised by drug therapy are especially susceptible to mycotic infections. Fungi are eukaryotes with unique cell walls containing glucans and chitin, and their eradication requires different strategies than those for treatment of bacterial infections. Available agents have effects on the synthesis of membrane and cell-wall components, on membrane permeability, on the synthesis of nucleic acids, and on microtubule/mitotic spindle function (Figure 57–1).

Antifungal agents described in this chapter are discussed under two major headings, systemic and topical, although this distinction is somewhat arbitrary. The imidazole, triazole, and polyene antifungal agents may be used either systemically or topically, and many superficial mycoses can be treated either systemically or topically.

Although Pneumocystis jirovecii, responsible for life-threatening pneumonia in immunocompromised patients, is a fungus and not a protozoan, its treatment is discussed elsewhere because the drugs used are primarily antibacterial or antiprotozoal rather than antifungal.

Major pharmaceutical companies have closed their antifungal development programs, although a few small firms continue to sponsor research in this field. Thus, the near future in this area is likely to be limited to expansion of experience with existing compounds (Table 57–1). The most recent systemic antifungals to reach clinical development, posaconazole (NOXAFIL) and isavuconazole (in phase III trials in the U.S.), are both triazoles.

**SYSTEMIC ANTIFUNGAL AGENTS: SYSTEMIC DRUGS FOR DEEPLY INVASIVE FUNGAL INFECTIONS**

**Amphotericin B**

_Chemistry._ Amphotericin B is one of a family of some 200 polyene macrolide compounds with antifungal activity. Those studied to date share the characteristics of four to seven conjugated double bonds, an internal cyclic ester, poor aqueous solubility, substantial toxicity on parenteral administration, and a common mechanism of antifungal action. Amphotericin B (see following structure) is a heptaene macrolide containing seven conjugated double bonds in the _trans_ position and 3-amino-3,6-dideoxymannose (mycosamine) connected to the main ring by a glycosidic bond. The amphoteric behavior for which the drug is named derives from the presence of a carboxyl group on the main ring and a primary amino group on mycosamine; these groups confer aqueous solubility at extremes of pH. X-ray crystallography has shown the molecule to be rigid and rod-shaped, with the hydrophilic hydroxyl groups of the macrolide ring forming an opposing face to the lipophilic polyenic portion.
Drug Formulations. There are currently four formulations of amphotericin B commercially available: conventional amphotericin B (C-AMB), liposomal amphotericin B (L-AMB), amphotericin B lipid complex (ABLC), and amphotericin B colloidal dispersion (ABCD). Table 57–2 summarizes the pharmacokinetic properties of these preparations.

**C-AMB** (Conventional amphotericin B, FUNGIZONE). Amphotericin B is insoluble in water but is formulated for intravenous infusion by complexing it with the bile salt deoxycholate. The complex is marketed as a lyophilized powder for injection. C-AMB forms a colloid in water, with particles largely <0.4 μm in diameter. Filters in intravenous infusion lines that trap particles >0.22 μm in diameter will remove significant amounts of drug. Addition of electrolytes to infusion solutions causes the colloid to aggregate.

**ABCD**. Amphotericin B colloidal dispersion (AMPHOTEC, AMPHOCIL) contains roughly equimolar amounts of amphotericin B and cholesterol sulfate formulated for injection. Like C-AMB, ABCD forms a colloidal solution when dispersed in aqueous solution. ABCD provides much lower blood levels than C-AMB in mice and humans. In a study in patients with neutropenic fever comparing daily ABCD (4 mg/kg) with C-AMB (0.8 mg/kg), chills and hypoxia were significantly more common with ABCD than with C-AMB (White et al., 1998). Hypoxia was associated with severe febrile reactions. In a comparison of ABCD (6 mg/kg) and C-AMB (1-1.5 mg/kg) in invasive aspergillosis patients, ABCD was less nephrotoxic than C-AMB (49% vs. 15%) but caused more fever (27% vs. 16%) and chills (53% vs. 30%) (Bowden et al., 2002). Administration of the recommended ABCD dose over 3-4 hours and use of premedication to reduce febrile reactions are advised, particularly with initial infusions. ABCD is approved at a recommended dose of 3-4 mg/kg intravenously daily for patients with invasive aspergillosis who are not responding to or are unable to tolerate C-AMB.

**L-AMB**. Liposomal amphotericin B is a small, unilamellar vesicle formulation of amphotericin B (AMBISOME). The drug is supplied as a lyophilized powder, which is reconstituted with sterile water for injection. Blood levels following intravenous infusion are almost equivalent to those obtained with C-AMB, and because L-AMB can be given at higher doses, blood levels have been achieved that exceed those obtained with C-AMB (Bowser et al., 1998) (Table 57–2). Amphotericin B accumulation in the liver and spleen is higher with L-AMB than with C-AMB. Adverse effects include nephrotoxicity, hypokalemia, and infusion-related reactions, such as fever, chills, hypoxia, hypotension, and hypertension, but these do not commonly lead to drug discontinuation. Infusion-related pain in the back, abdomen, or chest occurs in occasional patients, usually with the first few doses. Anaphylaxis also has been reported. As empirical therapy or prophylaxis in febrile neutropenic patients, CAMB and L-AMB are equivalent. As induction therapy of disseminated histoplasmosis in AIDS patients, L-AMB 3 mg/kg was superior to C-AMB 0.7 mg/kg (Johnson, 2002). L-AMB is approved for initial therapy of cryptococcal meningitis of AIDS patients and is listed as an alternative to C-AMB for induction therapy of both disseminated histoplasmosis and cryptococcal meningococcal infections in AIDS patients (Kaplan et al., 2009). L-AMB is approved for empirical therapy of fever in the neutropenic host not responding to appropriate antibacterial agents, as well as for salvage therapy of aspergillosis and candidiasis. The recommended daily intravenous dose for empirical therapy is 3 mg/kg; for treatment of mycoses, the dosage is 3-5 mg/kg. L-AMB also is effective in visceral leishmaniasis at doses of 3-4 mg/kg daily. The drug is administered in 5% dextrose in water, with initial doses infused over 2 hours. If well tolerated, infusion duration can be shortened to 1 hour. Doses up to 10 mg/kg have been used but are associated with higher toxicity and, in one randomized trial of aspergillosis, no improvement in efficacy (Cornely, 2007a).

**ABLC (ABELCET)**. Amphotericin B lipid complex is a complex of amphotericin B with lipids (dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol). ABLC is given in a dose of 5 mg/kg in 5% dextrose in water, infused intravenously once daily over 2 hours. Blood levels of amphotericin B are much lower with ABLC than with the same dose of C-AMB. ABLC is effective in a variety of mycoses, with the possible exception of cryptococcal meningitis. The drug is approved for salvage therapy of deep mycoses.

The three lipid formulations collectively appear to reduce the risk of the patient’s serum creatinine doubling during therapy by 58% (Barrett et al., 2003). In patients at high risk for nephrotoxicity, ABLC is more nephrotoxic than L-AMB (Wingard et al., 2000). In some patients, the additive burden of amphotericin B nephrotoxicity can help precipitate advanced renal failure, with attendant morbidity. Infusion-related reactions are not consistently reduced with the use of lipid preparations. ABCD causes more infusion-related reactions than C-AMB. Although L-AMB reportedly causes fewer infusion-related reactions than ABLC during the first dose (Wingard et al., 2000), the difference depends on whether premedication is given and varies considerably between patients. Infusion-related reactions typically decrease with subsequent infusions.
The cost of the lipid formulations of amphotericin B greatly exceeds that of C-AMB, making them unavailable in many countries.

**Mechanism of Action.** The antifungal activity of amphotericin B depends principally on its binding to a sterol moiety, primarily ergosterol in the membrane of sensitive fungi. By virtue of their interaction with these sterols, polyenes appear to form pores or channels that increase the permeability of the membrane, allowing leakage of a variety of small molecules (Figure 57–1).

**Absorption, Distribution, and Excretion.** Gastrointestinal (GI) absorption of all amphotericin B formulations is negligible. Pharmacokinetic properties differ markedly between preparations with L-AMB having the highest plasma concentrations at therapeutic doses.

</table>

(Table 57–2). C-AMB is released from its complex with deoxycholate in the bloodstream, and the amphotericin B that remains in plasma is more than 90% bound to proteins, largely β-lipoprotein. Excretion into the urine is negligible with all the formulations. Azotemia, liver failure, or hemodialysis does not have a measurable impact on plasma concentrations. Concentrations of amphotericin B (via C-AMB) in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are approximately two-thirds of trough concentrations in plasma. Little amphotericin B from any formulation penetrates into cerebrospinal fluid (CSF), vitreous humor, or normal amniotic fluid.

**Antifungal Activity.** Amphotericin B has useful clinical activity against *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Coccidioides* spp., *Paracoccidioides brasiliensis*, *Aspergillus* spp., *Penicillium marneffei*, and the agents of mucormycosis. Amphotericin B has limited activity against the protozoa *Leishmania* spp. and *Naegleria fowleri*. The drug has no antibacterial activity.

**Fungal Resistance.** Some isolates of *Candida lusitaniae* have been relatively resistant to amphotericin B. *Aspergillus terreus* and perhaps *Aspergillus nidulans* may be more resistant to amphotericin B than other *Aspergillus* species (Steinbach et al., 2004). Mutants selected *in vitro* for resistance to nystatin (a polyene antifungal discussed later) or amphotericin B replace ergosterol with certain precursor sterols. The rarity of significant amphotericin B resistance arising during therapy has left it unclear whether ergosterol-deficient mutants retain sufficient pathogenicity to survive in deep tissue.

**Therapeutic Uses.** The recommended doses were given earlier for each formulation. Candida esophagitis responds to much lower doses than deeply invasive mycoses. Intrathecal infusion of C-AMB is useful in patients with meningitis caused by *Coccidioides*. Too little is known about intrathecal administration of lipid formulations to recommend them. C-AMB can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Fever and headache are common reactions that may be decreased by intrathecal administration of 10-15 mg of hydrocortisone. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intracocular injection following pars plana vitrectomy has been used successfully for fungal endophthalmitis.

Intravenous administration of amphotericin B is the treatment of choice for mucormycosis and is used for initial treatment of cryptococcal meningitis, severe or rapidly progressing histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis marneffei, as well as in patients not responding to azole therapy of invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, and trichosporonosis. Amphotericin B (C-AMB or L-AMB) is often given to selected patients with profound neutropenia who have fever that does not respond to broad-spectrum antibacterial agents over 5-7 days.

**Untoward Effects.** The major acute reactions to intravenous amphotericin B formulations are fever and chills. Infusion-related reactions are worst with ABCD, slightly less with C-C-AMB, even less with ABLC, and least with L-AMB. Tachypnea and respiratory stridor or modest hypotension also may occur, but true bronchospasm or anaphylaxis is rare. Patients with pre-existing cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. The reaction ends spontaneously in 30-45 minutes; meperidine may shorten it. Pretreatment with oral acetaminophen or use of intravenous hydrocortisone hemisuccinate, 0.7 mg/kg, at the start of the infusion decreases reactions. Febrile reactions abate with subsequent infusions. Infants, children, and patients receiving therapeutic doses of glucocorticoids are less prone to reactions.

Azotemia occurs in 80% of patients who receive C-AMB for deep mycoses (Carlson and Condon, 1994). Lipid formulations are less nephrotoxic, being much less with ABLC, even less with L-AMB, and minimal with ABCD. Toxicity is dose-dependent and usually transient and increased by concurrent therapy with other nephrotoxic agents, such as aminoglycosides or cyclosporine. Although permanent histological changes in renal tubules occur even during short courses of C-AMB, permanent functional impairment is uncommon in adults with normal renal function prior to treatment unless the cumulative dose exceeds 3-4 g. Renal tubular acidosis and renal wasting of K⁺ and Mg²⁺ also may be seen during and for several weeks after therapy. Supplemental K⁺ is required in one-third of patients on prolonged therapy. Saline loading has decreased nephrotoxicity, even in the absence of water or salt deprivation. Administration of 1 L of normal saline intravenously on the day that C-AMB is to be given has been recommended for adults who are able to tolerate the Na⁺ load and who are not already receiving that amount in intravenous fluids.

Hypochromic, normocytic anemia commonly occurs during treatment with C-AMB. Anemia is less with lipid formulations and usually not seen over the first 2 weeks. The anemia is most likely...
due to decreased production of erythropoietin. Patients with low plasma erythropoietin may respond to administration of recombinant erythropoietin. Anemia reverses slowly following cessation of therapy. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common. Thrombocytopenia or mild leukopenia is observed rarely. Hepatotoxicity is not firmly established with any amphotericin B formulation. Arachnoiditis has been observed as a complication of injecting C-AMB into the CSF.

**Flucytosine**

**Chemistry.** Flucytosine is 5-fluorocytosine, a fluorinated pyrimidine related to fluorouracil and flouxuridine.

**Mechanism of Action.** All susceptible fungi are capable of deaminating flucytosine to 5-fluorouracil (Figure 57–2), a potent antimetabolite that is used in cancer chemotherapy (Chapter 61). Fluorouracil is metabolized first to 5-fluorouracil-ribose monophosphate (5-FUMP) by the enzyme uracil phosphorylase (UPRTase; also called uridine monophosphate pyrophosphorylase). As in mammalian cells, 5-FUMP then is either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or metabolized to 5-fluoro-2′-deoxyuridine-5′-monophosphate (5-FdUMP), a potent inhibitor of thymidylate synthetase. DNA synthesis is impaired as the ultimate result of this latter reaction. The selective action of flucytosine is due to the lack of cytosine deaminase in mammalian cells, which prevents metabolism to fluorouracil.

**Antifungal Activity.** Flucytosine has clinically useful activity against Cryptococcus neoformans, *Candida* spp., and the agents of chromoblastomycosis. Within these species, determination of susceptibility in vitro has been extremely dependent on the method employed, and susceptibility testing performed on isolates obtained prior to treatment has not correlated with clinical outcome.

**Fungal Resistance.** Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis. In chromoblastomycosis, resurgence of lesions after an initial response has led to the presumption of secondary drug resistance. In isolates of *Cryptococcus* and *Candida* species, secondary drug resistance has been accompanied by a change in the minimal inhibitory concentration from <2.5 μg/mL to >360 μg/mL. The mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase (Figure 57–2). In *Candida albicans*, substitution of thymidine for cytosine at nucleotide 301 in the gene encoding UPRTase (FUR1) causes a cysteine to become an arginine, modestly increasing flucytosine resistance (Dodgson et al., 2004). Flucytosine resistance is further increased if both FUR1 alleles in the diploid fungus are mutated.

**Absorption, Distribution, and Excretion.** Flucytosine is absorbed rapidly and well from the GI tract. It is widely distributed in the body, with a volume of distribution that approximates total body water, and is minimally bound to plasma proteins. The peak plasma concentration in patients with normal renal function is ~70-80 μg/mL, achieved 1-2 hours after a dose of 37.5 mg/kg. Approximately 80% of a given dose is excreted unchanged in the urine; concentrations in the urine range from 200-500 μg/mL. The t1/2 of the drug is 3-6 hours in normal individuals. In renal failure, the t1/2 may be as long as 200 hours. The clearance of flucytosine is approximately equivalent to that of creatinine. Reduction of dosage is necessary in patients with decreased renal function, and concentrations of drug in plasma should be measured periodically. Peak concentrations should range between 50 and 100 μg/mL. Flucytosine is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis; the drug also is removed by peritoneal dialysis.

Flucytosine concentration in CSF is ~65-90% of that found simultaneously in the plasma. The drug also appears to penetrate into the aqueous humor.

**Therapeutic Uses.** Flucytosine (ANCOBON) is given orally at 50-150 mg/kg per day, in four divided doses at 6-hour intervals. Dosage must be adjusted for decreased renal function. Flucytosine is used predominantly in combination with amphotericin B. Flucytosine caused no added toxicity when added to 0.7 mg/kg of amphotericin B for the initial 2 weeks of therapy of cryptococcal meningitis in AIDS patients. Although the CSF colony count diminished more rapidly with combination therapy, there was no apparent impact on mortality or morbidity (van der Horst et al., 1997). An all-oral regimen of flucytosine plus fluconazole also has been advocated for therapy of AIDS patients.
with cryptococcosis, but the combination has substantial GI toxicity with no evidence that flucytosine adds benefit (Larsen et al., 1994). In cryptococcal meningitis of non-AIDS patients, the role of flucytosine is more conjectural. The addition of flucytosine to ≥6 weeks of therapy with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward as amphotericin B–induced azotemia occurs. In the 2008 IDSA guidelines for the treatment of cryptococcal meningoencephalitis, addition of flucytosine (100 mg/kg orally in four divided doses) is recommended for the first 2 weeks of treatment with amphotericin B in AIDS patients. A similar practice is often used in HIV-negative patients but the benefit is unknown (Pappas et al., 2001).

Untoward Effects. Flucytosine may depress the bone marrow and lead to leukopenia and thrombocytopenia; patients are more prone to this complication if they have an underlying hematological disorder, are being treated with radiation or drugs that injure the bone marrow, or have a history of treatment with such agents. Other untoward effects—including rash, nausea, vomiting, diarrhea, and severe enterocolitis—have been noted. In ~5% of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia (including those who are receiving amphotericin B concurrently) and when plasma drug concentrations exceed 100 μg/mL. Toxicity may result from conversion of flucytosine to 5-fluorouracil by the microbial flora in the intestinal tract of the host.

Imidazoles and Triazoles

The azole antifungals include two broad classes, imidazoles and triazoles, which share the same antifungal spectrum and mechanism of action. The systemic triazoles are metabolized more slowly and have less effect on human sterol synthesis than the imidazoles. Because of these advantages, new congeners under development are mostly triazoles. Of the drugs now on the market in the U.S., clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole, and sulconazole are imidazoles; terconazole, itraconazole, fluconazole, voriconazole, posaconazole, and isavuconazole (an experimental drug) are triazoles. The topical use of azole antifungals is described in the second section of this chapter. The basic triazole structure is:

```
H
\[\begin{array}{c}
N^1 \\
N^2 \\
N^3 \\
N^4 \\
\end{array}\] \\
\text{TRIAZOLE}
```

Mechanism of Action. At concentrations achieved following systemic administration, the major effect of imidazoles and triazoles on fungi is inhibition of 14-α-sterol demethylase, a microsomal CYP (Figure 57–1). Imidazoles and triazoles thus impair the biosynthesis of ergosterol for the cytoplasmic membrane and lead to the accumulation of 14-α-methylsterols. These methylsterols may disrupt the close packing of acyl chains of phospholipids, impairing the functions of certain membrane-bound enzyme systems, thus inhibiting growth of the fungi. Some azoles directly increase permeability of the fungal cytoplasmic membrane, but the concentrations required are likely only obtained with topical use.

Antifungal Activity. Azoles as a group have clinically useful activity against Candida albicans, Candida tropicalis, Candida parapsilosis, Candida glabrata, Cryptococcus neoformans, Blastomyces dermatitidis, Histoplasma capsulatum, Coccidioides spp., Paracoccidioides brasiliensis, and ringworm fungi (dermatophytes). Aspergillus spp., Scedosporium apiospermum (Pseudoallescheria boydii), Fusarium, and Sporothrix schenckii are intermediate in susceptibility. Candida krusei and the agents of mucormycosis are more resistant. Thus, these drugs do not have any useful antibacterial or antiparasitic activity, with the possible exception of antiprotozoal effects against Leishmania major. Posaconazole has slightly improved activity in vitro against the agents of mucormycosis.

Resistance. Azole resistance emerges gradually during prolonged azole therapy, causing clinical failure in patients with far-advanced HIV infection and oropharyngeal or esophageal candidiasis. The primary mechanism of resistance in C. albicans is accumulation of mutations in ERG11, the gene coding for the 14-α-sterol demethylase. These mutations protect heme in the enzyme pocket from binding to the azole but allow access of the natural substrate for the enzyme lanosterol. Cross-resistance is conferred to all azoles. Increased azole efflux by both ATP-binding cassette (ABC) and major facilitator superfamily transporters can add to fluconazole resistance in C. albicans and C. glabrata. Increased production of C14-α-sterol demethylase is another potential cause of resistance. Mutation of the C5,6 sterol reductase gene ERG3 also can increase azole resistance in some species.

Primary azole resistance has been described in some isolates of Aspergillus fumigatus with increased azole transport and decreased ergosterol content, but the clinical significance is unknown. Decreased fluconazole susceptibility has been described in Cryptococcus neoformans isolated from AIDS patients failing prolonged therapy.

Interaction of Azole Anti-Fungals with Other Drugs. The azoles interact with hepatic CYPs as substrates and inhibitors (Table 57–3), providing myriad possibilities for the interaction of azoles with many other medications. Thus, azoles can elevate plasma levels of some co-administered drugs (Table 57–4). Other co-administered drugs can decrease plasma concentrations of azole antifungal agents (Table 57–5). As a consequence of myriad interactions, combinations of certain drugs with azole antifungal medications may be contraindicated (Table 57–6).

Ketoconazole

Ketoconazole, administered orally, has been replaced by itraconazole for the treatment of all mycoses except when the lower cost of ketoconazole outweighs the advantage of itraconazole. Itraconazole lacks ketoconazole’s corticosteroid suppression while retaining most of ketoconazole’s pharmacological properties and expanding the antifungal spectrum. Ketoconazole sometimes is used to inhibit excessive production of glucocorticoids in patients with Cushing’s syndrome (Chapter 42) and is available for topical use, as described later.

Itraconazole

This synthetic triazole is an equimolar racemic mixture of four diastereoisomers (two enantiomeric pairs), each

Mechanism of interaction presumably occurs largely at the level of hepatic CYPs, especially CYPs 3A4, 2C9, and 2D6, but can also involve P-glycoprotein and other mechanisms. Not all drugs listed interact equally with all azoles. For details, see Chapter 6 and Zonios (2008).

possessing three chiral centers. The structure is similar to that of the imidazole ketoconazole.

**Absorption, Distribution, and Excretion.** Itraconazole (SPORANOX, others) is available as a capsule and a solution in hydroxypropyl-β-cyclodextrin for oral use. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations >150% of those obtained with the capsule. Itraconazole is metabolized in the liver. It is both a substrate for and a potent inhibitor of CYP3A4. Itraconazole is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxy-itraconazole. Bioassays may report up to 3.3 times as much itraconazole in plasma as do physical methods such as high-performance liquid chromatography, depending on the susceptibility of the bioassay organism to hydroxy-itraconazole. The native drug and metabolite are >99%

</table>

<Chemical structure of Itraconazole>
bound to plasma proteins. Neither appears in urine or CSF. The $t_{1/2}$ of itraconazole at steady state is ~30-40 hours. Steady-state levels of itraconazole are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase itraconazole plasma concentrations, but azotemia and hemodialysis have no effect. Itraconazole is not carcinogenic but is teratogenic in rats and contraindicated for the treatment of onychomycosis during pregnancy or for women contemplating pregnancy (Category C).

**Drug Interactions.** Tables 57–4, 57–5, and 57–6 list select interactions of azoles with other drugs. Many of the interactions can result in serious toxicity from the companion drug, such as inducing potentially fatal cardiac arrhythmias when used with quinidine, halofantrine (an orphan drug used for malaria), levomethadyl (an orphan drug used for heroin addiction), pimozide (ORAP) or cisapride (only temporarily the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4-8 µg/mL after repetitive doses of 100 mg. Renal absorption, distribution, and excretion.

**Untoward Effects.** Adverse effects of itraconazole therapy can occur as a result of interactions with many other drugs (Tables 57–3 and 57–4). Serious hepatotoxicity has rarely led to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. Intravenous itraconazole causes a dose-dependent inotropic effect that can lead to congestive heart failure in patients with impaired ventricular function. In the absence of interacting drugs, itraconazole capsules and suspension are well tolerated at 200 mg daily. Some patients complain of the taste of the solution, and GI side effects are common, although adherence is generally unimpaired. Diarrhea, abdominal cramps, anorexia, and nausea are more common than with the capsules. In one series of patients receiving 50-400 mg of the capsules per day, nausea and vomiting were recorded in 10%, hypertriglyceridemia in 9%, hypokalemia in 6%, increased serum aminotransferase in 5%, rash in 2%, and at least one side effect in 39%. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving ≥600 mg daily and in those who recently have received prolonged amphotericin B therapy. Doses of 300 mg twice daily have led to other side effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least one case, rhabdomyolysis. Doses >400 mg per day are not recommended for long-term use. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome.

**Dosage.** In treating deep (life-threatening) mycoses, a loading dose of 200 mg of itraconazole is administered three times daily for the first 3 days. After the loading doses, two 100-mg capsules are given twice daily with food. The divided doses are alleged to increase the area under the plasma concentration versus time curve (AUC), even though the $t_{1/2}$ is ~30 hours. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or for infections isolated to fingernails, two monthly cycles consisting of 200 mg twice daily for 1 week followed by a 3-week period of no therapy—so-called pulse therapy (Evans and Sigurgeirsson, 1999). Retention of active drug in the nail keratin permits intermittent treatment. Daily therapy is preferred by some authorities for infections likely to be more refractory, but it costs twice as much as pulse therapy. Once-daily terbinafine (250 mg), however, is superior to pulse therapy with itraconazole. For oropharyngeal candidiasis, itraconazole oral solution should be taken fasting in a dose of 100 mg (10 mL) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect. Patients with esophageal thrush unresponsive or refractory to treatment with fluconazole tablets are given 100 mg of the solution twice a day for 2-4 weeks.

**Fluconazole**

Fluconazole is a fluorinated bistriazole.

**Absorption, Distribution, and Excretion.** Fluconazole is almost completely absorbed from the GI tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4-8 µg/mL after repetitive doses of 100 mg. Renal
excretion accounts for >90% of elimination, and the elimination t1/2 is 25-30 hours. Fluconazole diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50-90% of the simultaneous values in plasma. The dosage interval should be increased from 24-48 hours with a creatinine clearance of 21-40 mL/minute and to 72 hours at 10-20 mL/minute. A dose of 100-200 mg should be given after each hemodialysis. About 11-12% of drug in the plasma is protein bound.

Drug Interactions. Fluconazole is an inhibitor of CYP3A4 and CYP2C9. Fluconazole’s drug–drug interactions are shown in Tables 57–3 and 57–4. Patients who receive >400 mg daily or azotemic patients who have elevated fluconazole blood levels may experience drug interactions not otherwise seen.

Therapeutic Uses. Candidiasis. Fluconazole, 200 mg on the first day and then 100 mg daily for at least 2 weeks, is effective in oropharyngeal candidiasis. Doses of 100-200 mg daily have been used to decrease candiduria in high-risk patients. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A dose of 400 mg daily decreases the incidence of deep candidiasis in allogeneic bone marrow transplant recipients and is useful in treating candidemia of nonimmunosuppressed patients. In patients who have not been receiving fluconazole prophylaxis, the drug has been used successfully as empirical treatment of febrile neutropenia in patients not responding to antibacterial agents and who are not judged to be at high risk of mould infections. Although response to C. glabrata bloodstream infections in randomized trials using fluconazole has been comparable to that with C. albicans, C. glabrata becomes resistant upon prolonged exposure to fluconazole. Empirical use of fluconazole for suspected candidemia may not be advisable in patients who have been receiving long-term fluconazole prophylaxis and may be colonized with azole-resistant C. glabrata. Based on resistance in vitro, Candida krusei would not be expected to respond to fluconazole or other azoles.

Cryptococcosis. Following IDSA guidelines (Perfect et al., 2010), fluconazole, 400 mg daily, is used for the initial 8 weeks in the treatment of cryptococcal meningitis in patients with AIDS after the patient’s clinical condition has been stabilized with at least 2 weeks of intravenous amphotericin B. After 8 weeks in patients no longer symptomatic, the dose is decreased to 200 mg daily and continued indefinitely. If the patient has completed 12 months of treatment for cryptococcosis, responds to HAART, has a CD4 count maintained ≥200/mm³ for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance fluconazole as long as the CD4 response is maintained. Some would add that an undetectable viral load for 3 months is required. Fluconazole, 400 mg daily, has been recommended as continuation therapy in non-AIDS patients with cryptococcal meningitis who have responded to an initial course of C-AMB or L-AMB and for patients with pulmonary cryptococcosis.

Other Mycoses. Fluconazole is the drug of choice for treatment of coccidioidal meningitis because of good penetration into the CSF and much less morbidity than with intrathecal amphotericin B. In other forms of coccidioidomycosis, fluconazole is comparable to itraconazole. Fluconazole has no useful activity against histoplasmosis, blastomycosis, or sporotrichosis. Fluconazole is not effective in the prevention or treatment of aspergillosis. Fluconazole has some activity in ringworm but is not approved for that indication. As with other azoles, with the possible exception of posaconazole, there is no activity in mucormycosis.

Untoward Effects. Side effects in patients receiving >7 days of drug, regardless of dose, include the following: nausea 3.7%, headache 1.9%, skin rash 1.8%, vomiting 1.7%, abdominal pain 1.7%, and diarrhea 1.5%. Use of high doses may be limited by nausea. Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. Fluconazole is teratogenic in rodents and has been associated with skeletal and cardiac deformities in at least three infants born to two women taking high doses during pregnancy. Fluconazole is a Category C agent that should be avoided during pregnancy unless the potential benefit justifies the possible risk to the fetus.

Dosage. Fluconazole (DIFLUCAN, others) is marketed in the U.S. as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/mL, and intravenous solutions containing 2 mg/mL in saline and in dextrose solution. The daily dose of fluconazole should be based on the infecting organism and the patient’s response to therapy. Generally recommended dosages are 50-400 mg once daily for either oral or intravenous administration. A loading dose of twice the daily maintenance dose is generally administered on the first day of therapy. Prolonged maintenance therapy may be required to prevent relapse. Children are treated with 3-12 mg/kg once daily (maximum: 600 mg/day).

Voriconazole

Voriconazole (VFEND) is a triazole with a structure similar to fluconazole but with increased activity in vitro, an expanded spectrum, and poor aqueous solubility.

Absorption, Distribution, and Excretion. Oral bioavailability is 96% and protein binding 56% (Jeu et al., 2003). Volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through CYP2C19 and to a lesser extent CYP2C9; CYP3A4 plays a limited role. Less than 2% of parent drug is recovered from urine, although 80% of the inactive metabolites are excreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Peak plasma concentrations after oral doses of 200 mg orally twice daily are ~3 μg/mL. CSF concentrations of 1-3 μg/mL have been reported in a patient with fungal meningitis.

Plasma elimination t1/2 is 6 hours. Voriconazole exhibits non-linear metabolism so that higher doses cause greater-than-linear increases in systemic drug exposure. Genetic polymorphisms in CYP2C19 can cause up to 4-fold differences in drug exposure; 15-20% of Asians are homozygous poor metabolizers, compared with 2% of whites and African Americans. Patients >65 years and patients with mild or moderate hepatic insufficiency have elevated areas under the curve (AUCs). Patients with mild-to-moderate cirrhosis should receive the same loading dose of voriconazole but half...
the maintenance dose. There are no data to guide dosing in patients with severe hepatic insufficiency.

The intravenous formulation of voriconazole contains sulfo- butyl ether β-cycloaddextrin (SBEC). When voriconazole is given intravenously, SBEC is excreted completely by the kidney. Significant accumulation of SBEC occurs with a creatinine clearance <50 mL/minute. Because toxicity of SBEC at high plasma concentrations is unclear, oral voriconazole is preferred in azotemic patients.

**Drug Interactions.** Voriconazole is metabolized by, and inhibits, CYPs 2C19, 2C9, and CYP3A4 (in that order of decreasing potency). The major metabolite of voriconazole, the voriconazole N-oxide, also inhibits these CYPs. Inhibitors or inducers of these CYPs may increase or decrease voriconazole plasma concentrations, respectively. In addition, there is potential for voriconazole and its major metabolite to increase the plasma concentrations of other drugs metabolized by these enzymes (Tables 57–3, 57–4, and 57–5). Because the sirolimus AUC increases 11-fold when voriconazole is given, co-administration is contraindicated. When starting voricon-azole in a patient receiving ≥40 mg/day of omeprazole, the dose of omeprazole should be reduced by half.

**Therapeutic Uses.** In an open randomized trial, voriconazole provided superior efficiency to C-AMB in the primary therapy of invasive aspergillosis (Herbrecht et al., 2002). In a secondary analysis, survival also was superior in the voriconazole arm. Voriconazole was compared to L-AMB in an open randomized trial in the empirical therapy of neutropenic patients whose fever did not respond to >96 hours of antibacterial therapy. Because the 95% confidence interval in this noninferiority trial permitted the possibility that voriconazole might be >10% worse than L-AMB, the Food and Drug Administration did not approve voriconazole for this use (Walsh et al., 2002). However, in a secondary analysis, there were fewer breakthrough infections with voriconazole (1.9%) than with L-AMB (5%). Voriconazole is approved for use in esophageal candidiasis on the basis of a double-blind randomized comparison with fluconazole (Ally et al., 2001). In non-neutropenic patients with candidemia, voriconazole was comparable in efficacy and less toxic than initial C-AMB followed by fluconazole (Kullberg, 2005). Voriconazole is approved for initial treatment of candidemia and invasive aspergillosis, as well as for salvage therapy in patients with *Pseudallescheria boydii* (*Scedosporium apiospermum*) and *Fusarium* infections. Positive response of patients with cerebral fungal suggest that the drug penetrates infected brain.

**Untoward Effects.** Voriconazole is teratogenic in animals and generally contraindicated in pregnancy (Category D). Women of childbearing potential should use effective contraception during treatment. Although voriconazole is generally well tolerated, occasional cases of hepatoxicity have been reported, and liver function should be monitored. Voriconazole, like some other azoles, causes a prolongation of the QTc interval, which can become significant in patients with other risk factors for torsades de pointes. Patients must be warned about possible visual effects. Transient visual or auditory hallucinations are frequent after the first dose, usually at night and particularly with intravenous administration. Symptoms diminish with time (Zonios et al., 2008). Patients receiving their first intravenous infusion have had anaphylactoid reactions, with faintness, nausea, flushing, feverishness, and rash. In such patients, the infusion should be stopped. Rash has been reported in 5.8% of patients.

**Dosage.** Voriconazole for intravenous infusion is packaged as 200 mg with 3.2 g SBEC. Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 hours for two doses, followed by 3-4 mg/kg every 12 hours. It should be administered no faster than 3 mg/kg/hr (e.g., over 1-2 hours, not as an intravenous bolus). As the patient improves, oral administration is continued as 200 mg every 12 hours. Patients failing to respond may be given 300 mg every 12 hours. Voriconazole is available as 50- or 200-mg tablets or a suspension of 40 mg/mL when hydrated. The tablets, but not the suspension, contain lactose. Because high-fat meals reduce voricona-zole bioavailability, oral drug should be given either 1 hour before or 1 hour after meals. Children metabolize voriconazole more rapidly that adults (Walsh, 2004a).

**Posaconazole**

Posaconazole (NOXAFIL) is a synthetic structural analog of itraconazole with the same broad antifungal spectrum but with up to 4-fold greater activity in vitro against yeasts and filamentous fungi, including the agents of mucormycosis (Guinea et al., 2008; Frampton, 2008). Activity against yeasts in vitro is similar to voriconazole. The mechanism of action is the same as other imidazole, inhibition of sterol 14-α demethylase.

**Absorption, Distribution, and Excretion.** Posaconazole is available as a cherry-flavored suspension containing 40 mg/mL. Bioavailability is significantly enhanced by the presence of food (Courtney et al., 2003; Krieter, 2004). The drug has a long terminal phase t½ (25-31 hours), a large volume of distribution (331-1341 L), and extensive binding (>98%) to protein, predominantly albumin. Systemic exposure is four times higher in homozygous CYP2C19 slow metabolizers than in homozygous wild-type metabolizers. Steady-state concentrations are reached in 7-10 days when dosed four times daily. Saturation of absorption occurs at 800 mg/day (Ezzet et al., 2005; Ullmann et al., 2006). Renal impairment does not alter plasma concentrations; hepatic impairment causes a modest increase (Moton, 2008). With radiolabeled drug given to volunteers, 77% was excreted in the stool, with 66% of the administered dose appearing as unchanged drug. The major metabolic pathway is hepatic UDP glucuronidation (Krieter, 2004). Hemodialysis does not remove detectable amounts of this highly protein-bound drug from the circulation. Gastric acid improves absorption in that an acidic beverage, ginger ale, increased the AUC by 70% in the fasting state (Krisha et al., 2009b). Drugs that reduce gastric acid (e.g., cimetidine and esomeprazole) decreased posaconazole exposure by 32-50% (Frampton and Scott, 2008). Diarrhea reduced the average plasma concentration by 37% (Smith et al., 2009). Plasma concentrations in allogeneic stem cell transplant recipients were 52% lower than in patients not receiving a stem cell transplant (Ullmann et al., 2006). Although monitoring plasma concentrations has been advocated (Smith et al., 2009), the lower limit of therapeutic effect for any indication is unknown.

**Therapeutic Use.** Posaconazole is not inferior to fluconazole for treatment of oropharyngeal candidiasis, although fluconazole is the preferred drug because of safety, cost, and extensive experience. The dose is 100 mg twice daily the first day and once daily thereafter for
1582

CHEMOTHERAPY OF MICROBIAL DISEASES

SECTION VII

Isavuconazole (BAL8557) is an investigational water-soluble pro-drug of the synthetic triazole, BAL4815.

The pro-drug is readily cleaved by esterases in the human body to release the active triazole. In vitro activity is comparable to voriconazole (Guinea et al., 2008; Perkhofer et al., 2009).

Absorption, Distribution, and Excretion. Oral administration of once-daily doses equivalent to 100 mg BAL4815 for loading followed by 50 mg daily and 200 mg loading followed by 100 mg resulted in peak plasma concentrations at 21 days of 1.37 μg/mL and 3.5 μg/mL at 2.25 and 3.5 hours, respectively. The AUCs were 21.6 and 40.3 μg•h/mL, respectively (Schmitt-Hoffman et al., 2006). With intravenous administration there was close to a linear dose response, with a 5-fold accumulation over 14 days, a t1/2 of 84.5-117 hours, and a volume of distribution at steady state of 308-542 L. Excretion is by the liver with most drug appearing in feces.

Therapeutic Use. Isavuconazole has been found comparable to fluconazole in Candida esophagitis with all three isavuconazole regimens tested: loading dose of 200 followed by 50 mg daily, loading dose of 400 mg followed by 100 mg daily, or 400 mg once weekly for 14 days (Odds, 2006). The drug was well tolerated. Phase III trials are enrolling patients with deep invasive candidiasis and aspergillosis.

Echinocandins

Screening natural products of fungal fermentation in the 1970s led to the discovery that echinocandins had activity against Candida and that the biological activity was directed against formation of 1,3-β-D-glucans in the fungal cell wall (Wiederhold and Lewis, 2003). The inhibition of glucan synthesis reduces structural integrity of the fungal cell wall (Figure 57–3), resulting in osmotic instability and cell death. Three echinocandins are approved for clinical use: caspofungin, anidulafungin, and micafungin. All are cyclic lipopeptides with a hexapeptide nucleus. All have the same mechanism of action but differ in pharmacological properties. Susceptible fungi include Candida species and Aspergillus species (Bennett, 2006).

General Pharmacological Characteristics. Echinocandins differ somewhat pharmacokinetically (Table 57–7) but all share lack of oral bioavailability, extensive protein binding (>97%), inability to penetrate into CSF, lack of renal clearance, and only a slight to modest effect of hepatic insufficiency on plasma drug concentration (Kim et al., 2007; Wagner et al., 2006). Adverse effects are minimal and rarely lead to drug discontinuation (Kim et al., 2007). All three agents are pregnancy Category C. For a review of the basic and clinical pharmacology of the echinocandins, see Wiederhold and Lewis (2007).

The minimum inhibitory concentration (MIC) of Candida albicans and several other Candida species are in the range of 0.015-0.5 μg/mL, higher for caspofungin than micafungin or anidulafungin. In Candida spp., echinocandins cause cell death at concentrations only 2- to 4-fold higher than that needed to inhibit growth. Azole-resistant Candida species remain susceptible to echinocandins. MIC of Candida parapsilosis and C. guilliermondii are consistently higher than other Candida spp., usually 2 μg/mL with all three echinocandins. In none of the clinical trials of the three echinocandins has the higher MIC of C. parapsilosis been reflected in lower response rates. An unexplained and paradoxical effect of increased growth at concentrations above the MIC has been seen more often in C. parapsilosis than with other Candida spp. and more commonly with caspofungin than micafungin or anidulafungin (Chamilos et al., 2007). In Aspergillus, echinocandins are not cidal but change the shape of hyphae; thus, in vitro susceptibility testing is done with a “morphological” end point (change in hyphal shape). Animal models do not suggest activity against dimorphic fungi such as Aspergillus.
Histoplasma capsulatum. Echinocandins have no activity against Cryptococcus neoformans, Trichosporon spp., or agents of mucormycosis. In vitro studies have consistently failed to show synergism or antagonism between echinocandins and amphotericin B. There is no antagonism between echinocandins and azoles; an additive effect has been reported with Aspergillus in some in vitro systems and animals models. Echinocandins inhibit the activity of the glucan synthase complex, resulting in loss of the structural integrity of the cell wall. A subunit of glucan synthase designated Fks1p is thought to be the target of the echinocandin. Mutations in Fks1p, coded for by FSK1, cause resistance to echinocandins.

as Histoplasma capsulatum. Echinocandins have no activity against Cryptococcus neoformans, Trichosporon spp., or agents of mucormycosis. In vitro studies have consistently failed to show synergism or antagonism between echinocandins and amphotericin B. There is no antagonism between echinocandins and azoles; an additive effect has been reported with Aspergillus in some in vitro systems and animals models. A subunit of glucan synthase designated Fks1p is thought to be the target of the echinocandin. Mutations in Fks1p, coded for by FSK1, cause resistance to echinocandins.

Figure 57–3. The fungal cell wall and membrane and the action of echinocandins. The strength of the fungal cell wall is maintained by fibrillar polysaccharides, largely β-1,3-glucan and chitin, which bind covalently to each other and to proteins. A glucan synthase complex in the plasma membrane catalyzes the synthesis of beta-1,3-glucan; the glucan is extruded into the periplasm and incorporated into the cell wall. Echinocandins inhibit the activity of the glucan synthase complex, resulting in loss of the structural integrity of the cell wall. A subunit of glucan synthase designated Fks1p is thought to be the target of the echinocandin. Mutations in Fks1p, coded for by FSK1, cause resistance to echinocandins.

Caspofungin acetate (CANCIDAS) is a water-soluble, semisynthetic lipopeptide synthesized from the fermentation product of Glarea lozoyensis (Johnson and Perfect, 2003; Keating and Figgitt, 2003).

For details, see Wagner et al. (2006).
**Metabolism and Excretion.** Catabolism is largely by hydrolysis and N-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increases the AUC by 55% and 76%, respectively.

**Drug Interactions.** Caspofungin increase tacrolimus levels by 16%, which should be managed by standard monitoring. Cyclosporine slightly increases caspofungin levels. Rifampin and other drugs activating CYP3A4 can cause a slight reduction in caspofungin levels.

**Therapeutic Use.** Caspofungin is approved for initial therapy of deeply invasive candidiasis and as salvage therapy for patients with invasive aspergillosis who are failing or intolerant of approved drugs, such as amphotericin B formulations or voriconazole. Approval for salvage therapy of aspergillosis was based on a study of 63 patients in a noncomparative salvage trial. Caspofungin is also approved for esophageal candidiasis, based on randomized trials that found noninferiority to fluconazole and C-AMB (Villanueva et al., 2001). A blinded randomized clinical trial of caspofungin in deeply invasive candidiasis found noninferiority to C-AMB, leading to approval for that indication (Mora-Duarte et al., 2002). Most patients in that multicenter study were not neutropenic and had catheter-acquired candidemia. Efficacy was comparable to that of fluconazole in other studies of the same general patient population. Caspofungin is also approved for the treatment of persistently febrile neutropenic patients with suspected fungal infections, based on noninferiority to L-AMB in a randomized trial (Walsh et al., 2004).

**Untoward Effects.** Caspofungin has been remarkably well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. Other symptoms have been equivalent to those observed in patients receiving fluconazole in the comparator arm.

**Dosage.** Caspofungin is administered intravenously once daily over 1 hour. In candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose should be increased to 70 mg daily in patients receiving rifampin as well as in those failing to respond to 50 mg. Esophageal candidiasis is treated with 50 mg daily. In moderate hepatic failure, the dose should be reduced to 35 mg daily.

**Micafungin**

Micafungin (MYCAMINE) is a water-soluble semisynthetic echinocandin derived from the fungus Coleophoma empedri.

**Absorption, Distribution, and Excretion.** Micafungin has linear pharmacokinetics over a large range of doses (1-3 mg/kg) and ages (premature infants to elderly). Feces contain 71% of intravenously administered radiolabeled drug, including both native drug and metabolites (Wiederhold and Lewis, 2007). Small amounts of drug are metabolized in the liver by arylsulfatase and catechol O-methyltransferase. Hydroxylation by CYP3A4 is barely detectable. Reduction of dose in moderate hepatic failure is not required. Clearance is more rapid in premature infants and intermediate in children 2-8 years of age, compared to older children and adults.

**Drug Interactions.** In normal volunteers, micafungin appears to be a mild inhibitor of CYP3A4, increasing AUC of nifedipine by 18% and sirolimus by 21%. Micafungin has no effect on tacrolimus clearance.

**Therapeutic Use.** Micafungin is approved for the treatment of deeply invasive candidiasis (Fritz et al., 2008). Doses of 100 mg and 150 mg daily of micafungin were equivalent to caspofungin (Pappas et al., 2007). Micafungin, 100 mg/day, was also not inferior to L-AMB, 3 mg/kg (Kuse et al., 2007). Micafungin is also approved for treatment of esophageal candidiasis and prophylaxis of deeply invasive candidiasis in hematopoietic stem cell transplant recipients.

**Doses.** Micafungin is given intravenously as 100 mg daily over 1 hour for adults, with 50 mg recommended for prophylaxis and 150 mg for esophageal candidiasis. No loading dose is needed.

**Anidulafungin**

Anidulafungin (ERAXIS) is a water-insoluble semisynthetic compound extracted from the fungus Aspergillus nidulans, from which the drug’s name derives.
Absorption, Distribution and Excretion. Anidulafungin is cleared from the body by slow chemical degradation, first by opening the hexapeptide ring and then proteolysis of peptide bonds (Vazquez and Sobel, 2006). No metabolism by the liver or renal excretion of active drug occurs. No dose adjustment for hepatic or renal failure is needed. The drug diluent for intravenous infusion contains 3 mg ethanol for every 50 mg anidulafungin, an amount of ethanol insufficient to have a pharmacological effect.

Drug interactions. None are known.

Therapeutic Use. In a randomized double-blinded clinical trial, anidulafungin was noninferior to fluconazole in candidemia of non-neutropenic patients (Reboli et al., 2007). Anidulafungin is also approved for the treatment of esophageal candidiasis.

Dose. Drug dissolved in the supplied diluent is infused once daily in saline or 5% dextrose in water at a rate not exceeding 1.1 mg/minute. For deeply invasive candidiasis, anidulafungin is given daily as a loading dose of 200 mg followed by 100 mg daily. For esophageal candidiasis, a loading dose of 100 mg is followed by 50 mg daily.

Griseofulvin

The drug is practically insoluble in water.

Mechanism of Action. Griseofulvin inhibits microtubule function and thereby disrupts assembly of the mitotic spindle. Thus, a prominent morphological manifestation of the action of griseofulvin is the production of multinucleate cells as the drug inhibits fungal mitosis. Although the effects of the drug are similar to those of colchicine and the vinca alkaloids, griseofulvin’s binding sites on the microtubular protein are distinct. In addition to its binding to tubulin, griseofulvin interacts with microtubule-associated protein.

Absorption, Distribution, and Excretion. The oral administration of a 0.5 g dose of griseofulvin produces peak plasma concentrations of ~1 μg/mL in ~4 hours. Blood levels are quite variable, however. Some studies have shown improved absorption when the drug is taken with a fatty meal. Because the rates of dissolution and disaggregation limit the bioavailability of griseofulvin, micro-sized and ultra-micro-sized powders are now used in preparations (GRIFULVIN V and GRIS-PEG, respectively). Although the bioavailability of the ultra-microcrystalline preparation is said to be 50% greater than that of the conventional micro-sized powder, this may not always be true. Griseofulvin has a plasma t½ of ~1 day, and ~50% of the oral dose can be detected in the urine within 5 days, mostly in the form of metabolites. The primary metabolite is 6-methylgriseofulvin. Barbiturates decrease griseofulvin absorption from the GI tract.

Griseofulvin is deposited in keratin precursor cells; when these cells differentiate, the drug is tightly bound to, and persists in, keratin, providing prolonged resistance to fungal invasion. For this reason, the new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable in the stratum corneum of the skin within 4-8 hours of oral administration. Sweat and transepidermal fluid loss play an important role in the transfer of the drug in the stratum corneum. Only a very small fraction of a dose of the drug is present in body fluids and tissues.

Antifungal Activity. Griseofulvin is fungistatic in vitro for various species of the dermatophytes Microsporum, Epidermophyton, and Trichophyton. The drug has no effect on bacteria or on other fungi. Although failure of ringworm lesions to improve is not rare, isolates from these patients usually are still susceptible to griseofulvin in vitro.

Therapeutic Uses. Mycotic disease of the skin, hair, and nails due to Microsporum, Trichophyton, or Epidermophyton responds to griseofulvin therapy. For tinea capitis in children, griseofulvin remains the drug of choice for efficacy, safety, and availability as an oral suspension; efficacy is best for tinea capitis caused by Microsporum canis, Microsporum audouinii, Trichophyton schoenleini, and Trichophyton verrucosum. Griseofulvin is also effective for ringworm of the glabrous skin; tinea cruris and tinea corporis caused by M. canis, Trichophyton rubrum, T. verrucosum, and Epidermophyton floccosum; and tinea of the hands (T. rubrum and T. mentagrophytes) and beard (Trichophyton species). Griseofulvin also is highly effective in tinea pedis, the vesicular form of which is most commonly due to T. mentagrophytes and the hyperkeratotic type to T. rubrum. Topical therapy is sufficient for most cases of tinea pedis. T. rubrum and T. mentagrophytes infections may require higher-than-conventional doses of griseofulvin.

Dosage. The recommended daily dose of griseofulvin is 2.3 mg/kg (up to 500 mg) for children and 500 mg to 1 g for adults. Doses of 1.5-2 g daily may be used for short periods in severe or extensive infections. Best results are obtained when the daily dose is divided and given at 6-hour intervals, although the drug often is given once or twice per day. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6-9 months for fingernails, and at least a year for toenails. Itraconazole or terbinafine is much more effective for onychomycosis.

Untoward Effects. The incidence of serious reactions due to griseofulvin is very low. One of the minor effects is headache (incidence as high as 15%), which is sometimes severe and usually disappears as therapy is continued. Other nervous system manifestations include peripheral neuritis, lethargy, mental confusion, impairment of performance of routine tasks, fatigue, syncope, vertigo, blurred vision, transient macular edema, and augmentation of the effects of alcohol. Among the side effects involving the alimentary tract are nausea, vomiting, diarrhea, heartburn, flatulence, dry mouth, and angular stomatitis. Hepatotoxicity also has been observed. Hematological effects include leukopenia, neutropenia, punctate basophilia, and monocytosis; these often disappear despite continued therapy. Blood studies should be carried out at least once a week during the first month of treatment or longer. Common renal effects include albuminuria and cylindruria without evidence of renal insufficiency. Reactions involving the skin are cold and warm urticaria, photosensitivity, lichen planus, erythema, erythema multiforme–like rashes, and vesicular and morbilliform eruptions. Serum sickness syndromes...
and severe angioedema develop rarely during treatment with griseofulvin. Estrogen-like effects have been observed in children. A moderate but inconsistent increase of fecal protoporphyrins has been noted with chronic use.

Griseofulvin induces hepatic CYPs, thereby increasing the rate of metabolism of warfarin; adjustment of the dosage of the latter agent may be necessary in some patients. The drug may reduce the efficacy of low-estrogen oral contraceptive agents, probably by a similar mechanism.

**Terbinafine**

Terbinafine is a synthetic allylamine, structurally similar to the topical agent naftifine.

![Terbinafine structure](image)

Terbinafine is well absorbed, but bioavailability is decreased to ~40% because of first-pass metabolism in the liver. Proteins bind >99% of the drug in plasma. Drug accumulates in skin, nails, and fat. The initial t1/2 is ~12 hours but extends to 200-400 hours at steady state. Terbinafine is not recommended in patients with marked azotemia or hepatic failure because in the latter condition, terbinafine plasma levels are increased by unpredictable amounts. Rifampin decreases and cimetidine increases plasma terbinafine concentrations. The drug is well tolerated, with a low incidence of GI distress, headache, or rash. Very rarely, fatal hepatotoxicity, severe neutropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. The drug is pregnancy Category B and it is recommended that systemic terbinafine therapy for onychomycosis be postponed until after pregnancy is complete. Its mechanism of action is inhibition of fungal squalene epoxidase, blocking ergosterol biosynthesis. Increased intracellular squalene also impairs cell growth.

Terbinafine (LAMISIL, others), given as one 250-mg tablet daily for adults, is somewhat more effective for nail onychomycosis than 200 mg daily of itraconazole, and definitely more effective than pulse itraconazole therapy (Fernandez-Obregon et al., 2007). Duration of treatment varies with the site being treated but typically is 6-12 weeks. Efficacy in onychomycosis can be improved by the simultaneous use of amorolfine 5% nail lacquer (Baran et al., 2007). Terbinafine (250 mg daily) also is effective in tinea capitis and is used off-label for ringworm elsewhere on the body. The recommended dose is 125-250 mg (depending on weight) daily for 6 weeks. The topical use of terbinafine is discussed later.

**Topical Antifungal Agents**

Topical treatment is useful in many superficial fungal infections, i.e., those confined to the stratum corneum, squamous mucosa, or cornea. Such diseases include dermatophytosis (ringworm), candidiasis, tinea versicolor, piedra, tinea nigra, and fungal keratitis. Topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and has no place in the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. The efficacy of topical agents in the treatment of superficial mycoses depends not only on the type of lesion and the mechanism of action of the drug but also on the viscosity, hydrophobicity, and acidity of the formulation. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy and is the principal mode of action of Whitfield’s ointment. Similarly, 40% urea paste can be applied under occlusion to soften infected nails.

Among the topical agents, the preferred formulation for cutaneous application usually is a cream or solution. Ointments are messy and are too occlusive for macerated or fissured intertriginous lesions. The use of powders, whether applied by shake containers or aerosols, is largely confined to the feet and moist lesions of the groin and other intertriginous areas.

The systemic agents used for the treatment of superficial mycoses were discussed earlier. Some of these agents also are administered topically; their uses are described here and also in Chapter 65.

**Imidazoles and Triazoles for Topical Use**

These closely related classes of drugs are synthetic antifungal agents that are used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is very rare among the fungi that cause ringworm. Selection of one of these agents for topical use should be based on cost and availability because testing in vitro for fungal susceptibility to these drugs does not predict clinical responses.

**Cutaneous Application.** The preparations for cutaneous use described below are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3-6 weeks. Despite some activity in vitro against bacteria, this effect is not clinically useful. The cutaneous formulations are not suitable for oral, vaginal, or ocular use.

**Vaginal Application.** Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1-7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis, despite some activity in vitro. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended for the higher dose of each. These preparations are administered for 3-7 days. Approximately 3-10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience
mild penile irritation. Cross-allergenicity among these compounds is assumed to exist, based on their structural similarities.

**Oral Use.** Use of the oral troche of clotrimazole is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to the local concentration of the drug; there is no systemic effect.

### Clotrimazole

![CLOTRIMAZOLE](image)

Absorption of clotrimazole is <0.5% after application to the intact skin; from the vagina, it is 3-10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. The small amount absorbed is metabolized in the liver and excreted in bile. In adults, an oral dose of 200 mg/day will give rise initially to plasma concentrations of 0.2-0.35 μg/mL, followed by a progressive decline.

In a small fraction of recipients, clotrimazole on the skin may cause stinging, erythema, edema, vesication, desquamation, pruritus, and urticaria. When it is applied to the vagina, ~1.6% of recipients complain of a mild burning sensation, and rarely of lower abdominal cramps, a slight increase in urinary frequency, or skin rash. Occasionally, the sexual partner may experience penile or urethral irritation. By the oral route, clotrimazole can cause GI irritation. In patients using troches, the incidence of this side effect is ~5%.

**Therapeutic Uses.** Clotrimazole is available as a 1% cream, lotion, powder, aerosol solution, and solution (LOTRIMIN AF, MYCELEX, others), 1% or 2% vaginal cream, or vaginal tablets of 100, 200, or 500 mg (GYNE-LOTRIMIN, others), and 10-mg troches (MYCELEX, others). On the skin, applications are made twice a day. For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For oropharyngeal candidiasis, troches are to be dissolved slowly in the mouth five times a day for 14 days.

Topical clotrimazole cures dermatophyte infections in 60-100% of cases. The cure rates in cutaneous candidiasis are 80-100%. In vulvovaginal candidiasis, the cure rate is usually >80% when the 7-day regimen is used. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

### Econazole

Econazole is the deschloro derivative of miconazole. Econazole readily penetrates the stratum corneum and is found in effective concentrations down to the mid-dermis. However, <1% of an applied dose appears to be absorbed into the blood. Approximately 3% of recipients have local erythema, burning, stinging, or itching. Econazole nitrate (SPECTAZOLE, ECOSTATIN, others) is available as a water-miscible cream (1%) to be applied twice a day.

### Miconazole

Miconazole readily penetrates the stratum corneum of the skin and persists there for >4 days after application. Less than 1% is absorbed into the blood. Absorption is no more than 1.3% from the vagina.

Adverse effects from topical application to the vagina include burning, itching, or irritation in ~7% of recipients, and infrequently, pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use during pregnancy, although some authors avoid its vaginal use during the first trimester.

**Therapeutic Uses.** Miconazole nitrate is available as a 2% cream, ointment, lotion, powder, gel, aerosol powder, and aerosol solution (MICATIN, ZEASORB-AF, others). To avoid maceration, only the lotion should be applied to intertriginous areas. Miconazole is available as a 2% and 4% vaginal cream, and as 100-mg, 200-mg, or 1200-mg vaginal suppositories (MONISTAT 7, MONISTAT 3, MONISTAT 1, others), to be applied high in the vagina at bedtime for 7, 3, or 1 day(s), respectively.

In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate may be >90%. In the treatment of vulvovaginal candidiasis, the mycologic cure rate at the end of 1 month is ~80-95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *Candida glabrata* also respond.

### Terconazole and Butoconazole

Terconazole (TERAZOL, others) is a ketal triazole. The mechanism of action of terconazole is similar to that of the imidazoles. The 80-mg vaginal suppository is inserted at bedtime for 3 days; the 0.4% vaginal cream is used for 7 days and the 0.8% cream for 3 days. Clinical efficacy and patient acceptance of both preparations are at least as good as for clotrimazole in patients with vaginal candidiasis.

Butoconazole is an imidazole that is pharmacologically quite comparable to clotrimazole. Butoconazole nitrate (FEMSTAT 3, others) is available as a 2% vaginal cream. It is used at bedtime in nonpregnant females. Because of the slower response during pregnancy, a 6-day course is recommended (during the second and third trimester).

### Tioconazole

Tioconazole (VAGISTAT 1, others) is an imidazole marketed for treatment of *Candida* vulvovaginitis. A single 4.6-g dose of ointment (300 mg) is given at bedtime.
Oxiconazole, Sulconazole, and Sertaconazole

These imidazole derivatives are used for the topical treatment of infections caused by the common pathogenic dermatophytes. Oxiconazole nitrate (Oxistat) is available as a 1% cream and lotion; sulconazole nitrate (Exelderm, Sulcosyn) is supplied as a 1% solution and/or cream. Sertaconazole (Ertaczo) is a 2% cream marketed for tinea pedis.

Ketoconazole

This imidazole is available as a 0.5% cream, foam, gel, and shampoo (Nizoral, others) for common skin dermatophyte infections, for tinea versicolor, and seborrheic dermatitis.

Ciclopirox Olamine

Ciclopirox olamine (Loprox, others) has broad-spectrum antifungal activity. It is fungicidal to C. albicans, E. floccosum, M. canis, T. mentagrophytes, and T. rubrum. It also inhibits the growth of Malassezia furfur. After application to the skin, it penetrates through the epidermis into the dermis, but even under occlusion, <1.5% is absorbed into the systemic circulation. Because the t1/2 is 1.7 hours, no systemic accumulation occurs. The drug penetrates into hair follicles and sebaceous glands. It can sometimes cause hypersensitivity. It is available as a 0.77% cream, gel, suspension, and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. An 8% nail lacquer is available for onychomycosis. Cure rates in the dermatomycoses and candidal infections are 81-94%. No topical toxicity has been noted.

Haloprogin

Haloprogin (Halotex) cream or solution is applied twice a day for 2-4 weeks. Its principal use is against tinea pedis, for which the cure rate is ~80%; it is thus approximately equal in efficacy to tolnaftate. It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Haloprogin is no longer available in the U.S.

Tolnaftate

Tolnaftate is a thiocarbamate with the following structure:

TOLNAFTATE

Tolnaftate is effective in the treatment of most cutaneous mycoses caused by T. rubrum, T. mentagrophytes, T. tonsurans, E. floccosum, M. canis, M. audouini, Microsporum gypseum, and M. furfur; but it is ineffective against Candida. In tinea pedis, the cure rate is ~80%, compared with ~95% for miconazole. Toxic or allergic reactions to tolnaftate have not been reported.

Tolnaftate (Aftate, Tinactin, others) is available in a 1% concentration as a cream, gel, powder, aerosol powder, and topical solution, or as a topical aerosol liquid. The preparations are applied locally twice a day. Pruritus is usually relieved in 24-72 hours. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7-21 days.

Naftifine

Naftifine is representative of the allylamine class of synthetic agents that inhibit squalene-2,3-epoxidase and thus inhibit fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity in vitro. Naftifine hydrochloride (Naftin) is available as a 1% cream or gel. It is effective for the topical treatment of tinea corporis and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation has been observed in 3% of treated patients. Allergic contact dermatitis also has been reported. Naftifine also may be efficacious for cutaneous candidiasis and tinea versicolor, although the drug is not approved for these uses.

Terbinafine

Terbinafine 1% cream or spray is applied twice daily and is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against Candida species and Malassezia furfur, but the cream also can be used in cutaneous candidiasis and tinea versicolor. The systemic use of terbinafine was discussed earlier.
**Butenafine**

*Butenafine hydrochloride* (MENTAX, LOTRIMIN ULTRA) is a benzylamine derivative with a mechanism of action similar to that of terbinafine and naftifine. Its spectrum of antifungal activity and use also are similar to those of the allylamines.

**Polyene Antifungal Antibiotics**

**Nystatin.** Nystatin was discovered in the New York State Health Laboratory and was named accordingly; it is a tetraene macrolide produced by *Streptomyces noursei*, is structurally similar to amphotericin B, and has the same mechanism of action. The drug is not absorbed from the GI tract, skin, or vagina. A liposomal formulation (NYOTRAN) is in clinical trials for candidemia.

Nystatin (MYCOSTATIN, NILSTAT, others) is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Powders are preferred for moist lesions and are applied two to three times daily. Creams or ointments are used twice daily. Combinations of nystatin with antibacterial agents or corticosteroids also are available. Allergic reactions to nystatin are very uncommon. Although vaginal tablets of nystatin are well tolerated, imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis.

Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host. Patients should be instructed to swish the drug around in the mouth and then swallow; otherwise, the patient may expectorate the bitter liquid and fail to treat the infected mucosa in the posterior pharynx or esophagus. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon.

**Miscellaneous Antifungal Agents**

**Undecylenic Acid.** Undecylenic acid is 10-undecenoic acid, an 11-carbon unsaturated compound. It is a yellow liquid with a characteristic rancid odor. It is primarily fungistatic, although fungicidal activity may be observed with long exposure to high concentrations of the agent. The drug is active against a variety of fungi, including those that cause ringworm. Undecylenic acid (DESENEX, others) is available in a cream, powder, spray powder, soap, and liquid. Zinc undecylenate is marketed in combination with other ingredients. The zinc provides an astringent action that aids in the suppression of inflammation. Compound undecylenic acid ointment contains both undecylenic acid (~5%) and zinc undecylenate (~20%). Calcium undecylenate (CALDESENE, CRUEX) is available as a powder.

Undecylenic acid preparations are used in the treatment of various dermatomycoses, especially tinea pedis. Concentrations of the acid as high as 10%, as well as those of the acid and salt in the compound ointment, may be applied to the skin. The preparations as formulated are usually not irritating to tissue, and sensitization to them is uncommon. It is of undoubted benefit in retarding fungal growth in tinea pedis, but the infection frequently persists despite intensive treatment with preparations of the acid and the zinc salt. At best, the clinical “cure” rate is ~50%, which is much lower than that obtained with the imidazoles, haloprogin, or tolnaftate. Efficacy in the treatment of tinea capitis is marginal, and the drug is no longer approved for use in the treatment of diaper rash, tinea cruris, and other minor dermatologic conditions.

**Benzoic Acid and Salicylic Acid.** An ointment containing benzoic and salicylic acids is known as Whitfield’s ointment. It combines the fungistatic action of benzoic acid with the keratolytic action of salicylate. It contains benzoic acid and salicylic acid in a ratio of 2:1 (usually 6-3%) and is used mainly in the treatment of tinea pedis. Because benzoic acid is only fungistatic, eradication of the infection occurs only after the infected stratum corneum is shed, and continuous medication is required for several weeks to months. The salicylic acid accelerates the desquamation. The ointment also is sometimes used to treat tinea capitis. Mild irritation may occur at the site of application.

Antiviral Agents (Nonretroviral)

Edward P. Acosta
and Charles Flexner

Most antivirals currently available in the U.S. have been developed and approved in the last two decades. This flurry of activity was driven by successes in rational drug design and approval that began with the anti-herpesvirus nucleoside analog acyclovir, whose discovery and development resulted in the awarding of a Nobel Prize to Gertrude Elion and George Hitchings in 1988. Because viruses are obligatory intracellular microorganisms and rely on host biosynthetic machinery to reproduce, there were doubts about the possibility of developing antiviral drugs with selective toxicity, but those doubts have long been erased. Viruses are now obvious targets for effective antimicrobial chemotherapy, and it is certain that the number of available agents in this category will continue to increase.

Viruses are simple microorganisms that consist of either double- or single-stranded DNA or RNA enclosed in a protein coat called a capsid. Some viruses also possess a lipid envelope derived from the infected host cell, which, like the capsid, may contain antigenic glycoproteins. There are distinct stages of viral replication and the classes of antiviral agents that can act at each stage (Table 58–1). Effective antiviral agents inhibit virus-specific replicative events or preferentially inhibit virus-directed rather than host cell–directed nucleic acid or protein synthesis. Host cell molecules that are essential to viral replication also offer targets for intervention. Some effective antiviral agents (e.g., interferons; see Chapter 35) have multiple mechanisms of action that include modulation of host immune responses. Figure 58–1 gives a schematic diagram of the replicative cycle of typical DNA and RNA viruses. DNA viruses (and the diseases they cause) include poxviruses (smallpox), herpesviruses (chickenpox, shingles, oral and genital herpes), adenoviruses (conjunctivitis, sore throat), hepadnaviruses (hepatitis B [HBV]), and papillomaviruses (warts). Most DNA viruses enter the host cell nucleus, where the viral DNA is transcribed into mRNA by host cell polymerase; mRNA is translated in the usual host cell fashion into virus-specific proteins. An exception to this strategy are poxviruses, which carry their own RNA polymerase and replicate in the host cell cytoplasm.

For RNA viruses, the replication strategy relies either on enzymes in the virion to synthesize mRNA or has the viral RNA serving as its own mRNA. The mRNA is translated into various viral proteins, including RNA polymerase, which directs the synthesis of more viral mRNA and genomic RNA (Figure 58–1B). Most RNA viruses complete their replication in the cytoplasm, but some, such as influenza, are transcribed in the host cell nucleus. Examples of RNA viruses (and the diseases they cause) include rubella virus (German measles), rhabdoviruses (rabies), picornaviruses (poliomyelitis, meningitis, colds, hepatitis A), arenaviruses (meningitis, Lassa fever), flaviviruses (West Nile meningoencephalitis, yellow fever, hepatitis C), orthomyxoviruses (influenza), paramyxoviruses (measles, mumps), and coronaviruses (colds, severe acute respiratory syndrome [SARS]). Retroviruses are a special group of RNA viruses that include human immunodeficiency virus (HIV); chemotherapy for retroviruses is described in Chapter 59.

Table 58–2 summarizes currently approved drugs for nonretroviral infections. Their pharmacological properties are presented below, class by class, as listed in the table.

ANTI-HERPESVIRUS AGENTS

Infection with herpes simplex virus type 1 (HSV-1) typically causes diseases of the mouth, face, skin, esophagus, or brain. Herpes simplex virus type 2 (HSV-2) usually causes infections of the genitals, rectum, skin,
hands, or meninges. Both cause serious infections in neonates. HSV infection may be a primary one in a naive host, a nonprimary initial one in a host previously infected by other viruses, or the consequence of activation of a latent infection.

The first systemically administered anti-herpesvirus agent, vidarabine (no longer marketed in the U.S.), was approved by the FDA in 1977. However, toxicities restricted its use to life- or vision-threatening infections of HSV and varicella-zoster virus (VZV). The discovery and development of acyclovir, approved in 1982, provided the first effective treatment for less severe HSV and VZV infections in ambulatory patients. Intravenous acyclovir is superior to vidarabine in terms of efficacy and toxicity in HSV encephalitis and in VZV infections of immunocompromised patients. Intravenous acyclovir is superior to vidarabine in terms of efficacy and toxicity in HSV encephalitis and in VZV infections of immunocompromised patients. Acyclovir is the prototype of a group of antiviral agents that are phosphorylated intracellularly by a viral kinase and subsequently by host cell enzymes to become inhibitors of viral DNA synthesis. Other agents employing this strategy include penciclovir and ganciclovir.

**Acyclovir and Valacyclovir**

**Chemistry and Antiviral Activity.** Acyclovir is an acyclic guanine nucleoside analog that lacks a 3′-hydroxyl on the side chain. Valacyclovir is the L-valyl ester prodrug of acyclovir. Acyclovir and valacyclovir chemical structures are depicted in Figure 58–2.

Acyclovir’s clinically useful antiviral spectrum is limited to herpesviruses. *In vitro*, acyclovir is most active against HSV-1 (0.02–0.9 μg/mL), approximately half as active against HSV-2 (0.03–2.2 μg/mL), a tenth as potent against VZV (0.8–4.0 μg/mL) and Epstein-Barr virus (EBV), and least active against cytomegalovirus (CMV) (generally >20 μg/mL) and human herpesvirus 6 (HHV-6). Uninfected mammalian cell growth generally is unaffected by high acyclovir concentrations (>50 μg/mL).

**Mechanisms of Action and Resistance.** Acyclovir inhibits viral DNA synthesis via a mechanism outlined in Figure 58–3 (Elion, 1986). Its selectivity of action depends on interaction with two distinct viral proteins: HSV thymidine kinase and DNA polymerase. Cellular uptake and initial phosphorylation are facilitated by HSV thymidine kinase. The affinity of acyclovir for HSV thymidine kinase is ~200 times greater than for the mammalian enzyme. Cellular enzymes convert the monophosphate to acyclovir triphosphate, which is present in 40-100-fold higher concentrations in HSV-infected than in uninfected cells and competes for endogenous deoxyguanosine triphosphate (dGTP).
Replicative cycles of DNA (A) and RNA (B) viruses. The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. Key: mRNA = messenger RNA; cDNA = complementary DNA; vRNA = viral RNA; DNAp = DNA polymerase; RNAp = RNA polymerase; cRNA = complementary RNA. The symbol —— indicates a block to virus growth.

A. Replicative cycles of herpes simplex virus, a DNA virus, and the probable sites of action of antiviral agents. Herpesvirus replication is a regulated multistep process. After infection, a small number of immediate-early genes are transcribed; these genes encode proteins that regulate their own synthesis and are responsible for synthesis of early genes involved in genome replication, such as thymidine kinases, DNA polymerases, etc. After DNA replication, the bulk of the herpesvirus genes (called late genes) are expressed and encode proteins that either are incorporated into or aid in the assembly of progeny virions.

B. Replicative cycles of influenza, an RNA virus, and the loci for effects of antiviral agents. The mammalian cell shown is an airway epithelial cell. The M2 protein of influenza virus allows an influx of hydrogen ions into the virion interior, which in turn promotes dissociation of the RNP (ribonuclear protein) segments and release into the cytoplasm (uncoating). Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAp complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus. Small capitals indicate virus proteins.

Figure 58-1. Replicative cycles of DNA (A) and RNA (B) viruses. The replicative cycles of herpesvirus (A) and influenza (B) are examples of DNA-encoded and RNA-encoded viruses, respectively. Sites of action of antiviral agents also are shown. Key: mRNA = messenger RNA; cDNA = complementary DNA; vRNA = viral RNA; DNAp = DNA polymerase; RNAp = RNA polymerase; cRNA = complementary RNA. The symbol —— indicates a block to virus growth.

Influenza virus mRNA synthesis requires a primer cleared from cellular mRNA and used by the viral RNAp complex. The neuraminidase inhibitors zanamivir and oseltamivir specifically inhibit release of progeny virus. Small capitals indicate virus proteins.
Acyclovir resistance in HSV has been linked to one of three mechanisms: impaired production of viral thymidine kinase, altered thymidine kinase substrate specificity (e.g., phosphorylation of thymidine but not acyclovir), or altered viral DNA polymerase. Alterations in viral enzymes are caused by point mutations and base insertions or deletions in the corresponding genes. Resistant variants are present in native virus populations and in isolates from treated patients. The most common resistance mechanism in clinical HSV isolates is absent or deficient viral thymidine kinase activity; viral DNA polymerase mutants are rare. Phenotypic resistance

The immunosuppressive agent mycophenolate mofetil (Chapter 35) potentiates the anti-herpes activity of acyclovir and related agents by depleting intracellular dGTP pools. Acyclovir triphosphate competitively inhibits viral DNA polymerases and, to a much lesser extent, cellular DNA polymerases. Acyclovir triphosphate also is incorporated into viral DNA, where it acts as a chain terminator because of the lack of a 3' hydroxyl group. By a mechanism termed suicide inactivation, the terminated DNA template containing acyclovir binds the viral DNA polymerase and leads to its irreversible inactivation.

The nomenclature of antiviral agents is listed in Table 58–2.
typically is defined by in vitro inhibitory concentrations of >2-3 μg/mL, which predict failure of therapy in immunocompromised patients.

Acyclovir resistance in VZV isolates is caused by mutations in VZV thymidine kinase and less often by mutations in viral DNA polymerase.

Absorption, Distribution, and Elimination. The oral bioavailability of acyclovir ranges from 10-30% and decreases with increasing dose (Wagstaff et al., 1994). Peak plasma concentrations average 0.4-0.8 μg/mL after 200-mg doses and 1.6 μg/mL after 800-mg doses. Following intravenous dosing, peak and trough plasma concentrations average 9.8 and 0.7 μg/mL after 5 mg/kg every 8 hours and 20.7 and 2.3 μg/mL after 10 mg/kg every 8 hours, respectively.

Valacyclovir is converted rapidly and virtually completely to acyclovir after oral administration in healthy adults. This conversion is thought to result from first-pass intestinal and hepatic metabolism through enzymatic hydrolysis. Unlike acyclovir, valacyclovir is a substrate for intestinal and renal peptide transporters. The relative oral bioavailability of acyclovir increases 3-5 fold to ~70% following valacyclovir administration (Steingrimsdottir et al., 2000). Peak acyclovir concentrations average 5-6 μg/mL following single 1000-mg doses of oral valacyclovir and occur ~2 hours after dosing. Peak plasma concentrations of valacyclovir are only 4% of acyclovir levels. Less than 1% of an administered dose of valacyclovir is recovered in the urine; most is eliminated as acyclovir.

Acyclovir distributes widely in body fluids, including vesicular fluid, aqueous humor, and cerebrospinal fluid (CSF). Compared with plasma, salivary concentrations are low, and vaginal secretion concentrations vary widely. Acyclovir is concentrated in breast milk, amniotic fluid, and placenta. Newborn plasma levels are similar to maternal ones. Percutaneous absorption of acyclovir after topical administration is low.

The mean plasma elimination t_{1/2} of acyclovir is ~2.5 hours (range: 1.5-6 hours in adults with normal renal function). The elimination t_{1/2} of acyclovir is ~4 hours in neonates and increases to 20 hours in anuric patients (Wagstaff et al., 1994). Renal excretion of unmetabolized acyclovir by glomerular filtration and tubular
secretion is the principal route of elimination. Less than 15% is excreted as 9-carboxymethoxymethylguanine or minor metabolites. The pharmacokinetics of oral acyclovir and valacyclovir appear to be similar in pregnant and nonpregnant women (Kimberlin et al., 1998).

Untoward Effects. Acyclovir generally is well tolerated. Topical acyclovir in a polyethylene glycol base may cause mucosal irritation and transient burning when applied to genital lesions.

Oral acyclovir has been associated infrequently with nausea, diarrhea, rash, or headache and very rarely with renal insufficiency or neurotoxicity. Valacyclovir also may be associated with headache, nausea, diarrhea, nephrotoxicity, and central nervous system (CNS) symptoms. High doses of valacyclovir have been associated with confusion and hallucinations, nephrotoxicity, and uncommonly, severe thrombocytopenic syndromes, sometimes fatal, in immunocompromised patients. Acyclovir has been associated with neutropenia in neonates. Chronic acyclovir suppression of genital herpes has been used safely for up to 10 years. No excess frequency of congenital abnormalities has been recognized in infants born to women exposed to acyclovir during pregnancy (Ratanajamit et al., 2003).
The principal dose-limiting toxicities of intravenous acyclovir are renal insufficiency and CNS side effects. Preexisting renal insufficiency, high doses, and high acyclovir plasma levels (>25 μg/mL) are risk factors for both. Reversible renal dysfunction occurs in ~5% of patients, probably related to high urine levels causing crystalline nephropathy. Manifestations include nausea, emesis, flank pain, and increasing azotemia. Rapid infusion, dehydration, and inadequate urine flow increase the risk. Infusions should be given at a constant rate over at least an hour. Nephrotoxicity usually resolves with drug cessation and volume expansion. Neurotoxicity occurs in 1-4% of patients and may be manifested by altered sensorium, tremor, myoclonus, delirium, seizures, or extrapyramidal signs. Phlebitis following extravasation, rash, diaphoresis, nausea, hypotension, and interstitial nephritis also have been described. Hemodialysis may be useful in severe cases.

Severe somnolence and lethargy may occur with combinations of zidovudine and acyclovir. Concomitant cyclosporine and probably other nephrotoxic agents enhance the risk of nephrotoxicity. Probencid decreases the acyclovir renal clearance and prolongs the elimination t½. Acyclovir may decrease the renal clearance of other drugs eliminated by active renal secretion, such as methotrexate.

**Therapeutic Uses.** In immunocompetent persons, the clinical benefits of acyclovir and valacyclovir are greater in initial HSV infections than in recurrent ones, which typically are milder in severity. These drugs are particularly useful in immunocompromised patients because these individuals experience both more frequent and more severe HSV and VZV infections. Because VZV is less susceptible than HSV to acyclovir, higher doses must be used for treating varicella-zoster infections than for HSV infections. Oral valacyclovir is as effective as oral acyclovir in HSV infections and more effective for treating herpes zoster.

**Herpes Simplex Virus Infections.** In initial genital HSV infections, oral acyclovir (200 mg five times daily or 400 mg three times daily for 7-10 days) and valacyclovir (1000 mg twice daily for 7-10 days) are associated with significant reductions in virus shedding, symptoms, and time to healing (Kimberlin and Rouse, 2004). Intravenous acyclovir (5 mg/kg every 8 hours) has similar effects in patients hospitalized with severe primary genital HSV infections. Topical acyclovir is much less effective than systemic administration. None of these regimens reproducibly reduces the risk of recurrent genital lesions. Acyclovir (200 mg five times daily or 400 mg three times daily for 5 days or 800 mg three times daily for 2 days) or valacyclovir (500 mg twice daily for 3 or 5 days) shortens the manifestations of recurrent genital HSV episodes by 1-2 days. Frequently recurring genital herpes can be suppressed effectively with chronic oral acyclovir (400 mg twice daily or 200 mg three times daily) or with valacyclovir (500 mg or, for very frequent recurrences, 1000 mg once daily). During use, the rate of clinical recurrences decreases by ~90%, and subclinical shedding is markedly reduced, although not eliminated. Valacyclovir suppression of genital herpes reduces the risk of transmitting infection to a susceptible partner by ~50% over an 8-month period (Corey et al., 2004). Chronic suppression may be useful in those with disabling recurrences of herpetic whitlow or HSV-related erythema multiforme.

Oral acyclovir is effective in primary herpetic gingivostomatitis (600 mg/m² four times daily for 10 days in children) but provides only modest clinical benefit in recurrent orolabial herpes. Short-term, high-dose valacyclovir (2 g twice over 1 day) shortens the duration of recurrent orolabial herpes by ~1 day (Elish et al., 2004). The FDA has approved an acyclovir/hydrocortisone combination (LIPOVIR) for early treatment of recurrent herpes cold sores. Topical acyclovir cream is modestly effective in recurrent labial (Spruance et al., 2002) and genital herpes simplex virus infections. Preexposure acyclovir prophylaxis (400 mg twice daily for 1 week) reduces the overall risk of recurrence by 73% in those with sun-induced recurrences of HSV infections. Acyclovir during the last month of pregnancy reduces the likelihood of viral shedding and the frequency of cesarean delivery in women with primary or recurrent genital herpes (Corey and Wald, 2009).

In immunocompromised patients with mucocutaneous HSV infection, intravenous acyclovir (250 mg/m² every 8 hours for 7 days) shortens healing time, duration of pain, and the period of virus shedding. Oral acyclovir (800 mg five times per day) and valacyclovir (1000 mg twice daily) for 5-10 days are also effective. Recurrences are common after cessation of therapy and may require long-term suppression. In those with very localized labial or facial HSV infections, topical acyclovir may provide some benefit. Intravenous acyclovir may be beneficial in viscerally disseminating HSV in immunocompromised patients and in patients with HSV-infected burn wounds.

Systemic acyclovir prophylaxis is highly effective in preventing mucocutaneous HSV infections in seropositive patients undergoing immunosuppression. Intravenous acyclovir (250 mg/m² every 8-12 hours) begun prior to transplantation and continuing for several weeks prevents HSV disease in bone marrow transplant recipients. For patients who can tolerate oral medications, oral acyclovir (400 mg five times daily) is effective, and long-term oral acyclovir (200-400 mg three times daily for 6 months) also reduces the risk of VZV infection (Steer et al., 2000). In HSV encephalitis, acyclovir (10 mg/kg every 8 hours for a minimum of 10 days) reduces mortality by ~50% and improves overall neurologic outcome compared with vidarabine. Higher doses (15-20 mg/kg every 8 hours) and prolonged treatment (up to 21 days) are recommended by many experts. Intravenous acyclovir (20 mg/kg every 8 hours for 21 days) is more effective than lower doses in viscerally invasive neonatal HSV infections (Kimberlin et al., 2001). In neonates and immunosuppressed patients and, rarely, in previously healthy persons, relapses of encephalitis following acyclovir may occur. The value of continuing long-term suppression with valacyclovir after completing intravenous acyclovir is under study.

An ophthalmic formulation of acyclovir (not available in the U.S.) is at least as effective as topical vidarabine or trifluridine in herpetic keratoconjunctivitis.

Infection owing to resistant HSV is rare in immunocompetent persons; however, in immunocompromised hosts, acyclovir-resistant HSV isolates can cause extensive mucocutaneous disease and, rarely, meningoencephalitis, pneumonitis, or visceral disease. Resistant HSV can be recovered from 6-17% of immunocompromised patients receiving acyclovir treatment (Bacon et al., 2003). Recurrences after cessation of acyclovir usually are due to sensitive virus but may be due to acyclovir-resistant virus in AIDS patients. In patients with progressive disease, intravenous foscarnet therapy is effective, but vidarabine is not (Chilukuri and Rosen, 2003).

**Varicella-Zoster Virus Infections.** If begun within 24 hours of rash onset, oral acyclovir has therapeutic effects in varicella of children...
and adults. In children weighing up to 40 kg, acyclovir (20 mg/kg, up to 800 mg per dose, four times daily for 5 days) reduces fever and new lesion formation by ~1 day. Routine use in uncomplicated pediatric varicella is not recommended but should be considered in those at risk of moderate-to-severe illness (persons >12 years of age, secondary household cases, those with chronic cutaneous or pulmonary disorders, or those receiving corticosteroids or long-term salicylates) (Committee on Infectious Diseases, American Academy of Pediatrics, 2003). In adults treated within 24 hours, oral acyclovir (800 mg five times daily for 7 days) reduces the time to crusting of lesions by ~2 days, the maximum number of lesions by one-half, and the duration of fever. Intravenous acyclovir appears to be effective in varicella pneumonia or encephalitis of previously healthy adults. Oral acyclovir (10 mg/kg four times daily) given between 7 and 14 days after exposure may reduce the risk of varicella.

In older adults with localized herpes zoster, oral acyclovir (800 mg five times daily for 7 days) reduces pain and healing times if treatment can be initiated within 72 hours of rash onset. A reduction in ocular complications, particularly keratitis and anterior uveitis, occurs with treatment of zoster ophthalmicus. Prolonged acyclovir and concurrent prednisone for 21 days speed zoster healing and improve quality-of-life measures compared with each therapy alone. Valacyclovir (1000 mg three times daily for 7 days) provides more prompt relief of zoster-associated pain than acyclovir in older adults (≥50 years) with zoster.

In immunocompromised patients with herpes zoster, intravenous acyclovir (500 mg/m² every 8 hours for 7 days) reduces viral shedding, healing time, and the risks of cutaneous dissemination and visceral complications, as well as the length of hospitalization, in disseminating zoster. In immunosuppressed children with varicella, intravenous acyclovir decreases healing time and the risk of visceral complications.

Acyclovir-resistant VZV isolates uncommonly have been recovered from HIV-infected children and adults who may manifest chronic hyperkeratotic or verrucous lesions and sometimes meningoencephalitis. Intravenous foscarnet also appears to be effective for acyclovir-resistant VZV infections.

Other Viruses. Acyclovir is ineffective therapeutically in established cytomegalovirus (CMV) infections but ganciclovir is effective for CMV prophylaxis in immunocompromised patients. High-dose intravenous acyclovir (500 mg/m² every 8 hours for 1 month) in CMV-seropositive bone marrow transplant recipients is associated with ~50% lower risk of CMV disease and, when combined with prolonged oral acyclovir (800 mg four times daily through 6 months), improves survival. Following engraftment, valacyclovir (2000 mg four times daily to day 100) appears as effective as intravenous ganciclovir prophylaxis in such patients (Winston et al., 2003). High-dose oral acyclovir or valacyclovir (2000 mg four times daily) suppression for 3 months may reduce the risk of CMV disease and its sequelae in certain solid-organ transplant recipients (Lowrance et al., 1999), but oral valganciclovir is the preferred agent for mismatched graft recipients (Pereyra and Rubin, 2004). Compared with acyclovir, high-dose valacyclovir reduces CMV disease in advanced HIV infection but is associated with greater toxicity and possibly shorter survival.

In infectious mononucleosis, acyclovir is associated with transient antiviral effects but no clinical benefits. EBV-related oral hairy leukoplakia may improve with acyclovir. Oral acyclovir in conjunction with systemic corticosteroids appears beneficial in treating Bell’s palsy, but valacyclovir is ineffective in acute vestibular neuritis.

Cidofovir

Chemistry and Antiviral Activity. Cidofovir is a cytidine nucleotide analog with inhibitory activity against human herpes, papilloma, polyoma, pox, and adenoviruses (Hitchcock et al., 1996). It structure is shown in Figure 58–2.

In vitro inhibitory concentrations range from >0.2 to 0.7 μg/mL for CMV, 0.4 to 33 μg/mL for HSV, and 0.02–17 μg/mL for adenoviruses. Because cidofovir is a phosphate that is phosphorylated by cellular but not virus enzymes, it inhibits acyclovir-resistant thymidine kinase (TK)–deficient or TK-altered HSV or VZV strains, ganciclovir-resistant CMV strains with UL97 mutations but not those with DNA polymerase mutations, and some foscarnet-resistant CMV strains. Cidofovir synergistically inhibits CMV replication in combination with ganciclovir or foscarnet.

Mechanisms of Action and Resistance. Cidofovir inhibits viral DNA synthesis by slowing and eventually terminating chain elongation. Cidofovir is metabolized to its active diphosphate form by cellular enzymes; the levels of phosphorylated metabolites are similar in infected and uninfected cells. The diphosphate acts as both a competitive inhibitor with respect to dCTP and as an alternative substrate for viral DNA polymerase. The diphosphate has a prolonged intracellular t½ and competitively inhibits CMV and HSV DNA polymerases at concentrations one-eighth to one six-hundredth of those required to inhibit human DNA polymerases (Hitchcock et al., 1996). A phosphocholine metabolite also has a long intracellular t½ (~87 hours) and may serve as an intracellular reservoir of drug. The prolonged intracellular t½ of cidofovir diphosphate allows infrequent dosing regimens, and single doses are effective in experimental HSV, varicella, and poxvirus infections.

Cidofovir resistance in CMV is due to mutations in viral DNA polymerase. Low-level resistance to cidofovir develops in up to ~30% of retinitis patients by 3 months of therapy. Highly ganciclovir-resistant CMV isolates that possess DNA polymerase and UL97 kinase mutations are resistant to cidofovir, and prior ganciclovir therapy may select for cidofovir resistance. Some foscarnet-resistant CMV isolates show cross-resistance to cidofovir, and triple-drug-resistant variants with DNA polymerase mutations occur.

Absorption, Distribution, and Elimination. Cidofovir is dianionic at physiological pH and has very low oral bioavailability (Cundy, 1999). The plasma levels after intravenous dosing decline in a biphasic pattern with a terminal t½ that averages 2.6 hours. The volume of distribution approximates total-body water. Penetration into the
CNS or eye has not been well characterized, but CSF levels are low. Extemporaneously compounded topical cidofovir gel may result in low plasma concentrations (<0.5 μg/mL) in patients with large mucocutaneous lesions.

Cidofovir is cleared by the kidney via glomerular filtration and tubular secretion. Over 90% of the dose is recovered unchanged in the urine without significant metabolism in humans. The probenecid-sensitive organic anion transporter 1 mediates uptake of cidofovir into proximal renal tubular epithelial cells (Ho et al., 2000). High-dose probenecid (2 g three hours before and 1 g two and eight hours after each infusion) blocks tubular transport of cidofovir and reduces renal clearance and associated nephrotoxicity. At cidofovir doses of 5 mg/kg, peak plasma concentrations increase from 11.5-19.6 μg/mL with probenecid, and renal clearance is reduced to the level of glomerular filtration. Elimination relates linearly to creatinine clearance, and the t1/2 increases to 32.5 hours in patients on chronic ambulatory peritoneal dialysis (CAPD). Hemodialysis removes >50% of the administered dose (Cundy, 1999).

Untoward Effects. Nephrotoxicity is the principal dose-limiting side effect of intravenous cidofovir. Proximal tubular dysfunction includes proteinuria, azotemia, glycosuria, metabolic acidosis, and uncommonly, Fanconi’s syndrome. Concomitant oral probenecid and saline prehydration reduce the risk of renal toxicity. On maintenance doses of 5 mg/kg every 2 weeks, up to 50% of patients develop proteinuria, 10-15% show an elevated serum creatinine concentration, and 15-20% develop neutropenia. Anterior uveitis that is responsive to topical corticosteroids and cycloplegia occurs commonly and low intraocular pressure occurs infrequently with intravenous cidofovir. Concurrent probenecid administration is associated with gastrointestinal (GI) upset, constitutional symptoms, and hypersensitivity reactions, including fever, rash, and uncommonly, anaphylactoid manifestations. Administration with food and pretreatment with antiemetics, antihistamines, and/or acetaminophen may improve tolerance.

Probenecid, but not cidofovir, alters zidovudine pharmacokinetics such that zidovudine doses should be reduced when probenecid is present, as should the doses of other drugs whose renal secretion probenecid inhibits (e.g., β-lactam antibiotics, nonsteroidal anti-inflammatory drugs [NSAIDs], acyclovir, lorazepam, furosemide, methotrexate, theophylline, and rifampin). Concurrent nephrotoxic agents are contraindicated, and at least 7 days should elapse between the end of aminoglycoside therapy and initiation of cidofovir. The same interval should separate intravenous pentamidine, amphotericin B, foscartern, NSAID, or contrast dye and cidofovir. Cidofovir and oral ganciclovir are poorly tolerated in combination at full doses.

Topical application of cidofovir is associated with dose-related application-site reactions (e.g., burning, pain, and pruritus) in up to one-third of patients and occasionally ulceration. Intravitreal cidofovir may cause vitreitis, hypopyon, and visual loss and is contraindicated.

Preclinical studies indicate that cidofovir has mutagenic, gonadotoxic, embryotoxic, and teratogenic effects. Because cidofovir is carcinogenic in rats, it is considered a potential human carcinogen. It may cause infertility and is classified as pregnancy Category C.

Therapeutic Uses. Intravenous cidofovir is approved for the treatment of CMV retinitis in HIV-infected patients.

Intravenous cidofovir (5 mg/kg once a week for 2 weeks followed by dosing every 2 weeks) increases the time to progression of CMV retinitis in previously untreated patients and in those failing or intolerant of ganciclovir and foscarnet therapy. CMV viremia may persist during cidofovir administration. Maintenance doses of 5 mg/kg are more effective but less well tolerated than 3 mg/kg doses. Intravenous cidofovir has been used for treating acyclovir-resistant mucocutaneous HSV infection, adenovirus disease in transplant recipients (Ljungman et al., 2003), and extensive molluscum contagiosum in HIV patients. Reduced doses (0.25-1 mg/kg every 2-3 weeks) without probenecid may be beneficial in BK virus nephropathy in renal transplant patients (Vats et al., 2003).

Extemporaneously compounded topical cidofovir gel eliminates virus shedding and lesions in some HIV-infected patients with acyclovir-resistant mucocutaneous HSV infections and has been used in treating anogenital warts and molluscum contagiosum in immunocompromised patients and cervical intraepithelial neoplasia in women. Intralensal cidofovir induces remissions in adults and children with respiratory papillomatosis.

Famciclovir and Penciclovir

Chemistry and Antiviral Activity. Famciclovir is the diacetyl ester produg of 6-deoxy penciclovir and lacks intrinsic antiviral activity. Penciclovir is an acyclic guanine nucleoside analog. The side chain differs structurally in that the oxygen has been replaced by a carbon, and an additional hydroxymethyl group is present Figure 58–2.

Penciclovir is similar to acyclovir in its spectrum of activity and potency against HSV and VZV. The inhibitory concentrations of penciclovir depend on cell type but are usually within 2-fold of those of acyclovir for HSV and VZV. It also is inhibitory for HBV.

Mechanisms of Action and Resistance. Penciclovir is an inhibitor of viral DNA synthesis. In HSV- or VZV-infected cells, penciclovir is phosphorylated initially by viral thymidine kinase. Penciclovir triphosphate serves as a competitive inhibitor of viral DNA polymerase (Figure 58–3). Although penciclovir triphosphate is approximately one one-hundredth as potent as acyclovir triphosphate in inhibiting viral DNA polymerase, it is present in much higher concentrations and for more prolonged periods in infected cells than acyclovir triphosphate. The prolonged intracellular t1/2 of penciclovir triphosphate, 7-20 hours, is associated with prolonged antiviral effects. Because penciclovir has a 3′-hydroxyl group, it is not an obligate chain terminator but does inhibit DNA elongation.

Resistant variants owing to thymidine kinase or DNA polymerase mutations can be selected by passage in vitro, but the occurrence of resistance during clinical use is currently low (Bacon et al., 2003). Thymidine kinase–deficient, acyclovir-resistant herpes viruses are cross-resistant to penciclovir.
Absorption, Distribution, and Elimination. Oral penciclovir has low (<5%) bioavailability. In contrast, famciclovir is well absorbed orally (bioavailability ~75%) and is converted rapidly to penciclovir by deacetylation of the side chain and oxidation of the purine ring during and following absorption from the intestine (Gill and Wood, 1996). Thus, the bioavailability of penciclovir is ~75% following oral administration of famciclovir.

Food slows absorption but does not reduce overall bioavailability. After single 250- or 500-mg doses of famciclovir, the peak plasma concentration of penciclovir averages 1.6 and 3.3 μg/mL, respectively. A small quantity of the 6-deoxy precursor but no famciclovir is detectable in plasma. After intravenous infusion of penciclovir at 10 mg/kg, peak plasma levels average 12 μg/mL. The volume of distribution is about twice the volume of total-body water. The plasma elimination t1/2 of penciclovir averages ~2 hours, and >90% is excreted unchanged in the urine, probably by both filtration and active tubular secretion. Following oral famciclovir administration, nonrenal clearance accounts for ~10% of each dose, primarily through fecal excretion, but penciclovir (60% of dose) and its 6-deoxy precursor (<10% of dose) are eliminated primarily in the urine. The plasma t1/2 averages 9.9 hours in renal insufficiency (Clcr <30 mL/minute); hemodialysis efficiently removes penciclovir. Lower peak plasma concentrations of penciclovir, but no reduction in overall bioavailability of famciclovir, occur in compensated chronic hepatic insufficiency (Boike et al., 1994).

Untoward Effects. Oral famciclovir is well tolerated but may be associated with headache, diarrhea, and nausea. Urticaria, rash, and hallucinations or confusional states (predominantly in the elderly) have been reported. Topical penciclovir, which is formulated in 40% propylene glycol and a cetomacrogol base, is associated infrequently with application-site reactions (~1%). The short-term tolerance of famciclovir is comparable with that of acyclovir.

Penciclovir is mutagenic at high concentrations in vitro. Although studies in laboratory animals indicate that chronic famciclovir administration is tumorigenic and decreases spermatogenesis and fertility in rodents and dogs, long-term administration (1 year) does not affect spermatogenesis in men. No teratogenic effects have been observed in animals, but safety during pregnancy has not been established. No clinically important drug interactions have been identified to date with famciclovir or penciclovir (Gill and Wood, 1996).

Therapeutic Uses. Oral famciclovir, topical penciclovir, and intravenous penciclovir are approved for managing HSV and VZV infections (Sacks and Wilson, 1999).

Oral famciclovir (250 mg three times a day for 7-10 days) is as effective as acyclovir in treating first-episode genital herpes (Kimberlin and Rouse, 2004). In patients with recurrent genital HSV, patient-initiated famciclovir treatment (125 or 250 mg twice a day for 5 days) reduces healing time and symptoms by ~1 day. Famciclovir (250 mg twice a day for up to 1 year) is effective for suppression of recurrent genital HSV, but single daily doses are less effective. Higher doses (500 mg twice a day) reduce HSV recurrences in HIV-infected persons. Intravenous penciclovir (5 mg/kg every 8 or 12 hours for 7 days) (not available in the U.S.) is comparable to intravenous acyclovir for treating mucocutaneous HSV infections in immunocompromised hosts. In immunocompetent persons with recurrent orolabial HSV, topical 1% penciclovir cream (applied every 2 hours while awake for 4 days) shortens healing time and symptoms by ~1 day (Raborn et al., 2002).

In immunocompetent adults with herpes zoster of ≤3 days’ duration, famciclovir (500 mg three times a day for 10 days) is at least as effective as acyclovir (800 mg five times daily) in reducing healing time and zoster-associated pain, particularly in those ≥50 years of age. Famciclovir is comparable with valacyclovir in treating zoster and reducing associated pain in older adults (Tyring et al., 2000). Famciclovir (500 mg three times a day for 7-10 days) also is comparable with high-dose oral acyclovir in treating zoster in immunocompromised patients and in those with opthalmic zoster (Tyring et al., 2001).

Famciclovir is associated with dose-related reductions in HBV DNA and transaminase levels in patients with chronic HBV hepatitis but is less effective than lamivudine (Lai et al., 2002). Famciclovir is also ineffective in treating lamivudine-resistant HBV infections owing to emergence of multiply resistant variants.

Fomivirsen

Fomivirsen, a 21-base phosphorothioate oligonucleotide, was the first FDA-approved antisense therapy for viral infections. It is complementary to the messenger RNA sequence for the major immediate-early transcriptional region of CMV and inhibits CMV replication through sequence-specific and nonspecific mechanisms, including inhibition of virus binding to cells. Fomivirsen is active against CMV strains resistant to ganciclovir, foscarnet, and cidofovir. CMV variants with 10-fold reduced susceptibility to fomivirsen have been selected by in vitro passage.

Fomivirsen is given by intravitreal injection in the treatment of CMV retinitis for patients intolerant of or unresponsive to other therapies. Following injection, it is cleared slowly from the vitreous (t1/2 ~55 hours) through distribution to the retina and probable exonuclease digestion (Geary et al., 2002). Local metabolism by exonucleases accounts for elimination. In HIV-infected patients with refractory, sight-threatening CMV retinitis, fomivirsen injections (330 μg weekly for 3 weeks and then every 2 weeks or on days 1 and 15 followed by monthly) significantly delay time to retinitis progression (Vitravene Study Group, 2002). Ocular side effects include iritis in up to one-quarter of patients, which can be managed with topical corticosteroids; vitritis; cataracts; and increases in intraocular pressure in 15-20% of patients. Recent cidofovir use may increase the risk of inflammatory reactions. The drug is no longer available in the U.S.

Foscarnet

Chemistry and Antiviral Activity. Foscarnet (trisodium phosphonoformate; Figure 58–2) is an inorganic pyrophosphate analog that is inhibitory for all herpesviruses and HIV.

In vitro inhibitory concentrations are generally 100-300 μM for CMV and 80-200 μM for other herpesviruses, including most ganciclovir-resistant CMV and acyclovir-resistant HSV and VZV strains. Combinations
of foscarnet and ganciclovir synergistically inhibit CMV replication in vitro. Concentrations of 500-1000 μM reversibly inhibit the proliferation and DNA synthesis of uninfected cells.

**Mechanisms of Action and Resistance.** Foscarnet inhibits viral nucleic acid synthesis by interacting directly with herpesvirus DNA polymerase or HIV reverse transcriptase (Figure 58–3). It is taken up slowly by cells and does not undergo significant intracellular metabolism. Foscarnet reversibly blocks the pyrophosphate binding site of the viral polymerase in a noncompetitive manner and inhibits cleavage of pyrophosphate from deoxynucleotide triphosphates. Foscarnet has ~100-fold greater inhibitory effects against herpesvirus DNA polymerases than against cellular DNA polymerase-α. Herpesviruses resistant to foscarnet have point mutations in the viral DNA polymerase and are associated with 3- to 7-fold reductions in foscarnet activity in vitro.

**Absorption, Distribution, and Elimination.** Oral bioavailability of foscarnet is low. Following an intravenous infusion of 60 mg/kg every 8 hours, peak and trough plasma concentrations are ~450-575 and 80-150 μM, respectively. Vitreous levels approximate those in plasma, and CSF levels average 66% of those in plasma at steady state.

Over 80% of foscarnet is excreted unchanged in the urine by glomerular filtration and probably tubular secretion. Plasma clearance decreases proportionately with creatinine clearance, and dose adjustments are indicated for small decreases in renal function. Plasma elimination is complex, with initial bimodal half-lives totaling 4-8 hours and a prolonged terminal elimination t1/2 averaging 3-4 days. Sequestration in bone with gradual release accounts for the fate of an estimated 10-20% of a given dose. Foscarnet is cleared efficiently by hemodialysis (~50% of a dose).

**Untoward Effects.** Foscarnet’s major dose-limiting toxicities are nephrotoxicity and symptomatic hypocalcemia. Increases in serum creatinine occur in up to one-half of patients but are reversible after cessation in most patients. High doses, rapid infusion, dehydration, prior renal insufficiency, and concurrent nephrotoxic drugs are risk factors. Acute tubular necrosis, crystalline glomerulopathy, nephrogenic diabetes insipidus, and interstitial nephritis have been described. Saline loading may reduce the risk of nephrotoxicity.

Foscarnet is highly ionized at physiological pH, and metabolic abnormalities are very common. These include increases or decreases in Ca²⁺ and phosphate, hypomagnesemia, and hypokalemia. Decreased serum ionized Ca²⁺ may cause paresthesia, arrhythmias, tetany, seizures, and other CNS disturbances. Concomitant intravenous pentamidine administration increases the risk of symptomatic hypocalcemia. Parenteral magnesium sulfate does not alter foscarnet-induced hypocalcemia or symptoms (Huycke et al., 2000).

CNS side effects include headache in ~25% of patients, tremor, irritability, seizures, and hallucinosis. Other reported side effects are generalized rash, fever, nausea or emesis, anemia, leukopenia, abnormal liver function tests, electrocardiographic changes, infusion-related thrombophlebitis, and painful genital ulcerations. Topical foscarnet may cause local irritation and ulceration, and oral foscarnet may cause GI disturbance. Preclinical studies indicate that high foscarnet concentrations are mutagenic and may cause tooth and skeletal abnormalities in developing laboratory animals. Safety in pregnancy or childhood is uncertain.

**Therapeutic Uses.** Intravenous foscarnet is effective for treatment of CMV retinitis, including ganciclovir-resistant infections, other types of CMV infection, and acyclovir-resistant HSV and VZV infections. Foscarnet is poorly soluble in aqueous solutions and requires large volumes for administration.

In CMV retinitis in AIDS patients, foscarnet (60 mg/kg every 8 hours or 90 mg/kg every 12 hours for 14-21 days followed by chronic maintenance at 90 to 120 mg/kg every day in one dose) is associated with clinical stabilization in ~90% of patients. A comparative trial of foscarnet with ganciclovir found favorable control of CMV retinitis in AIDS patients but improved overall survival in the foscarnet-treated group (Studies of Ocular Complications of AIDS, 1992). This improved survival with foscarnet may be related to the drug’s intrinsic anti-HIV activity, but patients stop taking foscarnet over three times as often as ganciclovir because of side effects. A combination of foscarnet and ganciclovir is more effective than either drug alone in refractory retinitis; combinations may be useful in treating ganciclovir-resistant CMV infections in solid-organ transplant patients. Foscarnet benefits other CMV syndromes in AIDS or transplant patients but is ineffective as monotherapy in treating CMV pneumonia in bone marrow transplant patients (possibly effective if started early). When used for preemptive therapy of CMV viremia in bone marrow transplant recipients, foscarnet (60 mg/kg every 12 hours for 2 weeks followed by 90 mg/kg daily for 2 weeks) is as effective as intravenous ganciclovir and causes less neutropenia (Reusser et al., 2002). When used for CMV infections, foscarnet may reduce the risk of Kaposi’s sarcoma in HIV-infected patients. Intravitreal injections of foscarnet also have been used.

In acyclovir-resistant mucocutaneous HSV infections, lower doses of foscarnet (40 mg/kg every 8 hours for ≥7 days) are associated with cessation of viral shedding and with complete healing of lesions in about three-quarters of patients. Foscarnet also appears to be effective in acyclovir-resistant VZV infections. Topical foscarnet cream is ineffective in treating recurrent genital HSV in immuno-competent persons but appears to be useful in chronic acyclovir-resistant infections in immunocompromised patients.

Resistant clinical isolates of herpesviruses have emerged during therapeutic use and may be associated with poor clinical response to foscarnet treatment.

**Ganciclovir and Valganciclovir**

**Chemistry and Antiviral Activity.** Ganciclovir is an acyclic guanine nucleoside analog that is similar in structure to acyclovir except in having an additional hydroxymethyl group on the acyclic side chain. Valganciclovir is the L-valyl ester prodrug of ganciclovir. Their structures are shown in Figure 58–2.

Ganciclovir has inhibitory activity against all herpesviruses but is especially active against CMV (Noble
Inhibitory concentrations are similar to those of acyclovir for HSV and VZV but 10-100 times lower for human CMV strains (0.2-2.8 μg/mL).

Inhibitory concentrations for human bone marrow progenitor cells are similar to those inhibitory for CMV replication, a finding predictive of ganciclovir’s myelotoxicity during clinical use. Inhibition of human lymphocyte blastogenic responses also occurs at clinically achievable concentrations of 1-10 μg/mL.

Mechanisms of Action and Resistance. Ganciclovir inhibits viral DNA synthesis. It is monophosphorylated intracellularly by viral thymidine kinase during HSV infection and by a viral phosphotransferase encoded by the UL97 gene during CMV infection. Ganciclovir diphosphate and ganciclovir triphosphate are formed by cellular enzymes. At least 10-fold higher concentrations of ganciclovir triphosphate are present in CMV-infected than in uninfected cells. The triphosphate is a competitive inhibitor of deoxyguanosine triphosphate incorporation into DNA and preferentially inhibits viral rather than host cellular DNA polymerases. Ganciclovir is incorporated into both viral and cellular DNA. Incorporation into viral DNA causes eventual cessation of DNA chain elongation (Figures 58–1B and 58–3).

Intracellular ganciclovir triphosphate concentrations are 10-fold higher than those of acyclovir triphosphate and decline much more slowly with an intracellular elimination t1/2 >24 hours. These differences may account in part for ganciclovir’s greater anti-CMV activity and provide the rationale for single daily doses in suppressing human CMV infections.

CMV can become resistant to ganciclovir by one of two mechanisms: reduced intracellular ganciclovir phosphorylation owing to mutations in the viral phosphotransferase encoded by the UL97 gene and mutations in viral DNA polymerase (Schreiber et al., 2009). Resistant CMV clinical isolates have from 4- to >20-fold increases in inhibitory concentrations. Resistance has been associated primarily with impaired phosphorylation but sometimes only with DNA polymerase mutations. Highly resistant variants with dual UL97 gene and mutations in viral DNA polymerase (Schreiber et al., 2009). Highly resistant variants with dual UL97 gene and mutations in viral DNA polymerase (Schreiber et al., 2009). Highly resistant variants with dual UL97 gene and mutations in viral DNA polymerase (Schreiber et al., 2009).

Of concern is the potential for resistance to ganciclovir to develop during therapy with other anti-CMV agents. Resistance may occur concomitantly during treatment with, or in patients on, zidovudine, didanosine, and foscarnet. Cross-resistance is also evident with valganciclovir and foscarnet. Resistance to ganciclovir has been observed in vitro and in vivo in patients on long-term prophylaxis with ganciclovir, in association with other anti-CMV agents, or in patients not on anti-CMV therapy. Resistance to ganciclovir varies with the dose given and the duration of treatment. High-dose ganciclovir regimens are associated with increased resistance compared with low-dose therapy. Patients with CMV retinitis who are treated with ganciclovir for >6 months have a higher likelihood of developing resistant virus compared with patients treated for <6 months. Clinical isolates resistant to ganciclovir have been described. Ganciclovir-resistant CMV strains can be associated with treatment failure, clinical isolates with reduced sensitivity to ganciclovir can result in therapy failure, and the clinical significance of this resistance is unknown.

Ganciclovir-resistant CMV strains can be associated with treatment failure, clinical isolates with reduced sensitivity to ganciclovir can result in therapy failure, and the clinical significance of this resistance is unknown. Ganciclovir-resistant CMV strains can be associated with treatment failure, clinical isolates with reduced sensitivity to ganciclovir can result in therapy failure, and the clinical significance of this resistance is unknown. Ganciclovir-resistant CMV strains can be associated with treatment failure, clinical isolates with reduced sensitivity to ganciclovir can result in therapy failure, and the clinical significance of this resistance is unknown.
Ganciclovir therapy (5 mg/kg every 12 hours for 14-21 days) may benefit other CMV syndromes in AIDS patients or solid-organ transplant recipients (Infectious Disease Community of Practice et al., 2004). Response rates of ≥67% have been found in combination with a decrease in immunosuppressive therapy. The duration of therapy depends on demonstrating clearance of viremia; early switch from intravenous ganciclovir to oral valganciclovir is feasible. Recurrent CMV disease occurs commonly after initial treatment. In bone marrow transplant recipients with CMV pneumonia, ganciclovir alone appears ineffective. However, ganciclovir combined with intravenous immunoglobulin or CMV immunoglobulin reduces the mortality of CMV pneumonia by about one-half. Ganciclovir treatment improved hearing outcomes in neonates with symptomatic congenital CMV infections involving the CNS (Kimberlin et al., 2003).

Ganciclovir has been used for both prophylaxis and preemptive therapy of CMV infections in transplant recipients (Schreiber et al., 2009). In bone marrow transplant recipients, preemptive ganciclovir treatment (5 mg/kg every 12 hours for 7-14 days followed by 5 mg/kg every day to days 100-120 after transplant) starting when CMV is isolated from bronchoalveolar lavage or from other sites is highly effective in preventing CMV pneumonia and appears to reduce mortality in these patients. Initiation of ganciclovir at the time of engraftment also reduces CMV disease rates but does not improve survival in part because of infections owing to ganciclovir-related neutropenia.

Intravenous ganciclovir, oral ganciclovir, and oral valganciclovir reduce the risk of CMV disease in solid-organ transplant recipients (Infectious Disease Community of Practice et al., 2004). Oral ganciclovir (1000 mg three times daily for 3 months) reduces CMV disease risk in liver transplant recipients, including high-risk patients with primary infection or those receiving antilymphocyte antibodies. Oral valganciclovir prophylaxis generally is more effective than high-dose oral acyclovir. Oral valganciclovir (900 mg once daily) provides somewhat greater antiviral effects and similar reductions in CMV disease as oral ganciclovir in mismatched solid-organ transplant recipients (Schreiber et al., 2009). Valganciclovir has recently been approved for prevention of CMV in pediatric transplant patients.

In advanced HIV disease, oral ganciclovir (1000 mg three times daily) may reduce the risk of CMV disease and possibly mortality in those not receiving didanosine (Brosigart et al., 1998) but has been replaced for prophylaxis by oral valganciclovir. The addition of oral high-dose ganciclovir (1500 mg three times daily) to the intraocular ganciclovir implant further delays the time to retinitis progression and reduces the risk of new CMV disease and possibly the risk of Kaposi's sarcoma.

Ganciclovir resistance emerges in a minority of transplant patients, especially mismatched solid-organ recipients (Limaye et al., 2000), and is associated with poorer prognosis. The use of antithymocyte globulin and prolonged ganciclovir exposure are risk factors. Recovery of ganciclovir-resistant CMV isolates has been associated with progressive CMV disease in AIDS and other immunocompromised patients. Over one-quarter of retinitis patients have resistant isolates by 9 months of therapy, and resistant CMV has been recovered from CSF, vitreous fluid, and visceral sites.

A ganciclovir ophthalmic gel formulation (ZIRGAN) is effective in treating HSV keratitis (Colin et al., 1997). Oral ganciclovir also reduces HBV DNA levels and aminotransferase levels in chronic hepatitis B virus infection (Hadziyannis et al., 1999), but the drug is not approved for this indication.

Docosanol

Docosanol is a long-chain saturated alcohol that is FDA-approved as an over-the-counter 10% cream for the treatment of recurrent orolabial herpes. Docosanol inhibits the in vitro replication of many lipid-enveloped viruses, including HSV, at millimolar concentrations. It does not inactivate HSV directly but appears to block fusion between the cellular and viral envelope membranes and inhibits viral entry into the cell. Topical treatment beginning within 12 hours of prodromal symptoms or lesion onset reduces healing time by ~1 day and appears to be well tolerated (Elish et al., 2004). Treatment initiation at papular or later stages provides no benefit.

Idoxuridine

Idoxuridine (5-ido-2′-deoxyuridine) is an iodinated thymidine analog that inhibits the in vitro replication of various DNA viruses, including herpesviruses and poxviruses (Prusoff, 1988).

Inhibitory concentrations of idoxuridine for HSV-1 are 2-10 μg/mL, at least 10-fold higher than those of acyclovir. Idoxuridine lacks selectivity, in that low concentrations inhibit the growth of uninfected cells. The triphosphate inhibits viral DNA synthesis and is incorporated into both viral and cellular DNA. Such altered DNA is more susceptible to breakage and also leads to faulty transcription. Resistance to idoxuridine develops readily in vitro and occurs in viral isolates recovered from idoxuridine-treated patients with HSV keratitis.

In the U.S., idoxuridine is approved only for topical (ophthalmic) treatment of HSV keratitis. Idoxuridine formulated in dimethylsulfoxide is available outside the U.S. for topical treatment of herpes labialis, genitalis, and zoster. In ocular HSV infections, topical idoxuridine is more effective in epithelial infections, especially initial episodes, than in stromal infections. Adverse reactions include pain, pruritus, inflammation, and edema involving the eye or lids; rarely do allergic reactions occur.

Trifluridine

Trifluridine (5-trifluoromethyl-2′-deoxyuridine) is a fluorinated pyrimidine nucleoside that has in vitro inhibitory activity against HSV types 1 and 2, CMV, vaccinia, and to a lesser extent, certain adenoviruses.

Concentrations of trifluridine of 0.2-10 μg/mL inhibit replication of herpesviruses, including acyclovir-resistant strains. Trifluridine also inhibits cellular DNA synthesis at relatively low concentrations.

Trifluridine monophosphate irreversibly inhibits thymidylate synthase, and trifluridine triphosphate is a competitive inhibitor of thymidine triphosphate incorporation into DNA;
trifluridine is incorporated into viral and cellular DNA. Trifluridine-resistant HSV with altered thymidine kinase substrate specificity can be selected in vitro, and resistance in clinical isolates has been described.

Trifluridine currently is approved in the U.S. for treatment of primary keratoconjunctivitis and recurrent epithelial keratitis owing to HSV types 1 and 2. Topical trifluridine is more active than idoxuridine and comparable with vidarabine in HSV ocular infections. Adverse reactions include discomfort on instillation and palpebral edema. Hypersensitivity reactions, irritation, and superficial punctate or epithelial keratopathy are uncommon. Topical trifluridine also appears to be effective in some patients with acyclovir-resistant HSV cutaneous infections.

ANTI-INFLUENZA AGENTS

Four drugs are currently approved for the treatment and prevention of influenza virus infection. Over the past several years, there has been increasing concern about the possibility of new influenza pandemics, stemming from small but severe outbreaks of H5N1 avian influenza and the novel 2009 influenza A H1N1, thought to be of swine origin. This has prompted stockpiling of existing agents and motivated new drug discovery. Regulatory responses include Emergency Use Authorization (EUA) granted by the FDA, Centers for Disease Control and Prevention, and the World Health Organization to allow for treatment and prophylaxis of H1N1 in pediatric patients ≤1 year of age even though the four available agents were never granted conventional approval for this age group. In addition, peramivir, an investigational neuraminidase inhibitor, was made available for intravenous use via EUA authorization.

In the 2008–2009 influenza season, virtually all strains of influenza A H1N1 were resistant to the neuraminidase inhibitor oseltamivir (Moscona, 2009). This has arisen as a consequence of overuse of these drugs, including in veterinary applications. Fortunately the majority of 2009 H1N1 “swine” viruses were susceptible to oseltamivir; however, sporadic cases of oseltamivir resistance have been detected even with this strain. All such viruses tested to date were resistant to the adamantane antivirals, amantadine and rimantadine. Development of resistance to these drugs, and the spread of resistant viruses, is a major challenge in the chemotherapy and chemoprophylaxis of influenza and is likely to drive future recommendations for use of these drugs in global populations.

Amantadine and Rimantadine

Chemistry and Antiviral Activity. Amantadine (1-adamantanamine hydrochloride) and its α-methyl derivative rimantadine (α-methyl-1-adamantane methylamine hydrochloride) are uniquely configured tricyclic amines. Their structures are depicted in Figure 58–4.

Low concentrations of either agent specifically inhibit the replication of influenza A viruses (Schmidt, 2004). Depending on the assay method and strain, inhibitory concentrations of the drugs range from ~0.03–1.0 μg/mL for influenza A viruses. Rimantadine generally is 4–10 times more active than amantadine. Concentrations of ≥10 μg/mL inhibit other enveloped viruses but are not achievable in humans and may be cytotoxic. Rimantadine is inhibitory in vitro for Trypanosoma brucei, a cause of African sleeping sickness, at concentrations of 1–2.5 μg/mL. These agents do not inhibit hepatitis C virus (HCV) enzymes or internal ribosomal entry site–mediated translation but block the ion channel activity of the HCV p7 protein in vitro (Griffin et al., 2003).

Mechanisms of Action and Resistance. Amantadine and rimantadine share two mechanisms of antiviral action. They inhibit an early step in viral replication, probably viral uncoating; for some strains, they also have an effect on a late step in viral assembly probably mediated through altering hemagglutinin processing. The primary locus of action is the influenza A virus M2 protein, an integral membrane protein that functions as an ion channel. By interfering with this function of the M2 protein, the drugs inhibit the acid-mediated dissociation of the ribonucleoprotein complex early in replication and potentiate acidic pH–induced conformational changes in the hemagglutinin during its intracellular transport later in replication.

Absorption, Distribution, and Elimination. Amantadine and rimantadine are well absorbed after oral administration (Schmidt, 2004) (Table 58–3). Peak plasma concentrations of amantadine average 0.5–0.8 μg/mL on a 100-mg twice-daily regimen in healthy young adults. Comparable doses of rimantadine give peak and trough plasma concentrations of ~0.4–0.5 and 0.2–0.4 μg/mL, respectively. The elderly require only one-half the weight-adjusted dose of amantadine needed for young adults to achieve equivalent trough plasma levels of 0.3 μg/mL. Both drugs have very large volumes of distribution. Nasal secretion and salivary levels of amantadine approximate those found in the serum. Amantadine is excreted in breast milk. Rimantadine concentrations in nasal mucus average 50% higher than those in plasma.

Amantadine is excreted largely unmetabolized in the urine through glomerular filtration and probably tubular secretion. The plasma t1/2 of elimination is ~12–18 hours in young adults. Because amantadine’s elimination is highly dependent on renal function, the elimination t1/2 increases up to 2-fold in the elderly and even more in those with renal impairment. Dose adjustments are advisable in those with mild decrements in renal function. In contrast,
rimantadine is metabolized extensively by hydroxylation, conjugation, and glucuronidation prior to renal excretion. Following oral administration, the elimination $t_{1/2}$ of rimantadine averages 24-36 hours, and 60-90% is excreted in the urine as metabolites. Renal clearance of unchanged rimantadine is similar to creatinine clearance.

Untoward Effects. The most common side effects related to amantadine and rimantadine are minor dose-related CNS and gastrointestinal (Schmidt, 2004). These include nervousness, light-headedness, difficulty concentrating, insomnia, and loss of appetite or nausea. CNS side effects occur in 5-33% of patients treated with amantadine at doses of 200 mg/day but are significantly less frequent with rimantadine. The neurotoxic effects of amantadine appear to be increased by concomitant ingestion of antihistamines and psychotropic or anticholinergic drugs, especially in the elderly. Amantadine dose reductions are required in older adults (100 mg/day) because of decreased renal function, but 20-40% of infirm elderly will experience side effects even at this lower dose. At comparable doses of 100 mg/day, rimantadine is significantly better tolerated in nursing home residents than amantadine (Keyser et al., 2000).

High amantadine plasma concentrations (1.0-5.0 $\mu$g/mL) have been associated with serious neurotoxic reactions, including delirium, hallucinosis, seizures, and coma, and cardiac arrhythmias. Exacerbations of preexisting seizure disorders and psychiatric symptoms may occur with amantadine and possibly with rimantadine. Amantadine is teratogenic in animals. Both drugs are considered pregnancy Category C because safety has not been established in pregnancy.

Therapeutic Uses. Seasonal prophylaxis with either amantadine or rimantadine (a total of 200 mg/day in one or two divided doses in young adults) is ~70-90% protective against influenza A illness. Efficacy has been shown during pandemic influenza, in preventing nosocomial influenza, and in curtailing nosocomial outbreaks. Doses of 100 mg/day are better tolerated and still appear to be protective against influenzal illness. Postexposure prophylaxis with either drug provides protection of exposed family contacts if ill young children are not concurrently treated (Schmidt, 2004).

Seasonal prophylaxis is an alternative in high-risk patients if the influenza vaccine cannot be administered or may be ineffective (i.e., in immunocompromised patients). Prophylaxis should be started as soon as influenza is identified in a community or region and should be continued throughout the period of risk (usually 4-8 weeks) because any protective effects are lost several days after cessation of therapy. Alternatively, the drugs can be started in conjunction with immunization and continued for 2 weeks until protective immune responses develop.

The amantadines are effective against influenza A H1N1 in adults and children if treatment is initiated within 2 days of the onset of symptoms (Schmidt, 2004). Therapy reduces duration of viral excretion, fever, and other systemic complaints, but resistance has become more widespread with use. Duration of illness is shortened by ~1 day. In uncomplicated influenza A illness of adults, early
amantadine or rimantadine treatment (200 mg/day for 5 days) reduces the duration of fever and systemic complaints by 1-2 days, speeds functional recovery, and sometimes decreases the duration of virus shedding (Schmidt, 2004). In children, rimantadine treatment may be associated with less illness and lower viral titers during the first 2 days of treatment, but rimantadine-treated children have more prolonged shedding of virus. The usual regimen in children (≥1 year of age) is 5 mg/kg/day, up to 150 mg, administered once or twice daily.

Resistant variants have been recovered from ~30% of treated children or outpatient adults by the fifth day of therapy (Schmidt, 2004). Resistant variants also arise commonly in immunocompromised patients (Englund et al., 1998). Illnesses owing to apparent transmission of resistant virus associated with failure of drug prophylaxis have been documented in contacts of drug-treated ill persons in households and in nursing homes (Schmidt, 2004). Resistant variants appear to be pathogenic and can cause typical disabling influenza.

Although both drugs are useful for the prevention and treatment of infections caused by influenza A virus, vaccination against influenza is a more cost-effective means of reducing disease burden. The utility of the amantadines has been limited by the development of resistance. Amantadine and rimantadine are active only against susceptible influenza A viruses (not influenza B); rimantadine is 4- to 10-fold more active than amantadine. Currently, virtually all H3N2 strains of influenza circulating worldwide are resistant to these drugs. Resistance to these drugs results from a mutation in the RNA sequence encoding for the M2 protein transmembrane domain (Schmidt, 2004), and resistant isolates typically appears in the treated patient within 2-3 days of starting therapy.

**Oseltamivir**

**Chemistry and Antiviral Activity.** Oseltamivir carboxylate (Figure 58–4) is a transition-state analog of sialic acid that is a potent selective inhibitor of influenza A and B virus neuraminidases. Oseltamivir phosphate is an ethyl ester prodrug that lacks antiviral activity.

Oseltamivir carboxylate has an antiviral spectrum and potency similar to that of zanamivir. It inhibits amantadine and rimantadine-resistant influenza A viruses and some zanamivir-resistant variants.

**Mechanisms of Action and Resistance.** Influenza neuraminidase cleaves terminal sialic acid residues and destroys the receptors recognized by viral hemagglutinin, which are present on the cell surface, in progeny virions, and in respiratory secretions (Schirmer and Holodniy, 2009). This enzymatic action is essential for release of virus from infected cells. Interaction of oseltamivir carboxylate with the neuraminidase causes a conformational change within the enzyme’s active site and inhibits its activity. Inhibition of neuraminidase activity leads to viral aggregation at the cell surface and reduced virus spread within the respiratory tract.

Influenza variants selected *in vitro* for resistance to oseltamivir carboxylate contain hemagglutinin and/or neuraminidase mutations. The most commonly recognized variants (mutations at positions 292 in N2 and 274 in N1 neuraminidases) have reduced infectivity and virulence in animal models. Outpatient oseltamivir therapy has been associated with recovery of resistant variants in ~0.5% of adults and 5.5% of children; a higher frequency (~18%) occurs in hospitalized children. Seasonal influenza A (H1N1) has become virtually 100% resistant to oseltamivir worldwide (Moscona, 2009; Schirmer and Holodniy, 2009). Importantly, novel H1N1 (nH1N1 or swine influenza) remains susceptible to oseltamivir.

**Absorption, Distribution, and Elimination.** Oral oseltamivir phosphate is absorbed rapidly (Table 58–3) and cleaved by esterases in the GI tract and liver to the active carboxylate. Low blood levels of the phosphate are detectable, but exposure is only 3-5% of that of the metabolite. The bioavailability of the carboxylate is estimated to be ~80%. The time to maximum plasma concentrations of the carboxylate is ~2.5-5 hours. Food does not decrease bioavailability but reduces the risk of GI intolerance. After 75-mg doses, peak plasma concentrations average 0.07 μg/mL for oseltamivir phosphate and 0.35 μg/mL for the carboxylate. The carboxylate has a volume of distribution similar to extracellular water. Bronchoalveolar lavage levels in animals and middle ear fluid and sinus concentrations in humans are comparable with plasma levels. Following oral administration, the plasma t1/2 of oseltamivir phosphate is 1-3 hours; that of the carboxylate is 6-10 hours. Both the prodrug and active metabolite are eliminated primarily unchanged through the kidney. Probenecid doubles the plasma t1/2 of the carboxylate, which indicates tubular secretion by the anionic pathway. Children <2 years of age exhibit age-related changes in oseltamivir carboxylate clearance and total drug exposure (Kimberlin et al., 2009).

**Untoward Effects.** Oral oseltamivir is associated with nausea, abdominal discomfort, and, less often, emesis, probably owing to local irritation. GI complaints usually are mild to moderate in intensity, typically resolve in 1-2 days despite continued dosing, and are preventable by administration with food. The frequency of such complaints is ~10-15% when oseltamivir is used for the treatment of influenza illness and <5% when used for prophylaxis. An increased frequency of headache was reported in one prophylaxis study in elderly adults.

Oseltamivir phosphate and the carboxylate do not interact with CYPs *in vitro*. Their binding to protein is low. No clinically significant drug interactions have been recognized to date. Oseltamivir does not appear to impair fertility or to be teratogenic in animal studies, but safety in pregnancy is uncertain (pregnancy Category C). Very high doses have been associated with increased mortality, perhaps related to increased brain concentrations, in unweaned rats.

**Therapeutic Uses.** Oral oseltamivir is effective in the treatment and prevention of influenza A and B virus infections.

Treatment of previously healthy adults (75 mg twice daily for 5 days) or children 1-12 years of age (weight-adjusted dosing) with acute influenza reduces illness duration by ~1-2 days, speeds functional recovery, and reduces the risk of complications leading to antibiotic use by 40-50% (Whitley et al., 2001). Treatment is associated with approximate halving of the risk of subsequent hospitalization in adults (Kaiser et al., 2003). When used for prophylaxis during the typical influenza season, oseltamivir (75 mg once daily) is effective (~70-90%) in reducing the likelihood of influenza illness in both unimmunized working adults and in immunized nursing
home residents; short-term use (7-10 days) protects against influenza in household contacts (Schirmer and Holodniy, 2009).

Because of the global development of resistance of H1N1 seasonal influenza, treatment recommendations issued by the CDC for the 2008–2009 influenza season required the co-administration of an adamantane and a neuraminidase inhibitor. An intravenous formulation of oseltamivir is being evaluated in adults and children under the 2009 EUA. Until recently, oseltamivir was only licensed for patients >2 years of age; however, with the introduction of 2009 nH1N1, an EUA allows for therapy for all ages (Centers for Disease Control and Prevention, 2009).

Zanamivir

Chemistry and Antiviral Activity. Zanamivir (Figure 58–4) is a sialic acid analog that potently and specifically inhibits the neuraminidases of influenza A and B viruses.

Depending on the strain, zanamivir competitively inhibits influenza neuraminidase activity at concentrations of ~0.2-3 ng/mL but affects neuraminidases from other pathogens and mammalian sources only at 10-fold higher concentrations. Zanamivir inhibits in vitro replication of influenza A and B viruses, including amantadine- and rimantadine-resistant strains and several oseltamivir-resistant variants. It is active after topical administration in animal influenza models.

Mechanisms of Action and Resistance. Like oseltamivir, zanamivir inhibits viral neuraminidase and thus causes viral aggregation at the cell surface and reduced spread of virus within the respiratory tract (Eiland and Eiland, 2007).

In vitro selection of viruses resistant to zanamivir is associated with mutations in the viral hemagglutinin and/or neuraminidase. Hemagglutinin variants generally have mutations in or near the receptor binding site that make them less dependent on neuraminidase action for release from cells in vitro, although they typically retain susceptibility in vivo. Hemagglutinin variants are cross-resistant to other neuraminidase inhibitors. Neuraminidase variants contain mutations in the enzyme active site that diminish binding of zanamivir, but the altered enzymes show reduced activity or stability. Zanamivir-resistant variants usually have decreased infectivity in animals. Resistance has not been documented in immunocompetent hosts to date but has been seen rarely in highly immunocompromised patients (Eiland and Eiland, 2007).

Absorption, Distribution, and Elimination. The oral bioavailability of zanamivir is low (<5%) (Table 58–3), and the commercial form is delivered by oral inhalation of dry powder in a lactose carrier. The proprietary inhaler device is breath-actuated and requires a cooperative patient. Following inhalation of the dry powder, ~15% is deposited in the lower respiratory tract and ~80% in the oropharynx. Overall bioavailability is 4-17%, and plasma levels after 10-mg inhaled doses average ~35-100 ng/mL in adults and children. Median zanamivir concentrations in induced sputum samples are 1336 ng/mL at 6 hours and 47 ng/mL at 24 hours after a single 10-mg dose in healthy volunteers. The plasma t½ of zanamivir averages 2.5-5 hours after oral inhalation but only 1.7 hours following intravenous dosing. Over 90% is eliminated in the urine as the parent compound (Eiland and Eiland, 2007).

Untoward Effects. Orally inhaled zanamivir generally is well tolerated in ambulatory adults and children with influenza. Wheezing and bronchospasm have been reported in some influenza-infected patients.

A fifth agent, permavir, is investigational in the U.S. and approved in Japan at a dose of 600 mg intravenously once daily in adults. Its elimination is primarily renal, with dosage adjustment required for renal insufficiency.

*Investigational at present. †Systemic absorption 4-17% after inhalation. ‡For antivirally active oseltamivir carboxylate. §Inhaled formulation only. Clcr, creatinine clearance.
without known airway disease, and acute deteriorations in lung function, including fatal outcomes, have occurred in those with underlying asthma or chronic obstructive airway disease. Tolerability in more serious bronchopulmonary disorders or in intubated patients is uncertain. Zanamivir is not generally recommended for treatment of patients with underlying airway disease (e.g., asthma or chronic obstructive pulmonary disease) because of the risk of serious adverse events.

Preclinical studies of zanamivir revealed no evidence of mutagenic, teratogenic, or oncogenic effects (pregnancy Category C). No clinically significant drug interactions have been recognized to date. Zanamivir does not diminish the immune response to injected influenza vaccine.

**Therapeutic Uses.** Inhaled zanamivir is effective for the prevention and treatment of influenza A and B virus infections.

Early zanamivir treatment (10 mg [two inhalations] twice daily for 5 days) of febrile influenza in ambulatory adults and children ≥5 years of age shortens the time to illness resolution by 1-3 days (Eiland and Eiland, 2007) and in adults reduces by 40% the risk of lower respiratory tract complications leading to antibiotic use (Kaiser et al., 2000). Once-daily inhaled, but not intranasal, zanamivir is highly protective against community-acquired influenza illness, and when given for 10 days, it protects against household transmission (Eiland and Eiland, 2007). Intravenous zanamivir is protective against experimental human influenza and is being evaluated for the 2009 nH1N1 EUA.

**ANTI-HEPATITIS VIRUS AGENTS**

A number of agents are available for treatment of hepatitis B virus (HBV) and hepatitis C virus (HCV) infections. Several agents (e.g., interferons, ribavirin, and the nucleoside/nucleotide analogs lamivudine, telbivudine, and tenofovir) have other uses as well (Chapters 59 and 65). Therapeutic strategies for these two chronic viral infections, hepatitis B and C, are very different and are described separately.

**Drugs Used Mainly for Hepatitis C Virus Infection**

Hepatitis C is one of the most common chronic virus infections in the developed world and is associated with significant morbidity and mortality. Untreated, this virus can cause progressive hepatocellular injury with fibrosis and eventual cirrhosis. Chronic HCV is also a major risk factor for hepatocellular carcinoma.

Although the virus is quite prolific, producing several billion new particles every few days in an infected individual, this RNA virus does not integrate into chromosomal DNA, and it does not establish latency per se. Therefore the infection is, in theory, curable in all affected individuals. The current standard of care for treatment is a combination of peginterferon alfa and ribavirin, which produces a high cure rate in selected virus genotypes only (McHutchison et al., 2009). Recent advent of highly effective oral agents that are pharmacologically selective for this pathogen, including HCV protease inhibitors and polymerase inhibitors, bring hope for curative combinations of oral agents. It is likely that treatment recommendations for this infection will change radically in the coming decade.

**Interferons**

**Classification and Antiviral Activity.** Interferons (IFNs) are potent cytokines that possess antiviral, immunomodulatory, and antiproliferative activities (Biron, 2001; Samuel, 2001) (Chapter 35). These proteins are synthesized by host cells in response to various inducers and, in turn, cause biochemical changes leading to an antiviral state in cells. Three major classes of human interferons with significant antiviral activity currently are recognized: α (>18 individual species), β, and γ. Clinically used recombinant α-IFNs (Table 58–2) are non-glycosylated proteins of ~19,500 Da, the pegylated forms predominating in the U.S. market.

IFN-α and IFN-β may be produced by nearly all cells in response to viral infection and a variety of other stimuli, including double-stranded RNA and certain cytokines (e.g., interleukin 1, interleukin 2, and tumor necrosis factor). IFN-γ production is restricted to T-lymphocytes and natural killer cells responding to antigenic stimuli, mitogens, and specific cytokines. IFN-α and IFN-β exhibit antiviral and antiproliferative actions; stimulate the cytotoxic activity of lymphocytes, natural killer cells, and macrophages; and upregulate class I major histocompatibility (MHC) antigens and other surface markers. IFN-γ has less antiviral activity but more potent immunoregulatory effects, particularly macrophage activation, expression of class II MHC antigens, and mediation of local inflammatory responses. In addition, interferons downregulate production of a number of cellular proteins, which may be an equally important mediator of the pharmacological benefit of these agents.

Most animal viruses are inhibited by IFNs, although many DNA viruses are relatively insensitive. Considerable differences in sensitivity to the effects of IFNs exist among different viruses and assay systems. The biological activity of IFN usually is measured in terms of antiviral effects in cell culture and generally is expressed as international units (IU) relative to reference standards.

**Mechanisms of Action.** Following binding to specific cellular receptors, IFNs activate the JAK-STAT signal-transduction pathway and lead to the nuclear translocation of a cellular protein complex that binds to genes
containing an IFN-specific response element. This, in turn, leads to synthesis of over two dozen proteins that contribute to viral resistance mediated at different stages of viral penetration (Samuel, 2001) (Figure 58–5).

Inhibition of protein synthesis is the major inhibitory effect for many viruses. IFN-induced proteins include 2′-5′-oligoadenylate [2-5(A)] synthetase and a protein kinase, either of which can inhibit protein synthesis in the presence of double-stranded RNA. The 2-5(A) synthetase produces adenylate oligomers that activate a latent cellular endoribonuclease (RNase L) to cleave both cellular and viral single-stranded RNAs. The protein kinase selectively phosphorylates and inactivates a protein involved in protein synthesis, eukaryotic initiation factor 2 (eIF-2). IFN-induced protein kinase also may be an important effector of apoptosis. In addition, IFN induces a phosphodiesterase that cleaves a portion of transfer RNA and thus prevents peptide elongation. A given virus may be inhibited at several steps, and the principal inhibitory effect differs among virus families. Certain viruses are able to counter IFN effects by blocking production or activity of selected IFN-inducible proteins. For example, IFN resistance in hepatitis C virus is attributable to inhibition of the IFN-induced protein kinase, among other mechanisms.

Complex interactions exist between IFNs and other parts of the immune system, so IFNs may ameliorate viral infections by exerting direct antiviral effects and/or by modifying the immune response to infection (Biron, 2001). For example, IFN resistance in hepatitis C virus is attributable to inhibition of the IFN-induced protein kinase, among other mechanisms.

**Figure 58–5. Interferon-Mediated Antiviral Activity Occurs via Multiple Mechanisms.** The binding of IFN to specific cell surface receptor molecules signals the cell to produce a series of antiviral proteins. The stages of viral replication that are inhibited by various IFN-induced antiviral proteins are shown. Most of these act to inhibit the translation of viral replication (mechanism 2), but other steps in viral replication also are affected (mechanisms 1, 3, and 4). The roles of these mechanisms in the other actions of IFNs are under study. Key: IFN = interferon; mRNA = messenger RNA; Mx = IFN-induced cellular protein with anti-viral activity; tRNA = transfer RNA; RNase L = latent cellular endoribonuclease; 2′5′A = 2′-5′-oligoadenylates; eIF-2α = protein synthesis initiation factor. (Modified from Baron et al., 1992, with permission.)
Absorption, Distribution, and Elimination. Oral administration does not result in detectable IFN levels in serum or increases in 2-5(A) synthetase activity in peripheral blood mononuclear cells (used as a marker of IFN’s biologic activity). After intramuscular or subcutaneous injection of IFN-α, absorption exceeds 80%. Plasma levels are dose related, peaking at 4-8 hours and returning to baseline by 18-36 hours. Levels of 2-5(A) synthetase in peripheral blood mononuclear cells show increases beginning at 6 hours and lasting through 4 days after a single injection. An antiviral state in peripheral blood mononuclear cells peaks at 24 hours and decreases slowly to baseline by 6 days after injection. Intramuscular or subcutaneous injections of IFN-β result in negligible plasma levels, although increases in 2-5(A) synthetase levels may occur. After systemic administration, low levels of IFN are detected in respiratory secretions, CSF, eye, and brain.

Because IFNs induce long-lasting cellular effects, their activities are not easily predictable from usual pharmacokinetic measures. After intravenous dosing, clearance of IFN from plasma occurs in a complex manner (Bocci, 1992). With subcutaneous or intramuscular dosing, the plasma t1/2 of IFN-α ranges is variable, 3-8 hours. Elimination from the blood relates to distribution to the tissues, cellular uptake, and catabolism primarily in the kidney and liver. Negligible amounts are excreted in the urine. Clearance of IFN-α2B is reduced by ~80% in hemodialysis patients (Uchiharaa et al., 1998).

Attachment of IFN proteins to large inert polyethylene glycol (PEG) molecules (pegylation) slows absorption, decreases clearance, and provides higher and more prolonged serum concentrations that enable once-weekly dosing (Bruno et al., 2004). Two pegylated IFNs are available commercially: peginterferon alfa-2a (PEGASYS) and peginterferon alfa-2B (PEGINTERON). PegIFN alfa-2B has a straight-chain 12,000-Da type of PEG that increases the plasma t1/2 from ~2-3 hours to ~30-54 hours (Glue et al., 2000). PegIFN alfa-2a consists of an ester derivative of a branched-chain 40,000-Da PEG bonded to IFN-α2A and has a plasma t1/2 averaging ~80-90 hours. PegIFN alfa-2A is more stable and dispensed in solution, whereas pegIFN alfa-2B requires reconstitution prior to use. For pegIFN alfa-2A, peak serum concentrations occur up to 120 hours after dosing and remain detectable throughout the weekly dosing interval (Bruno et al., 2004); steady-state levels occur 5-8 weeks after initiation of weekly dosing (Keating and Curran, 2003). For pegIFN alfa-2A, dose-related maximum plasma concentrations occur at 15-44 hours after dosing and decline by 96-168 hours. These differences in pharmacokinetics may be associated with differences in antiviral effects (Bruno et al., 2004). Increasing PEG size is associated with longer t1/2 and less renal clearance. About 30% of pegIFN alfa-2B is cleared by the kidneys; pegIFN alfa-2A also is cleared primarily by the liver. Dose reductions in both pegylated IFNs are indicated in end-stage renal disease.

Untoward Effects. Injection of recombinant IFN doses of ≥1 to 2 million units (MU) usually is associated with an acute influenza-like syndrome beginning several hours after injection. Symptoms include fever, chills, headache, myalgia, arthralgia, nausea, vomiting, and diarrhea. Fever usually resolves within 12 hours. Tolerance develops gradually in most patients. Fibrile responses can be moderated by pretreatment with antipyretics. Up to one-half of patients receiving intralesional therapy for genital warts experience the influenza-like illness initially, as well as discomfort at the injection site, and leukopenia.

The principal dose-limiting toxicities of systemic IFN are depression, myelosuppression with granulocytopenia and thrombocytopenia; neurotoxicity manifested by somnolence, confusion, behavioral disturbance, and rarely, seizures; debilitating neurasthenia and depression; autoimmune disorders including thyroiditis and hypothyroidism; and uncommonly, cardiovascular effects with hypotension and tachycardia. The risk of depression appears to be higher in chronically infected HCV than in HBV patients (Marcellin et al., 2004). Elevations in hepatic enzymes and triglycerides, alopecia, proteinuria and azotemia, interstitial nephritis, autoantibody formation, pneumonia, and hepatotoxicity may occur. Alopecia and personality change are common in IFN-treated children (Sokal et al., 1998). The development of serum neutralizing antibodies to exogenous IFNs may be associated infrequently with loss of clinical responsiveness. IFN may impair fertility, and safety during pregnancy is not established. IFNs can increase the hematological toxicity of drugs such as zidovudine and ribavirin and may increase the neurotoxicity and cardiotoxic effects of other drugs. Thyroid function and hepatic enzymes should be monitored during IFN therapy.

Pegylated IFNs are generally better tolerated than standard IFNs, with discontinuation rates ranging from 2-11%, although the frequencies of fever, nausea, injection-site inflammation, and neutropenia may be somewhat higher. Laboratory abnormalities, including severe neutropenia and the need for dose modifications, are higher in HIV-co-infected persons.

Therapeutic Uses. Recombinant, natural, and pegylated IFNs currently are approved in the U.S., depending on the specific IFN type, for treatment of condyloma acuminatum, chronic HCV infection, chronic HBV infection, Kaposi’s sarcoma in HIV-infected patients, other malignancies, and multiple sclerosis. In addition, interferons have been granted orphan drug status for a variety of rare disease states including idopathic pulmonary fibrosis, laryngeal papillomatosis, juvenile rheumatoid arthritis, and infections associated with chronic granulomatous disease.

Hepatitis B Virus. In patients with chronic HBV infection, parenteral administration of various IFNs is associated with loss of HBV DNA, loss of HBeAg and development of anti-HBe antibody, and biochemical and histological improvement in ~25-50% of the patients.

Lasting responses require moderately high IFN doses and prolonged administration (typically 5 MU/day or 10 MU in adults and 6 MU/m² in children three times per week of IFNα-2B for 4 to 6 weeks) (Sokal et al., 1998). Plasma HBV DNA and polymerase activity decline promptly in most patients, but complete disappearance is sustained in only about one-third of patients or less. Low pretherapy serum HBV DNA levels and high aminotransferase levels are predictors of response. Sustained responses are infrequent in those with vertically acquired infection, anti-HBe positivity, or concurrent immunosuppression owing to HIV. PegIFN alfa-2A appears superior to conventional IFN alfa-2A in HBeAg-positive patients (Cooksley et al., 2003), and treatment (180 µg once weekly for 24-48 weeks) is associated with normalization of aminotransferases in ~60% and sustained viral suppression in ~20% of HBeAg-negative patients (Marcellin et al., 2004). Responses with seroconversion to anti-HBe usually are associated with aminotransferase elevations and often a hepatitis-like illness during the second or third month of therapy, likely related to immune clearance of infected hepatocytes. High-dose
IFN can cause myelosuppression and clinical deterioration in those with decompensated liver disease.

Remissions in chronic hepatitis B induced by IFN are sustained in >80% of patients treated and frequently are followed by loss of HBV surface antigen (HBsAg), histological improvement or stabilization, and reduced risk of liver-related complications and mortality (Lau et al., 1997). IFN may benefit some patients with nosophic syndrome and glomerulonephritis owing to chronic HBV infection. Antiviral effects and improvements occur in about one-half of chronic hepatitis D virus (HDV) infections, but relapse is common unless HBsAg disappears. IFN does not appear to be beneficial in acute HBV or HDV infections.

**Hepatitis C Virus.** In chronic HCV infection, IFN alfa-2B monotherapy (3 MU three times a week) is associated with an approximate 50-70% rate of aminotransferase normalization and loss of plasma viral RNA, but relapse rates are high, and sustained virologic remission (absence of detectable HCV RNA) is observed in only 10-25% of patients.

Sustained viral responses are associated with long-term histological improvement and probably reduced risk of hepatocellular carcinoma and hepatic failure (Coverdale et al., 2004). Viral genotype and pretreatment RNA level influence response to treatment, but early viral clearance is the best predictor of sustained response. Failure to achieve an early viral response (nondetectable HCV RNA or reduction ≥2 log₁₀ units compared with baseline at 12 weeks) predicts lack of sustained viral response with continued treatment (Seeff and Hoofnagle, 2002). Nonresponders generally do not benefit from IFN monotherapy retreatment, but they and patients relapsing after monotherapy often respond to combined pegylated IFN and ribavirin treatment. IFN treatment may benefit HCV-associated cryoglobulinemia and glomerulonephritis. IFN administration during acute HCV infection appears to reduce the risk of chronicity (Alberti et al., 2002).

Pegylated IFNs are superior to conventional thrice-weekly IFN monotherapy in inducing sustained remissions in treatment-naive patients. Monotherapy with pegIFN alfa-2A (180 μg subcutaneously weekly for 48 weeks) or pegIFN alfa-2B (weight-adjusted doses of 1.5 μg/kg/week for 1 year) is associated with sustained response in 30-39%, including stable cirrhotic patients (Heathcote et al., 2000), and it is a treatment option in patients unable to take ribavirin. Studies of prolonged (4 years) maintenance monotherapy with pegylated IFNs are in progress for those not responding to IFN-ribavirin combinations. A large randomized comparison of pegIFN alfa-2A versus alfa-2B combined with ribavirin found no difference in response rates (McHutchison et al., 2009).

The efficacy of conventional and pegylated IFNs is enhanced by the addition of ribavirin to the treatment regimens, particularly for genotype 1 infections. Combined therapy with pegIFN alfa-2A (180 μg once weekly for 48 weeks) and ribavirin (1000-1200 mg/day in divided doses) gives higher sustained viral response rates than IFN-ribavirin combinations in previously untreated patients (Fried et al., 2002). A shorter duration of therapy (24 weeks) and lower ribavirin dose (800 mg/day) are effective in genotype 2 and 3 infections, but prolonged therapy and higher ribavirin doses are needed for genotype 1 and 4 infections (Hadjizyannis et al., 2004). Approximately 15-20% of those failing to respond to combined IFN-ribavirin will have sustained responses to combined pegIFN-ribavirin. Histological improvement may occur in patients who do not achieve sustained viral responses. In patients with compensated cirrhosis, treatment may reverse cirrhotic changes and possibly reduce the risk of hepatocellular carcinoma (Poynard et al., 2002).

**Papillomavirus.** In refractory condylomata acuminata (genital warts), intralesional injection of various natural and recombinant IFNs is associated with complete clearance of injected warts in 36-62% of patients, but other treatments are preferred (Wiley et al., 2002). Relapse occurs in 20-30% of patients. Verruca vulgaris may respond to intralesional IFN-α. Intramuscular or subcutaneous administration is associated with some regression in wart size but greater toxicity. Systemic IFN may provide adjunctive benefit in recurrent juvenile laryngeal papillomatosis and in treating laryngeal disease in older patients.

**Other Viruses.** IFNs have been shown to have virological and clinical effects in various herpesvirus infections including genital HSV infections, localized herpes-zoster infection of cancer patients or of older adults, and CMV infections of renal transplant patients. However, IFN generally is associated with more side effects and inferior clinical benefits compared with conventional antiviral therapies. Topically applied IFN and trifluridine combinations appear active in acyclovir-resistant mucocutaneous HSV infections.

In HIV-infected persons, IFNs have been associated with antiretroviral effects. In advanced infection, however, the combination of zidovudine and IFN is associated with only transient benefit and excessive hematological toxicity. IFN-α (3 MU three times weekly) is effective for treatment of HIV-related thrombocytopenia resistant to zidovudine therapy.

Except for adenovirus, IFN has broad-spectrum antiviral activity against respiratory viruses in vitro. However, prophylactic intranasal IFN-α is protective only against rhinovirus colds, and chronic use is limited by the occurrence of nasal side effects. Intranasal IFN is therapeutically ineffective in established rhinovirus colds. Systemically administered IFN-α may be beneficial in early treatment of SARS (Loutfy et al., 2003).

**Ribavirin**

**Chemistry and Antiviral Activity.** Ribavirin is a purine nucleoside analog with a modified base and D-ribose sugar (Figure 58–6).

Ribavirin inhibits the replication of a wide range of RNA and DNA viruses, including orthomyxo-, paramyxo-, arena-, bunya-, and flaviviruses in vitro. In vitro inhibitory concentrations range from 3 to 10 μg/mL for influenza viruses, parainfluenza viruses, and respiratory syncytial viruses (RSV). Similar concentrations may reversibly inhibit macromolecular synthesis and proliferation of uninfected cells, suppress lymphocyte responses, and alter cytokine profiles in vitro.

**Mechanisms of Action and Resistance.** The antiviral mechanism of ribavirin is incompletely understood but relates to alteration of cellular nucleotide pools and inhibition of viral messenger RNA synthesis (Tam et al., 2002).
Intracellular phosphorylation to the mono-, di-, and triphosphate derivatives is mediated by host cell enzymes. In both uninfected and RSV-infected cells, the predominant derivative (>80%) is the triphosphate, which has an intracellular t1/2 <2 hours.

Ribavirin monophosphate competitively inhibits cellular inosine-5′-phosphate dehydrogenase and interferes with the synthesis of GTP and thus nucleic acid synthesis in general. Ribavirin triphosphate also competitively inhibits the GTP-dependent 5′ capping of viral messenger RNA and specifically influenza virus transcriptase activity. Ribavirin appears to have multiple sites of action, and some of these (e.g., inhibition of GTP synthesis) may potentiate others (e.g., inhibition of GTP-dependent enzymes). Ribavirin also may enhance viral mutagenesis to an extent that some viruses may be inhibited from effective replication, so-called lethal mutagenesis (Hong and Cameron, 2002).

Emergence of viral resistance to ribavirin has not been documented in most viruses but has been reported in Sindbis and HCV (Young et al., 2003); it has been possible to select cells that do not phosphorylate ribavirin to its active forms.

Absorption, Distribution, and Elimination. Ribavirin is actively taken up by nucleoside transporters in the proximal small bowel; oral bioavailability averages ~50% (Glue, 1999). Extensive accumulation occurs in plasma, and steady state is reached by ~4 weeks. Food increases plasma levels substantially (Glue, 1999). Following single or multiple oral doses of 600 mg, peak plasma concentrations average ~0.8 and 3.7 μg/mL, respectively. After intravenous doses of 1000 and 500 mg, plasma concentrations average ~24 and 17 μg/mL, respectively. With aerosol administration, plasma levels increase with the duration of exposure and range from 0.2 to 1.0 μg/mL after 5 days (Englund et al., 1990). Levels in respiratory secretions are much higher but vary up to 1000-fold.

The apparent volume of distribution for ribavirin is large (~10 L/kg) owing to its cellular uptake. Plasma protein binding is negligible. The elimination of ribavirin is complex. The plasma t1/2 increases to ~200-300 hours at steady state. Erythrocytes concentrate ribavirin triphosphate; the drug exits red cells gradually, with a t1/2 of ~40 days. Hepatic metabolism and renal excretion of ribavirin and its metabolites are the principal routes of elimination. Hepatic metabolism involves deribosylation and hydrolysis to yield a triazole carboxamide. Ribavirin clearance decreases by two-thirds in those with advanced renal insufficiency (Clcr = 10-30 mL/minute); the drug should be used cautiously in patients with creatinine clearances of <50 mL/minute (Glue, 1999).

Untoward Effects. Aerosolized ribavirin may cause conjunctival irritation, rash, transient wheezing, and occasional reversible deterioration in pulmonary function. When used in conjunction with mechanical ventilation, equipment modifications and frequent monitoring are required to prevent plugging of ventilator valves and
tubing with ribavirin. Techniques to reduce environmental exposure of healthcare workers are recommended.

Systemic ribavirin causes dose-related reversible anemia owing to extravascular hemolysis and suppression of bone marrow. Associated increases occur in reticulocyte counts and in serum bilirubin, iron, and uric acid concentrations. High ribavirin triphosphate levels may cause oxidative damage to membranes, leading to erythropagocytosis by the reticuloendothelial system. About 20% of chronic HCV infection patients receiving combination IFN-ribavirin therapy discontinue treatment early because of side effects. In addition to IFN toxicities, oral ribavirin increases the risk of fatigue, cough, rash, pruritus, nausea, insomnia, dyspnea, depression, and particularly, anemia. Preclinical studies indicate that ribavirin is teratogenic, embryotoxic, oncogenic, and possibly gonadotoxic. To prevent possible teratogenic effects, up to 6 months is required for washout following cessation of long-term treatment (Glue, 1999). Bolus intravenous infusion may cause rigors.

Pregnant women should not directly care for patients receiving ribavirin aerosol (FDA pregnancy Category X).

Ribavirin inhibits the phosphorylation and antiviral activity of pyrimidine nucleoside HIV reverse-transcriptase inhibitors such as zidovudine and stavudine but increases the activity of purine nucleoside reverse-transcriptase inhibitors (e.g., didanosine) in vitro. It appears to increase the risk of mitochondrial toxicity from didanosine (Chapter 59).

**Therapeutic Uses.** Oral ribavirin in combination with injected pegIFN alfa-2A or -2B has become standard treatment for chronic HCV infection (Reddy et al., 2009; Seeff and Hoofnagle, 2002).

Ribavirin monotherapy for 6-12 months reversibly decreases aminotransferase elevations to normal in ~30% of patients but does not affect HCV RNA levels. Combination therapy with pegIFN alfa-2A and oral ribavirin (500 mg, or 600 mg if weight is >75 kg, twice daily for 24-48 weeks) increases the likelihood of sustained biochemical and virologic responses to ~56% depending on genotype (Fried et al., 2002). The combination is superior to IFN or pegIFN monotherapy and combinations of pegIFN alfa-2 and ribavirin in both treatment-naive patients and those not responding to, or relapsing after, IFN monotherapy. A longer duration of therapy (48 weeks) appears necessary in those with genotype 1 infections, whereas 24 weeks’ therapy is adequate in genotype 2 and 3 infections (Hadjizyannis et al., 2004). Combined ribavirin and pegIFN alfa-2A or -2B is effective in achieving sustained viral responses in a minority of HCV/HIV co-infected patients (Reddy et al., 2009). Combined therapy has been used in the management of recurrent HCV infection after liver transplantation.

Ribavirin aerosol is approved in the U.S. for treatment of RSV bronchiolitis and pneumonia in hospitalized children. Aerosolized ribavirin (usual dose of 20 mg/mL as the starting solution in the drug reservoir of the small aerosol generator unit for 18 hours’ exposure per day for 3-7 days) may reduce some illness measures, but its use generally is not recommended (Committee on Infectious Diseases, American Academy of Pediatrics, 2003). No consistent beneficial effects on duration of hospitalization, ventilatory support, mortality, or long-term pulmonary function have been found. High-dose, reduced-duration therapy (60 mg/mL in the drug reservoir of the small particle aerosol generator unit for 2 hours three times daily) has been used. Aerosol ribavirin combined with intravenous immunoglobulin appears to reduce mortality of RSV infection in bone marrow transplant and other highly immunocompromised patients (Ghosh et al., 2000).

Intravenous and/or aerosol ribavirin has been used occasionally in treating severe influenza virus infection and in the treatment of immunosuppressed patients with adenovirus, vaccinia, parainfluenza, or measles virus infections. Aerosolized ribavirin is associated with reduced duration of fever but no other clinical or antiviral effects in influenza infections in hospitalized children. Intravenous ribavirin decreases mortality in Lassa fever and has been used in treating other arenavirus-related hemorrhagic fevers. Intravenous ribavirin is beneficial in hemorrhagic fever with renal syndrome owing to Hantavirus infection but appears ineffective in hantavirus-associated cardiopulmonary syndrome or SARS. Oral ribavirin has been used for the treatment and prevention of Crimean-Congo hemorrhagic fever and treatment of Nipah virus infections (Mardani et al., 2003). Intravenous ribavirin is investigational in the U.S.

**Drugs for Hepatitis B Virus Infection**

Unlike hepatitis C virus, hepatitis B virus is transcribed into DNA that can be integrated into host chromosomal DNA and is capable of establishing lifelong chronic infection in ~10% of patients. Those with chronic HBV may develop active hepatitis that can lead to fibrosis and cirrhosis, but all such individuals have a greatly increased incidence of hepatocellular carcinoma.

Interferon, or a combination of interferon and ribavirin, can cure patients with chronic infection but is associated with a high rate of side effects, often leading to premature treatment discontinuation. Several antiretroviral nucleoside or nucleotide analog polymerase inhibitors, including lamivudine, telbivudine, and tenofovir, have potent anti-HBV activity and have provided a popular alternative therapy: chronic suppressive oral single agent or combination treatment. These regimens are much better tolerated than IFN-containing regimens but are not usually curative.

**Adefovir**

**Chemistry and Antiviral Activity.** Adefovir dipivoxil (9-[2-[[bis[(pivaloyloxy)methoxy]phosphinyl]methoxy]ethyl]adenine, bis-POM PMEA) is a diester prodrug of adefovir, an acyclic phosphonate nucleotide analog of adenosine monophosphate (Figure 58–6).

It is inhibitory in vitro against a range of DNA and RNA viruses, but its clinical use is limited to HBV infections (De Clercq, 2003). Inhibitory concentrations for HBV range from 0.2 to 1.2 μM in cell culture, and it is active against lamivudine-resistant HBV strains. Oral adefovir dipivoxil shows dose-dependent inhibition of hepadnavirus replication in animal models. In vitro combinations of adefovir and lamivudine or other
anti-HBV nucleosides show enhanced antihepadnavirus activity in vitro (Delaney et al., 2004), and trials of dual therapy are in progress.

Mechanisms of Action and Resistance. Adefovir dipivoxil enters cells and is deesterified to adefovir. Adefovir is converted by cellular enzymes to the diphosphate, which acts as a competitive inhibitor of viral DNA polymerases and reverse transcriptases with respect to deoxyadenosine triphosphate and also serves as a chain terminator of viral DNA synthesis (Cundy, 1999). Its selectivity relates to a higher affinity for HBV DNA polymerase compared with cellular polymerases.

The intracellular $t_{1/2}$ of the diphosphate is prolonged, ranging from 5 to 18 hours, so once-daily dosing is feasible. Adefovir resistance has been detected in a small proportion (~4%) of chronically infected HBV patients during 3 years of treatment. Such variants have unique point mutations in the HBV polymerase but retain susceptibility to lamivudine. The consequences of the emergence of resistance remain to be determined.

Absorption, Distribution, and Elimination. The parent compound has low oral bioavailability (<12%), whereas the dipivoxil prodrug is absorbed rapidly and hydrolyzed by esterases in the intestine and blood to adefovir with liberation of pivalic acid, providing a bioavailability ~30-60%. After 10-mg doses of the pro-drug, peak serum concentrations of adefovir average 0.02 μg/mL, and the pro-drug is not detectable. Food does not affect bioavailability. Adefovir is scantily protein bound (<5%) and has a volume of distribution similar to body water (~0.4 L/kg).

Adefovir is eliminated unchanged by renal excretion through a combination of glomerular filtration and tubular secretion. After oral administration of adefovir dipivoxil, ~30-45% of the dose is recovered within 24 hours; the serum $t_{1/2}$ of elimination is 5-7.5 hours. Dose reductions are recommended for $Cl_{cr}$ values <50 mL/minute. Adefovir is removed by hemodialysis, but the effects of peritoneal dialysis or severe hepatic insufficiency on pharmacokinetics are unknown.

Pivalic acid is a product of adefovir dipivoxil metabolism that can cause reduced free carnitine levels. Although L-carnitine has kinetics are unknown.

Untoward Effects. Adefovir dipivoxil causes dose-related nephrotoxicity and tubular dysfunction, manifested by azotemia and hypophosphatemia, acidosis, glycosuria, and proteinuria that usually are reversible months after discontinuation. The lower dose (10 mg/day) used in chronic HBV infection patients has been associated with few adverse events (e.g., headache, abdominal discomfort, diarrhea, and asthenia) and negligible renal toxicity compared with a 3-fold higher dose (Hadziyannis et al., 2003; Marcellin et al., 2003). Adverse events lead to premature discontinuation in ~2% of patients. After 2 years of dosing, the risk of serum creatinine levels rising above 0.5 mg/dL is ~2% but is higher in those with preexisting renal insufficiency. Acute, sometimes severe exacerbations of hepatitis can occur in patients stopping adefovir or other anti-HBV therapies. Close monitoring is necessary, and resumption of antiviral therapy may be required in some patients.

No clinically important drug interactions have been recognized to date, although drugs that reduce renal function or compete for active tubular secretion could decrease adefovir clearance. Ibuprofen increases adefovir exposure modestly. An increased risk of lactic acidosis and steatosis may exist when adefovir is used in conjunction with nucleoside analogs or other antiretroviral agents. Adefovir is transported efficiently into tubular epithelium by a probenecid-sensitive organic anion transporter (hOAT1).

Adefovir is genotoxic, and high doses cause hepatotoxicity, lymphoid toxicity, and renal tubular nephropathy in animals. The diphosphate’s inhibitory effects on renal adenyl cyclase may contribute to nephrotoxicity. Adefovir dipivoxil is not associated with reproductive toxicity, although high intravenous doses of adefovir cause maternal and embryotoxicity with fetal malformations in rats (pregnancy Category C).

Therapeutic Uses. Adefovir dipivoxil is approved for treatment of chronic HBV infections.

In patients with HBV e-antigen (HBeAg)–positive chronic hepatitis B, adefovir dipivoxil (10 mg/day) reduces serum HBV DNA levels by 99% and, in about one-half of patients, improves hepatic histology and normalization of aminotransferase levels by 48 weeks (Marcellin et al., 2003). Continued therapy is associated with increasing frequencies of aminotransferase normalization and HBeAg seroconversion (De Clercq, 2003). In patients with HBeAg-negative chronic HBV, adefovir is associated with similar biochemical and histological benefits (Hadziyannis et al., 2003). Regression of cirrhosis may occur in some patients.

In patients with lamivudine-resistant HBV infections, adefovir dipivoxil monotherapy results in sustained reductions in serum HBV DNA levels, but lamivudine alone or added to adefovir is not beneficial (Peters et al., 2004). In patients with dual HIV and lamivudine-resistant HBV infections, adefovir dipivoxil (10 mg/day) causes significant HBV DNA level reductions (Benhamou et al., 2001), and it also has been used successfully in patients with lamivudine-resistant HBV infections both before and following liver transplantation. The optimal duration of treatment in different populations, possible long-term effects on HBV complications, and combined use with other anti-HBV agents are under study.

**Entecavir**

Chemistry and Antiviral Activity. Entecavir is a guanosine nucleoside analog with selective activity against HBV polymerase (Figure 58–6).

Mechanisms of Action and Resistance. Entecavir requires intracellular phosphorylation. Entecavir triphosphate competes with endogenous deoxyguanosine triphosphate and inhibits all three activities of the HBV polymerase (reverse transcriptase):

- base priming
- reverse transcription of the negative strand from the pregenomic messenger RNA
- synthesis of the positive strand of HBV DNA
Entecavir triphosphate is a weak inhibitor of cellular DNA polymerases α, β, and δ and mitochondrial DNA polymerase γ. The inhibitory concentration against HBV is 0.004 μM in transfected cells and ranges from 0.01 to 0.059 μM against lamivudine-resistant (L180M, M204V) HBV. Eight- to 30-fold reductions in entecavir susceptibility were observed for lamivudine-resistant strains in cell-based assays (Scott and Keating, 2009).

Entecavir selected for an M184I substitution in HIV reverse transcriptase at μM concentrations in cell culture, and HIV variants containing the M184V substitution showed loss of susceptibility to entecavir. In patients, entecavir decreased HIV-1 RNA in three persons with HIV-1 and HBV co-infection and led to HIV-1 variants with the M184V lamivudine-resistant mutation in one subject (McMahon et al., 2007). Lamivudine and telbivudine resistance conferred decreased susceptibility to entecavir. In patients with preexisting lamivudine resistance, entecavir resistance emerged in 7% and 43% after 1 and 4 years, respectively (Dienstag, 2009).

Absorption, Distribution, and Elimination. Following multiple daily doses ranging from 0.1 to 1.0 mg, Cmax and area under the concentration-time curve (AUC) at steady-state increased in proportion to dose. Time to peak occurs in 0.5-1.5 hours. Steady-state is reached after 6-10 days of once daily dosing. The tablet and oral solution can be used interchangeably. Administration with food decreases Cmax by 44-46% and AUC by 18-20%; thus entecavir should be administered on an empty stomach.

Entecavir is extensively distributed in tissues and is 13% bound to serum proteins. It is primarily eliminated unchanged in the kidney. Renal clearance is independent of dose and ranges from 360 to 471 mL/minute, suggesting that entecavir undergoes both glomerular filtration and net tubular secretion. Entecavir exhibits biphasic elimination, with a terminal t1/2 of 128-149 hours; the active triphosphate has an elimination t1/2 of 15 hours. Dose reductions are needed for patients with ClCr <50 mL/minute, typically by extension of the dosing interval (Scott and Keating, 2009).

Untoward Effects. Severe acute exacerbations of hepatitis B have been reported in patients who have discontinued anti-HBV therapy, including entecavir. Hepatic function should be monitored closely with both clinical and laboratory follow-up for at least several months in patients who discontinue anti-HBV therapy. There is a potential for development of resistance to nucleoside reverse transcriptase inhibitors in HBV/HIV co-infection especially if HIV is not being treated. Lactic acidosis and severe hepatomegaly with steatosis, including fatal cases, have been reported, mostly in women with some antiretroviral nucleoside analogs (Chapter 59), but not with entecavir. Other common adverse reactions include headache, fatigue, dizziness, and nausea (Scott and Keating, 2009).

Therapeutic Uses. Entecavir is indicated for the treatment of chronic HBV infection in adults with active viral replication and either evidence of persistent elevations in serum aminotransferases or histologically active disease.

The recommended dose for nucleoside-treatment-naive adults (>16 years of age) is 0.5 mg once daily. For patients with lamivudine or telbivudine resistance, the dose is 1 mg once daily. Entecavir is superior to lamivudine in the degree of suppression and associated with a more frequent fall of HBV DNA to undetectable levels (Dienstag, 2009). Durability of HBeAg responses is comparable to other oral agents. Entecavir had negligible resistance (≤1%) for up to 4 years and is active against adefovir-resistant HBV.

Lamivudine

Chemistry and Antiviral Activity. Lamivudine, the (-)-enantiomer of 2′,3′-dideoxy-3′-thiacytidine, is a nucleoside analog that inhibits HIV reverse transcriptase and HBV DNA polymerase (Figure 58–6). Its use as an antiretroviral agent is discussed in Chapter 59.

It inhibits HBV replication in vitro by 50% at concentrations of 4-7 ng/mL with negligible cellular cytotoxicity. Cellular enzymes convert lamivudine to the triphosphate, which competitively inhibits HBV DNA polymerase and causes chain termination.

Mechanisms of Action and Resistance. Lamivudine triphosphate is a potent inhibitor of the DNA polymerase/reverse transcriptase of HBV; the intracellular t1/2 of the triphosphate averages 17-19 hours in HBV-infected cells, so once-daily dosing is possible.

Oral lamivudine is active in animal models of hepadnavirus infection. Lamivudine shows enhanced antiviral activity in combination with adefovir or penciclovir against hepadnaviruses. Point mutations in the YMDD motif of HBV DNA polymerase result in a 40- to 104-fold reduction in in vitro susceptibility (Ono et al., 2001). Lamivudine resistance confers cross-resistance to related agents such as emtricitabine and the investigational agent, clevudine, and is often associated with an additional non-YMDD mutation that confers cross-resistance to famciclovir. Lamivudine-resistant HBV retains susceptibility to adefovir, tenofovir, and partially to entecavir (Ono et al., 2001). Viruses bearing YMDD mutations are less replication competent in vitro than wild-type HBV. However, lamivudine resistance is associated with elevated HBV DNA levels, decreased likelihood of HBeAg loss or seroconversion, hepatitis exacerbations, and progressive fibrosis and graft loss in transplant recipients (Dienstag et al., 2003; Lai et al., 2002).

Absorption, Distribution, and Elimination. The pharmacokinetic properties of lamivudine are described in detail in Chapter 59. In HBV-infected children, doses of 3 mg/kg/day provide plasma exposure and trough plasma levels comparable with those in adults receiving 100 mg daily (Sokal et al., 2000). Dose reductions are indicated for moderate renal insufficiency (creatinine clearance <50 mL/minute). Trimethoprim decreases the renal clearance of lamivudine.

Untoward Effects. At the doses used for chronic HBV infection, lamivudine generally has been well tolerated. Aminotransferase rises after therapy occur more often in lamivudine recipients, and flares in post-treatment aminotransferase elevations (>500 IU/mL) occur in ~15% of patients after cessation.

Therapeutic Uses. Lamivudine is approved for the treatment of chronic HBV hepatitis in adults and children.

In adults, doses of 100 mg/day for 1 year cause suppression of HBV DNA levels, normalization of aminotransferase levels in
Telbivudine

Chemistry and Antiviral Activity. Telbivudine (Figure 58-6) is a synthetic thymidine nucleoside analog with activity against HBV DNA polymerase.

Mechanisms of Action and Resistance. Telbivudine is phosphorylated by cellular kinases to the active triphosphate form, which has a t1/2 of 14 hours. Telbivudine 5’-triphosphate inhibits HBV DNA polymerase (reverse transcriptase) by competing with the natural substrate, thymidine 5’-triphosphate. Incorporation of telbivudine 5’-triphosphate into viral DNA causes chain termination. Telbivudine 5’-triphosphate at concentrations up to 100 μM did not inhibit human cellular DNA polymerases α, β, or γ.

In cell-based assays, lamivudine-resistant HBV strains expressing either the M204I substitution or the L180M/V204I double substitution had ≥1000-fold reduced susceptibility. Telbivudine retained wild-type phenotypic activity against the lamivudine-resistant-associated substitution M204V alone. HBV encoding the adefovir mutation A181T showed 3- to 5-fold reduced susceptibility, but N236T remained susceptible. The A181S and A181T substitutions conferred 2.7- and 3.5-fold reductions in susceptibility to telbivudine, respectively. The A181T substitution is associated with decreased clinical response in patients with HBV treated with adefovir and entecavir (Hadziyannis and Vassilopoulos, 2008).

In a cell culture model, the EC_{50} for inhibition of viral DNA synthesis by telbivudine was 0.2 μM. The anti-HBV activity of telbivudine is additive with that of adefovir in cell culture, and it is not antagonized by the HIV-1 nucleoside analogs didanosine and stavudine (Hadziyannis and Vassilopoulos, 2008).

Absorption, Distribution, and Elimination. At 600 mg once daily, steady-state peak concentrations are ~3.7 μg/mL at a median of 2 hours post-dose. Steady state is achieved after ~5-7 days of once-daily administration with ~1.5-fold accumulation. In vitro protein binding is low (3.3%) and telbivudine is widely distributed into tissues. Telbivudine concentrations decline biexponentially with an elimination t1/2 of 40-49 hours. The drug is eliminated unchanged in the urine. Patients with moderate-to-severe renal dysfunction and those undergoing hemodialysis require dose adjustments.

Untoward Effects. Telbivudine is generally well tolerated and safe. The most common adverse events resulting in telbivudine discontinuation included increased creatine kinase, nausea, diarrhea, fatigue, myalgia, and myopathy. Elevations of creatine kinase activity, mostly asymptomatic grade 3-4, were more common in telbivudine-treated patients after 2 years of therapy than with lamivudine.

Therapeutic Uses. Similar to other oral HBV agents, telbivudine is indicated for the treatment of chronic HBV in adult patients with evidence of viral replication and either evidence of persistent elevations in serum aminotransferases (ALT or AST) or histologically active disease.

The recommended dose is 600 mg orally once daily without regard to food. An oral solution is also available. This dose is based on pharmacodynamic analyses showing a relationship between telbivudine dose and changes in HBV DNA from baseline to week 4 (Lai et al., 2004). The dose producing the maximum effect was between 400 and 800 mg/day. The drug has not been studied in patients with HBV/HIV co-infection. Telbivudine resistance is substantial (25%) after 2 years of treatment and higher than observed with other oral anti-HBV agents (Dienstag, 2009; Hadziyannis and Vassilopoulos, 2008). Cross-resistance and treatment-emergent resistance have limited the use of telbivudine for patients with chronic HBV, compared to alternative agents.

Tenofovir

Tenofovir is a nucleotide analog with activity against both HIV-1 and HBV (Figure 58-6). It is administered orally as the disoproxil prodrug. Chemistry, pharmacokinetic properties, untoward effects, precautions, and interactions for this drug are covered in more detail in Chapter 59.

In in vitro cell cultures, the EC_{50} for tenofovir against HBV ranged from 0.14 to 1.5 μM, with cytotoxicity concentrations >100 μM. No antagonistic activity was observed when combined with other oral anti-HBV agents. In cell-based assays, mutant HBV (V173L, L180M, and M204I/V) associated with resistance to lamivudine and telbivudine showed a susceptibility to tenofovir of 0.7-3.4 times that of wild-type virus. Overall, tenofovir has a favorable resistance profile and has been effective in treating lamivudine-resistant HBV (Dienstag, 2009).
Therapeutic Uses. Tenofovir is approved for treatment of HBV infection in adults at a dose of 300 mg once daily without regard to food. In HBeAg-negative patients, tenofovir suppressed HBV DNA to <400 copies/mL in 93% of subjects at 48 weeks, compared to 63% for adefovir. Tenofovir resistance was not evident over 48 weeks of treatment. Due to the safety, efficacy, and resistance profile of tenofovir, it will likely supersede most adefovir use for the treatment of chronic HBV infection.

The tenofovir dose should be adjusted for impaired renal function: For Clcr of 30-49 mL/minute, 300 mg every 48 hours; 10-29 mL/minute, 300 mg every 72-96 hours. During hemodialysis the dose is 300 mg every 7 days or after 12 hours of dialysis.

Clevudine

Clevudine is a nucleoside analog with potent activity against HBV. The oral drug is approved for use in South Korea and the Philippines. However the drug caused myopathy in large Phase 3 clinical trials, casting doubt on its future approval in the U.S.

OTHER AGENTS

Imiquimod

*Imiquimod* [1-(2-methylpropyl)-1H-imidazo[4,5-c]quinolin-4-amine] is a novel immunomodulatory agent that is effective for topical treatment of condylomata acuminata, molluscum contagiosum, and certain other dermatologic conditions associated with DNA virus infections (Skinner, 2003). It lacks direct antiviral or antiproliferative effects *in vitro* but rather induces cytokines and chemokines with antiviral and immunomodulating effects.

Imiquimod shows antiviral activity in animal models after systemic or topical administration. When applied topically as a 5% cream to genital warts in humans, it induces local IFN-α, -β, and -γ and TNFα responses and causes reductions in viral load and wart size. When applied topically (three times weekly for up to 16 weeks), imiquimod cream is associated with complete clearance of treated genital and perianal warts in ~50% of patients, with response rates higher in women than in men (Skinner, 2003; Wiley et al., 2002). The median time to clearance is 8-10 weeks; relapses are not uncommon. Application is associated with local erythema in ~20% of patients, excoriation/flaking in 18-26%, itching in 10-20%, burning in 5-12%, and less often, erosions or ulcerations.

I. Overview of HIV Infection and its Treatment

There are currently several million people taking chronic combination antiretroviral therapy to suppress human immunodeficiency virus (HIV) infection, including >3 million in sub-Saharan Africa alone. This is an amazing achievement for a disease that was uniformly fatal and with few treatment options just two decades ago. Combination antiretroviral therapy prolongs life and prevents progression of disease caused by HIV. The pharmacotherapy of HIV infection is a rapidly moving field. In 2009, 24 antiretroviral drugs were available in the U.S. Three-drug combinations are the minimum standard of care for this infection, so current agents constitute several thousand possible regimens. The long-term management of a patient on antiretroviral therapy can be daunting, even for experienced healthcare providers. Knowing the essential features of the pathophysiology of this disease and how chemotherapeutic agents affect the virus and the host is critical in developing a rational approach to therapy. Unique features of this drug class include the need for lifelong administration to control virus replication and the possibility of rapid emergence of permanent drug resistance if these agents are not used properly.

Increasingly, the public health impact of this epidemic has shifted to those regions least able to afford treatment. Because combination antiretroviral therapy has the capacity to improve the quality of human health and to produce near-normal life expectancies (Lee et al., 2001), there is a strong impetus to provide these drugs to as many infected individuals as possible. Through a combination of increased foreign aid, access to generic antiretrovirals, and willingness on the part of legacy pharmaceutical companies to allow violation of intellectual property law for this class of drugs, HIV treatment is now a possibility for much of the world. Because the number of effective treatment options is large, emphasis is shifting from efficacy to long-term convenience, tolerability, and safety. One outcome has been the development of single tablet fixed-dose combinations of drugs that can be taken orally once or twice a day. Because treatment is taken for years if not decades, the potential adverse effects of each drug take on increasing importance.

PATHOGENESIS OF HIV-RELATED DISEASE

Human immunodeficiency viruses (HIV) are lentiviruses, a family of mammalian retroviruses evolved to establish chronic persistent infection with gradual onset of clinical symptoms. Unlike herpesviruses, replication is constant following infection, and although some infected cells may harbor nonreplicating virus for years, in the absence of treatment there generally is no true period of viral latency following infection (Greene and Peterlin, 2002). Humans and nonhuman primates are the only natural hosts for these viruses.

There are two major families of HIV. Most of the epidemic involves HIV-1; HIV-2 is more closely related to simian immunodeficiency virus (SIV) and is concentrated in western Africa. HIV-1 is genetically diverse, with at least five distinct subfamilies or clades. HIV-1 and HIV-2 have similar in vitro sensitivity to most antiretroviral drugs, although the non-nucleoside reverse transcriptase inhibitors (NNRTIs) are HIV-1-specific and have no activity against HIV-2. Within HIV-1 isolates,
clade per se does not seem to have a major effect on drug sensitivity.

**Virus Structure.** HIV is a typical retrovirus with a small RNA genome of 9300 base pairs. Two copies of the genome are contained in a nucleocapsid core surrounded by a lipid bilayer, or envelope, that is derived from the host cell plasma membrane (Figure 59–1). The viral genome encodes three major open reading frames: *gag* encodes a polyprotein that is processed to release the major structural proteins of the virus; *pol* overlaps *gag* and encodes three important enzyme activities—an RNA-dependent DNA polymerase or reverse transcriptase with RNAase activity, protease, and the viral integrase; and *env* encodes the large transmembrane envelope protein responsible for cell binding and entry. Several small genes encode regulatory proteins that enhance virion production or combat host defenses. These include *tat, rev, nef,* and *vpr* (Greene and Peterlin, 2002).

**Virus Life Cycle.** HIV tropism is controlled by the envelope protein gp160 (env) (Figure 59–1). The major target for env binding is the CD4 receptor present on lymphocytes and macrophages, although cell entry also requires binding to a coreceptor, generally the chemokine receptor CCR5 or CXCR4 (Greene and Peterlin, 2002). CCR5 is present on macrophage lineage cells. Most infected individuals harbor predominantly the CCR5-tropic virus; HIV with this tropism is responsible for nearly all naturally acquired infections. A shift from CCR5 to CXCR4 utilization is associated with advancing disease, and the increased affinity of HIV-1 for CXCR4 allows infection of T-lymphocyte lines (Berger et al., 1999). A phenotypic switch from CCR5 to CXCR4 heralds accelerated loss of CD4+ helper T cells and increased risk of immunosuppression. Whether coreceptor switch is a cause or a consequence of advancing disease is still unknown, but it is possible to develop clinical AIDS without this switch.

The gp41 domain of env controls the fusion of the virus lipid bilayer with that of the host cell. Following fusion, full-length viral RNA enters the cytoplasm, where it undergoes replication to a short-lived RNA-DNA duplex; the original RNA is degraded by RNase H to allow creation of a full-length double-stranded DNA copy of the virus (Figure 59–1). Because the HIV reverse transcriptase is error prone and lacks a proof-reading function, mutation is quite frequent and estimated...
to occur at approximately three bases out of every full-length (9300-base-pair) replication (Coffin, 1995). Virus DNA is transported into the nucleus, where it is integrated into a host chromosome by the viral integrase in a random or quasi-random location (Greene and Peterlin, 2002).

Following integration, the virus may remain in a quiescent state, not producing RNA or protein but replicating as the cell divides. When a cell that harbors the virus is activated, viral RNA and proteins are produced. Structural proteins assemble around full-length genomic RNA to form a nucleocapsid (Figure 59–1). The envelope and structural proteins assemble at the cell surface, concentrated in cholesterol-rich lipid rafts. The nucleocapsid cores are directed to these sites and bud through the cell membrane, creating new enveloped HIV particles containing two complete single-stranded RNA genomes. Reverse transcriptase is incorporated into virus particles so replication can begin immediately after the virus enters a new cell (Greene and Peterlin, 2002).

How the Virus Causes Disease. Sexual acquisition of HIV infection is thought to be mediated by one or, at most, a handful of infectious virus particles. Soon after infection, there is a rapid burst of replication peaking at 2–4 weeks, with ≥10⁹ cells becoming infected. This peak is associated with a transient dip in the number of peripheral CD4+ (helper) T-lymphocytes. As a result of new host immune responses and target cell depletion, the number of infectious virions as reflected by the viral load declines to a quasi-steady state. This level of virus activity has been termed the set point and reflects the interplay between host immunity and the pathogenicity of the infecting virus (Coffin, 1995). Most viruses are derived from CD4+ cells that turn over with a 1/2 of 2.2 days (Perelson et al., 1996). Thus, in the average infected individual, several billion infectious virus particles are produced every few days.

Eventually, the host CD4+ T-lymphocyte count begins a steady decline, accompanied by a rise in the plasma HIV RNA concentration. Once the peripheral CD4 cell count falls below 200 cells/mm³, there is an increasing risk of opportunistic diseases and ultimately death. Sexual acquisition of CCR5-tropic HIV-1 is associated with a median time to clinical AIDS of 8–10 years. Some patients, termed long-term nonprogressors, can harbor HIV for more than two decades without significant decline in peripheral CD4 cell count or clinical immunosuppression; this may reflect a combination of favorable host immunogenetics and immune responses (Fauci, 1996).

An important question relevant to treatment is whether HIV disease is a consequence of CD4+ lymphocyte depletion alone. Most natural history data suggest that this is true, although both the amount of virus measurable in the patient’s circulation and the CD4 cell count are independent predictors of disease progression (Mellors et al., 1996, 1997). Regardless, successful therapy is based on inhibition of HIV replication; interventions designed specifically to boost the host immune response without exerting a direct antiviral effect have had no reliable clinical benefit.

History of Antiretroviral Therapy. The first effective antiretroviral agent, zidovudine, was synthesized by Horwitz in 1964 as a false nucleoside with disappointing anticancer activity. The drug was shown by Osterag in 1972 to inhibit the in vitro replication of a murine type D retrovirus (McLeod and Hammer, 1992). Mitsuya and Broder, working in Bethesda in 1985, reported that this drug had potent in vitro anti-HIV activity (Mitsuya et al., 1985). Clinical studies of zidovudine began that same year, and by 1987 this drug was approved and marketed for the control of HIV infection based on the results of a small but definitive randomized clinical trial (Fischl et al., 1987). Large numbers of nucleoside analogs already had been synthesized as potential anticancer and immunomodulatory drugs, and this made it possible for similar nucleoside reverse transcriptase inhibitors (NRTIs) to be tested efficiently and approved.

Selective non-nucleoside reverse transcriptase inhibitors (NNRTIs) were identified by iterative screening using purified viral enzyme (Pauwels et al., 1990). The clinical development of these drugs was hindered by the rapid emergence of drug resistance (Wei et al., 1995). However, three drugs in this category were approved by 1998 (Table 59–1). HIV protease inhibitors (PIs) were the products of rational drug design, relying on technology developed to identify transition-state peptidomimetic antagonists of proteases in the renin-angiotensin cascade (Flexner, 1998). Highly selective antagonists of the HIV protease were reported as early as 1987. Phase 1 trials of the first of these drugs, saquinavir, began in 1989, and this drug was approved for prescription use in 1995. Two additional protease inhibitors, ritonavir and indinavir, were approved within the next 4 months.

Innovation in drug approval and regulation facilitated the availability of multiple agents capable of fighting this infection. In 1989, the FDA agreed to make promising agents available to patients with advanced disease through an expanded access program. The capacity to measure plasma HIV RNA concentrations and CD4 cell counts, and proof of the predictive value of these surrogate end points (Mellors et al., 1996) made it possible to collapse the time frame for clinical drug development. The most promising drug combinations were identified by their effect on these end points in clinical trials as short as 6 months.

A detailed understanding of the molecular basis of drug resistance guides the search for new agents and informs the selection of combination strategies for existing drugs. The large number of possible drug combinations has given patients more chances at virus
control but also complicates the practice of HIV medicine. Current challenges include access to effective long-term treatment in resource-poor countries and the continuing need for identification of new drugs for treatment-experienced patients with resistance to approved drugs (Flexner, 2007).

### PRINCIPLES OF HIV CHEMOTHERAPY

Current treatment assumes that all aspects of disease derive from the direct toxic effects of HIV on host cells, mainly CD4+ T-lymphocytes. All treatment regimens associated with long-term suppression of HIV replication (as measured by decreased plasma HIV RNA) and repletion of peripheral CD4 cells are clinically beneficial (Lee et al., 2001). The goal of therapy is to suppress virus replication as much as possible for as long as possible.

Deciding when to start antiretroviral therapy has been a shifting target during the epidemic. Current guidelines in the U.S. recommend starting therapy in all those with a CD4 count of ≤350 cells/mm³ (Department of Health and Human Services, 2010). Treatment is also recommended for HIV-infected pregnant women, those with HIV nephropathy, and those with concurrent hepatitis B virus infection requiring treatment regardless of CD4 count. Increasing evidence supports the clinical benefit and cost effectiveness of starting treatment at higher CD4 counts. With more active drug combinations, large systematic reviews of observational studies and a few randomized clinical trials suggest measurable clinical benefit the earlier treatment is initiated, beginning at CD4 counts ≤500 (Kitahata et al., 2009; When to Start Consortium, 2009). In the foreseeable future, treatment may be recommended for all infected adults and children (Flexner, 2007).

Increasing evidence supports the value of antiretroviral therapy in preventing transmission of the virus from person to person. Although most antiretroviral therapy is used in chronic treatment of established infection, these medications are also used in short courses to prevent infection in post-exposure settings and to prevent mother-to-child transmission (Department of Health and Human Services, 2010). Epidemiological modeling suggests that overall transmission rates are likely to fall in endemic areas where antiretroviral therapy is widely used (Granich et al., 2009). The possible value of targeted antiretroviral therapy to reduce new infections, or even to reduce or eliminate epidemic transmission, has not been adequately explored (Dieffenbach and Fauci, 2009).

A number of studies have confirmed the low likelihood that HIV can be eradicated with drug therapy.

a A number of fixed-dose co-formulations are available: zidovudine + lamivudine (COMBIVIR); zidovudine + lamivudine + abacavir (TRIZIVR); abacavir + lamivudine (EPZICOM); tenofovir + emtricitabine (TRUVADA); tenofovir + efavirenz + emtricitabine (ATRIPLA).

b Lopinavir is available only as part of a fixed-dose co-formulation with ritonavir (KALETRA/ALUVIA).

f No longer marketed worldwide.
A reservoir of long-lived quiescent T cells harboring infectious HIV DNA integrated into the host chromosome was identified independently by several groups of investigators (Chun et al., 1998; Finzi et al., 1997). Infectious HIV can be produced by these quiescent cells after chemical activation ex vivo (and presumably if the cells are activated by immune stimuli in vivo), but the nonreplicating form of the viral genome is not susceptible to antiretroviral drugs. Most estimates suggest that at least some of these cells will survive for decades and probably for the life of the patient (Siliciano et al., 2003) regardless of the type of anti-HIV treatment. Fortunately, in the presence of suppressive combination antiretroviral therapy it appears that residual viremia is the consequence of release of virus from pre-formed latent reservoirs, and the risk of developing drug resistance in such treated patients is negligible (Nettles et al., 2005). Episodic detection of low level plasma HIV RNA in otherwise suppressed individuals (also known as blips) almost certainly represents release of previously formed virus from resting cells; intermittent detection of HIV RNA at a concentrations <500 copies/mL is not associated with increased risk of treatment failure or drug resistance, unless this is accompanied by nonadherence (Kieffer et al., 2004).

Drug resistance is a key problem that must be prevented and circumvented through a combination of regimen selection and patient education. There is a high likelihood that all untreated infected individuals harbor viruses with single-amino-acid mutations conferring some degree of resistance to every known antiretroviral drug because of the high mutation rate of HIV and the tremendous number of infectious virions (Coffin, 1995). Starting treatment with only a single antiretroviral drug inevitably provokes the emergence of drug-resistant virus, in some cases within a few weeks (Wei et al., 1995). Drug therapy does not cause mutation but rather provides the necessary selective pressure to promote growth of drug-resistant viruses that arise naturally (Coffin, 1995). A combination of active agents therefore is required to prevent drug resistance, analogous to strategies employed in the treatment of tuberculosis (Chapter 56). Intentional drug holidays, also known as structured treatment interruptions, allow the virus to replicate anew and increase the risk of drug resistance and disease progression (Lawrence et al., 2003). Recrudescence replication of HIV after stopping therapy is associated with an acute increase in the risk of death, mainly from cardiovascular events (El-Sadr et al., 2006). This may be the consequence of increased immune activation that accompanies replication of the virus; HIV infection is associated with endothelial cell dysfunction, although the absolute increase in cardiovascular risk after controlling for other risk factors is small (Aberg, 2009).

The current standard of care is to use at least three drugs simultaneously for the entire duration of treatment. The expected outcome of initial therapy in a previously untreated patient is an undetectable viral load (plasma HIV RNA <50 copies/mL) within 24 weeks of starting treatment (Department of Health and Human Services, 2010). In prospective comparative trials, two-drug regimens were more effective than single-drug regimens (Fischl et al., 1995; Hammer et al., 1996; Saag et al., 1998), and three-drug regimens are more effective still (Collier et al., 1996; Gulick et al., 1997; Hammer et al., 1997). Mathematical models of HIV replication suggested that three is the minimum number of agents required to guarantee effective long-term suppression of HIV replication without resistance (Muller and Bonhoeffer, 2003). However, earlier models may not adequately predict the effects of newer and more potent antiretrovirals.

Randomized controlled trials found that a combination of two potent drugs (e.g., an NNRTI plus a PI) had equivalent virologic efficacy to either agent plus two NRTIs (Riddler et al., 2008). In treatment-naïve patients, a regimen containing a non-nucleoside plus two nucleoside reverse transcriptase inhibitors was as effective as a regimen containing an additional nucleoside (Shafer et al., 2003), indicating the equivalence of these three-drug and four-drug regimens. Four or more drugs may be used simultaneously in pretreated patients harboring drug-resistant virus, but the number of agents a patient can take is limited by toxicity and inconvenience. Even for heavily treatment-experienced patients, a three-drug regimen containing at least two potent active agents is often as effective as regimens containing additional active agents (Steigbigel et al., 2008).

Several small studies have now shown that patients who are fully suppressed (HIV plasma RNA <50 copies/mL) for months on a triple drug combination may be switched to a single “boosted” protease inhibitor (e.g., lopinavir/ritonavir or atazanavir/ritonavir) and maintain full suppression of viral replication for years on antiretroviral monotherapy. Such simplification strategies are investigational and should only be used in patients who are known to be highly adherent and are closely monitored, because randomized trials have found higher failure rates in patients maintained on only a single active agent (Wilkin et al., 2009).

Pharmacodynamic synergy is probably not an important consideration in regimen selection, although most prescribers prefer to use drugs that attack at least two different molecular sites. This could include NRTIs that target the active site of the enzyme combined with an NNRTI that binds to a different site on the same enzyme, or an inhibitor of a different enzyme, such as HIV protease or integrase. Regimens containing an NNRTI or PI plus two NRTIs have similar long-term efficacy.
Failure of an antiretroviral regimen is defined as a persistent increase in plasma HIV RNA concentrations in a patient with previously undetectable virus, despite continued treatment with that regimen (Department of Health and Human Services, 2010). This indicates resistance to one or more drugs in the regimen and necessitates a change in treatment. Once resistance occurs, resistant strains remain in cells (mainly T-lymphocytes) indefinitely, even though the resistant virus may not be detectable in the plasma. For example, women who received a single dose of nevirapine to prevent mother-to-child transmission of HIV (and thus were more likely to harbor nevirapine-resistant virus) had a higher treatment failure rate if initiating therapy with nevirapine within 6 months, compared to treated women who had never received nevirapine (Lockman et al., 2007). The selection of new agents is therefore informed by the patient’s treatment history, as well as viral resistance testing, preferably obtained while the patient is still taking a failing regimen to facilitate proper recovery and characterization of the patient’s virus (Kuritzkes, 2004). Treatment failure generally requires implementation of a completely new combination of drugs. Adding a single active agent to a failing regimen is functional monotherapy if the patient is resistant to all drugs in the regimen and is likely to produce resistance to the new agent.

Treatment failure is usually the consequence of non-adherence. The risk of failing a regimen depends on the percentage of prescribed doses taken during any given period of treatment, but it also depends on the drugs in the regimen. Efavirenz-based regimens may be more forgiving of occasional skipped doses, and thus more useful because of the long $t_{1/2}$ of that drug; ritonavir-boosted PI regimens may be relatively more forgiving because of their higher genetic barrier to resistance (Gardner et al., 2009).

As antiretroviral therapy becomes more effective and easier to take, long-term toxicity of these drugs is of greater concern. An important consequence of long-term therapy is the development of a metabolic syndrome characterized by insulin resistance, fat redistribution, and hyperlipidemia and known as the HIV lipodystrophy syndrome. Lipodystrophy occurs in 10-40% of treated patients and has been seen with most drug combinations used in clinical trials. Symptomatic manifestations have been most strongly linked to the older generation of NRTIs, especially stavudine, which had more substantial mitochondrial toxicities; these drugs are now less commonly used in the developed world. The pathogenesis is still somewhat mysterious but involves phenotypic and metabolic changes similar to those seen with other human lipodystrophy syndromes (Garg, 2004). Clinical features include peripheral fat wasting (lipodystrophy), central fat accumulation including enlarged breasts and buffalo hump, insulin resistance and hyperglycemia, and elevations in serum cholesterol and triglycerides. Switching from one drug regimen to another may not reverse the symptoms, emphasizing its ubiquitous nature and possible role of HIV infection per se. Treatment is symptom directed and should include management of hyperlipidemias as recommended by the American Heart Association (Chapter 31). Lipodystrophy has been associated with an increased risk of myocardial infarction in virologically controlled patients, emphasizing the importance of cardiovascular risk factor reduction.

There is evidence that chronic HIV infection per se increases long-term cardiovascular risks, but the quantitative contribution of drug therapy to this risk is not well defined. Metabolic abnormalities associated with chronic HIV infection and possibly exacerbated by some drugs include insulin resistance, hyperglycemia, and increased risk of diabetes mellitus, as well as osteopenia and its attendant complications (Calmy et al., 2009).

A potential concern that applies to all protease inhibitors and NNRTIs is clinically significant pharmacokinetic drug interactions (Piscitelli and Gallicano, 2001). All agents in these two drug classes can act as inhibitors and/or inducers of hepatic CYPs and other drug metabolizing enzymes, as well as drug transport proteins. Prescribing practices should be guided by up-to-date knowledge of these potential effects. Internet-based educational resources are updated frequently (see, e.g., Flexner and Pham, 2009) and are an excellent way to track evolving knowledge about the undesired effects of drugs used in combination with antiretrovirals.

An increasingly recognized complication of initiating antiretroviral therapy is accelerated inflammatory reaction to overt or subclinical opportunistic infections or malignancies. This is thought to reflect reversal of immunodeficiency, resulting in new antimicrobial host defenses. This immune reconstitution inflammatory syndrome (IRIS) is most commonly seen when initiating therapy in individuals with low CD4 counts and/or advanced HIV disease, and it is associated with a better virologic response to therapy (Manabe et al., 2007). Not surprisingly, this is now most prevalent in resource-poor countries, where it may occur in >10% of newly treated patients. Infections most commonly associated with IRIS include tuberculosis and other mycobacterial diseases, cryptococcosis, hepatitis virus infections, and Pneumocystis pneumonia. Duration of symptoms ranges from a few days to more than a year. Symptomatic relief can be obtained with anti-inflammatory drugs, but systemic corticosteroids do not appear to shorten the course of symptoms (Manabe et al., 2007).

II. Drugs Used to Treat HIV Infection

NUCLEOSIDE AND NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS

The HIV-encoded, RNA-dependent DNA polymerase, also called reverse transcriptase, converts viral RNA into proviral DNA that is then incorporated into a host cell chromosome. Available inhibitors of this enzyme are either nucleoside/nucleotide analogs or non-nucleoside inhibitors (Figure 59–2 and Table 59–2).

Like all available antiretroviral drugs, nucleoside and nucleotide reverse transcriptase inhibitors prevent infection of susceptible cells but do not eradicate the virus from cells that already harbor integrated proviral DNA. Nucleoside and nucleotide analogs must enter cells and undergo phosphorylation to generate synthetic substrates for the enzyme (Table 59–2). The fully phosphorylated analogs block replication of the viral genome both by competitively inhibiting incorporation of native nucleotides and by terminating elongation of nascent proviral DNA because they lack a 3′-hydroxyl group (Dudley, 1995).

All but one of the drugs in this class are nucleosides that must be triphosphorylated at the 5′-hydroxyl to exert activity. The sole exception, tenofovir, is a nucleotide monophosphate analog that requires two additional phosphates to acquire full activity. These compounds inhibit both HIV-1 and HIV-2, and several have broad-spectrum activity against other human and animal retroviruses; emtricitabine, lamivudine, and tenofovir are active against hepatitis B virus (HBV), and tenofovir also has activity against herpesviruses (Chapter 58; De Clercq, 2003).

The selective toxicity of these drugs depends on their ability to inhibit the HIV reverse transcriptase without inhibiting host cell DNA polymerases. Although the intracellular triphosphates for all these drugs have low affinity for human DNA polymerase-α and -β, some are capable of inhibiting human DNA polymerase-γ, which is the mitochondrial enzyme. As a result, the important toxicities common to this class of drugs result in part from the inhibition of mitochondrial DNA synthesis (Lee et al., 2003). These toxicities include anemia, granulocytopenia, myopathy, peripheral neuropathy, and pancreatitis. Lactic acidosis with or without hepatomegaly and hepatic steatosis is a rare but potentially fatal complication seen with stavudine, zidovudine, and didanosine; it is probably not associated independently with the other drugs (Tripuraneni et al., 2004). Phosphorylated emtricitabine, lamivudine, and tenofovir have low affinity for DNA polymerase-γ and are largely devoid of mitochondrial toxicity.

The chemical structures of nucleoside and nucleotide reverse transcriptase inhibitors approved for treating HIV infection are shown in Figure 59–2; their pharmacokinetic properties are summarized in Table 59–2. Phosphorylation pathways for these eight drugs are summarized in Figure 59–3. Most nucleoside and nucleotide reverse transcriptase inhibitors are

![Figure 59–3. Intracellular activation of nucleoside analog reverse transcriptase inhibitors. nucleoside analogs have favorable safety and tolerability profiles and this class. Although modest in their own antiviral potency, several starting antiretroviral treatment do so with at least one agent from drugs remain a critical component of therapy, and nearly all patients in 2003; see Chapter 5).

inhibition of OATP drug transporters (Chapman et al., and protease inhibitors are likely to be explained by cally significant pharmacokinetic drug interactions inhibitors are dosed once or twice daily.

nucleoside and nucleotide reverse transcriptase inhibitors are dosed once or twice daily.

These drugs generally are not involved in clini-cally significant pharmacokinetic drug interactions because they are not major substrates for hepatic CYPs. Pharmacokinetic drug interactions involving tenofovir and protease inhibitors are likely to be explained by inhibition of OATP drug transporters (Chapman et al., 2003; see Chapter 5).

High-level resistance to nucleoside/nucleotide reverse transcriptase inhibitors, especially thymidine analogs, occurs slowly by comparison to NNRTIs and first-generation protease inhibitors. For example, zidovudine resistance was noted in only one-third of treated subjects after 1 year of monotherapy (Fischl et al., 1995). High-level resistance can occur rapidly with lamivudine and emtricitabine. In most cases, high-level resistance requires accumulation of a minimum of three to four codon substitutions, although a two-amino-acid insertion is associated with resistance to all drugs in this class (Gallant et al., 2003). Cross-resistance is common but often confined to drugs having similar chemical structures; zidovudine is a thymidine analog, and a zidovudine-resistant isolate is much more likely to be cross-resistant to the thymidine analog stavudine than to the cytidine analog lamivudine.

Nucleoside/nucleotide analogs are generally less active as single agents than other antiretroviral drugs. When used investigationally as monotherapy, most of these drugs produced only a 30-90% mean peak decrease in plasma concentrations of HIV RNA; abacavir monotherapy, however, produced up to a 99% decrease (Hervey and Perry, 2000). CD4 lymphocyte count increases were also modest with nucleoside monotherapy (mean increases of 50-100 cells/mm³, depending on disease stage). Nonetheless, these drugs remain a critical component of therapy, and nearly all patients starting antiretroviral treatment do so with at least one agent from this class. Although modest in their own antiviral potency, several nucleoside analogs have favorable safety and tolerability profiles and are useful in suppressing the emergence of HIV isolates resistant to the more potent drugs in combination regimens.

Zidovudine

Chemistry and Antiviral Activity. Zidovudine (3’-azido-3’-deoxythymidine; AZT) is a synthetic thymidine ana-log with potent in vitro activity against a broad spectrum of retroviruses including HIV-1, HIV-2, and human T-cell lymphotrophic viruses (HTLV) I and II (McLeod and Hammer, 1992). Its IC₅₀ against laboratory and clinical isolates of HIV-1 ranges from 10 to 48 nM.

Zidovudine is active in lymphoblastic and monocytic cell lines but is substantially less active in chronically infected cells (Geleziunas et al., 1993), probably because it has no impact on cells already infected with HIV. Zidovudine appears to be more active in lymphoocytes than in monocyte-macrophage cells because of enhanced phosphor-ylation in the former. For the same reason, the drug is more potent in activated than in resting lymphocytes because the phosphorylating enzyme, thymidine kinase, is S-phase-specific (Gao et al., 1994).

Mechanisms of Action and Resistance. Like other nucleoside analogs, intracellular zidovudine is phosphor-ylated by thymidine kinase to zidovudine 5’-monophosphate, which is then phosphorylated by thymidylate kinase to the diphosphate and by nucleo-side diphosphate kinase to zidovudine 5’-triphosphate (Figure 59–3). Zidovudine 5’-triphosphate terminates the elongation of proviral DNA because it is incorpo-rated by reverse transcriptase into nascent DNA but lacks a 3’-hydroxyl group. The monophosphate com-petitively inhibits cellular thymidylate kinase, and this may reduce the amount of intracellular thymidine triphosphate. Zidovudine 5’-triphosphate only weakly inhibits cellular DNA polymerase-α but is a more potent inhibitor of mitochondrial polymerase-γ.

Because the conversion of zidovudine 5’-monophosphate to diphosphate is very inefficient, high concentrations of the monophosphate accumulate inside cells (Dudley, 1995) and may serve as a precursor depot for formation of triphosphate. As a con-sequence, there is little correlation between extracel-lular concentrations of parent drug and intracellular concentrations of triphosphate, and higher plasma concentrations of zidovudine do not increase intracellular triphosphate concentrations proportionately.

Resistance to zidovudine is associated with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219 (Gallant et al., 2003). These mutations are referred to as thymidine analog mutations (TAMs) because of their ability to confer cross-resistance to other thymidine analogs such as stavudine. Two clusters of resistance mutations occur commonly. The pattern of 41L, 210W, and 215Y is associated with high-level resistance to zidovudine, as well as cross-resistance to other drugs in this class, includ-ing tenofovir and abacavir. The pattern 67N, 70R, 215F, and 219Q is less common and also associated with lower levels of resistance
and cross-resistance. TAMs associated with resistance to zidovudine and stavudine promote excision of the incorporated nucleotide anabolites through pyrophosphorylase (Naeger et al., 2002). Mutations accumulated gradually when zidovudine was used as the sole antiretroviral agent, and clinical resistance developed in only 31% of patients after 1 year of zidovudine monotherapy (Fischl et al., 1995). Cross-resistance to multiple nucleoside analogs has been reported following prolonged therapy and has been associated with a mutation cluster involving codons 62, 75, 77, 116, and 151. A mutation at codon 69 (typically T69S) followed by a two-amino-acid insertion cross-resistance to all available nucleoside and nucleotide analogs (Gallant et al., 2003).

The M184V substitution in the reverse transcriptase gene associated with the use of lamivudine or emtricitabine greatly restores sensitivity to zidovudine (Gallant et al., 2003). The combination of zidovudine and lamivudine produces greater long-term suppression of plasma HIV RNA than does zidovudine alone (Eron et al., 1995). As a result, this agent is usually combined with lamivudine in clinical practice.

Absorption, Distribution, and Elimination. Zidovudine is absorbed rapidly and reaches peak plasma concentrations within 1 hour (Dudley, 1995). Like other nucleoside analogs, the elimination t1/2 of the parent compound (~1 hour) is considerably shorter than that of the intracellular triphosphate, which is 3–4 hours (Table 59–2). Failure to recognize this led to serious overdosing of the drug when it was first approved; the recommended dose was 250 mg every 4 hours in 1987, compared with 300 mg twice a day presently.

Zidovudine undergoes rapid first-pass hepatic metabolism by conversion to 5-glucuronyl zidovudine, which limits systemic bioavailability to ~64%. Food may slow absorption but does not alter the AUC (area under the plasma concentration-time curve) (Table 59–2), and the drug can be administered regardless of food intake (Dudley, 1995). The pharmacokinetic profile of zidovudine is not altered significantly during pregnancy, and drug concentrations in the newborn approach those of the mother. Parent drug crosses the blood-brain barrier relatively well and achieves a cerebrospinal fluid (CSF)-to-plasma ratio of ~0.6. Zidovudine also is detectable in breast milk, semen, and fetal tissue. Zidovudine concentrations are higher in the male genital tract than in the peripheral circulation, suggesting active transport or trapping.

Untoward Effects. Patients initiating zidovudine treatment often complain of fatigue, malaise, myalgia, nausea, anorexia, headache, and insomnia. These symptoms usually resolve within the first few weeks of treatment. Bone marrow suppression, mainly anemia and granulocytopenia, occurs most often in individuals with advanced HIV disease and very low CD4 counts and also was more common with the higher doses used when the drug was first approved. Erythrocytic macrocytosis is seen in ~90% of all patients but usually is not associated with anemia.

Chronic zidovudine administration has been associated with nail hyperpigmentation. Skeletal muscle myopathy can occur and is associated with depletion of mitochondrial DNA, most likely as a consequence of inhibition of DNA polymerase-γ. Serious hepatic toxicity, with or without steatosis and lactic acidosis, is rare but can be fatal. Risk factors for the lactic acidosis-steatosis syndrome include female sex, obesity, and prolonged exposure to the drug (Tripuraneni et al., 2004).

Precautions and Interactions. Zidovudine is not a substrate or inhibitor of CYPs. However, probenecid, fluconazole, atovaquone, and valproic acid may increase plasma concentrations of zidovudine probably through inhibition of glucuronosyl transferase (Dudley, 1995). The clinical significance of these interactions is unknown because intracellular triphosphate levels may be unchanged despite higher plasma concentrations. Zidovudine can cause bone marrow suppression and should be used cautiously in patients with preexisting anemia or granulocytopenia and in those taking other marrow-suppressive drugs. Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly. Three clinical trials found a significantly worse virologic outcome in patients taking these two drugs together as compared with either agent used alone (Havlir et al., 2000).

Therapeutic Use. Zidovudine is FDA-approved for the treatment of adults and children with HIV infection and for preventing mother-to-child transmission of HIV infection; it is still recommended for post-exposure prophylaxis in HIV-exposed healthcare workers because of the large amount of data supporting its effectiveness in this setting (Centers for Disease Control and Prevention, 2005).

Despite being the oldest antiretroviral drug, zidovudine is still in widespread use, especially in resource-poor settings. This is a consequence of broad experience with the drug and its well-known tolerability, toxicity, and efficacy profiles. Zidovudine (RETROVIR, others) is marketed in oral tablets, capsules, and solution as well as a solution for intravenous injection. Zidovudine is available in coformulated tablets with lamivudine (COMBIVIR) or with lamivudine and abacavir (TRIZIVIR). Zidovudine monotherapy reduced the risk of perinatal transmission of HIV by 67% (Connor et al., 1994), and combining zidovudine with other antiretroviral drugs is even more efficacious in this setting.

Stavudine

Chemistry and Antiviral Activity. Stavudine (2′,3′-didehydro-2′,3′-dideoxythymidine; d4T) is a synthetic thymidine analog reverse transcriptase inhibitor that is active in vitro against HIV-1 and HIV-2. Its IC50 in lymphoblastoid and monocytic cell lines and in primary mononuclear cells ranges from 0.009 to 4 μM (Hurst and Noble, 1999).

Mechanisms of Action and Resistance. Intracellular stavudine is phosphorylated by thymidine kinase to stavudine 5′-monophosphate, which is then phosphorylated by thymidylyl kinase to the diphosphate and by nucleoside diphosphate kinase to stavudine 5′-triphosphate (Hurst and Noble, 1999) (Figure 59–3). Unlike zidovudine monophosphate, stavudine monophosphate does not
accumulate in the cell, and the rate-limiting step in activation appears to be generation of the monophosphate. Like zidovudine, stavudine is most potent in activated cells, probably because thymidine kinase is an S-phase-specific enzyme (Gao et al., 1994). Stavudine and zidovudine are antagonistic in vitro, and thymidine kinase has a higher affinity for zidovudine than for stavudine.

Stavudine resistance is seen most frequently with mutations at reverse transcriptase codons 41, 44, 67, 70, 210, 215, and 219 (Gallant et al., 2003), which are the same mutations associated with zidovudine resistance. Clusters of resistance mutations that include M41L, K70R, and T215Y are associated with a lower level of in vitro resistance than seen with zidovudine but are found in up to 38% of patients who fail to respond to stavudine. TAMS associated with resistance to zidovudine and stavudine promote excision of the incorporated triphosphate anabolites through pyrophosphorolysis (Naeger et al., 2002). As with zidovudine, resistance mutations for stavudine appear to accumulate slowly. Cross-resistance to multiple nucleoside analogs has been reported following prolonged therapy and has been associated with a mutation cluster involving codons 62, 75, 77, 116, and 151. In addition, a mutation at codon 69 (typically T69S) followed by a 2-amino acid insertion produces cross-resistance to all current nucleoside and nucleotide analogs (Gallant et al., 2003).

Absorption, Distribution, and Elimination. Stavudine is well absorbed and reaches peak plasma concentrations within 1 hour (Hurst and Noble, 1999). Bioavailability is not affected by food. The drug undergoes active tubular secretion, and renal elimination accounts for ~40% of parent drug.

Stavudine concentrations are higher in patients with low body weight, and the dose should be decreased from 40 to 30 mg twice daily in patients weighing <60 kg, although WHO recommends 30 mg twice daily in all patients. Dose also should be adjusted in patients with renal insufficiency (Jayasekara et al., 1999). Plasma protein binding is <5%. The drug penetrates well into the CSF, achieving concentrations that are ~40% of those in plasma. Placental concentrations of stavudine are about half those of zidovudine, possibly reflecting stavudine’s lower lipid solubility.

Untoward Effects. The most common serious toxicity of stavudine is peripheral neuropathy.

Neuropathy occurred in up to 71% of patients in initial monotherapy trials with a dose of 4 mg/kg per day. With the current recommended dose of 40 mg twice daily, the neuropathy incidence is ~12% (Hurst and Noble, 1999). Although this is thought to reflect mitochondrial toxicity, stavudine is a less potent inhibitor of DNA polymerase-γ than either didanosine or zalcitabine, suggesting that other mechanisms may be involved. Peripheral neuropathy is more common with higher doses or concentrations of stavudine and is more prevalent in patients with underlying HIV-related neuropathy or in those receiving other neurotoxic drugs. Stavudine is also associated with a progressive motor neuropathy characterized by weakness and in some cases respiratory failure, similar to Guillain-Barré syndrome (HIV Neuromuscular Syndrome Study Group, 2004).

Lactic acidosis and hepatic steatosis have been associated with stavudine use. This may be more common when stavudine and didanosine are combined. Elevated serum lactate is more common with stavudine than with zidovudine or abacavir (Tripuraneni et al., 2004), but the comparative risk of hepatic steatosis is unknown. Acute pancreatitis is not highly associated with stavudine but is more common when stavudine is combined with didanosine than when didanosine is given alone (Havlir et al., 2001).

Of all nucleoside analogs, stavudine use is associated most strongly with fat wasting, or lipoatrophy (Calmy et al., 2009). Whether this is a consequence of the extensive use of this agent combined with its mitochondrial toxicity or reflects a pathogenetic mechanism that has yet to be discovered remains to be determined. Stavudine has fallen out of favor in the developed world largely because of this toxicity. Other reported adverse effects include elevated hepatic transaminases, headache, nausea, and rash; however, these side effects are almost never severe enough to cause discontinuation of the drug.

Precautions and Interactions. Stavudine is mainly renally cleared and is not subject to metabolic drug interactions. The incidence and severity of peripheral neuropathy may be increased when stavudine is combined with other neuropathic medications, and therefore drugs such as ethambutol, isoniazid, phenytoin, and vincristine should be avoided.

Combining stavudine with didanosine leads to increased risk and severity of peripheral neuropathy and potentially fatal pancreatitis; therefore, these two drugs should not be used together (Havlir et al., 2001). Stavudine and zidovudine compete for intracellular phosphorylation and should not be used concomitantly. Three clinical trials found a significantly worse virologic outcome in patients taking these two drugs together as compared with either agent used alone (Havlir et al., 2000).

Therapeutic Use. Stavudine (ZERIT, others) is approved for use in HIV-infected adults and children, including neonates.

In early monotherapy trials, stavudine reduced plasma HIV RNA by 70-90% and delayed disease progression compared with continued zidovudine therapy. Lamivudine improves the long-term virologic response to stavudine, possibly reflecting the benefits of the M184V mutation (Kuritzkes et al., 1999). Many large prospective clinical trials have demonstrated potent and durable suppression of viremia and sustained increases in CD4+ cell counts when stavudine is combined with other nucleoside analogs plus NNRTIs or protease inhibitors (Hurst and Noble, 1999). Stavudine is no longer a popular drug in the developed world because of toxicity. However, it continues to be widely used in resource-poor settings because of its availability as an inexpensive generic version, often co-formulated with nevirapine and lamivudine.

Lamivudine

Chemistry and Antiviral Activity. Lamivudine [(-)2, 3′-dideoxy, 3′-thiacytidine; 3TC] is a cytidine analog reverse transcriptase inhibitor that is active against HIV-1, HIV-2, and HBV.

The molecule has two chiral centers and is manufactured as the pure 2R, cis(-)-enantiomer (Figure 59–2). The racemic mixture from which lamivudine originates has antiretroviral activity but is
Mechanisms of Action and Resistance. Lamivudine enters cells by passive diffusion, is converted to the monophosphate by deoxycytidine kinase, and undergoes further phosphorylation by deoxycytidine monophosphate kinase and nucleoside diphosphate kinase to yield lamivudine 5′-triphosphate, which is the active anabolite (Perry and Faulds, 1997) (Figure 59–3). Lamivudine is phosphorylated more efficiently in resting cells, which may explain its reduced potency in primary peripheral blood mononuclear cells as compared with cell lines (Gao et al., 1994). Lamivudine has low affinity for human DNA polymerases, explaining its low toxicity to the host.

High-level resistance to lamivudine occurs with single-amino-acid substitutions, M184V or M184I. These mutations can reduce in vitro sensitivity to lamivudine by up to 1000-fold (Perry and Faulds, 1997). The same mutations confer high-level cross-resistance to emtricitabine and a lesser degree of resistance to abacavir (Gallant et al., 2003). The M184V mutation restores zidovudine susceptibility in zidovudine-resistant HIV (Larder et al., 1995) and also partially restores tenofovir susceptibility in tenofovir-resistant HIV harboring the K65R mutation (Wainberg et al., 1999). The same K65R mutation confers resistance to lamivudine, emtricitabine, didanosine, stavudine, and abacavir.

HIV-1 isolates harboring the M184V mutation have increased transcriptional fidelity in vitro (Wainberg et al., 1996) and decreased replication capacity (Miller et al., 1999). Variants with the M184I mutation are even more impaired with regard to in vitro replication (Larder et al., 1995) and usually are replaced in lamivudine-treated patients by the M184V mutation. The reduced fitness of lamivudine-resistant viruses harboring these mutations, and their ability to prevent or partially reverse the effect of thymidine analog mutations, may contribute to the sustained virologic benefit of zidovudine and lamivudine combination therapy (Eron et al., 1995).

Lamivudine is used to treat HBV infection (Chapter 58), and some parallels in drug resistance are worth noting. High-level resistance to lamivudine occurs with a single mutation in the HBV DNA polymerase gene; as with HIV, this consists of a methionine-to-valine substitution (M204V) in the enzyme active site. Resistance to lamivudine occurs in up to 90% of HIV/HBV co-infected patients after 4 years of treatment. However, virologic benefits persist in some treated patients harboring lamivudine-resistant HBV possibly because the mutated virus has substantially reduced replicative capacity (Leung et al., 2001).

Absorption, Distribution, and Elimination. The oral bioavailability of lamivudine is >80% and is not affected by food. Although lamivudine was marketed originally with a recommended dose of 150 mg twice daily based on the short plasma t1/2 of the parent compound, the intracellular t1/2 of lamivudine 5′-triphosphate is 12-18 hours, and the drug is now approved for use once daily at 300 mg (Moore et al., 1999).

Lamivudine is excreted primarily unchanged in the urine, and dose adjustment is recommended for patients with a creatinine clearance <50 mL/minute (Jayasekara et al., 1999). Lamivudine does not bind significantly to plasma proteins and freely crosses the placenta into the fetal circulation. Like zidovudine, lamivudine concentrations are higher in the male genital tract than in the peripheral circulation, suggesting active transport or trapping. Penetration to the CNS appears to be moderate, with a CSF-to-plasma concentration ratio of ≤0.15 (Perry and Faulds, 1997). The clinical significance of the low CSF penetration is unknown.

Untoward Effects. Lamivudine is one of the least toxic antiretroviral drugs and has few significant adverse effects.

Neutropenia, headache, and nausea have been reported at higher than recommended doses. Pancreatitis has been reported in pediatric patients, but this has not been confirmed in controlled trials of adults or children. Because lamivudine also has activity against HBV and substantially lowers plasma HBV DNA concentrations, caution is warranted in using this drug in patients co-infected with HBV or in HBV-endemic areas; discontinuation of lamivudine may be associated with a rebound of HBV replication and exacerbation of hepatitis.

Precautions and Interactions. Because lamivudine and emtricitabine have nearly identical resistance and activity patterns, there is no rationale for their combined use. Lamivudine is synergistic with most other nucleoside analogs in vitro (Perry and Faulds, 1997).

Therapeutic Use. Lamivudine (EPIVIR) is approved for HIV in adults and children ≥3 months of age.

In early monotherapy studies, initial declines in plasma HIV-1 RNA concentrations of up to 90% occurred within 14 days but rebounded rapidly with emergence of lamivudine-resistant HIV (Perry and Faulds, 1997). Patients randomized to the combination of lamivudine plus zidovudine had substantially better mean decreases in plasma HIV-1 RNA at 52 weeks (97% vs. 70% decrease in copies/mL) and increases in CD4+ lymphocyte counts (+61 versus −53 cells/mm3) compared with those receiving zidovudine alone (Eron et al., 1995). In a large randomized double-blind trial, combining lamivudine with zidovudine or stavudine caused a 12-fold further decline in viral load at 24 weeks compared with zidovudine or stavudine monotherapy (Kuritzkes et al., 1999); in the same trial, combining lamivudine with didanosine conferred no additional benefits. Lamivudine has been effective in combination with other antiretroviral drugs in both treatment-naive and experienced patients (Perry and Faulds, 1997) and is a common component of therapy, given its safety, convenience, and efficacy.

Lamivudine (EPIVIR-HBV) also is approved for treatment of chronic hepatitis B.

Abacavir

Chemistry and Antiviral Activity. Abacavir is a synthetic carbocyclic purine analog (Figure 59–2).
Carbovir, a related guanine analog, was withdrawn from clinical development owing to poor oral bioavailability (Hervey and Perry, 2000). The IC_{50} of abacavir for primary clinical HIV-1 isolates is 0.26 μM, and its IC_{50} for laboratory strains ranges from 0.07 to 5.8 μM.

Mechanisms of Action and Resistance. Abacavir is the only approved antiretroviral that is active as a guanosine analog. It is initially monophosphorylated by adenosine phosphotransferase. The monophosphate is then converted to (−)-carbovir 3′-monophosphate, which is then phosphorylated to the di- and triphosphates by cellular kinases (Figure 59–3). Carbovir 5′-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent DNA but lacks a 3′-hydroxy group.

Clinical resistance to abacavir is associated with four specific codon substitutions: K65R, L74V, Y115F, and M184V (Gallant et al., 2003). Individually, these substitutions produce only modest (2- to 4-fold) resistance to abacavir, but in combination can reduce susceptibility by up to 10-fold. The Y115F mutation is seen uniquely with abacavir and causes low-level resistance. The L74V mutation is associated with cross-resistance to the purine analog didanosine. K65R confers cross-resistance to all nucleosides except zidovudine. An alternate pathway for abacavir resistance involves mutations at codons 41, 210, and 215, which have been associated with a reduced likelihood of virologic response. Abacavir sensitivity is greatly reduced by the multinucleoside resistance clusters, including that associated with the Q151M, as well as the 2-amino acid insertion following codon 69 (Gallant et al., 2003).

Absorption, Distribution, and Elimination. Abacavir’s oral bioavailability is >80% regardless of food intake (Table 59–2). Abacavir is eliminated by metabolism to the 5′-carboxylic acid derivative catalyzed by alcohol dehydrogenase, and by glucuronidation to the 5′-glucuronide (Figure 59–3). These metabolites account for 30% and 36% of elimination, respectively (Hervey and Perry, 2000). Abacavir is not a substrate or inhibitor of CYPs. Abacavir is 50% bound to plasma proteins, and the CSF/plasma AUC ratio is ~0.3. Although the introduced dose of abacavir was 300 mg twice daily, carbovir triphosphate accumulates inside the cell and has a reported elimination t_{1/2} of up to 21 hours (Hervey and Perry, 2000); thus a regimen of 600 mg once daily is approved now.

Untoward Effects. The most important adverse effect of abacavir is a unique and potentially fatal hypersensitivity syndrome. This syndrome is characterized by fever, abdominal pain, and other gastrointestinal (GI) complaints; a mild maculopapular rash; and malaise or fatigue. Respiratory complaints (cough, pharyngitis, dyspnea), musculoskeletal complaints, headache, and paresthesias are reported less commonly. Median time to onset of symptoms is 11 days, and 93% of cases occur within 6 weeks of initiating therapy (Hetherington et al., 2002). The presence of concurrent fever, abdominal pain, and rash within 6 weeks of starting abacavir is diagnostic and necessitates immediate discontinuation of the drug. Patients having only one of these symptoms may be observed to see if additional symptoms appear. Unlike many hypersensitivity syndromes, this condition worsens with continued treatment. Abacavir can never be restarted once discontinued for hypersensitivity because reintroduction of the drug leads to rapid recurrence of severe symptoms, accompanied by hypotension, a shocklike state, and possibly death. The reported mortality rate of restarting abacavir in sensitive individuals is 4% (Hervey and Perry, 2000).

Abacavir hypersensitivity occurs in 2-9% of patients depending on the population studied. The cause is a genetically mediated immune response linked to both the HLA-B*5701 locus and the M493T allele in the heat-shock locus Hsp70-Hom (Mallal et al., 2008). The latter gene is implicated in antigen presentation, and this haplotype is associated with aberrant tumor necrosis factor-α release after exposure of human lymphocytes to abacavir ex vivo. This is one of the strongest pharmacogenetic associations ever described. In one white population, the combination of these two markers occurred in 94.4% of cases and <0.5% of controls for a positive predictive value of 93.8% and a negative predictive value of 99.5% (Mallal et al., 2008). Abacavir should not be given to those with the HLA-B*5701 genotype; in all others, the risk of true hypersensitivity is essentially zero (Mallal et al., 2008). Aside from hypersensitivity, abacavir is a well-tolerated drug. Carbovir 5′-triphosphate is a weak inhibitor of human DNA polymerases, including DNA polymerase-γ (Hervey and Perry, 2000). Abacavir therefore has not been associated with adverse events thought to be due to mitochondrial toxicity. Epidemiological associations link abacavir use and increased risk of myocardial infarction (D:A:D Study Group et al., 2008).

Precautions and Interactions. Abacavir is not associated with any clinically significant pharmacokinetic drug interactions. However, a large dose of ethanol (0.7 g/kg) increased the abacavir plasma AUC by 41% and prolonged the elimination t_{1/2} by 26% (McDowell et al., 2000) possibly owing to competition for alcohol dehydrogenase.

Therapeutic Use. Abacavir (ZIAGEN) is approved for the treatment of HIV-1 infection, in combination with other antiretroviral agents. In initial monotherapy studies, abacavir reduced HIV plasma RNA concentrations up to 300 times more than that seen with other antiretroviral nucleosides, and it increased CD4+ lymphocyte counts by 80-200 cells/mm³ (Hervey and Perry, 2000). Abacavir is not a more potent inhibitor of HIV replication than other nucleosides in vitro, and the mechanism for its more potent in vivo monotherapy activity is unexplained.

Abacavir is effective in combination with other nucleoside analogs, NNRTIs, and protease inhibitors. Adding abacavir to zidovudine and lamivudine resulted in a substantially greater decrease in plasma HIV-1 RNA than seen with the two-drug regimen of zidovudine plus lamivudine in adults or children (Hervey and Perry, 2000). Abacavir is available in a co-formulation with zidovudine and lamivudine (TRIZIVIR) for twice-daily dosing. However, the combination of abacavir, zidovudine, and lamivudine was less effective in a randomized, double-blind, placebo-controlled trial in treatment-naive patients than was the combination of zidovudine, lamivudine, and efavirenz or the four-drug regimen of zidovudine,
lamivudine, abacavir, and efavirenz; 79% of patients in the abacavir, lamivudine, lamivudine group had undetectable plasma HIV RNA at 32 weeks as compared with 89% with the other regimens (Gulick et al., 2004).

Abacavir is available in a co-formulation with lamivudine (EPZICOM) for once-daily dosing, which is how it is most commonly used. Abacavir is approved for use in adult and pediatric patients ≥3 months of age, with dosing in the latter based on body weight.

### Tenofovir

**Chemistry and Antiviral Activity.** Tenofovir disoproxil is a derivative of adenosine 5'-monophosphate lacking a complete ribose ring, and it is the only nucleotide analog currently marketed for the treatment of HIV infection (Figure 59–2).

Because the parent compound had very poor oral bioavailability, tenofovir is available only as the disoproxil prodrug, which substantially improves oral absorption and cellular penetration. Like lamivudine and emtricitabine, tenofovir is active against HIV-1, HIV-2, and HBV. The IC$_{50}$ of tenofovir disoproxil against laboratory strains of HIV-1 ranges from 2 to 7 nM, making the prodrug ~100-fold more active in vitro than the parent compound (Chapman et al., 2003).

**Mechanisms of Action and Resistance.** Tenofovir disoproxil is hydrolyzed rapidly to tenofovir and then is phosphorylated by cellular kinases to its active metabolite, tenofovir diphosphate (which is actually a triphosphate: the parent drug is a monophosphate) (Figure 59–3). Tenofovir diphosphate is a competitive inhibitor of viral reverse transcriptases and is incorporated into HIV DNA to cause chain termination because it has an incomplete ribose ring. Although tenofovir diphosphate has broad-spectrum activity against viral DNA polymerases, it has low affinity for human DNA polymerases-α, -β, and -γ, which is the basis for its selective toxicity.

Specific resistance occurs with a single substitution at codon 65 of reverse transcriptase (K65R). This mutation reduces in vitro sensitivity by only 3- to 4-fold but has been associated with clinical failure of tenofovir-containing regimens (Chapman et al., 2003). Tenofovir sensitivity and virologic efficacy also are reduced in patients harboring HIV isolates with high-level resistance to zidovudine or stavudine, specifically those having three or more TAMs, patients harboring HIV isolates with high-level resistance to zidovudine or stavudine, specifically those having three or more TAMs, specifically those having three or more TAMs, specifically those having three or more TAMs, specifically those having three or more TAMs, specifically those having three or more TAMs.

**Untoward Effects.** Tenofovir generally is well tolerated, with few significant adverse effects reported except for flatulence.

In placebo-controlled double-blinded trials, the drug had no other adverse effects reported more frequently than with placebo after treatment for up to 24 weeks. Unlike the antiviral nucleotides adefovir and cidofovir (Chapter 58), tenofovir is not toxic to human renal tubular cells in vitro (Chapman et al., 2003). However, rare episodes of acute renal failure and Fanconi’s syndrome have been reported with tenofovir, and this drug should be used with caution in patients with preexisting renal disease. Tenofovir use is associated with small declines in estimated creatinine clearance after months of treatment in some patients (Gallant and Moore, 2009), and because the dose needs to be reduced if renal insufficiency is present, renal function (creatinine and phosphorus) should be monitored regularly in patient taking this drug. Because tenofovir also has activity against HBV and may lower plasma HBV DNA concentrations, caution is warranted in using this drug in patients co-infected with HBV and in regions with high HBV seroprevalence because discontinuation of tenofovir may be associated with a rebound of HBV replication and exacerbation of hepatitis.

**Precautions and Interactions.** Tenofovir is not metabolized to a significant extent by CYPs and is not known to inhibit or induce these enzymes. However, tenofovir has been associated with a few potentially important pharmacokinetic drug interactions.

A 300-mg dose of tenofovir increased the didanosine AUC by 44-60%, probably as a consequence of inhibition of purine nucleoside phosphorylase by both tenofovir and tenofovir monophosphate (Robbins et al., 2003). These two drugs probably should not be used together; if the combination is essential, the dose of didanosine should be reduced from 400 to 250 mg/day (Chapman et al., 2003). Although tenofovir is not known to induce CYPs, it has been reported to reduce the atazanavir AUC by ~26%. In addition, low-dose ritonavir (100 mg twice daily) increases the mean tenofovir AUC by 34%, lopinavir/ritonavir increases the AUC by 32%, and was not associated with treatment failure. Patients failing most tenofovir-containing regimens are more likely to harbor genotypic resistance to the other drugs in the regimen. Notable exceptions are once-daily combination regimens of three nucleosides, specifically tenofovir plus didanosine and lamivudine and tenofovir plus abacavir and lamivudine. Both of these regimens were associated with very high early rates of virologic failure or nonresponse, and at the time of failure, the K65R mutation was present in 36-64% of virus isolated from patients (Department of Health and Human Services, 2010); these combinations should be avoided.

**Absorption, Distribution, and Elimination.** Tenofovir disoproxil has an oral bioavailability of 25%. A high-fat meal increases the bioavailability to 39%, but the drug can be taken without regard to food (Chapman et al., 2003). Tenofovir is not bound significantly to plasma proteins. The plasma elimination t$_{1/2}$ ranges from 14 to 17 hours. The reported t$_{1/2}$ of intracellular tenofovir diphosphate is 11 hours in activated peripheral blood mononuclear cells and ≥49 hours in resting cells (Chapman et al., 2003). The drug therefore can be dosed once daily. Tenofovir undergoes both glomerular filtration and active tubular secretion. Following an intravenous dose, 70-80% of the drug is recovered unchanged in the urine. Doses should be decreased in those with renal insufficiency (Chapman et al., 2003).
atazanavir increases the tenofovir AUC by 25%. These interactions are most likely mediated by tenofovir’s interaction with drug transport proteins.

**Therapeutic Use.** Tenofovir (VIREAD) is FDA approved for treating HIV infection in adults in combination with other antiretroviral agents.

The use of tenofovir in antiretroviral-experienced patients resulted in a further sustained decrease in HIV plasma RNA concentrations of 4.5-7.4-fold relative to placebo after 48 weeks of treatment (Chapman et al., 2003). Several large trials have confirmed the antiretroviral activity of tenofovir in three-drug regimens with other agents, including other nucleoside analogs, protease inhibitors, and/or NNRTIs. In a randomized double-blind comparison trial in which treatment-naive patients also received lamivudine and efavirenz, tenofovir 300 mg once daily was as effective and less toxic than stavudine 40 mg twice daily (Gallant et al., 2004). Tenofovir is also being investigated as a component of prophylactic regimens, including in the prevention of mother-to-child transmission, and it may have advantages over zidovudine in these settings (Foster et al., 2009).

Tenofovir is also approved for the treatment of chronic hepatitis B in adults.

**Emtricitabine**

**Chemistry and Antiviral Activity.** Emtricitabine is a cytidine analog chemically related to lamivudine and shares many of that drug’s pharmacodynamic properties.

Like lamivudine, it has two chiral centers and is manufactured as the enantiomerically pure (2R,5S)-5-fluoro-1-[2-(hydroxymethyl)-1,3-oxathiolan-5-yl]cytosine (FTC) (Figure 59–2). Emtricitabine is active against HIV-1, HIV-2, and HBV. The IC₅₀ of emtricitabine against laboratory strains of HIV-1 ranges from 2 to 530 nM, although, on average, the drug is ~10 times more active in vitro than lamivudine (Saag, 2006).

**Mechanisms of Action and Resistance.** Emtricitabine enters cells by passive diffusion and is phosphorylated by deoxycytidine kinase and cellular kinases to enter cells by passive diffusion and is phosphorylated to beyond lamivudine (Saag, 2006). The IC₅₀ of emtricitabine against laboratory strains of HIV-1 ranges from 2 to 530 nM, although, on average, the drug is ~10 times more active in vitro than lamivudine (Saag, 2006).

Tenofovir susceptibility to zidovudine-resistant HIV and also partially restores tenofovir susceptibility to tenofovir-resistant HIV harboring the K65R mutation (Wainberg et al., 1999). The same K65R mutation confers resistance to emtricitabine and the other cytidine analog lamivudine, as well as didanosine, stavudine, and abacavir.

**Absorption, Distribution, and Elimination.** Emtricitabine is absorbed rapidly and has an oral bioavailability of 93%. Food reduces the Cmax but does not affect the AUC, and the drug can be taken without regard to meals. Emtricitabine is not bound significantly to plasma proteins. Compared with other nucleoside analogs, the drug has a slow systemic clearance and long elimination t1/2 of 8-10 hours (Saag, 2006). In addition, the estimated t1/2 of the intracellular triphosphate is long, possibly up to 39 hours, providing the pharmacokinetic rationale for once-daily dosing. Emtricitabine is excreted primarily unchanged in the urine, undergoing glomerular filtration and active tubular secretion. The dose should be reduced in those with estimated creatinine clearances of <50 mL/minute.

**Untoward Effects.** Emtricitabine is one of the least toxic antiretroviral drugs and, like its chemical relative lamivudine, has few significant adverse effects and no effect on mitochondrial DNA in vitro (Saag, 2006).

Prolonged exposure has been associated with hyperpigmentation of the skin, especially in sun-exposed areas. Elevated hepatic transaminases, hepatitis, and pancreatitis have been reported, but these have occurred in association with other drugs known to cause these toxicities. Because emtricitabine also has in vitro activity against HBV, caution is warranted in using this drug in patients co-infected with HBV and in regions with high HBV seroprevalence; discontinuation of lamivudine, which is closely related to emtricitabine, has been associated with a rebound of HBV replication and exacerbation of hepatitis.

**Precautions and Interactions.** Emtricitabine is not metabolized to a significant extent by CYPs, and it is not susceptible to any known metabolic drug interactions. The possibility of a pharmacokinetic interaction involving renal tubular secretion, such as that between trimethoprim and lamivudine, has not been investigated for emtricitabine; the drug does not alter the pharmacokinetics of tenofovir.

**Therapeutic Use.** Emtricitabine (EMTRIVA) is FDA-approved for treating HIV infection in adults in combination with other antiretroviral agents. Emtricitabine is available co-formulated with tenofovir ± efavirenz.

Two small monotherapy trials showed that the maximal antiretroviral effect of emtricitabine (mean 1.9 log unit decrease in plasma HIV RNA concentration) was achieved with a dose of 200 mg/day. Several large trials have confirmed the antiretroviral activity of emtricitabine in three-drug regimens with other agents, including nucleoside or nucleotide analogs, protease inhibitors, and/or NNRTIs. In two randomized comparison studies, emtricitabine- and lamivudine-based triple-combination regimens had similar efficacy (Saag, 2006).

**Didanosine**

**Chemistry and Antiviral Activity.** Didanosine (2’,3’-dideoxyinosine; ddI) is a purine nucleoside analog active against HIV-1, HIV-2, and other retroviruses including HTLV-1 (Perry and Noble, 1999). Its IC₅₀ against HIV-1 ranges from 10 nM in monocytes-macrophage cells, to 10 µM in lymphoblast cell lines. Didanosine has been supplanted by less toxic drugs.
Mechanisms of Action and Resistance. Didanosine is transported into cells by a nucleobase carrier and undergoes initial phosphorylation by 5′-nucleotidase and inosine 5′-monophosphate phosphotransferase (Dudley, 1995; Khoo et al., 2002). Didanosine 5′-monophosphate is then converted to dideoxyadenosine 5′-monophosphate by adenylosuccinate synthetase and adenylosuccinate lyase (Figure 59–3). Adenylate kinase and phosphoribosyl pyrophosphate synthetase produce dideoxyadenosine 5′-diphosphate, which is converted to the triphosphate by creatine kinase and phosphoribosyl pyrophosphate synthetase. Dideoxyadenosine 5′-triphosphate is the active anabolite of didanosine, which therefore functions as an antiviral adenosine analog. Dideoxyadenosine 5′-triphosphate terminates the elongation of proviral DNA because it is incorporated by reverse transcriptase into nascent HIV DNA but lacks a 3′-hydroxyl group.

Resistance to didanosine is associated with mutations at reverse transcriptase codons 65 and 74. The L74V substitution, which reduces susceptibility 5- to 26-fold in vitro, is seen most commonly in patients failing to respond to didanosine. Other nucleoside analog mutations, including thymidine analog mutations, can contribute to didanosine resistance even though the drug does not appear to select for these mutations de novo. The reverse transcriptase insertion mutations at codon 69 produce cross-resistance to all current nucleoside analogs, including didanosine (Gallant et al., 2003). The M184V mutation seen in response to emtricitabine and lamivudine reduces didanosine susceptibility in vitro but probably plays no role in clinical resistance to this drug.

Absorption, Distribution, and Elimination. Didanosine is acid labile and is degraded at low gastric pH (Dudley, 1995). An antacid buffer is used in some formulations to improve bioavailability. Chewable tablets contain calcium carbonate and magnesium hydroxide, whereas the powder form contains citrate-phosphate buffer. The pediatric powder formulation lacks buffer and is reconstituted with purified water and mixed with a liquid antacid preparation. Food decreases didanosine bioavailability (AUC) by ~55%, so all formulations of didanosine must be administered at least 30 minutes before or 2 hours after eating (Moreno et al., 2007). This complicates dosing of didanosine in combination with antiretroviral drugs that must be given with food, as is the case for most HIV protease inhibitors. The enzyme purine nucleoside phosphorylase (PNP) probably contributes to the presystemic clearance of didanosine because tenofovir, which inhibits PNP, greatly increases concentrations of orally administered didanosine (Robbins et al., 2003). PNP converts didanosine to hypoxanthine, which is ultimately converted to uric acid.

Peak plasma concentrations of didanosine are seen ~1 hour after oral administration of the chewable tablets or powder formulations and 2 hours after delayed-release capsules. The plasma elimination t1/2 of parent drug is ~1.5 hours, but the estimated intracellular t1/2 of dideoxyadenosine 5′-triphosphate is substantially longer, 25-40 hours (Moreno et al., 2007). As a result, didanosine can be administered once daily. Didanosine is excreted both by glomerular filtration and by tubular secretion and does not undergo metabolism to a significant degree. Drug doses therefore must be adjusted in patients with renal insufficiency or renal failure (Jayasekara et al., 1999). Didanosine is not protein bound to a significant degree. The cerebrospinal penetration of didanosine is less than that of zidovudine, with a CSF-to-plasma ratio of 0.2, but the clinical significance of this is unclear.

Untoward Effects. The most serious toxicities associated with didanosine include peripheral neuropathy and pancreatitis, both of which are thought to be a consequence of mitochondrial toxicity. Up to 20% of patients reported peripheral neuropathy in early clinical trials (Moreno et al., 2007). As with other dideoxynucleosides, peripheral neuropathy is more common with higher doses or concentrations of didanosine and is more prevalent in patients with underlying HIV-related neuropathy, low CD4 count, or in those receiving other neurotoxic drugs. Typically, this is a symmetrical distal sensory neuropathy that begins in the feet and lower extremities but may involve the hands as it progresses (stocking/glove distribution). Patients complain of pain, numbness, and tingling in the affected extremities. If the drug is stopped as soon as symptoms appear, the neuropathy will stabilize and should improve or resolve. However, irreversible neuropathy can occur with continued use. Retinal changes and optic neuritis also have been reported with didanosine, and patients should undergo periodic retinal examinations.

Acute pancreatitis is a rare but potentially fatal complication of didanosine. Acute pancreatitis is associated with higher doses and concentrations of didanosine but has occurred in up to 7% of patients using the recommended dose of 200 mg twice daily (Moreno et al., 2007). Pancreatitis is more common with advanced HIV disease, and other risk factors include a previous history of pancreatitis, alcohol or illicit drug use, and hypertriglyceridemia. Combining didanosine with stavudine, which is also associated with peripheral neuropathy and pancreatitis, increases the risk and severity of both toxicities (Havlir et al., 2001).

As with other dideoxynucleosides and zidovudine, serious hepatic toxicity—with or without steatosis, hepatomegaly, and lactic acidosis—occurs very rarely but can be fatal. Risk factors for the lactic acidosis-steatosis syndrome include female sex, obesity, and prolonged exposure to the drug (Triipurani et al., 2004). Other reported adverse effects include elevated hepatic transaminases, headache, and asymptomatic hyperuricemia and portal hypertension. The impact of didanosine on heart attack risk is under review. Diarrhea is reported more frequently with didanosine than with other nucleoside analogs and has been attributed to the antacid in the buffered oral preparations (Moreno et al., 2007). Didanosine chewable tablets contain 36.5 mg phenylalanine and should be avoided in those with phenylketonuria. Buffered powder for oral solution contains 1.4 g sodium per packet and should be used cautiously in those on sodium-restricted diets.

Precautions and Interactions. Buffering agents included in didanosine formulations can interfere with the bioavailability of some co-administered drugs because of altered pH or chelation with cations in the buffer. For example, the ciprofloxacin AUC is decreased by up to 98% when given with didanosine, and concentrations of ketoconazole anditraconazole, whose absorption is pH dependent, also are diminished (Piscielli and Gallicano, 2001). A 200-mg dose of buffered didanosine reduced the indinavir AUC by 84%. These interactions
generally can be avoided by separating administration of didanosine from that of other agents by at least 2 hours after or 6 hours before the interacting drug. The enteric-coated formulation of didanosine does not alter ciprofloxacin or indinavir absorption.

Didanosine is excreted renally, and shared renal excretory mechanisms provide a basis for drug interactions. Oral ganciclovir can increase plasma didanosine concentrations approximately 2-fold and may be associated with an increase in didanosine toxicity. Allopurinol can increase the didanosine AUC more than 4-fold and is contraindicated. Tenofovir increases the didanosine AUC by 44-60% and also may increase the risk of didanosine toxicity. If these two drugs must be given together, it is recommended to decrease the didanosine dose from 400 to 250 mg once daily for patients ≥60 kg (Chapman et al., 2003). Methadone decreases the didanosine AUC by 57-63% (Rainey et al., 2000) possibly as a consequence of altered GI motility and delayed absorption, although this has not been associated with a higher risk of failing didanosine treatment.

Didanosine should be avoided in patients with a history of pancreatitis or neuropathy because the risk and severity of both complications increase. Co-administration of other drugs that cause pancreatitis or neuropathy also will increase the risk and severity of these symptoms. Ethambutol, isoniazid, vincristine, cisplatin, and pentamidine also should be avoided.

The combination of didanosine and hydroxyurea was used to exploit a beneficial interaction that creates a favorable intracellular ratio of concentrations of dideoxycytidine 5′-triphosphate to deoxynucleoside 5′-triphosphate (Frank et al., 2004). Although this combination may boost didanosine antiviral activity modestly, it also increases toxicity, producing peripheral neuropathy and fatal pancreatitis, and should be avoided (Havlir et al., 2001).

**Therapeutic Use.** Didanosine (VIDEX, VIDEX EC) is FDA-approved for adults and children with HIV infection in combination with other antiretroviral agents. Didanosine has long-term efficacy when combined with other nucleoside analogs and HIV protease inhibitors or NNRTIs. Didanosine as a component of combination therapy also has beneficial effects in infants and children (Moreno et al., 2007). However, this drug is no longer widely prescribed in the developed world because of the availability of other agents with less toxicity.

**Zalcitabine**

Zalcitabine (2′,3′-dideoxyctydine; ddC) is a synthetic cytidine analog reverse transcriptase inhibitor that is designated as an orphan drug for the treatment of advanced HIV infection. It is no longer marketed because of toxicity (mainly peripheral neuropathy) and the need for thrice daily dosing. It is active against HIV-1, HIV-2, and hepatitis B virus (HBV). For additional information on this drug, see the 11th edition of this book.

**NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS**

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) include a variety of chemical substrates that bind to a hydrophobic pocket in the p66 subunit of the HIV-1 reverse transcriptase. The NNRTI-binding pocket is not essential for the function of the enzyme and is distant from the active site. These compounds induce a conformational change in the three-dimensional structure of the enzyme that greatly reduces its activity, and thus they act as noncompetitive inhibitors. Unlike nucleoside and nucleotide reverse transcriptase inhibitors, these compounds do not require intracellular phosphorylation to attain activity. Because the binding site for NNRTIs is virus-strain-specific, the approved agents are active against HIV-1 but not HIV-2 or other retroviruses and should not be used to treat HIV-2 infection (Harris and Montaner, 2000). These compounds also have no activity against host cell DNA polymerases. The two most commonly used agents in this category, efavirenz and nevirapine, are quite potent and transiently decrease plasma HIV RNA concentrations by two orders of magnitude or more when used as sole agents (Havlir et al., 1995; Wei et al., 1995). The chemical structures of the four approved NNRTIs are shown in Figure 59–4, and their pharmacokinetic properties are summarized in Table 59–3.

All approved NNRTIs are eliminated from the body by hepatic metabolism. Nevirapine and delavirdine are primarily substrates for CYP3A4, whereas efavirenz is a substrate for CYPs 2B6 and 3A4, and etravirine is subject to mixed metabolism. The steady-state elimination half-lives of efavirenz and nevirapine range from 24 to 72 hours, allowing daily dosing. Efavirenz, etravirine, and nevirapine are moderately potent inducers of hepatic drug-metabolizing enzymes including CYP3A4, whereas delavirdine is mainly a CYP3A4 inhibitor. Pharmacokinetic drug interactions are thus an important consideration with this class of compounds and represent a potential toxicity.

All NNRTIs except etravirine are susceptible to high-level drug resistance caused by single-amino-acid changes in the NNRTI-binding pocket (usually in codons 103 or 181). Unlike nucleoside analogs or protease inhibitors, efavirenz or nevirapine can induce resistance and virologic relapse within a few days or weeks if given as monotherapy (Wei et al., 1995). Exposure to even a single dose of nevirapine in the absence of other antiretroviral drugs is associated with resistance mutations in up to one-third of patients (Eshleman et al., 2004). **These agents are potent and highly effective but must be combined with at least two other active agents to avoid resistance.**

The use of efavirenz or nevirapine in combination with other antiretroviral drugs is associated with favorable long-term suppression of viremia and elevation of CD4+ lymphocyte counts (Sheran, 2005). Efavirenz in particular is a common component of first regimens.
Efavirenz binds to a non-essential site distant from the enzyme catalytic site.

Figure 59–4. Structures and mechanism of non-nucleoside reverse transcriptase inhibitors.
for treatment-naive patients in recognition of its convenience, tolerability, and potency. Rashes occur frequently with all NNRTIs, usually during the first 4 weeks of therapy. These generally are mild and self-limited, although rare cases of potentially fatal Stevens-Johnson syndrome have been reported with nevirapine, efavirenz, and etravirine. Fat accumulation can be seen after long-term use of NNRTIs (Calmy et al., 2009), and fatal hepatitis has been associated with nevirapine use.

Nevirapine

Chemistry and Antiviral Activity. Nevirapine is a dipyridodiazepinone NNRTI with potent activity against HIV-1 (Figure 59–4).

The in vitro IC_{50} of this drug ranges from 10 to 100 nM. Like other compounds in this class, nevirapine does not have significant activity against HIV-2 or other retroviruses (Sheran, 2005).

Mechanisms of Action and Resistance. A single mutation at either codon 103 or codon 181 of reverse transcriptase decreases susceptibility by more than two orders of magnitude (Kuritzkes, 2004). Nevirapine resistance is also associated with mutations at codons 100, 106, 108, 188, and 190, but either the K103N or the Y181C mutation is sufficient to produce high-level resistance and clinical treatment failure (Eshleman et al., 2004). Cross-resistance extends to efavirenz and delavirdine, and any patient who fails treatment with this NNRTI should not be treated with those drugs.

Absorption, Distribution, and Elimination. Nevirapine is well absorbed, and its bioavailability is not altered by food or antacids. The drug readily crosses the placenta and has been found in breast milk, a feature that has encouraged use of nevirapine for prevention of mother-to-child transmission of HIV (Mirochnick et al., 1998).

Nevirapine is eliminated mainly by oxidative metabolism involving CYP3A4 and CYP2B6. Less than 3% of the parent drug is eliminated unchanged in the urine. Nevirapine has a long elimination t_{1/2} of 25-30 hours at steady state, but t_{1/2} may be longer in some individuals, especially those of African descent (Sheran, 2005). The drug is a moderate inducer of CYPs, including CYP3A4; thus the drug induces its own metabolism, which decreases the t_{1/2} from 45 hours following the first dose to 25-30 hours after 2 weeks. To compensate for this, it is recommended that the drug be initiated at a dose of 200 mg once daily for 14 days, with the dose then increased to 200 mg twice daily if no adverse reactions have occurred. Clinical studies of nevirapine have investigated once-daily use, but this dosing regimen is not approved.

Untoward Effects. The most frequent adverse event associated with nevirapine is rash, which occurs in ~16% of patients. Mild macular or papular eruptions commonly involve the trunk, face, and extremities and generally occur within the first 6 weeks of therapy. Pruritus is also common. In most patients the rash resolves with continued administration of drug. Up to 7% of patients discontinue therapy owing to rash; administration of glucocorticoids may cause a more severe rash. Life-threatening Stevens-Johnson syndrome is rare but occurs in up to 0.3% of recipients (Sheran, 2005).

Elevated hepatic transaminases occur in up to 14% of patients. Clinical hepatitis occurs in up to 1% of patients. Severe and fatal hepatitis has been associated with nevirapine use, and this may be more common in women with CD4 counts >250 cells/mm^3, especially during pregnancy (Sheran, 2005). Other reported side effects include fever, fatigue, headache, somnolence, and nausea.

Precautions and Interactions. Because nevirapine induces CYP3A4, this drug may lower plasma concentrations of co-administered CYP3A4 substrates. Methadone withdrawal has been reported in patients receiving nevirapine, presumably as a consequence of enhanced methadone clearance. Plasma ethinyl estradiol and norethindrone concentrations decrease by 20% with nevirapine, and alternative methods of birth control are advised.

**ABBREVIATIONS:** AUC, area under plasma concentration–time curve; t_{1/2}, elim, half-life of elimination; ↑, increase; ↓, decrease; ↔, no effect; NR, not reported; CYP, cytochrome P450; UGT, UDP-glucuronosyltransferase.

*Reported mean values in adults with normal renal and hepatic function. Ab reported at steady state after multiple oral doses.
**Therapeutic Use.** Nevirapine (VIRAMUNE) is FDA approved for the treatment of HIV-1 infection in adults and children in combination with other antiretroviral agents.

In original monotherapy studies, a rapid fall in plasma HIV RNA concentrations of ≥99% was followed by a return toward baseline within 8 weeks because of rapid emergence of resistance (Havlir et al., 1995; Wei et al., 1995). **Nevirapine should never be used as a single agent or as the sole addition to a failing regimen.** Nevirapine is approved for use in infants and children ≥15 days old, with dosing based on body surface area.

Single-dose nevirapine has been used commonly in pregnant HIV-infected women to prevent mother-to-child transmission. A single oral intrapartum dose of 200 mg nevirapine followed by a single dose given to the newborn reduced neonatal HIV infection to 13% compared with 21.5% infection with a more complicated zidovudine regimen (Sheran, 2005). Although this regimen is very inexpensive and generally well tolerated, the high prevalence of nevirapine resistance following the single oral dose (Eshleman et al., 2004), coupled with the recent recognition of fatal nevirapine hepatitis, has prompted a reexamination of the role this regimen should play in the prevention of vertical transmission (Department of Health and Human Services, 2010).

**Efavirenz**

**Chemistry and Antiviral Activity.** Efavirenz is a 1,4-dihydro-2H-3,1-benzoxazin-2-one NNRTI (Figure 59–4) with potent activity against HIV-1. The in vitro IC\(_{50}\) of this drug ranges from 3 to 9 nM (Sheran, 2005). Like other compounds in this class, efavirenz does not have significant activity against HIV-2 or other retroviruses.

**Mechanisms of Resistance.** The most common efavirenz resistance mutation seen clinically is at codon 103 of reverse transcriptase (K103N), and this decreases susceptibility up to ≥100-fold (Kuritzkes, 2004). Additional resistance mutations have been seen at codons 100, 106, 108, 181, 188, 190, and 225, but either the K103N or Y181C mutation is sufficient to produce clinical treatment failure. Cross-resistance extends to nevirapine and delavirdine.

**Absorption, Distribution, and Elimination.** Efavirenz is well absorbed from the GI tract and reaches peak plasma concentrations within 5 hours. There is diminished absorption of the drug with increasing doses. Bioavailability (AUC) is increased by 22% with a high-fat meal.

Efavirenz is >99% bound to plasma proteins and, as a consequence, has a low CSF-to-plasma ratio of 0.01. The clinical significance of this low CNS penetration is unclear, especially because the major toxicities of efavirenz involve the CNS. The drug should be taken initially on an empty stomach at bedtime to reduce side effects (Sheran, 2005).

Efavirenz is cleared via oxidative metabolism, mainly by CYP2B6 and to a lesser extent by CYP3A4. The parent drug is not excreted renally to a significant degree. Efavirenz is cleared slowly, with an elimination t\(_{1/2}\) of 40-55 hours at steady state. This safely allows once-daily dosing. Clearance is even slower in recipients with the 516G→T and 983C→T CYP2B6 genotype (Haas et al., 2009), a common polymorphism in those of Japanese and African ancestry.

**Untoward Effects.** The most important adverse effects of efavirenz involve the CNS. Up to 53% of patients report some CNS or psychiatric side effects, but <5% discontinue the drug for this reason. CNS symptoms may occur with the first dose and for hours; more severe symptoms may require weeks to resolve. Patients commonly report dizziness, impaired concentration, dysphoria, vivid or disturbing dreams, and insomnia. Episodes of frank psychosis (depression, hallucinations, and/or mania) have been associated with initiating efavirenz. Fortunately, CNS side effects generally become more tolerable and resolve within the first 4 weeks of therapy.

Rash occurs frequently with efavirenz, in up to 27% of adult patients (Sheran, 2005). Rash usually occurs within the first few weeks of treatment but resolves spontaneously and rarely requires drug discontinuation. Life-threatening skin eruptions such as Stevens-Johnson syndrome have been reported during postmarketing experience with efavirenz but are rare.

Other side effects reported with efavirenz include headache, increased hepatic transaminases, and elevated serum cholesterol. False-positive urine screening tests for marijuana metabolites also can occur depending on the assay used (Sheran, 2005).

Efavirenz is the only antiretroviral drug that is unequivocally teratogenic in primates. When efavirenz was administered to pregnant cynomolgus monkeys, 25% of fetuses developed malformations. In 13 known cases where women were exposed to efavirenz during the first trimester of pregnancy, fetuses or infants had significant malformations, mainly of the brain and spinal cord. **Women of childbearing potential therefore should use two methods of birth control and avoid pregnancy while taking efavirenz.**

**Precautions and Interactions.** Efavirenz is a moderate inducer of hepatic enzymes, especially CYP3A4, but also a weak to moderate CYP inhibitor; because of the drug’s long t\(_{1/2}\), there is no need to alter drug dose during the first few weeks of treatment.

Efavirenz decreases concentrations of phenobarbital, phenytoin, and carbamazepine; the methadone AUC is reduced by 33-66% at steady state. Rifampin concentrations are unchanged by concurrent efavirenz, but rifampin may reduce efavirenz concentrations slightly. Efavirenz reduces the rifabutin AUC by 38% on average. Efavirenz has a variable effect on HIV protease inhibitors. Indinavir, saquinavir, and amprenavir concentrations are reduced, but ritonavir and nelfinavir concentrations are increased. Drugs that induce CYPs 2B6 or 3A4 (e.g., phenobarbital, phenytoin, and carbamazepine) would be expected to increase the clearance of efavirenz and should be avoided (Sheran, 2005).

**Therapeutic Use.** Efavirenz (SUSTIVA) was the first antiretroviral agent approved by the FDA for once-daily administration. Initial short-term monotherapy studies showed substantial decreases in plasma HIV RNA, but the drug should only be used in combination with other effective agents and should not be added as the sole new agent to a failing regimen. Efavirenz has also been
effective in patients who have failed previous antiretroviral therapy not containing an NNRTI (Sheran, 2005).

Efavirenz is used widely in the developed world because of its convenience, effectiveness, and long-term tolerability. Especially popular is the once-daily pill co-formulation of efavirenz, tenofovir, and emtricitabine (ATRIPLA). To date, no antiretroviral regimen has produced better long-term treatment responses than efavirenz-containing regimens in randomized prospective clinical trials. As a result, efavirenz plus two nucleoside reverse transcriptase inhibitors remains a preferred regimen for treatment-naïve patients. Generic efavirenz is available at a lower cost than many other active antiretroviral.

Efavirenz is approved for adult and pediatric patients ≥3 years of age and weighing at least 10 kg. Efavirenz is only available as tablets and capsules; pediatric dosing is based on weight range.

Etravirine

Chemistry and Antiviral Activity. Etravirine is a diarylpyrimidine NNRTI that is active against HIV-1 (Figure 59–4). The IC₅₀ for HIV-1 in various in vitro assays ranges from 1 to 5 nM, but like other NNRTIs, etravirine has no activity against HIV-2 (Deeks and Keating, 2008).

Mechanisms of Action and Resistance. Etravirine is unique in its ability to inhibit reverse transcriptase that is resistant to other available NNRTIs. Specifically, activity of the drug is not affected by the K103N, Y181C, or Y188L mutations or the K103N/Y181C double mutations that confer high-level resistance to efavirenz, nevirapine, and delavirdine.

Etravirine appears to have conformational and positional flexibility in the NNRTI binding pocket that allow it to inhibit the function of the HIV-1 reverse transcriptase in the presence of common NNRTI resistance mutations (Deeks and Keating, 2008). Clinically significant drug resistance and treatment failure require the presence of multiple mutations, including V90I, A98G, L100I, K101E/P, V106I, V179D/F, Y181C/I/V, and G190A/S. Best response to an etravirine-containing regimen is seen in patients harboring three or fewer resistance mutations, although likelihood of virologic benefit decreases with each additional mutation. One limitation of etravirine resistance data is that most information comes from patients also receiving darunavir, and few resistance and response data are available for other regimens (Fulco and McNicholl, 2009).

Absorption, Distribution, and Elimination. Etravirine is absorbed rapidly after oral administration with peak concentrations occurring 2.5-4 hours after dosing. Food increases the etravirine AUC by 50% (Deeks and Keating, 2008), and it is therefore recommended that the drug be administered with food. Methyl- and dimethyl-hydroxylated metabolites are produced in the liver primarily by CYPs 3A4, 2C9, and 2C19, accounting for most of the elimination of this drug. No unchanged drug is detected in the urine. The terminal elimination t₁/₂ is ~41 hours; twice-daily dosing of this drug is the historical consequence of enormous pill burdens from older formulations that are no longer in use, and it is likely that the drug could be given once daily (Deeks and Keating, 2008). Etravirine is 99% bound to plasma proteins, mainly to albumin and α₁-acid glycoprotein.

Untoward Effects. In randomized placebo-controlled trials combining etravirine with darunavir in treatment-experienced patients, the only side effect occurring more commonly with etravirine than with placebo was rash (17% versus 9%), usually occurring within a few weeks of starting therapy and resolving within 1-3 weeks. Overall, 2% of patients in these trials discontinued etravirine because of rash. Severe rash including Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported. Etravirine was not associated with more neuropsychiatric or hepatic adverse effects than placebo (Deeks and Keating, 2008).

Precautions and Interactions. Etravirine is an inducer of CYP3A4 and glucuronosyl transferases, and an inhibitor of CYPs 2C9 and 2C19, and can therefore be involved in a number of clinically significant pharmacokinetic drug interactions.

Etravirine can be combined with darunavir/ritonavir, lopinavir/ritonavir, and saquinavir/ritonavir without the need for dose adjustments. The dose of maraviroc should be doubled to 600 mg twice daily when these two drugs are combined. Etravirine should not be administered with tipranavir/ritonavir, fosamprenavir/ritonavir, or atazanavir/ritonavir in the absence of better data to guide dosing. Etravirine should not be combined with efavirenz, nevirapine, or delavirdine. Unlike other NNRTIs, etravirine does not appear to alter the clearance of methadone (Fulco and McNicholl, 2009).

Therapeutic Use. Etravirine (INTELENCE) is approved for use only in treatment-experienced HIV-infected adults. NNRTI-experienced patients should not receive etravirine plus NRTIs alone. Etravirine has not yet been approved for pediatric use.

In a pooled analysis of >1200 treatment-experienced patients taking darunavir/ritonavir, 61% of patients randomized to etravirine achieved a plasma HIV RNA <50 copies/mL at 48 weeks compared to 40% on placebo (p < 0.0001). Etravirine-treated patients also had a moderately better mean CD4 cell count increase at week 48 (98 vs. 73 cells/mm³). Week 48 virologic responses were dependent on the number of baseline etravirine-resistance mutations, with a differential versus placebo of 75% versus 44% if no mutations were present, falling to 25% versus 17% if four or more were present (Fulco and McNicholl, 2009). In small studies, virologic response with etravirine was poor unless the regimen contained at least one other active antiretroviral.

Delavirdine

Delavirdine is a bisbeteroarylpiperazine NNRTI that selectively inhibits HIV-1 (Figure 59–4). The in vitro IC₅₀ ranges from 6 to 30 nM for laboratory HIV-1 isolates to 1 to 700 nM for clinical isolates (Scott and Perry, 2000). Delavirdine (RESCRIPTOR) is no longer used widely because of its short t₁/₂ and requirement for thrice-daily dosing.

Delavirdine does not have significant activity against HIV-2 or other retroviruses. Delavirdine shares resistance mutations with
efavirenz and nevirapine, and any patient who fails treatment with this NNRTI should not be treated with those drugs.

Delavirdine is well absorbed, especially at pH<2. Antacids, histamine H₂-receptor antagonists, proton pump inhibitors, and achlorhydra may decrease its absorption. Standard meals do not alter the delavirdine AUC, and the drug can be administered irrespective of food. The drug may have nonlinear pharmacokinetics because the plasma t₁/₂ increases with increasing doses (Scott and Perry, 2000). Delavirdine clearance is primarily through oxidative metabolism by CYP3A4, with <5% of a dose recovered unchanged in the urine. At the recommended dose of 400 mg three times daily, the mean elimination t₁/₂ is 5.8 hours (range: 2-11 hours because of the considerable interpatient variability in clearance).

As with all drugs in this class, the most common side effect of delavirdine is rash, which occurs in 18-36% of subjects. Rash usually is seen in the first few weeks of treatment and often resolves despite continued therapy. Severe dermatitis, including erythema multiforme and Stevens-Johnson syndrome, has been reported but is rare. Elevated hepatic transaminases and hepatic failure also have been reported. Neutropenia also may occur rarely (Scott and Perry, 2000).

Delavirdine is both a substrate for and an inhibitor of CYP3A4 and can alter the metabolism of other CYP3A4 substrates. Potent inducers of CYP3A4, such as carbamazepine, phenobarbital, phenytoin, rifabutin, and rifampin, may decrease delavirdine concentrations and should be avoided. Delavirdine increases the plasma concentrations of most HIV protease inhibitors (Scott and Perry, 2000).

Initial monotherapy studies with delavirdine produced only transient decreases in plasma HIV RNA concentrations owing to rapid emergence of resistance. Later studies of delavirdine in combination with nucleoside analogs showed sustained decreases in HIV-1 RNA.

**HIV PROTEASE INHIBITORS**

HIV protease inhibitors are peptide-like chemicals that competitively inhibit the action of the virus aspartyl protease (Figure 59–5). This protease is a homodimer consisting of two 99-amino acid monomers; each monomer contributes an aspartic acid residue that is essential for catalysis (Flexner, 1998). The preferred cleavage site for this enzyme is the N-terminal side of proline residues, especially between phenylalanine and proline. Human aspartyl proteases (i.e., renin, pepsin, gastricsin, and cathepsins D and E) contain only one polypeptide chain and are not significantly inhibited by HIV protease inhibitors.

These drugs prevent proteolytic cleavage of HIV gag and pol precursor polypeptides that include essential structural (p17, p24, p9, and p7) and enzymatic (reverse transcriptase, protease, and integrase) components of the virus. This prevents the metamorphosis of HIV virus particles into their mature infectious form (Flexner, 1998). Infected patients treated with HIV protease inhibitors as sole agents experienced a 100- to 1000-fold mean decrease in plasma HIV RNA concentrations within 12 weeks, an effect similar in magnitude to that produced by NNRTIs (Ho et al., 1995).

The pharmacokinetic properties of HIV protease inhibitors are characterized by high interindividual variability, which may reflect differential activity of intestinal and hepatic CYPs (Flexner, 1998). Clearance is mainly through hepatic oxidative metabolism. All except nelfinavir are metabolized predominantly by CYP3A4 (and nelfinavir’s major metabolite is cleared by CYP3A4). Elimination half-lives of the HIV protease inhibitors range from 1.8 to 10 hours (Table 59–4), and most of these drugs can be dosed once or twice daily. Most HIV protease inhibitors are highly protein bound in plasma, and adding plasma proteins will increase their in vitro IC₅₀ (Molla et al., 1998). Fractional penetration into the CSF is also low for most of these agents, although the clinical significance is unknown.

An important toxicity common to all approved HIV protease inhibitors is the potential for metabolic drug interactions. Most of these drugs inhibit CYP3A4 at clinically achieved concentrations, although the magnitude of inhibition varies greatly, with ritonavir by far the most potent (Piscitelli and Gallicano, 2001). It is now a common practice to combine HIV protease inhibitors with a low dose of ritonavir to take advantage of that drug’s remarkable capacity to inhibit CYP3A4 metabolism (Flexner, 2000).

Although the approved dose of ritonavir for antiretroviral treatment is 600 mg twice daily, doses of 100 or 200 mg once or twice daily are sufficient to inhibit CYP3A4 and increase (“boost”) the concentrations of most concurrently administered CYP3A4 substrates. Lower doses of ritonavir are much better tolerated. The enhanced pharmacokinetic profile of HIV protease inhibitors administered with ritonavir reflects inhibition of both first-pass and systemic clearance, resulting in improved oral bioavailability and a longer elimination t₁/₂ of the co-administered drug. This allows a reduction in both drug dose and dosing frequency while increasing systemic concentrations (Flexner, 2000). Combinations of darunavir, lopinavir, fosamprenavir, and atazanavir with ritonavir are approved for once-daily administration.

Most HIV protease inhibitors are substrates for the P-glycoprotein efflux pump (P-gp) (Chapter 5).

P-gp in capillary endothelial cells of the blood-brain barrier limits the penetration of HIV protease inhibitors into the brain (Kim et al., 1998), although the low CSF-to-plasma drug concentration ratio characteristic of these drugs also may reflect extensive binding to plasma proteins. Most HIV protease inhibitors penetrate less well into semen than do nucleoside reverse transcriptase inhibitors and NNRTIs. Virologic responses in plasma, CSF, and semen usually are concordant (Taylor et al., 1999), and the clinical significance of P-gp and protein-binding effects is unclear.
Figure 59–5. Mechanism of action of an HIV protease inhibitor. Shown here is a phenylalanine-proline target peptide sequence (in blue) for the protease enzyme (in golden brown) with chemical structures of the native amino acids (in lower box) to emphasize homology of their structures to that of saquinavir (at top).

**Abbreviations:** AUC area under plasma concentration–time curve; t<sub>1/2</sub> half-life of elimination; ↑, increase; ↓, decrease; ↔, no effect; CYP, cytochrome P450; ND, not determined; +, weak; ++, moderate; ++++, substantial. *Reported mean values in adults with normal renal and hepatic function. **Parameters reported for the saquinavir soft-gel capsule formulation. *Values for lopinavir, tipranavir, and darunavir reflect coadministration with ritonavir.
GI side effects including nausea, vomiting, and diarrhea are common, although symptoms generally resolve within 4 weeks of starting treatment.

The speed with which HIV develops resistance to unboosted protease inhibitors is intermediate between that of nucleoside analogs and NNRTIs. In initial monotherapy studies, the median time to rebound in HIV plasma RNA concentrations of one log or greater was 3-4 months (Flexner, 1998). In contrast to NNRTIs, high-level resistance to these drugs generally requires accumulation of a minimum of four to five codon substitutions, which may take many months.

Initial (primary) resistance mutations in the enzymatic active site confer only a 3- to 5-fold drop in sensitivity to most drugs; these are followed by secondary mutations often distant from the active site that compensate for the reduction in proteolytic efficiency. Accumulation of secondary resistance mutations increases the likelihood of cross-resistance to other PIs (Flexner, 1998; Kuritzkes, 2004). Patients failing boosted PI-based combination regimens are more likely to have resistance mutations to the other drugs in the regimen, especially NRTIs (Kuritzkes, 2004), suggesting a high genetic barrier to resistance.

With potent activity and favorable resistance profiles, these drugs are a common component of regimens for treatment-experienced patients. However, the virologic benefits of these drugs must be balanced against short- and long-term toxicities, including the risk of insulin resistance and lipodystrophy (Garg, 2004). Improvements in pill burden, convenience, and tolerability have greatly improved adherence to drugs in this class (Gardner et al., 2009).

**Saquinavir**

**Chemistry and Antiviral Activity.** Saquinavir, the first approved HIV protease inhibitor, is a peptidomimetic hydroxyethylamine (Figure 59–6). It is a transition-state analog of a phenylalanine-proline cleavage site in one of the native substrate sequences for the HIV aspartyl protease and was the product of a rational drug-design program (Roberts et al., 1990). Saquinavir inhibits both HIV-1 and HIV-2 replication and has an in vitro IC\textsubscript{50} in peripheral blood lymphocytes that ranges from 3.5 to 10 nM (Noble and Faulds, 1996).

**Mechanisms of Resistance.** As is typical of HIV protease inhibitors, high-level resistance requires accumulation of multiple resistance mutations.

The primary saquinavir resistance mutation occurs at HIV protease codon 90 (a leucine-to-methionine substitution), although primary resistance also has been reported with a glycine-to-valine substitution at codon 48. Secondary resistance mutations occur at codons 36, 46, 82, 84, and others, and these are associated with clinical saquinavir resistance as well as cross-resistance to most other HIV protease inhibitors (Noble and Faulds, 1996).

**Absorption, Distribution, and Elimination.** Fractional oral bioavailability is low (~4%) owing mainly to extensive first-pass metabolism (Flexner, 1998), and so this drug should always be given in combination with ritonavir. Low doses of ritonavir increase the saquinavir steady-state AUC by 20- to 30-fold (Flexner, 2000), allowing administration once or twice daily.

Substances that inhibit intestinal but not hepatic CYP3A4, such as grapefruit juice, increase the saquinavir AUC by 3-fold at most (Flexner, 2000). Saquinavir is metabolized primarily by intestinal and hepatic CYP3A4 (Fitzsimmons and Collins, 1997); its metabolites are not known to be active against HIV-1. The parent drug and its metabolites are eliminated through the biliary system and feces (>95% of drug), with minimal urinary excretion (<3%).

**Untoward Effects.** The most frequent side effects of saquinavir are GI: nausea, vomiting, diarrhea, and abdominal discomfort. Most side effects of saquinavir are mild and short lived, although long-term use is associated with lipodystrophy.

**Precautions and Interactions.** Saquinavir clearance is increased with CYP3A4 induction; thus, co-administration of inducers of CYP3A4 such as rifampin, phenytoin, or carbamazepine lowers saquinavir concentrations and should be avoided (Flexner, 1998). The effect of nevirapine or efavirenz on saquinavir may be partially or completely reversed with ritonavir. Most drug interactions seen with saquinavir/ritonavir reflect the effect of the boosting agent.

**Therapeutic Use.** Saquinavir is available as a hard-gelatin capsule (INVIRASE). In initial clinical trials, unboosted saquinavir at the approved dose (600 mg three times daily) produced only modest virologic benefit because of its poor oral bioavailability. When combined with ritonavir and nucleoside analogs, saquinavir produces viral load reductions comparable with those of other HIV protease inhibitor regimens (Flexner, 2000). Saquinavir is no longer widely prescribed in the developed world because of its relatively high pill burden, but the drug remains popular as a generic combined with ritonavir in resource-limited settings because of its favorable toxicity and efficacy profile.

**Ritonavir**

**Chemistry and Antiviral Activity.** Ritonavir is a peptidomimetic HIV protease inhibitor designed to complement the C\textsubscript{2} axis of symmetry of the enzyme active site (Flexner, 1998) (Figure 59–5). Ritonavir is active against both HIV-1 and HIV-2, although it may be slightly less active against the latter. Its IC\textsubscript{50} for wild-type HIV-1 variants in the absence of human serum ranges from 4 to 150 nM.

**Mechanisms of Resistance.** Ritonavir is mostly used as a pharmacokinetic enhancer (CYP 3A4 inhibitor), and
Figure 59–6. Structure of available HIV protease inhibitors.
the low doses used for this purpose are not known to induce ritonavir resistance mutations.

The primary ritonavir resistance mutation is usually at protease codon 82 (several possible substitutions for valine) or codon 84 (isoleucine-to-valine substitution). Additional mutations associated with increasing resistance occur at codons 20, 32, 46, 54, 63, 71, 84, and 90. High-level resistance requires accumulation of multiple mutations.

Absorption, Distribution, and Elimination. Absorption of ritonavir is rapid and is only slightly affected by food, depending on the formulation. The overall absorption of ritonavir from the capsule formulation increases by 13% when the capsule is taken with meals, but the bioavailability of the oral solution decreases by 7% (Flexner, 1998). A heat-stable 100-mg tablet formulation is now available. Interindividual variability in pharmacokinetics is high, with a variability exceeding 6-fold in trough concentrations among patients given 600 mg ritonavir every 12 hours as capsules (Hsu et al., 1998).

Ritonavir is metabolized primarily by CYP3A4 and to a lesser extent by CYP2D6. Ritonavir and its metabolites are mainly eliminated in feces (86% of parent drug and metabolites), with only 3% of drug eliminated unchanged in the urine. Ritonavir induces its own metabolism; steady-state concentrations are reached within 2 weeks. Ritonavir is 98-99% bound to plasma proteins, mainly to α1-acid glycoprotein. Physiological concentrations of α1-acid glycoprotein increase the in vitro IC50 by a factor of 10, whereas albumin increases the IC50 by a factor of 4 (Molla et al., 1998).

Untoward Effects. The major side effects of ritonavir are GI and include dose-dependent nausea, vomiting, diarrhea, anorexia, abdominal pain, and taste perversion. GI toxicity may be reduced if the drug is taken with meals. Peripheral and perioral paresthesias can occur at the therapeutic dose of 600 mg twice daily. These side effects generally abate within a few weeks of starting therapy. Ritonavir also causes dose-dependent elevations in serum total cholesterol and triglycerides, as well as other signs of lipodystrophy, and it could increase the long-term risk of atherosclerosis in some patients.

Precautions and Interactions. Ritonavir is one of the most potent known inhibitors of CYP3A4, markedly increasing the plasma concentrations and prolonging the elimination of many drugs. Ritonavir should be used with caution in combination with any CYP3A4 substrate and should not be combined with drugs that have a narrow therapeutic index such as midazolam, triazolam, fentanyl, and ergot derivatives (Flexner, 1998). Ritonavir is a mixed competitive and irreversible inhibitor of CYP 3A4 and its effects can persist for 2-3 days after the drug is discontinued (Washington et al., 2003). Ritonavir is also a weak inhibitor of CYP2D6. Potent inducers of CYP3A4 activity such as rifampin may lower ritonavir concentrations and should be avoided or dosage adjustments considered. The capsule and solution formulations of ritonavir contain alcohol and should not be administered with disulfiram or metronidazole (Chapter 23).

Ritonavir is also a moderate inducer of CYP3A4, glucuronosyl S-transferase, and possibly other hepatic enzymes and drug transport proteins. The concentrations of some drugs therefore will be decreased in the presence of ritonavir. Ritonavir reduces the ethinyl estradiol AUC by 40%, and alternative forms of contraception should be used (Piscitelli and Gallicano, 2001).

Therapeutic Use. Among patients with susceptible strains of HIV-1, ritonavir (NORVIR) as a sole agent lowered plasma HIV-1 RNA concentrations by 100- to 1000-fold (Ho et al., 1995). In a trial in patients with advanced HIV disease, the addition of ritonavir to current therapy reduced HIV-related mortality and disease progression by ~50% over a median of 6 months of follow-up (Flexner, 1998). Ritonavir is used infrequently as the sole protease inhibitor in combination regimens because of GI toxicity. However, numerous clinical trials have shown benefit of ritonavir as a pharmacokinetic enhancer in various dual protease inhibitor combinations (Flexner, 2000).

Use of Ritonavir as a CYP3A4 Inhibitor. Ritonavir inhibits the metabolism of all current HIV protease inhibitors and is frequently used in combination with most of these drugs, with the exception of nelfinavir, to enhance their pharmacokinetic profile and allow a reduction in dose and dosing frequency of the co-administered drug (Flexner, 2000). Ritonavir also overcomes the deleterious effect of food on indinavir bioavailability. Under most circumstances, low doses of ritonavir (100 or 200 mg once or twice daily) are just as effective at inhibiting CYP3A4 and are much better tolerated than the 600 mg twice-daily treatment dose.

**Fosamprenavir**

**Chemistry and Antiviral Activity.** Fosamprenavir is a phosphonoxy prodrug of amprenavir that has the advantage of greatly increased water solubility and improved oral bioavailability (Arvieux and Tribut, 2005). This allowed reduction in the pill burden from 16 capsules to 4 tablets per day. Fosamprenavir is as effective, more convenient, and generally better tolerated than amprenavir, and as a result, amprenavir is no longer marketed.

Amprenavir is an N,N-disubstituted (hydroxyethyl) amino sulfonamide nonpeptide HIV protease inhibitor. Although developed using a sophisticated structure-based drug-design program, the same compound was identified previously using a more traditional high-throughput screen of an available chemical library (Werth, 1994). Amprenavir contains a sulfonamide moiety, which may play a role in its dermatologic side effects. The drug is active against both HIV-1 and HIV-2, with an IC50 for wild-type HIV-1 of ~80 nM.

**Mechanisms of Resistance.** Amprenavir’s primary resistance mutation occurs at HIV protease codon 50; this isoleucine-to-valine substitution confers only 2-fold decreased susceptibility in vitro. Primary resistance
occurs less frequently at codon 84. Secondary resistance mutations occur at codons 10, 32, 46, 47, 54, 73, and 90, which greatly increase resistance and cross-resistance (Arvieux and Tribut, 2005).

Absorption, Distribution, and Elimination. Fosamprenavir is dephosphorylated rapidly to amprenavir in the intestinal mucosa. The phosphorylated prodrug is ~2000 times more water soluble than amprenavir. Meals have no significant effect on fosamprenavir pharmacokinetics (Arvieux and Tribut, 2005). Amprenavir is 90% bound to plasma proteins, mostly α1-acid glycoprotein. This binding is relatively weak, and physiological concentrations of α1-acid glycoprotein increase the in vitro IC50 only 3- to 5-fold. Amprenavir clearance is mainly by hepatic CYP3A4, and excretion is by the biliary route. Amprenavir is a moderate inhibitor and inducer of CYP3A4. Ritonavir increases amprenavir concentrations by inhibiting CYP3A4, allowing lower fosamprenavir doses. The daily fosamprenavir dose may be reduced from 1400 mg twice daily to 1400 mg plus 200 mg ritonavir when given once daily, or 700 mg (one tablet) plus 100 mg ritonavir twice daily.

Untoward Effects. The most common adverse effects associated with fosamprenavir are GI and include diarrhea, nausea, and vomiting. Hyperglycemia, fatigue, paresthesias, and headache also have been reported. Fosamprenavir can produce skin eruptions; moderate to severe rash is reported in up to 8% of recipients, and onset is usually within 2 weeks of starting therapy (Arvieux and Tribut, 2005). Fosamprenavir has fewer effects on plasma lipid profiles than lopinavir-based regimens.

Precautions and Interactions. Inducers of hepatic CYP3A4 activity (e.g., rifampin and efavirenz) may lower plasma amprenavir concentrations. Because amprenavir is both a CYP3A4 inhibitor and inducer, pharmacokinetic drug interactions can occur and may be unpredictable. For example, atorvastatin, ketoconazole, and rifabutin decrease amprenavir concentrations. Many drugs have genetic resistance to the other drugs in the regimen (Oldfield and Plosker, 2006). For treatment-experienced patients, accumulation of four or more HIV protease inhibitor resistance mutations is associated with a reduced likelihood of virus suppression after starting fosamprenavir (Kuritzkes, 2004).

Therapeutic Use. Clinical trials have demonstrated long-term virologic benefit in treatment-naive and treatment-experienced patients receiving fosamprenavir (LEXIVA) with or without ritonavir, in combination with nucleoside analogs (Arvieux and Tribut, 2005).

Twice-daily fosamprenavir/ritonavir produces virologic outcomes equivalent to lopinavir/ritonavir in both treatment-naive and treatment-experienced patients (Arvieux and Tribut, 2005). However, once-daily fosamprenavir/ritonavir is inferior to lopinavir/ritonavir in protease-inhibitor experienced patients, and the drug should only be given twice daily in this patient population. Fosamprenavir is approved for use in treatment-naive pediatric patients ≥2 years of age and treatment-experienced patients ≥6 years of age, at a dose of 30 mg/kg twice daily or 18 mg/kg plus ritonavir 3 mg/kg twice daily.

Lopinavir

Chemistry and Antiviral Activity. Lopinavir is a peptidomimetic HIV protease inhibitor that is structurally similar to ritonavir (Figure 59–6) but is 3- to 10-fold more potent against HIV-1 in vitro. Lopinavir is active against both HIV-1 and HIV-2; its IC50 for wild-type HIV variants in the presence of 50% human serum ranges from 65 to 290 nM. Lopinavir is available only in co-formulation with low doses of ritonavir (KALETRA), which is used to inhibit CYP3A4 metabolism and increase concentrations of lopinavir (Oldfield and Plosker, 2006).

Mechanisms of Action and Resistance. Treatment-naive patients who fail a first regimen containing lopinavir generally do not have HIV protease mutations but may have genetic resistance to the other drugs in the regimen (Oldfield and Plosker, 2006). For treatment-experienced patients, accumulation of four or more HIV protease inhibitor resistance mutations is associated with a reduced likelihood of virus suppression after starting lopinavir (Kuritzkes, 2004).

Mutations most likely to be associated with resistance include I47A/V, V32I, and L76V. Additional mutations associated with lopinavir failure in treatment-experienced patients include those at HIV protease codons 10, 20, 24, 33, 46, 50, 53, 54, 63, 71, 73, 82, 84, and 90 (Oldfield and Plosker, 2006). There is no evidence that exposure to the low doses of ritonavir in the lopinavir/ritonavir co-formulation selects for ritonavir-specific resistance mutations.

Absorption, Distribution, and Elimination. Lopinavir is absorbed rapidly after oral administration. Food has a minimal effect on bioavailability of lopinavir/ritonavir tablets, and the drug can be taken with or without food. Although the tablets contain lopinavir/ritonavir in a fixed 4:1 ratio, the observed plasma concentration ratio for these two drugs following oral administration is nearly 20:1, reflecting the sensitivity of lopinavir to the inhibitory effect of ritonavir on CYP3A4. Lopinavir undergoes extensive hepatic oxidative metabolism by CYP3A4. Approximately 90% of total drug in plasma is the parent compound, and <3% of a dose is eliminated unchanged in the urine. Both lopinavir and ritonavir are highly bound to plasma proteins, mainly to α1-acid glycoprotein, and have a low fractional penetration into CSF and semen.

When administered orally without ritonavir, lopinavir plasma concentrations were exceedingly low mainly owing to first-pass metabolism. Both the first-pass metabolism and systemic clearance of lopinavir are very sensitive to inhibition by ritonavir.

A single 50-mg dose of ritonavir increased the lopinavir AUC by 77-fold compared with 400 mg lopinavir alone; 100 mg ritonavir increased the lopinavir AUC by 155-fold. Lopinavir trough concentrations were increased 50- to 100-fold by co-administration of low doses of ritonavir (Oldfield and Plosker, 2006). Multiple-dose pharmacokinetic studies have not been conducted with lopinavir in the absence of ritonavir. Adding 100 mg ritonavir twice daily to the lopinavir/ritonavir co-formulation (a total of 200 mg twice daily of ritonavir) has only a modest further effect on lopinavir concentrations, increasing the mean steady-state AUC by 46%.

Untoward Effects. The most common adverse events reported with the lopinavir/ritonavir co-formulation have been GI: loose stools,
diarrhea, nausea, and vomiting. These are less frequent and less severe than those reported with the 600 mg twice-daily standard dose of ritonavir but more common compared to those of boosted atazanavir and darunavir. The most common laboratory abnormalities include elevated total cholesterol and triglycerides. Because the same adverse effects occur with ritonavir, it is unclear whether these side effects are due to ritonavir, lopinavir, or both.

Precautions and Interactions. Because lopinavir metabolism is highly dependent on CYP3A4, concomitant administration of agents that induce CYP3A4, such as rifampin, may lower plasma lopinavir concentrations considerably. St. John’s wort is a known inducer of CYP3A4, leading to lower concentrations of lopinavir and possible loss of antiviral effectiveness. Co-administration of other antiretrovirals that can induce CYP3A4, including amprenavir, nevirapine or efavirenz, may require increasing the dose of lopinavir (Oldfield and Plosker, 2006).

Although lopinavir is a weak inhibitor of CYP3A4 in vitro, the ritonavir in the co-formulated capsule strongly inhibits CYP3A4 activity and probably dwarfs any lopinavir effect. The liquid formulation of lopinavir contains 42% ethanol and should not be administered with disulfiram or metronidazole (Chapter 23). Ritonavir is also a moderate CYP inducer at the dose employed in the co-formulation and can adversely decrease concentrations of some co-administered drugs (e.g., oral contraceptives). There is no direct proof that lopinavir is a CYP inducer in vivo; however, concentrations of some co-administered drugs (e.g., amprenavir and phenytoin) are lower with the lopinavir/ritonavir co-formulation than would have been expected with low-dose ritonavir alone (Oldfield and Plosker, 2006).

Therapeutic Use. In comparative clinical trials, lopinavir has antiretroviral activity at least comparable with that of other potent HIV protease inhibitors and better than that of nelfinavir. Lopinavir also has considerable and sustained antiretroviral activity in patients who failed previous HIV protease inhibitor–containing regimens.

In one study, 70 subjects who had failed therapy with one previous HIV protease inhibitor were treated for 2 weeks with lopinavir, followed by the addition of nevirapine. At 48 weeks, 60% of subjects had plasma HIV-1 RNA levels of <50 copies/mL despite substantial phenotypic resistance to other HIV protease inhibitors (Oldfield and Plosker, 2006). Because plasma concentrations of lopinavir generally are much higher than those required to suppress HIV replication in vitro, the drug may be capable of suppressing HIV isolates with low-level protease inhibitor resistance.

The adult lopinavir/ritonavir dose is 400/100 mg (two tablets) twice daily, or 800/200 mg (four tablets) once daily, with or without food. Lopinavir/ritonavir should not be dosed once daily in treatment-experienced patients. Lopinavir/ritonavir is approved for use in pediatric patients ≥14 days, with dosing based on either weight or body surface area. A pediatric tablet formulation is available for use in children >6 months of age.

Atazanavir

Chemistry and Antiviral Activity. Atazanavir is anaza-peptide protease inhibitor with a C₅-symmetrical chemical structure that is active against both HIV-1 and HIV-2 (Croom et al., 2009) (Figure 59–6). The IC₅₀ for HIV-1 in various in vitro assays ranges from 2 to 15 nM. In the presence of 40% human serum, the in vitro IC₅₀ is increased 3– to 4-fold (Croom et al., 2009).

Mechanisms of Resistance. The primary atazanavir resistance mutation occurs at HIV protease codon 50 and confers abut a 9-fold decreased susceptibility. This isoleucine-to-leucine substitution (I50L) is distinct from the isoleucine-to-valine substitution selected by fosamprenavir and darunavir.

This mutation was present in 100% of viruses isolated from patients failing therapy in one clinical trial (Croom et al., 2009). Isolates with only this mutation are still susceptible to inhibition by other protease inhibitors. Sensitivity to atazanavir is affected by various primary and secondary mutations that accumulate in patients who have failed other HIV protease inhibitors, with high-level resistance more likely if five or more additional mutations are present (Croom et al., 2009).

Absorption, Distribution, and Elimination. Atazanavir is absorbed rapidly after oral administration, with peak concentrations occurring ~2 hours after dosing. Atazanavir absorption is sensitive to food: a light meal increases the AUC by 70%, whereas a high-fat meal increases the AUC by 35% (Croom et al., 2009). It is therefore recommended that the drug be administered with food, which also decreases the interindividual variability in pharmacokinetics, unless given with ritonavir. Absorption is pH dependent, and proton pump inhibitors or other acid-reducing agents substantially reduce atazanavir concentrations after oral dosing; this effect is only partially reversed by concomitant ritonavir.

Atazanavir undergoes oxidative metabolism in the liver primarily by CYP3A4, which accounts for most of the elimination of this drug. Only 7% of the parent drug is excreted unchanged in the urine. The mean elimination t₁/₂ of atazanavir at the standard 400-mg once-daily dose is ~7 hours; however, the drug has nonlinear pharmacokinetics, and the t₁/₂ increases to nearly 10 hours at a dose of 600 mg (Croom et al., 2009). Atazanavir is 86% bound to plasma proteins, both to albumin and α₁-acid glycoprotein. It is present in CSF at <3% of plasma concentrations but has excellent penetration into seminal fluid (Croom et al., 2009).

Untoward Effects. Like indinavir, atazanavir frequently causes unconjugated hyperbilirubinemia, although this is mainly a cosmetic side effect and not associated with hepatotoxicity.

Approximately 40% of subjects receiving 400 mg atazanavir once daily in initial clinical trials developed a significant increase in total bilirubin (Croom et al., 2009), although only 5% developed jaundice. This is a consequence of inhibition of UDP-glucuronosyltransferase by atazanavir, and the side effect occurs more prominently in those who are genetically deficient in this enzyme, e.g., patients with Gilbert’s syndrome (Rotger et al., 2005). Postmarketing reports include hepatic adverse reactions of cholecystitis, cholelithiasis, cholestasis, and other hepatic function abnormalities.

Other side effects reported with atazanavir include diarrhea and nausea, mainly during the first few weeks of therapy. Overall,
6% of patients discontinued atazanavir because of side effects during 48 weeks of treatment. Patients treated with atazanavir in randomized clinical trials had significantly lower fasting triglyceride and cholesterol concentrations than patients treated with nelfinavir, lopinavir, or efavirenz (Croom et al., 2009), suggesting a reduced propensity to cause these side effects. In addition, atazanavir is not known to cause glucose intolerance or changes in insulin sensitivity.

Precautions and Interactions. Because atazanavir is metabolized by CYP3A4, concomitant administration of agents that induce this enzyme (e.g., rifampin) is contraindicated. Efavirenz 600 mg once daily reduced the unboosted atazanavir AUC by 74%. Atazanavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Atazanavir inhibits CYP3A4 less than ritonavir and does not appear to inhibit other CYP isozymes. Atazanavir is a moderate UGT 1A1 inhibitor, and when given with or without ritonavir increases the raltegravir AUC 41-72% and increases the raltegravir C_{12h} approximately 2-fold. Atazanavir is not known to induce hepatic drug-metabolizing enzymes.

Ritonavir significantly increases the atazanavir AUC and reduces atazanavir systemic clearance. Ritonavir 100 mg once daily increases the atazanavir 300 mg once-daily steady-state AUC by 2.5-fold and increases the C_{min} 6.5-fold (Croom et al., 2009). Low-dose ritonavir also counters the effect of some inducers, for example efavirenz, on the atazanavir AUC.

Proton pump inhibitors reduce atazanavir concentrations substantially with concomitant administration. These drugs and H₂ blockers should be avoided in patients receiving atazanavir without ritonavir.

Therapeutic Use. In treatment-experienced patients, atazanavir (REYATAZ) 400 mg once daily without ritonavir was inferior to the lopinavir/ritonavir co-formulation given twice daily; 81% of lopinavir/ritonavir-treated patients had plasma HIV RNA concentrations <400 copies/mL at week 24 compared with 61% of atazanavir-treated patients. The combination of atazanavir and low-dose ritonavir had a similar viral-load effect as the lopinavir/ritonavir co-formulation in one study (Croom et al., 2009), suggesting that this drug should be combined with ritonavir in treatment-experienced patients—and perhaps in treatment-naïve patients with high baseline viral load—in order to take advantage of the enhanced pharmacokinetic profile.

In addition to its use for treatment-naïve and experienced adults, atazanavir, in combination with ritonavir, is approved for treatment of pediatric patients >6 years of age, with dosing based on weight.

Darunavir
Chemistry and Antiviral Activity. Darunavir is a non-peptidic protease inhibitor that is active against both HIV-1 and HIV-2 (Figure 59–6). The IC_{50} for HIV-1 in various in vitro assays ranges from 1 to 5 nM, although human serum and α₁-acid glycoprotein increase the IC_{50} by 20-fold (McKeage et al., 2009).

Mechanisms of Action and Resistance. Darunavir binds tightly but reversibly to the active site of HIV protease but has also been shown to prevent protease dimerization.

Clinically significant drug resistance requires accumulation of multiple primary mutations. At least three darunavir-associated resistance mutations are required to confer resistance, and the most commonly seen are V32I, L33F, I47V, I54L and L89V (McKeage et al., 2009). Pretreatment resistance to darunavir is highly unlikely in treatment-naïve patients and occurs in <10% of protease inhibitor-experienced patients.

Absorption, Distribution, and Elimination. Darunavir is absorbed rapidly after oral administration with ritonavir, with peak concentrations occurring 2-4 hours after dosing. Ritonavir increases darunavir bioavailability and increases the darunavir AUC by up to 14-fold. The drug should be taken with food because food increases the darunavir AUC by 30% (McKeage et al., 2009).

Darunavir undergoes oxidative metabolism in the liver primarily by CYP3A4, accounting for most of the elimination of this drug. About 8% of the parent drug is excreted unchanged in the urine. When combined with ritonavir, the mean elimination t_{1/2} of darunavir is ~15 hours. In the presence of ritonavir 100 mg twice daily, the AUC after a 600-mg dose administered twice daily was increased 14-fold (McKeage et al., 2009). Darunavir is 95% bound to plasma proteins, mainly to α₁-acid glycoprotein.

Untoward Effects. Because darunavir must be combined with a low dose of ritonavir, drug administration can be accompanied by all of the side effects caused by ritonavir, including GI complaints in up to 20% of patients. Darunavir, like fosamprenavir, contains a sulfa moiety, and rash has been reported in up to 10% of recipients.

Overall, 3% of patients in randomized clinical trials discontinued darunavir because of side effects during 48 weeks of treatment, compared to 7% of patients treated with lopinavir/ritonavir. Darunavir/ritonavir is associated with increases in plasma triglycerides and cholesterol, although the magnitude of increase is lower than that seen with lopinavir/ritonavir (McKeage et al., 2009). Although causality is not firmly established, darunavir has been associated with episodes of hepatotoxicity.

Precautions and Interactions. Because darunavir is metabolized by CYP3A4, concomitant administration of agents that induce this enzyme (e.g., rifampin) is contraindicated. The drug interaction profile of darunavir/ritonavir is dominated by those expected with ritonavir.

Efavirenz 600 mg once daily reduced the darunavir AUC by 13% when combined with darunavir/ritonavir 300/100 mg twice daily. Darunavir/ritonavir 600/100 twice daily increased the maraviroc AUC by 344%, and the maraviroc dose should be reduced to 150 mg twice daily when combined with darunavir.

Therapeutic Use. Darunavir (PREZISTA) in combination with ritonavir is approved for use in HIV-infected adults.
In treatment-naive patients receiving tenofovir plus entecavir or lamivudine randomized to darunavir/ritonavir 800/100 mg once daily, virologic outcomes after 48 weeks were comparable to those seen with lopinavir/ritonavir 800/200 mg once daily (84% vs. 78%, respectively, achieved plasma HIV RNA <50 copies/mL). In protease inhibitor–experienced patients receiving an optimized background regimen and randomized to darunavir/ritonavir 600/100 mg twice daily, virologic outcomes after 48 weeks were better than those seen with lopinavir/ritonavir 400/100 mg twice daily (71% vs. 60%, respectively, achieving plasma HIV RNA <50 copies/mL) (McKeage et al., 2009).

Darunavir/ritonavir can be used as a once-daily (800/100 mg) or twice-daily (600/100 mg) regimen with nucleosides in treatment-naive adults and as a twice-daily regimen in treatment-experienced adults, taken with food. Darunavir/ritonavir twice daily is approved for use in pediatric patients >6 years of age, with dosing based on weight.

**Indinavir**

**Chemistry and Antiviral Activity.** Indinavir is a peptidomimetic hydroxyethylene HIV protease inhibitor (Figure 59–6) whose structure was based on a renin inhibitor with some similarity to the phenylalanine-proline cleavage site in the HIV gag polyprotein (Plosker and Noble, 1999), although indinavir is not itself a renin inhibitor. Indinavir is 10-fold more potent against the HIV-1 protease than that of HIV-2, and its 95% inhibitory concentration (IC50) for wild-type HIV-1 ranges from 25 to 100 nM.

**Mechanisms of Resistance.** The primary indinavir resistance mutations occur at HIV protease codons 46 (a methionine-to-isoleucine or leucine), 82, and 84. However, secondary resistance mutations can accumulate at codons 10, 20, 24, 46, 54, 63, 71, 82, 84, and 90, and these are associated with clinical indinavir resistance as well as cross-resistance to other HIV protease inhibitors (Plosker and Noble, 1999).

**Absorption, Distribution, and Elimination.** Indinavir is absorbed rapidly after oral administration, with peak concentrations achieved in ~1 hour. Unlike other drugs in this class, food can adversely affect indinavir bioavailability; a high-calorie, high-fat meal reduces plasma concentrations by 75% (Plosker and Noble, 1999). Therefore, indinavir must be taken with ritonavir or while fasting or with a light low-fat meal.

Indinavir has the lowest protein binding of the HIV protease inhibitors, with only 60% of drug bound to plasma proteins (Plosker and Noble, 1999). As a consequence, indinavir has higher fractional CSF penetration than other drugs in this class, although the clinical significance of this is unknown.

The short t1/2 of indinavir makes thrice-daily (every 8 hours) dosing necessary unless the drug is combined with ritonavir. Indinavir clearance is greatly reduced by low doses of ritonavir, which also overcome the deleterious effects of food on bioavailability (Flexner, 2000). This allows indinavir to be dosed twice daily regardless of meals.

**Untoward Effects.** A unique and common adverse effect of indinavir is crystalluria and nephrolithiasis. This stems from the poor solubility of the drug, which is lower at pH 7.4 than at pH 3.5 (Plosker and Noble, 1999). Precipitation of indinavir and its metabolites in urine can cause renal colic, and nephrolithiasis occurs in ~3% of patients. Patients must drink sufficient fluids to maintain dilute urine and prevent renal complications. Risk of nephrolithiasis is related to higher plasma drug concentrations, which presumably produce higher urine concentrations, regardless of whether or not the drug is combined with ritonavir (Dieleman et al., 1999).

Like atazanavir, indinavir frequently causes unconjugated hyperbilirubinemia, and 10% of patients develop an indirect serum bilirubin concentration >2.5 mg/dL (Plosker and Noble, 1999). This is generally asymptomatic and not associated with serious long-term sequelae. As with other HIV protease inhibitors, prolonged administration of indinavir is associated with the HIV lipodystrophy syndrome, especially fat accumulation. Indinavir has been associated with hyperglycemia and can induce a relative state of insulin resistance in healthy HIV-seronegative volunteers following a single 800-mg dose (Noor et al., 2002). Dermatologic complications have been reported, including hair loss, dry skin, dry and cracked lips, and ingrown toenails (Plosker and Noble, 1999).

**Precautions and Interactions.** Patients taking indinavir should drink at least 2 L of water daily to prevent renal complications. This is especially problematic for those who live in warm climates. Because indinavir solubility decreases at higher pH, antacids or other buffering agents should not be taken at the same time. Didanosine formulations containing an antacid buffer should not be taken within 2 hours before or 1 hour after indinavir. Like most other HIV protease inhibitors, indinavir is metabolized by CYP3A4 and is a moderately potent CYP3A4 inhibitor. Indinavir should not be co-administered with other CYP3A4 substrates that have a narrow therapeutic index. Drugs that induce CYP3A4 may lower indinavir concentrations and should be avoided.

**Therapeutic Use.** Indinavir (CRIXIVAN) is no longer widely prescribed because of problems with nephrolithiasis and other nephrotoxicities, and it lacks significant advantages over other available HIV protease inhibitors. When combined with ritonavir and nucleoside analogs, twice-daily indinavir produces viral load reductions comparable with those of other HIV protease inhibitor regimens (Flexner, 2000).

**Nelfinavir**

**Chemistry and Antiviral Activity.** Nelfinavir is a nonpeptidic hydroxyethylene HIV protease inhibitor that is active against both HIV-1 and HIV-2 (Bardsley-Elliot and Plosker, 2000) (Figure 59–6). The mean IC50 for HIV-1 in various in vitro assays is 59 nM.

**Mechanisms of Action and Resistance.** The primary nelfinavir resistance mutation is unique to this drug and occurs at HIV protease codon 30 (aspartic acid-to-asparagine substitution); this mutation results in a 7-fold decrease in susceptibility. Isolates with only this mutation retain full sensitivity to other HIV protease inhibitors (Bardsley-Elliot and Plosker, 2000). Less commonly, a primary resistance mutation occurs at position 90, which can confer cross-resistance. In addition, secondary resistance mutations can accumulate at codons 35, 36, 46, 71, 77, 88, and 90, and these are associated with further resistance to nelfinavir, as well as cross-resistance to other HIV protease inhibitors.

**Absorption, Distribution, and Elimination.** Nelfinavir absorption is very sensitive to food effects; a moderate-fat meal increases the AUC 2- to 3-fold, and higher concentrations are achieved with
high-fat meals (Bardsley-Elliot and Plosker, 2000). Intraindividual and interindividual variabilities in plasma nelfinavir concentrations are large as a consequence of variable absorption. Originally approved at a dose of 750 mg three times daily, nelfinavir is now administered at a dose of 1250 mg twice daily using a reduced-volume 625-mg tablet. Nelfinavir’s high dependence on fatty foods for optimal absorption, combined with the fact that nelfinavir is the only HIV protease inhibitor whose pharmacokinetics are not substantially improved with ritonavir, have reduced its popularity.

Nelfinavir undergoes oxidative metabolism primarily by CYP2C19 but also by CYP3A4 and CYP2D6. Its major hydroxy-t-butyramide metabolite, M8, is formed by CYP2C19 and has in vitro antiretroviral activity similar to that of the parent drug. This is the only known active metabolite of any HIV protease inhibitor. Nelfinavir induces its own metabolism, and average trough concentrations after 1 week of therapy are approximately one-half those at day 2 of therapy (Bardsley-Elliot and Plosker, 2000).

Untoward Effects. The most important side effect of nelfinavir is diarrhea or loose stools, which resolve in most patients within the first 4 weeks of therapy. Up to 20% of patients report chronic occasional diarrhea lasting >3 months, although <2% of patients discontinue the drug because of diarrhea. Nelfinavir augments intestinal calcium-dependent chloride channel secretory responses in vitro, and electrolyte analysis of stool is most consistent with a secretory diarrhea (Rufo et al., 2004). Otherwise, nelfinavir is generally well tolerated but has been associated with glucose intolerance, elevated cholesterol levels, and elevated triglycerides, like other drugs in this class.

Precautions and Interactions. Because nelfinavir is metabolized by CYPs 2C19 and 3A4, concomitant administration of agents that induce these enzymes may be contraindicated (as with rifampin) or may necessitate an increased nelfinavir dose (as with rifabutin). Nelfinavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Nelfinavir inhibits CYP3A4 much less than does ritonavir and does not appear to inhibit other CYP isofoms. Nelfinavir also induces hepatic drug-metabolizing enzymes, reducing the AUC of ethinyl estradiol by 47% and norethindrone by 18% (Flexner, 1998). Combination oral contraceptives therefore should not be used as the sole form of contraception in patients taking nelfinavir. Nelfinavir reduces the zidovudine AUC by 35%, suggesting induction of glucuronosyl S-transferase.

Therapeutic Use. Nelfinavir (Viracept) is approved for the treatment of HIV infection in adults and children in combination with other antiretroviral drugs. In large randomized comparative trials, long-term virologic suppression with nelfinavir-based combination regimens is statistically significantly inferior to lopinavir/ritonavir, atazanavir, or efavirenz-based regimens. This possibly reflects the unpredictable nature of nelfinavir absorption but contributes to the decreasing popularity of this drug. Nelfinavir is well tolerated in pregnant HIV-infected women and shows no evidence of teratogenicity (Bardsley-Elliot and Plosker, 2000) but detection of a potentially carcinogenic contaminant in 2007 led to a recommendation that the drug not be used pregnant women.

Tipranavir
Chemistry and Antiviral Activity. Tipranavir is a non-peptidic, dihydropyrimone protease inhibitor that is active against both HIV-1 and HIV-2 (Figure 59–6). The IC50 for HIV-1 in vitro ranges from 30 to 70 nM, although human plasma increases the IC50 by 4-fold (Orman and Perry, 2008).

Mechanisms of Action and Resistance. Tipranavir binding to the active site of the HIV protease depends less on water-mediated hydrogen bonding than other molecules in this class, which may explain, in part, its unique resistance profile. Clinically significant drug resistance requires accumulation of multiple mutations. The three mutations most commonly associated with treatment failure were L33F/I/V, V82T/L and I84V, although 21 mutations in 16 amino acids have been associated with reduced susceptibility to this drug. In general, tipranavir-resistant HIV retains sensitivity only to saquinavir and darunavir (Orman and Perry, 2008). Fewer than 3% of patients who have failed other protease inhibitors harbor virus with >10-fold resistance tipranavir. Because most HIV strains sensitive to tipranavir are also sensitive to darunavir, the latter drug is preferred for most treatment-experienced patients because of its better tolerability and toxicity profile.

Absorption, Distribution, and Elimination. Tipranavir must be administered with ritonavir because of poor oral bioavailability. The recommended regimen of tipranavir/ritonavir 500/200 mg twice daily includes a ritonavir dose higher than that of other boosted HIV protease inhibitors; lower doses of ritonavir should not be used. Food does not alter pharmacokinetics in the presence of ritonavir but may reduce GI side effects. Tipranavir is 99.9% bound in the presence of plasma proteins (Orman and Perry, 2008). Metabolism is mainly via CYP3A4; mean elimination t1/2 is 5-6 hours in the presence of ritonavir.

Untoward Effects. Tipranavir use has been associated with rare fatal hepatotoxicity. Through 48 weeks of treatment, grade 3 or 4 elevation of hepatic transaminases occurred in 20% of treatment-naive and 10% of treatment-experienced patients. Tipranavir use has been associated with rare intracranial hemorrhage (including fatalities) and bleeding episodes in patients with hemophilia. The drug has anticoagulant properties in vitro and in animal models, and these effects are potentiated by vitamin E (Flexner et al., 2005). Tipranavir is more likely to cause elevation in lipids and triglycerides than other boosted PIs, possibly due to the higher dose of ritonavir. Tipranavir contains a sulfa moiety, and ~10% of treated patients report a transient rash. The current formulation contains a high amount of vitamin E, and patients should not take supplements containing this fat-soluble vitamin while taking tipranavir (Orman and Perry, 2008).

Precautions and Interactions. Like ritonavir, tipranavir is a substrate, inhibitor, and inducer of CYP enzymes. In combination, these two agents produce a broad array of clinically significant pharmacokinetic drug interactions. Tipranavir/ritonavir reduces the concentrations (AUC) of all co-administered protease inhibitors by 44-76% and should not be administered with any of these agents (Orman and Perry, 2008). This reflects the combined effect of the increased ritonavir dose, as well as tipranavir’s unique capacity among PIs to induce expression of the P-glycoprotein drug transporter.

Therapeutic Use. Tipranavir (Aptivus) is approved for use only in treatment-experienced adult and pediatric patients whose HIV is resistant to one or more protease inhibitors. In nearly 1500 patients with at least one major PI resistance mutation randomized to
tipranavir/ritonavir or a comparator PI regimen, 34% had at least a one log sustained drop in plasma HIV RNA by week 48 compared to 15% of controls. However, 5.4% of tipranavir recipients discontinued treatment because of adverse events, compared to 1.6% of controls (Orman and Perry, 2008). Combining tipranavir with at least one other active antiretroviral drug, usually enfuvirtide, greatly improved virologic responses in these studies. Tipranavir/ritonavir is approved for use in adults and pediatric patients ≥2 years of age, with pediatric dosing based on weight or body surface area.

**ENTRY INHIBITORS**

There are two drugs available in this class, enfuvirtide and maraviroc, that have different mechanisms of action (Figure 59–1). Enfuvirtide inhibits fusion of the viral and cell membranes mediated by gp41 and CD4 interactions. Maraviroc is a chemokine receptor antagonist and binds to the host cell CCR5 receptor to block binding of viral gp120. As such, maraviroc is the only approved antiretroviral drug that targets a host protein. One other CCR5 receptor antagonist, vicriviroc, is in advanced clinical development.

CXCR4, the co-receptor for T-lymphocyte tropic HIV, would seem to be an equally good target for antiretroviral drug development. However, two investigational CXCR4 antagonists produced no substantial drop in plasma HIV RNA in most treated patients, even though they efficiently eliminated CXCR4-tropic virus from the circulation (Stone et al., 2007), suggesting that these drugs cause rapid selection for HIV that is CXCR5-tropic. Although these compounds are no longer in development for HIV infection, they do cause an increase in circulating leukocytes, presumably as a direct consequence of CXCR4 blockade. One of these compounds, plerixafor, is now approved as an adjunct to stem cell mobilization after cancer chemotherapy (Chapter 37).

**Maraviroc**

**Chemistry and Mechanisms of Action and Resistance.** Maraviroc blocks the binding of the HIV outer envelope protein gp120 to the CCR5 chemokine receptor (Figure 59–7). Maraviroc is active only against CCR5-tropic strains of HIV and has no activity against viruses that are CXCR4-tropic or dual-tropic. The reported *in vitro* IC₅₀ for CCR5-tropic HIV-1 ranges from 0.1 to 4.5 nM depending on the virus strain and testing method employed (MacArthur and Novak, 2008). Maraviroc retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through two distinct pathways. A patient starting maraviroc therapy with HIV that is predominantly CCR5-tropic may experience a shift in tropism to CXCR4- or dual/mixed-tropic predominance. This is especially likely in patients harboring low-level but undetected CXCR4- or dual/mixed-tropic virus prior to initiation of maraviroc. Alternatively, HIV can retain its CCR5-tropism but gain resistance to the drug through specific mutations in the V3 loop of gp120 that allow virus binding in the presence of inhibitor (MacArthur and Novak, 2008). This results in both an increase in IC₅₀ and a decrease in maximum percent inhibition of virus replication for such viruses *in vitro*.

**Absorption, Distribution, and Elimination.** The oral bioavailability of maraviroc, 23–33%, is dose dependent. Food decreases bioavailability (AUC) as much as 50%, but there are no food requirements for drug administration because clinical efficacy trials were conducted without food restrictions. Maraviroc is 76% protein bound in human plasma, with a volume of distribution of 194 L. Elimination is mainly via CYP3A4 with an elimination t½ of 10.6 hours (MacArthur and Novak, 2008).

**Untoward Effects.** Maraviroc is generally well tolerated, with little significant toxicity.

One case of serious hepatotoxicity with allergic features has been reported, but in controlled trials significant (grade 3 or 4) hepatotoxicity was no more frequent with maraviroc than with placebo. There is a theoretical concern that CCR5 inhibition might interfere with immune function; for example, humans with the Δ32 genetic deletion in CCR5 that prevents HIV-1 entry are also more likely to develop severe West Nile virus encephalopathy (MacArthur and Novak, 2008). However, to date there has been no obvious increase in serious infections or malignancies with maraviroc treatment.

**Precautions and Interactions.** Maraviroc is a CYP3A4 substrate and susceptible to pharmacokinetic drug interactions involving CYP3A4 inhibitors or inducers. Recommended dosing of this drug depends on concomitant medications. Maraviroc is not itself a CYP inhibitor or inducer *in vivo*, although high-dose maraviroc (600 mg daily) increased concentrations of the CYP2D6 substrate debrisoquine.

**Therapeutic Uses.** Maraviroc (SELZENTRY) is approved for use in HIV-infected adults who have baseline evidence of predominantly CCR5-tropic virus. Maraviroc is the only antiretroviral drug approved at three different starting doses, depending on concomitant medications. When combined with most CYP3A inhibitors, the starting dose is 150 mg twice daily; when combined with most CYP3A inducers, the starting dose is 600 mg twice daily; for other concomitant medications, the starting dose is 300 mg twice daily.

In phase 3 clinical trials involving heavily pretreated patients with documented multidrug-resistant HIV-1, the addition of maraviroc to optimized background therapy (OBT) resulted in an undetectable (<50 copies/mL) plasma HIV-1 RNA in 44% of patients after 24 weeks, compared to 17% with OBT alone; maraviroc-treated patients also had higher mean CD4 lymphocyte count increases (120 versus 61 cells/mL). A maraviroc-based regimen was inferior to an efavirenz-based regimen in one clinical trial in treatment-naïve patients (MacArthur and Novak, 2008). Maraviroc has little to no efficacy in patients harboring CXCR4- or dual/mixed-tropic virus at
baseline. In addition, the requirement for an expensive baseline phenotype test limits its cost effectiveness.

**Enfuvirtide**

**Chemistry and Antiviral Activity.** Enfuvirtide is a 36-amino-acid synthetic peptide whose sequence is derived from a part of the transmembrane gp41 region of HIV-1 that is involved in fusion of the virus membrane lipid bilayer with that of the host cell membrane. Enfuvirtide is not active against HIV-2 but has a broad range of potencies against HIV-1 laboratory and clinical isolates. The reported in vitro IC50 ranges from 0.1 nM to 1.7 μM depending on the HIV-1 strain and testing method employed (Dando and Perry, 2003).

Enfuvirtide was investigated originally as a possible vaccine component, in part because of a high degree of sequence conservation among HIV-1 strains. This peptide turned out to have potent anti-HIV activity in vitro, a property eventually attributed to selective inhibition of HIV-mediated membrane fusion (Jiang et al., 1993; Wild et al., 1994). Enfuvirtide is expensive to manufacture and must be administered by subcutaneous injection twice daily. Thus cost and route of administration limit its use to those with no other treatment options.

**Mechanisms of Action and Resistance.** Enfuvirtide has a unique mechanism of antiretroviral action. The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil. This prevents formation of a six-helix bundle critical for membrane fusion and viral entry into the host cell. Enfuvirtide inhibits infection of CD4+ cells by free virus particles, as well as cell-to-cell transmission of HIV in vitro. Enfuvirtide retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through specific mutations in the enfuvirtide-binding domain of gp41. Of the patients experiencing virologic failure during enfuvirtide treatment, 94% had virus with mutations in the gp41 region associated with enfuvirtide resistance in vitro. The most common mutations involve a V38A or N43D substitution. Single-amino-acid substitutions can confer up to 450-fold resistance in vitro, although high-level clinical resistance is usually associated with two or more amino acid changes (Dando and Perry, 2003).

**Absorption, Distribution, and Elimination.** Enfuvirtide is the only approved antiretroviral drug that must be administered parenterally. The bioavailability of subcutaneous enfuvirtide is 84% compared

**Figure 59–7. Mechanism of action of the HIV entry inhibitor maraviroc.**

1. gp 120 anchors HIV to target cell by binding to CD4.
2. CCR5 chemokine receptor binding stabilizes complex and allows gp41-mediated fusion of virus membrane with target cell membrane.
3. Maraviroc binds to CCR5, preventing gp120 binding, fusion, and entry.
with an intravenous dose (Dando and Perry, 2003). Pharmacokinetics of the subcutaneous drug are not affected by site of injection.

The major route of elimination for enfuvirtide has not been determined; only a deamidated metabolite at the C-terminal phenylalanine has been detected (Dando and Perry, 2003). The mean elimination t1/2 of parenteral drug is 3.8 hours, necessitating twice-daily administration. Enfuvirtide is 98% bound to plasma proteins, mainly albumin.

Untoward Effects. The most prominent adverse effects of enfuvirtide are injection-site reactions. About 98% of patients develop local side effects including pain, erythema, and induration at the site of injection; 80% of patients develop nodules or cysts (Dando and Perry, 2003). Between 4% and 5% of patients discontinue treatment because of local reactions. Use of enfuvirtide has been associated with a higher incidence of lymphadenopathy and pneumonia in at least one study. Whether these are direct drug effects, a secondary consequence of drug-related immune dysfunction, or effects from another mechanism is the subject of investigation. Enfuvirtide suppresses interleukin-12 production in vitro by >90% at concentrations equal to or less than those required to inhibit HIV replication (Braun et al., 2001); the role this might play in clinical immunosuppression is unclear.

Precautions and Interactions. Enfuvirtide is not metabolized to a significant extent and not known to alter the concentrations of any co-administered drugs. Ritonavir, rifampin, or ritonavir plus saquinavir did not alter enfuvirtide concentrations (Dando and Perry, 2003).

Therapeutic Use. Enfuvirtide (FUZEON) is FDA-approved for use only in treatment-experienced adults who have evidence of HIV replication despite ongoing antiretroviral therapy.

In phase 3 clinical trials involving heavily pretreated patients with documented multidrug-resistant HIV-1, inclusion of enfuvirtide (90 mg subcutaneously twice daily) in combination with an optimized background regimen enhanced the fraction of patients with undetectable (<50 copies/mL) plasma HIV-1 RNA concentrations after 24 weeks of treatment (~16% on enfuvirtide versus ~6% without) (Dando and Perry, 2003). Treatment response is more likely in patients with at least two other active drugs in the regimen, based on history and HIV genotype. Given the cost, inconvenience, and cutaneous toxicity of this drug, enfuvirtide generally is reserved for patients who have failed all other feasible antiretroviral regimens.

INTEGRASE INHIBITORS

Chromosomal integration is a defining characteristic of retrovirus life cycles and allows viral DNA to remain in the host cell nucleus for a prolonged period of inactivity or latency (Figure 59–1). Because human DNA is not known to undergo excision and reintegration, this is an excellent target for antiviral intervention. The first approved HIV integrase inhibitor, raltegravir, was licensed in 2007. It prevents the formation of covalent bonds between host and viral DNA—a process known as strand transfer—presumably by interfering with essential divalent cations in the enzyme’s catalytic core (Hicks and Gulick, 2009; Figure 59–8).

Raltegravir

Chemistry and Mechanism of Action. Raltegravir blocks the catalytic activity of the HIV-encoded integrase, thus preventing integration of virus DNA into the host chromosome (Figure 59–8).

Raltegravir has potent activity against both HIV-1 and HIV-2, with an in vitro IC95 range of 6-30 nM (Hicks and Gulick, 2009). Raltegravir retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

The two major raltegravir resistance pathways involve primary mutations Q184R/H/K, or N155H in the integrase gene. Either mutation can confer 25- to 50-fold changes in drug sensitivity in...
Absorption, Distribution, and Elimination. Peak concentrations of raltegravir occur ~1-3 hours after oral dosing. Elimination is biphasic, with a β-phase $t_{1/2}$ of ~1 hour and a terminal β-phase $t_{1/2}$ of 9 hours. The pharmacokinetics of raltegravir are highly variable. Moderate- and high-fat meals increased raltegravir apparent bioavailability (AUC) by as much as 2-fold; a low-fat meal decreased AUC modestly (46%). There are no food requirements for raltegravir administration because clinical efficacy trials were conducted without food restrictions and because initial antiviral effects were maximal at all concentrations produced with the 400 mg twice-daily dose in clinical studies. Raltegravir is 83% protein bound in human plasma. Raltegravir is eliminated mainly via glucuronidation by UGT1A1.

Untoward Effects. Raltegravir is generally well tolerated, with remarkably little clinical toxicity. In clinical trials, the most common complaints occurring at a frequency higher than in placebo recipients were headache, nausea, asthenia, and fatigue. Creatine kinase elevations, myopathy, and rhabdomyolysis have been reported, although a causal relationship to drug exposure is unproven. Exacerbation of depression has also been reported (Hicks and Gulick, 2009).

Precautions and Interactions. As a UGT1A1 substrate, raltegravir is susceptible to pharmacokinetic drug interactions involving inhibitors or inducers of this enzyme. Atazanavir, a moderate UGT1A1 inhibitor, increases the raltegravir AUC 41-72%. Tenofivir increased the raltegravir AUC by 49%, but the mechanism for this interaction is unknown. When raltegravir is combined with the CYP inducer rifampin, the raltegravir dose should be doubled to 800 mg twice daily, although no clinical data on this combination have been published. Raltegravir is not a significant enzyme inhibitor or inducer in vitro and has little effect on the pharmacokinetics of co-administered drugs.

Therapeutic Uses. Raltegravir (ISENTRESS) is approved for use in HIV-infected adults.

In phase 3 clinical trials involving heavily pretreated patients with documented multidrug-resistant HIV-1, the addition of raltegravir to optimized background therapy (OBT) resulted in an undetectable (<50 copies/mL) plasma HIV-1 RNA in 62% of patients after 48 weeks, compared to 33% with placebo (Hicks and Gulick, 2009). Response rates in this study ranged from 45-77%, depending on the number of additional active drugs in the regimen (0, 1, or 2). Raltegravir-treated patients also had higher mean CD4 lymphocyte count increases (109 versus 45 cells/mL).

Raltegravir has also been studied in treatment-naive patients and was recently approved for use in patients who have not taken prior antiretroviral therapy. In 10-day monotherapy studies, raltegravir decreased mean HIV-1 RNA by 1.7 log at a dose of 400 mg twice daily. In a prospective randomized comparison, raltegravir was as efficacious as efavirenz when combined with two nucleosides, with 83% and 84% of subjects, respectively, having undetectable HIV-1 RNA (<50 copies/mL) after 96 weeks of treatment. Raltegravir-treated subjects achieve an undetectable plasma HIV RNA faster than efavirenz-treated subjects, although the clinical significance of this effect is unknown (Hicks and Gulick, 2009).

CLINICAL SUMMARY

Although there has been great progress in the management of HIV and its complications, enormous challenges remain. Whereas a decade ago most treatment took place in developed countries, today most treated patients reside in resource-poor settings. In these locations, decision making is driven by availability of low-cost generic drugs. In addition, concurrent infections such as tuberculosis and hepatitis B virus are common and alter the choice of antiretroviral drugs. Potentially detrimental drug interactions and effects of traditional and herbal medicines are of increasing concern (Dooley et al., 2008). Although co-formulation of antiretroviral agents is a current trend intended to improve convenience and adherence, this can complicate management of those who require dose individualization, e.g., young children or those with hepatic or renal insufficiency.

Several expert panels issue periodic recommendations for use of antiretroviral drugs for treatment-naive and treatment-experienced adults and children. In the U.S., the Panel on Clinical Practices for Treatment of HIV Infection issues updated guidelines approximately every 6 months; their most recent guidelines can be accessed at http://www.aidsinfo.nih.gov/Guidelines (Department of Health and Human Services). These recommendations are based on a consensus assessment of the results of published clinical studies. Practitioners need to be aware that such documents are intended to provide general guidance rather than absolute recommendations and may need to be modified based on intercurrent disease, concurrent medications, and other circumstances. U.S. guidelines sometimes are contradicted by guidelines designed for use in other countries or specific patient populations; these differences may reflect different priorities assigned to drug costs, as well as the relative importance of long-term and short-term toxicities.

Current treatment recommendations center around making two important clinical decisions:

- When to start therapy in treatment-naive individuals
- When to change therapy in individuals who are failing their current regimen
In each of these settings, there is a complex algorithm of possible drug choices depending on patient and viral characteristics. The specific drugs recommended may change from year to year as new choices become available and clinical research data accumulate. Selection of drugs in the developed world will be driven by genotypic and phenotypic resistance testing. However, it is likely that future treatment guidelines will continue to be driven by three principles:

- Use of combination therapy to prevent the emergence of resistant virus;
- Emphasis on regimen convenience, tolerability, and adherence to chronically suppress HIV replication;
- Realization of the need for lifelong treatment under most circumstances.

Treatment guidelines are not sufficient to dictate all aspects of patient management. Prescribers of antiretroviral therapy must maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the prescribing of these drugs should be limited to those with specialized training.

Chemotherapy of Neoplastic Diseases

**Chapter 60.** General Principles of Cancer Chemotherapy / 1667

**Chapter 61.** Cytotoxic Agents / 1677

**Chapter 62.** Targeted Therapies: Tyrosine Kinase Inhibitors, Monoclonal Antibodies, and Cytokines / 1731

**Chapter 63.** Natural Products in Cancer Chemotherapy: Hormones and Related Agents / 1755
Introduction. The practice of cancer medicine has changed dramatically as curative treatments have been identified for many previously fatal malignancies such as testicular cancer, lymphomas, and leukemia. Adjuvant chemotherapy and hormonal therapy can extend life and prevent disease recurrence following surgical resection of localized breast, colorectal, and lung cancers. Chemotherapy is also employed as part of the multimodal treatment of locally advanced head and neck, breast, lung, and esophageal cancers, soft-tissue sarcomas, and pediatric solid tumors, thereby allowing for more limited surgery and even cure in these formerly incurable cases. Colony-stimulating factors restore bone marrow function and expand the utility of high-dose chemotherapy. Chemotherapeutic drugs are increasingly used in nonmalignant diseases: cytotoxic antitumor agents have become standard in treating autoimmune diseases, including rheumatoid arthritis (methotrexate and cyclophosphamide), Crohn’s disease (6-mercaptopurine), organ transplantation (methotrexate and azathioprine), sickle cell anemia (hydroxyurea), and psoriasis (methotrexate). Despite these therapeutic successes, few categories of medication have a narrower therapeutic index and greater potential for causing harmful effects than the cytotoxic antineoplastic drugs. A thorough understanding of their pharmacology, including drug interactions and clinical pharmacokinetics, is essential for their safe and effective use in humans.

The compounds used in the chemotherapy of neoplastic disease are quite varied in structure and mechanism of action, including alkylating agents; antimetabolite analogs of folic acid, pyrimidine, and purine; natural products; hormones and hormone antagonists; and a variety of agents directed at specific molecular targets. Tables 60-1 through 60-5 summarize of the main classes and examples of these drugs. Figure 60–1 depicts the cellular targets of chemotherapeutic agents.

The strategy for the discovery of anticancer drugs has undergone a dramatic transformation in the past 15 years, based largely on advances in understanding the molecular basis of malignant transformation. In prior years, cancer drugs were discovered through the large-scale testing of synthetic chemicals and natural products against rapidly proliferating animal tumor systems, primarily murine leukemias (Chabner and Roberts, 2005). Most of the agents discovered in these screens interacted with DNA or its precursors, inhibiting the synthesis of new genetic material and causing broad-based damage to DNA in both normal and malignant cells. The rapidly expanding knowledge of cancer biology has led to the discovery of entirely new and more cancer-specific targets (e.g., growth factor receptors, intracellular signaling pathways, epigenetic processes, tumor vascularity, DNA repair defects, and cell death pathways). For example, in many tumors, proliferation and survival depends on the constitutive activity of a single growth factor pathway, or so-called oncogene addiction (i.e., the “Achilles heel”), and inhibition of that pathway leads to cell death (Weinstein and Joe, 2006). Thus, imatinib (GLEEVEC) attacks the unique and specific bcr-abl translocation in chronic myelocytic leukemia. Imatinib also inhibits c-kit and produces extended control of gastrointestinal stromal tumors that express a mutated and constitutively activated form of c-kit. Monoclonal antibodies effectively inhibit tumor-associated antigens such as the amplified her-2/neu receptor in breast cancer cells. These examples emphasize that entirely new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology. Figure 60–1 outlines the common targets of cancer

chemotherapeutic agents. New clinical trial designs, aimed at determining effects of new drugs at the molecular level, increasingly employ biomarkers derived from samples of biological fluids or tumors to assess the effects of these new agents on signaling pathways, tumor proliferation and cell death, and angiogenesis (Maheswaran et al., 2008). Imaging of molecular, metabolic, and physiological effects of drugs will become increasingly important in establishing that drugs effectively engage their targets.

Although molecularly targeted drugs have had outstanding successes in selected types of cancer, new therapies are not likely to replace cytotoxics in the foreseeable future. Rather, the targeted drugs and cytotoxics will continue to be used in combination. For instance, monoclonal antibodies such as trastuzumab (HERCEPTIN) and bevacizumab (AVASTIN) are dramatically effective (Romond et al., 2005; Slamon et al., 2001). At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better anti-nausea medications (Chapters 13 and 46) and with granulocyte colony-stimulating factor and erythropoietin to restore bone marrow function (Chapters 37 and 62). Finally, targeted drugs are helping to overcome resistance to chemotherapeutic agents by normalizing blood flow, promoting apoptosis, and inhibiting pro-survival signals from growth factor pathways. Tumor angiogenesis leads to increased interstitial pressure and diminishes delivery of drugs to tumor cells; inhibitors of angiogenesis (e.g., bevacizumab) normalize blood flow and interstitial pressure (Batchelor et al., 2007), improve drug delivery, and are thus synergistic with cytotoxic drugs in the treatment of lung, breast, and other cancers.

Drug resistance remains a major obstacle to successful cancer treatment. Resistance results from a variety of pharmacokinetic and molecular changes that can defeat the best designed treatments, including poor drug absorption and delivery; genetically determined variability in drug transport, activation, and clearance; and mutations, amplifications, or deletions in drug targets. The resistance process is best understood for targeted agents. Tumors developing resistance to bcr-abl inhibitors and to inhibitors of the epidermal growth factor receptor (EGFR) express mutations in the target enzyme. Cells exhibiting drug-resistant mutations exist in the patient prior to drug treatment and are selected by drug exposure. Resistance to inhibitors of the EGFR may develop through expression of an alternative receptor, c-met, which bypasses EGFR blockade and stimulates proliferation (Engelman et al., 2008). Defects in recognition of DNA breaks and overexpression of specific repair enzymes may also contribute to resistance to cytotoxic drugs (Holleman et al., 2006), and a loss of apoptotic pathways can lead to resistance to both cytotoxic and targeted agents.

In designing specific clinical regimens, a number of factors must be considered. Drugs in combination can negate the effects of a resistance mechanism specific for a single agent, and they may be synergistic because of their biochemical interactions. Ideally, drug combinations should not overlap in their major toxicities. In general, cytotoxic drugs are used as close as possible to their maximally tolerated individual doses and should be given as frequently as tolerated to discourage tumor regrowth. Because the tumor cell population in patients with clinically detectable disease exceeds 1 g, or $10^9$ cells, and each cycle of therapy kills <99% of the cells, it is necessary to repeat treatments in multiple, carefully timed cycles to achieve cure.

The Cell Cycle. An understanding of the life cycle of tumors is essential for the rational use of antineoplastic agents (Figure 60–2). Many cytotoxic agents act by

---

**Figure 60–1. Summary of the mechanisms and sites of action of some chemotherapeutic agents useful in neoplastic disease.**
damaging DNA. Their toxicity is greatest during the S, or DNA synthetic, phase of the cell cycle. Others, such as the vinca alkaloids and taxanes, block the formation of a functional mitotic spindle in the M phase. These agents are most effective on cells entering mitosis, the most vulnerable phase of the cell cycle. Accordingly, human neoplasms most susceptible to chemotherapeutic measures, including leukemias and lymphomas, are those having a high percentage of proliferating cells. Normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are thus highly susceptible to damage from cytotoxic drugs.

Slowly growing tumors with a small growth fraction (e.g., carcinomas of the colon or non–small cell lung cancer) are less responsive to cycle-specific drugs. More effective are agents that inflict high levels of DNA damage (e.g., alkylating agents) or those that remain at high concentrations inside the cell for extended periods of time (e.g., fluoropyrimidines). The results of comparative clinical trials provide evidence for the most effective regimens for specific tumors. The clinical benefit of cytotoxic drugs has primarily been measured by radiological assessment of drug effects on tumor size; newer “targeted” agents, however, may simply slow or halt tumor growth so their effects may best be measured in the assessment of time to disease progression. More recently, there is growing interest in designing drugs that selectively kill the stem cell component of tumors because these cells are believed to be responsible for the continuous proliferation and repopulation of tumors after a toxic exposure to chemotherapy or targeted therapy. For example, bone marrow and epithelial tissues contain a compartment of normal non-dividing stem cells that display resistance to cytotoxic drugs and retain the capacity to regenerate the normal cell population. Tumor stem cells exhibit the same resistance to chemotherapy, radiotherapy, and oxidative insults, and thus they may represent a significant barrier to the cure of neoplasms (Diehn et al., 2009).

Although cells from different tumors display differences in the duration of their transit through the cell cycle, and in the fraction of cells in active proliferation, all cells display a similar pattern of cell cycle progression (Figure 60-2):

- a phase that precedes DNA synthesis (G₁)
- a DNA synthetic phase (S)
- an interval following the termination of DNA synthesis (G₂)
- the mitotic phase (M) in which the cell, containing a double complement of DNA, divides into two daughter G₁ cells
- a probability of moving into a quiescent state (G₀) and failing to move forward for long periods of time

At each transition point in the cell cycle, specific proteins such as p53 and chk-1 and 2, monitor the integrity of DNA and, upon detection of DNA damage, may initiate DNA repair processes or, in the presence of massive damage, direct cells down a cell death (apoptosis) pathway. Some cancer chemotherapeutic drugs act at specific phases, in the cell cycle, mainly at the S phase and M phase; other agents are cytotoxic at any point in the cell cycle and are termed cell cycle phase nonspecific agents.

Each transition point in the cell cycle requires the activation of specific cyclin-dependent kinases (CDKs), which, in their active forms, couple with corresponding regulatory proteins called cyclins. The proliferative impact of CDKs is in turn dampened by inhibitory proteins such as p16. Tumor cells often exhibit changes in cell-cycle regulation that lead to relentless proliferation (e.g., mutations or loss of p16 or other inhibitory components of the so-called retinoblastoma pathway, enhanced cyclin or CDK activity). Consequently, CDKs and their effector proteins have become attractive targets for discovery of anti-neoplastic agents.

Because of the central importance of DNA to the identity and functionality of a cell, elaborate mechanisms ("checkpoints") have evolved to monitor DNA
integrity. If a cell possesses normal checkpoint function, drug-induced DNA damage will activate apoptosis when the cell reaches the G1/S or G2/M boundary. If the p53 gene product or other checkpoint proteins are mutated or absent and the checkpoint function fails, damaged cells will not divert to the apoptotic pathway but will proceed through the S phase and mitosis. The cell progeny will emerge as a mutated and potentially drug-resistant population. Thus, alterations in the regulation of cell-cycle kinetics and checkpoint controls are critical factors in determining sensitivity to cytotoxic drugs and understanding the success or failure of new agents.

Achieving Therapeutic Integration and Efficacy. The treatment of cancer patients requires a skillful interdigitation of pharmacotherapy with other modalities of treatment (e.g., surgery and irradiation). Each treatment modality carries its own risks and benefits, with the potential for both antagonistic and synergistic interactions between modalities, particularly between drugs and irradiation. Furthermore, individual patient characteristics determine the choice of modalities. Not all patients can tolerate drugs, and not all drug regimens are appropriate for a given patient. Renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems all come into consideration in making a therapeutic plan. Other less quantifiable considerations, such as the natural history of the tumor, the patient’s willingness to undergo difficult and potentially dangerous treatments, and the patient’s physical and emotional tolerance for side effects, enter the equation, with the goal of balancing the likely long-term gains and risks in the individual patient.

One of the great challenges of therapeutics is to adjust drug regimens to achieve a therapeutic but nontoxic outcome. Although it is customary to base dose on body surface area for individual patients, this practice is not necessarily supported by evidence in the literature (Sawyer and Ratain, 2001). Orally administered drugs are now frequently prescribed using uniform dosing for all adult patients. Dose adjustment based on renal function, on hepatic function, or on pharmacokinetic monitoring does facilitate meeting specific targets such as desired drug concentration in plasma or area under the concentration-time curve (AUC), a measure of the pattern of systemic exposure to the agent in question. Unfortunately, there are few good guidelines for adjusting dose on the basis of obesity or age. Elderly patients, particularly those >70 years of age, exhibit less tolerance for chemotherapy because of decreased renal and hepatic drug clearance, lower protein binding, and less bone marrow reserve, but individuals vary widely. Drug clearance decreases in morbidly obese patients, and dosage should probably be capped for these patients at no more than 150% of the dosage for patients of average body surface area (1.73 m²) (Rodvold et al., 1988), with adjustment upward for tolerance after each subsequent dose.

Even patients with normal renal and hepatic function exhibit significant variability in pharmacokinetics of anticancer drugs that can reduce efficacy or cause excess toxicity. The following examples illustrate the potential of using pharmacokinetic targeting to improve therapy:

1. The thrombocytopenia caused by carboplatin is a direct function of AUC, which in turn is determined by renal clearance of the parent drug. Calvert and Egorin (2002) have devised a formula for targeting a desired AUC based on creatinine clearance.
2. Monitoring of 5-fluorouracil levels in plasma allows dose adjustment to improve response rates in patients with rapid drug clearance, and to avoid toxicity in those with slow drug clearance (Gamelin et al., 2008).
3. High-dose methotrexate therapy requires drug-level monitoring to detect patients at high risk for renal failure and severe myelosuppression. Patients with inappropriately high concentrations of methotrexate at specific time points can be rescued from toxicity by the administration of leucovorin, and in extreme cases, by dialysis or administration of a methotrexate-cleaving enzyme and orphan drug, glucarpidase (VORAXAZE; recombinant carboxypeptidase G2).

Molecular Testing to Select Patients for Chemotherapy. Molecular tests are increasingly employed to identify patients likely to benefit from treatment and those at highest risk of toxicity (Roberts and Chabner, 2004). Pretreatment testing has become standard practice to select patients for hormonal therapy of breast cancer and for treatment with antibodies such as trastuzumab (her-2/neu receptor) and rituximab (CD20). The presence of a mutated k-ras gene indicates that a colorectal cancer patient’s tumor will not respond to anti-EGFR antibodies (Tol et al., 2009); mutations of EGFR signal a 70% likelihood of response to erlotinib (TARCEVA) and gefitinib (IRESSA), both inhibitors of this receptor (Sequist and Lynch, 2008). Although not yet routinely
employed in traditional cytotoxic therapy, molecular testing of tumors could improve outcomes by pairing patients with drugs likely to be effective against mutations that drive tumor proliferation or survival. Mutations of the \( b-Raf \), \( HER \ 2/\text{neu} \), and \( \text{Alk} \), which are found in subsets of solid tumors in human subjects, represent examples of promising targets for solid tumor chemotherapy.

Inherited differences in protein sequence polymorphisms or levels of RNA expression influence toxicity and anti-tumor response. For example, tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer (Pullarkat et al., 2001). Polymorphisms of the dihydropyrimidine dehydrogenase gene, the product of which is responsible for degradation of 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual homozygous for the polymorphic genes (Van Kuilenburg et al., 2002). Other polymorphisms appear to affect the clearance and therapeutic activity of cancer drugs, including tamoxifen (Schroth et al., 2007), methotrexate, irinotecan, and 6-mercaptopurine (Cheok and Evans, 2006).

Other aspects of molecular biology are entering into clinical decision making in oncology. Gene expression profiling, in which the levels of messenger RNA from thousands of genes are randomly surveyed using gene arrays, has revealed tumor profiles that are highly associated with metastasis (Ramaswamy et al., 2003). The expression of the transcription factor HOX B13 correlates with disease recurrence in patients receiving adjuvant hormonal therapy in breast cancer (Ma et al., 2004). Gene expression profiles also predict the benefit of adjuvant chemotherapy for breast cancer patients (Sotiriou and Pusztai, 2009) and the response of ovarian cancer patients to platinum-based therapy (Dressman et al., 2007).

New molecular tests and their more widespread use likely will shorten the time for drug development and approval, realize savings by avoiding the cost and toxicity of ineffective drugs, and ultimately improve patient outcome (Chabner and Roberts, 2005; Roberts and Chabner, 2004). Undoubtedly, molecular testing to select patients for specific treatments will be a cornerstone of cancer chemotherapy for years to come.

A Cautionary Note. Although advances in drug discovery and molecular profiling of tumors offer great promise for improving the outcomes of cancer treatment, a final word of caution regarding all treatment regimen deserves emphasis. The pharmacokinetics and toxicities of cancer drugs vary among individual patients. It is imperative to recognize toxicities early, to alter doses or discontinue offending medication to relieve symptoms and reduce risk, and to provide vigorous supportive care (platelet transfusions, antibiotics, and hematopoietic growth factors). Toxicities affecting the heart, lungs, or kidneys may be irreversible if recognized late in their course, leading to permanent organ damage or death. Fortunately, such toxicities can be minimized by early recognition and by adherence to standardized protocols and to the guidelines for drug use.

BIBLIOGRAPHY

This page intentionally left blank
I. Alkylating Agents and Platinum Coordination Complexes

The pervasive toxic effects of sulfur mustard gas were noted as the result of its use in World War I. A potent vesicant, the gas caused a topical burn to skin, eyes, lungs, and mucosa and, after massive exposure, aplasia of the bone marrow and lymphoid tissue and ulceration of the GI tract. Early clinical experiments with topically applied sulfur mustard led to regression of penile tumors. Thereafter, Goodman, Gilman, the originators of this text, working with colleagues at Yale in a consortium organized by the U.S. Department of Defense, confirmed the antineoplastic action of the nitrogen mustards against a murine lymphoma. In 1942, they began clinical studies of intravenous nitrogen mustards in patients with lymphoma, launching the modern era of cancer chemotherapy (Gilman and Philips, 1946).

At present, six major types of alkylating agents are used in the chemotherapy of neoplastic diseases:

- nitrogen mustards
- ethyleneimines
- alkyl sulfonates
- nitrosoureas
- the triazenes
- DNA-methylating drugs, including procarbazine, temozolomide, and dacarbazine

In addition, because of similarities in their mechanisms of action and resistance, platinum complexes are discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA. The mechanism of action of alkylating agents is shown in Figure 61–1.

Chemistry. The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulfhydryl, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygens, or phosphates on DNA. The N7 atom of guanine is particularly susceptible to the formation of a covalent bond with bifunctional alkylating agents and may represent the key target that determines their biological effects. Other atoms in the purine and pyrimidine bases of DNA, including N1 and N3 of the adenine ring, N3 of cytosine, and O6 of guanine, react with these agents, as do the amino and sulfhydryl groups of proteins and the sulfhydryls of glutathione.

The possible actions of alkylating agents on DNA are illustrated in Figure 61–1 with mechlorethamine (nitrogen mustard). First, one 2-chloroethyl side chain undergoes a first-order ($S_N1$) intramolecular cyclization, with release of $\text{Cl}^-$ and formation of a highly reactive ethyleneimine intermediate (Figure 61–1). The unstable quaternary amine then reacts with a variety of electron-dense sites. This latter reaction proceeds as a second-order ($S_N2$) nucleophilic substitution. Alkylation of the N7 of guanine in DNA, a highly favored reaction, exerts several biologically important effects. Guanine residues in DNA exist predominantly as the keto tautomer and readily make Watson-Crick base pairs by hydrogen bonding with cytosine residues. However, when the N7 of guanine is alkylated (to become a quaternary ammonium nitrogen) the guanine residue is more acidic and the enol tautomer is favored. The modified guanine can mispair with thymine residues during DNA synthesis, leading to the substitution of thymine for cytosine. Second, alkylation of the N7 creates lability in the imidazole ring, leading to opening of the ring and excision of the damaged guanine residue. Mispairing and imidazole ring opening can lead to attempts to repair the damaged stretch of DNA, causing strand breakage. Third, with bifunctional alkylating agents such as nitrogen mustard, the second 2-chloroethyl side chain can undergo a similar cyclization
reaction and alkylate a second guanine residue or another nucleophilic moiety, resulting in the cross-linking of two nucleic acid chains or the linking of a nucleic acid to a protein, alterations that would cause a major disruption in nucleic acid function. Any of these effects could contribute to both the mutagenic and cytotoxic effects of alkylating agents. The extreme cytotoxicity of bifunctional alkylators correlates very closely with interstrand cross-linkage of DNA (Garcia et al., 1988).

The ultimate cause of cell death related to DNA damage is not known. Specific cellular responses include cell-cycle arrest and attempts to repair DNA. The specific repair enzyme complex utilized will depend on two factors: the chemistry of the adduct formed and the repair capacity of the cell involved. The process of recognizing and repairing DNA generally requires an intact nucleotide excision repair (NER) complex, but, as discussed in the rest of this section, may differ with each drug and with each tumor. Alternatively, recognition of extensively damaged DNA by p53 can trigger apoptosis. Mutations of p53 lead to alkylating agent resistance (Kastan, 1999).

Structure-Activity Relationships. Although these alkylating agents share the capacity to alkylate biologically important molecules, modification of the basic chloroethylamino structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which properties determine drug activity in vivo. With several of the most valuable agents (e.g., cyclophosphamide, ifosfamide), the active alkylating moieties are generated in vivo through hepatic metabolism.

The biological activity of alkylators of the nitrogen mustard type is based on the presence of the bis-(2-chloroethyl) group. Although mechlorethamine has been widely used in the past, linkage of the bis-(2-chloroethyl) group to electrophilic substitutions such as unsaturated ring systems has yielded more stable drugs with better pharmacodynamic properties and with greater selective killing of tumor cells. Bis-(2-chloroethyl) groups linked to amino acids (phenylalanine) and substituted phenyl groups (aminophenol butyric acid, as in chlorambucil) create a more stable and orally available form. The structures of important nitrogen mustards are shown in Figure 61–2.

A classical example of the role of host metabolism in the activation and degradation of an alkylating agent is seen with cyclophosphamide, now the most widely used agent of this class. The drug undergoes metabolic activation (hydroxylation) by CYP2B (Figure 61–3), with subsequent transport of the activated intermediate to sites of action. The selectivity of cyclophosphamide against certain malignant tissues may result in part from the capacity of normal tissues to degrade the activated intermediates via aldehyde dehydrogenase, glutathione transferase, and other pathways.

Ifosfamide is an oxazaphosphorine, similar to cyclophosphamide. Cyclophosphamide has two chloroethyl groups on the exocyclic nitrogen atom, whereas one of the 2-chloroethyl groups of

---
Ifosfamide is on the cyclic phosphoramide nitrogen of the oxazaphosphorine ring. Ifosfamide is activated in the liver by CYP3A4. The activation of ifosfamide proceeds more slowly, with greater production of dechlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of ifosfamide required for equitoxic effects, the greater neurotoxicity of ifosfamide, and the possible differences in antitumor spectrum of the two agents.

The newest approved alkylating agent, bendamustine, has the typical chloroethyl reactive groups attached to a benzimidazole backbone. The unique properties and activity of this drug may derive from this purine-like structure; the agent produces slowly repaired DNA cross-links, lacks cross-resistance with other classical alkylators (Leoni et al., 2008), and has significant activity in chronic lymphocytic leukemia (CLL) and large-cell lymphomas refractory to standard alkylators.

A unique class of alkylating agents transfers methyl rather than ethyl groups to DNA. The triazene derivative 5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide, usually referred to as dacarbazine or DTIC, is prototypical of methylating agents.

Dacarbazine requires initial activation by hepatic CYPs through an N-demethylation reaction. In the target cell, spontaneous cleavage of the metabolite, methyl-triazeno-imidazole-carboxamide (MTIC), yields an alkylating moiety, a methyl diazonium ion. A related triazene, temozolomide, undergoes spontaneous, nonenzymatic activation to MTIC and has significant activity against gliomas.

The nitrosoureas, which include compounds such as 1,3-bis-(2-chloroethyl)-1-nitrosourea (carmustine; BCNU), 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (lomustine; CCNU), and its methyl derivative (semustine; methyl-CCNU), as well as the antibiotic streptozocin (streptozotocin), exert their cytotoxicity through the spontaneous breakdown to an alkylating intermediate, the 2-chloroethyl diazonium ion.

The 2-chloroethyl diazonium ion, a strong electrophile, can alkylate guanine, cytidine, and adenine bases (Ludlum, 1990). Displacement of the halogen atom can then lead to interstrand or intrastrand cross-linking of DNA. The formation of cross-links after the initial alkylation reaction proceeds relatively slowly and can be reversed by the DNA repair enzyme O6-alkyl, methyl guanine methyltransferase (MGMT), which displaces the chloroethyl adduct from its binding to guanine in a suicide reaction. The same enzyme, when expressed in human gliomas, produces resistance to nitrosoureas and to other methylating agents, including DTIC, temozolomide, and procarbazine. As with the nitrogen mustards, interstrand cross-linking appears to be the primary lesion responsible for the cytotoxicity of nitrosoureas (Ludlum, 1990). The reactions of the nitrosoureas with macromolecules are shown in Figure 61–4.
Because the formation of the ethyleneimine ion constitutes the initial reaction of the nitrogen mustards, it is not surprising that stable ethyleneimine derivatives have antitumor activity. Several compounds of this type, including triethylenemelamine (TEM) and triethylenethiophosphoramidate (thiotepa), have been used clinically. In standard doses, thiotepa produces little toxicity other than myelosuppression; it also is used for high-dose chemotherapy regimens, in which it causes both mucosal and central nervous system toxicity. Altretamine (hexamethylmelamine; HMM) is mentioned here because of its chemical similarity to TEM. The methylmelamines are N-demethylated by hepatic microsomes with the release of formaldehyde, and there is a direct relationship between the degree of the demethylation and their activity against murine tumors.

Esters of alkane sulfonic acids alkylate DNA through the release of methyl radicals. Busulfan is of value in high-dose chemotherapy.

### Pharmacological Actions

#### Cytotoxic Actions

The capacity of alkylating agents to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Acute effects manifest primarily against rapidly proliferating tissues; however, certain alkylating agents may have damaging effects on tissues with normally low mitotic indices (e.g., liver, kidney, and mature lymphocytes), which usually are affected in a delayed time frame. Lethality of DNA alkylation depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. The actual mechanism(s) of cell death related to DNA alkylation are not yet well characterized.

In non-dividing cells, DNA damage activates a checkpoint that depends on the presence of a normal p53 gene. Cells thus blocked in the G1/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progression, do not undergo apoptosis, and exhibit resistance to these drugs.

Although DNA is the ultimate target of all alkylating agents, a crucial distinction must be made between the bifunctional agents, in which cytotoxic effects predominate, and the monofunctional methylating agents (procarbazine, temozolomide), which have greater capacity for mutagenesis and carcinogenesis. This suggests that the cross-linking of DNA strands represents a much greater threat to cellular survival than do other effects, such as single-base alkylation and the resulting depurination and single-chain scission. On the other hand, simple methylation may be bypassed by DNA polymerases, leading to mispairing reactions that permanently modify DNA sequence. These new sequences are transmitted to subsequent generations and may result in mutagenesis or carcinogenesis. Some methylating agents, such as procarbazine, are highly carcinogenic.

DNA repair systems play an important role in removing adducts, and thereby determine the selectivity of action against particular cell types, and acquired resistance to alkylating agents. Alkylation of a single strand of DNA (mono-adducts) is repaired by the nucleotide excision repair pathway, while the less frequent cross-links require participation of nonhomologous end joining, an error-prone pathway, or the error-free homologous recombination pathway. After drug infusion in humans, mono-adducts appear rapidly and peak within 2 hours of drug exposure, while cross-links peak at 8 hours. The t1/2 for repair of adducts varies among normal tissues and tumors; in peripheral blood mononuclear cells, both mono-adducts and cross-links disappear with a t1/2 of 12-16 hours (Souliotis et al., 1990).

The homologous end-joining pathway has multiple components (Wang et al., 2001):

- sensors of DNA integrity (such as p53)
- activation signals such as the ataxia-telangiectasia-mutated (ATM) and ataxia-telangiectasia and rad-related (ATR) proteins
- the activated repair complex composed of Fanconi anemia proteins and BRCA2, all of which localize at the site of DNA damage and initiate removal of the cross-linked segment of DNA
- homologous recombination, which allows resynthesis of the damaged DNA sequence followed by re-ligation of the repaired sequences

The process depends on the presence and accurate functioning of multiple proteins. Their absence or mutation, as in Fanconi anemia or ataxia telangiectasia, leads to extreme sensitivity to DNA cross-linking agents such as mitomycin, cisplatin, or classical alkylators.
Other repair enzymes are specific for removing methyl and ethyl adducts from the O-6 of guanine (MGMT) and for repair of alklylation of the N-3 of adenine and N-7 of guanine (3-methyladenine-DNA glycosylase) (Matijasevic et al., 1993). High expression of MGMT protects cells from cytotoxic effects of nitrosoureas and methylating agents and confers drug resistance, while methylation and silencing of the gene in brain tumors are associated with clinical response to BCNU and temozolomide (Hegi et al., 2008).

Bendamustine differs from classical chloroethyln alkylators in activating base excision repair, rather than the more complex double-strand break repair or MGMT. It impairs physiological arrest of adduct-containing cells at mitotic checkpoints and leads to mitotic catastrophe rather than apoptosis, and does not require an intact p53 to cause cytotoxicity.

Finally, recognition of DNA adducts is an essential step in promoting attempts at repair and ultimately leading to apoptosis. The Fanconi pathway, consisting of 12 proteins, recognizes adducts and signals the need for repair of a broad array of DNA-damaging drugs and irradiation (Chen et al., 2007). Absence or inactivation of components of this pathway leads to increased sensitivity to DNA damage. Conversely, for the methylating drugs, nitrosoureas, cisplatin and carboplatin, and thiopurine analogs, the mismatch repair (MMR) pathway is essential for cytotoxicity, causing strand breaks at sites of adduct formation, creating mispairing of thymine residues, and triggering apoptosis.

**Mechanisms of Resistance to Alkylating Agents.** Resistance to an alkylating agent develops rapidly when it is used as a single agent. Specific biochemical changes implicated in the development of resistance include:

- Decreased permeation of actively transported drugs (mechloretamine and melphalan).
- Increased intracellular concentrations of nucleophilic substances, principally thiols such as glutathione, which can conjugate with and detoxify electrophilic intermediates.
- Increased activity of DNA repair pathways, which may differ for the various alkylating agents.
- Impaired apoptotic pathways, with overexpression of bcl-2 as an example, confer resistance.
- Loss of ability to recognize adducts formed by nitrosoureas and methylating agents, as the result of defective MMR capability, confers resistance, as does defective checkpoint function for virtually all alkylating drugs.

The MSH6 component of the MMR system seems particularly susceptible to mutation by exposure to alkylating agents; in studies of brain tumor resistance to therapy, loss of MSH6 conferred resistance to temozolomide and related drugs (Cahill et al., 2008).

To reverse cellular changes that lead to resistance, strategies that are effective in selected experimental tumors have been devised. These include the use of compounds that deplete glutathione, such as l-buthionine-sulfoximine; sulphydryl compounds such as amifostine (WR-2721) that selectively detoxify alkylating species in normal cells and thereby prevent toxicity; O\(^\text{2+}\)-benzylguanine, which inactivates MGMT; and compounds such as ethacrynic acid, which inhibits glutathione transferases. Although each of these modalities has experimental evidence to support its use, their clinical efficacy has not yet been proven.

### TOXICITIES OF ALKYLATING AGENTS

#### Bone Marrow Toxicity

The alkylating agents differ in their patterns of antitumor activity and in the sites and severity of their side effects. Most cause dose-limiting toxicity to bone marrow elements and, to a lesser extent, intestinal mucosa. Most alkylating agents (i.e., melphalan, chlorambucil, cyclophosphamide, and ifosfamide) cause acute myelosuppression, with a nadir of the peripheral blood granulocyte count at 6-10 days and recovery in 14-21 days.

Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogenic bone marrow transplantation. Carmustine and other chloroethylnitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4-6 weeks after drug administration and reversing slowly thereafter.

Both cellular and humoral immunity are suppressed by alkylating agents, which have been used to treat various auto-immune diseases. Immunosuppression
is reversible at usual doses, but opportunistic infections such as *Pneumocystis jiroveci* pneumonia, or fungal infections, may occur with extended treatment, and reactivation of hepatitis B has been described, prompting some authors to advocate antiviral prophylaxis in hepatitis B carriers undergoing intensive alkylating agent chemotherapy (Grewal et al., 2007).

**Mucosal Toxicity**

Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, leading to oral mucosal ulceration, intestinal denudation, and alopecia.

The mucosal effects are particularly damaging in high-dose chemotherapy protocols associated with bone marrow reconstitution, as they predispose to bacterial sepsis arising from the GI tract. In these protocols, cyclophosphamide, melphalan, and thiotepe have the advantage of causing less mucosal damage than the other agents. In high-dose protocols, however, other toxicities become limiting, as delineated in Table 61–1.

**Neurotoxicity**

Nausea and vomiting commonly follow agent administration of nitrogen mustard or BCNU. Ifosfamide is the most neurotoxic agent of this class and may produce altered mental status, coma, generalized seizures, and cerebellar ataxia. These side effects result from the release of chloroacetaldehyde from the phosphate-linked chloroethyl side chain of ifosfamide. High-dose busulfan can cause seizures; in addition, it accelerates the clearance of phenytoin, an anti-seizure medication.

**Other Organ Toxicities.** Although mucosal and bone marrow toxicities occur predictably and acutely with conventional doses of these drugs, other organ toxicities may supervene after prolonged or high-dose use; these effects can appear after months or years and may be irreversible and even lethal. All alkylating agents, including temozolomide, have caused pulmonary fibrosis, usually several months after treatment. In high-dose regimens, particularly those employing busulfan or BCNU, vascular endothelial damage may precipitate veno-occlusive disease (VOD) of the liver, an often fatal side effect that is successfully reversed by the investigational drug defibrotide (Richardson et al., 2003). The nitrosoureas and ifosfamide, after multiple cycles of therapy, may lead to renal failure. Cyclophosphamide and ifosfamide release a nephrotoxic and urotoxic metabolite, acrolein, which causes a severe hemorrhagic cystitis in high-dose regimens. This adverse effect can be prevented by co-administration of 2-mercaptoethanesulfonate (mesna; MESNEX), which conjugates acrolein in urine. Ifosfamide in high doses for transplant causes a chronic, and often irreversible, renal toxicity. Proximal and, less commonly, distal tubules may be affected, leading to defective Ca2+ and Mg2+ reabsorption, glycosuria, and renal tubular acidosis. Nephrotoxicity correlates with the total dose of drug received and increases in frequency in children <5 years of age. The syndrome may be due to chloroacetaldehyde and/or acrolein excreted in the urine.

The more unstable alkylating agents (particularly mechlorethamine and the nitrosoureas) have strong vesicant properties, damage veins with repeated use and, if extravasated, produce ulceration.

Finally, all alkylating agents have toxic effects on the male and female reproductive systems, causing an often permanent amenorrhea, particularly in perimenopausal women, and an irreversible azoospermia in men.

**Leukemogenesis.** As a class of drugs, the alkylating agents are highly leukemogenic. Acute nonlymphocytic leukemia, often associated with partial or total deletions of chromosome 5 or 7, peaks in incidence ~4 years after therapy and may affect up to 5% of patients treated on regimens containing alkylating drugs. Leukemia often is preceded by a period of neutropenia or anemia and by bone marrow morphology consistent with myelodysplasia. Melphalan, the nitrosoureas, and the methylating agent procarbazine have the greatest propensity to cause leukemia, while it is less common after cyclophosphamide.

Nitrogen Mustards

The chemistry and the pharmacological actions of the alkylating agents as a group, and of the nitrogen mustards, have been presented in the preceding sections. Only the unique pharmacological characteristics of the individual agents are considered in this section.

Mechlorethamine. Mechlorethamine was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It rarely is used in current practice.

Absorption and Fate. Severe local reactions of exposed tissues necessitate rapid intravenous injection of mechlorethamine for most clinical uses. In either water or body fluids, at rates affected markedly by pH, mechlorethamine rapidly undergoes chemical degradation as it combines with either water or cellular nucleophiles, and the parent compound disappears from the bloodstream within minutes.

Therapeutic Uses. Mechlorethamine HCl (Mustargen) formerly was used in the combination chemotherapy regimen MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) in patients with Hodgkin’s disease. It is given by intravenous bolus administration in doses of 6 mg/m² on days 1 and 8 of the 28-day cycles of each course of treatment. It has been largely replaced by cyclophosphamide, melphalan, and other, more stable alkylating agents.

It also is used topically for treatment of cutaneous T-cell lymphoma (CTCL) as a solution that is rapidly mixed and applied to affected areas of the skin.

Clinical Toxicity. The major acute toxic manifestations of mechlorethamine are nausea and vomiting, lacrimation, and myelosuppression. Leukopenia and thrombocytopenia limit the amount of drug that can be given in a single course.

Cyclophosphamide

Absorption, Fate, and Excretion. Cyclophosphamide is well absorbed orally and is activated to the 4-hydroxy intermediate (Xie et al., 2003) (Figure 61–3). 4-Hydroxycyclophosphamide exists in equilibrium with the acyclic tautomer aldophosphamide. The rate of metabolic activation of cyclophosphamide exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at infusion rates of >4 g/90 min and concentrations of the parent compound >150 μM (Chen et al., 1995). 4-Hydroxycyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. The hydroxyl metabolite of ifosfamide similarly is inactivated by aldehyde dehydrogenase. 4-Hydroxycyclophosphamide and its tautomer, aldophosphamide, travel in the circulation to tumor cells where aldophosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramido mustard and acrolein. Phosphoramido mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide. Cystitis can be reduced in intensity or prevented by the parenteral co-administration of mesna.

Patients should receive vigorous intravenous hydration during high-dose treatment. Brisk hematuria in a patient receiving daily oral therapy should lead to immediate drug discontinuation. Refractory bladder hemorrhage can become life-threatening, and cystectomy may be necessary for control of bleeding.

Inappropriate secretion of antidiuretic hormone has been observed in patients receiving cyclophosphamide, usually at doses >50 mg/kg (see Chapter 25). It is important to be aware of the possibility of water intoxication, because these patients usually are vigorously hydrated to prevent bladder toxicity.

Pretreatment with CYP inducers such as phenobarbital enhances the rate of activation of the azoxyphosphorenes but does not alter total exposure to active metabolites over time and does not affect toxicity or therapeutic activity in humans. Cyclophosphamide can be used in full doses in patients with renal dysfunction, because it is eliminated by hepatic metabolism. Patients with mild hepatic dysfunction (bilirubin <3 mg/dL) can be treated with full doses of this drug, but those with more significant hepatic dysfunction should receive reduced doses.

Urinary and fecal excretion of unchanged cyclophosphamide is minimal after intravenous administration. Maximal concentrations in plasma are achieved 1 hour after oral administration, and the t½ of parent drug in plasma is ~7 hours.

Therapeutic Uses. Cyclophosphamide (Lyophilized Cytoxan, others) is administered orally or intravenously. Recommended doses vary widely, and standard protocols for determining the schedule and dose of cyclophosphamide in combination with other chemotherapeutic agents should be consulted.

As a single agent, a daily oral dose of 100 mg/m² for 14 days has been recommended for patients with lymphomas and CLL. Higher doses of 500 mg/m² intravenously every 2-4 weeks are used in combination with other drugs in the treatment of breast cancer and lymphomas. The neutrophil nadir of 500-1000 cells/mm³ generally serves as a lower limit for dosage adjustments in prolonged therapy. In regimens associated with bone marrow or peripheral stem cell rescue, cyclophosphamide may be given in total doses of 5-7 g/m² over a 3- to 5-day period. GI ulceration, cystitis (counteracted by mesna and diuresis), and, less commonly, pulmonary, renal, hepatic, and cardiac toxicities (a hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses >200 mg/kg.

The clinical spectrum of activity for cyclophosphamide is very broad. It is an essential component of many effective drug combinations for non-Hodgkin’s lymphomas, other lymphoid malignancies, breast and ovarian cancers, and solid tumors in children. Complete remissions and presumed cures have been reported when cyclophosphamide was given as a single agent for Burkitt’s lymphoma. It frequently is used in combination with doxorubicin and a taxane as adjuvant therapy after surgery for carcinoma of the breast.

Because of its potent immunosuppressive properties, cyclophosphamide has been used to treat auto-immune disorders, including Wegener’s granulomatosis, rheumatoid arthritis, and the nephrotic syndrome. Caution is advised when the drug is considered for non-neoplastic conditions, not only because of its acute toxic effects but also because of its potential for inducing sterility, teratogenic effects, and leukemia.

Ifosfamide. Ifosfamide (Ifex, others) is an analog of cyclophosphamide. Severe urinary tract and central nervous system (CNS) toxicity limited the use of ifosfamide when it first was introduced in the early 1970s.
However, adequate hydration and co-administration of mesna have reduced its bladder toxicity.

**Therapeutic Uses.** Iosfamide is approved for treatment of relapsed germ cell testicular cancer and is frequently used for first-time treatment of pediatric and adult sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue; in these regimens, in total doses of 12-14 g/m², it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 hours to 7 days after beginning the ifosfamide infusion. This toxicity is thought to result from a metabolite, chloroaacetaldehyde. In addition, ifosfamide causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver.

In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 minutes at a dose of ≤1.2 g/m²/day for 5 days. Intravenous mesna is given as bolus injections in a dose equal to 20% of the ifosfamide dose concomitantly and an additional 20% again 4 and 8 hours later, for a total mesna dose of 60% of the ifosfamide dose. For ifosfamide doses ≤2 g/m², oral mesna, at a dose equal to 40% of the ifosfamide dose, can be substituted for the second and third IV mesna doses, given at 2 and 6 hours after each dose of ifosfamide, for a total mesna dose equal to the ifosfamide dose. Alternatively, mesna may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles are repeated every 3-4 weeks after hematological recovery.

**Pharmacokinetics.** The parent compound, ifosfamide, has an elimination t½ in plasma of ~1.5 hours after doses of 3.8-5 g/m² and a somewhat shorter t½ at lower doses, although its pharmacokinetics are highly variable from patient to patient due to variable rates of hepatic metabolism. Hydroxylation by CYPs generates an active phosphoramidate mustard.

**Toxicity.** Ifosfamide has virtually the same toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and in the absence of mesna, urothelial damage.

**Melphalan.** This alkylating agent primarily is used to treat multiple myeloma and, less commonly, in high-dose chemotherapy with marrow transplantation.

**Pharmacological and Cytotoxic Actions.** The general pharmacological and cytotoxic actions of melphalan are similar to those of other bifunctional alkylators. The drug is not a vesicant.

**Absorption, Fate, and Excretion.** Oral melphalan is absorbed in an inconsistent manner and, for most indications, is given as an intravenous infusion. The drug has a t½ in plasma of ~45-90 minutes, and 10-15% of an administered dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression.

**Therapeutic Uses.** Melphalan (ALKERAN) for multiple myeloma is given in doses of 4-10 mg orally for 4-7 days every 28 days, with dexamethasone or thalidomide. Treatment is repeated at 4-week intervals based on response and tolerance. Dosage adjustments should be based on blood cell counts. Melphalan also may be used in myeloablative regimens followed by bone marrow or peripheral blood stem cell reconstitution. For this use, the dose is 180-200 mg/m².

**Clinical Toxicity.** The clinical toxicity of melphalan is mostly hematological and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. The drug causes less alopecia and, rarely, renal or hepatic dysfunction.

**Chlorambucil.** This agent is almost exclusively used in treating CLL, and in this disease has largely been replaced by fludarabine and cyclophosphamide.

**Pharmacological and Cytotoxic Actions.** The cytotoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other nitrogen mustards. As an orally administered agent, chlorambucil is well tolerated in small daily doses and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of ≥20 mg.

**Absorption, Fate, and Excretion.** Oral absorption of chlorambucil is adequate and reliable. The drug has a t½ in plasma of ~1.5 hours, and is hydrolyzed to inactive products.

**Therapeutic Uses.** In treating CLL, the standard initial daily dose of chlorambucil (LEUKERAN) is 0.1-0.2 mg/kg, given once daily and continued for 3-6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy (usually 2 mg daily) often is required to maintain clinical response.

**Clinical Toxicity.** In CLL, chlorambucil treatment may continue for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow.

Although it is possible to induce marked hypoplasia of the bone marrow with excessive doses, its myelosuppressive effects are moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, seizures, dermatitis, and hepatotoxicity rarely may be encountered. A marked increase in the incidence of acute myelocytic leukemia (AML) and other tumors was noted in the treatment of polycythemia vera and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy (Lerner, 1978).

**Bendamustine.** This drug is approved for treatment of CLL and non-Hodgkin’s lymphoma.

Bendamustine is given as a 30-minute intravenous infusion in dosages of 100 mg/m²/day on days 1 and 2 of a 28-day cycle. Lower doses may be indicated in heavily pretreated patients. It is rapidly degraded through sulfhydryl interaction and adduct formation with macromolecules, and <5% of the parent drug is excreted in the urine intact. N-demethylation and oxidation produces metabolites that have antitumor activity, but less than that of the parent molecule. The parent drug has a t½ in plasma of ~30 minutes (Teichert et al., 2007).

The clinical toxicity pattern of bendamustine is typical of classical alkylators, with a rapidly reversible myelosuppression and mucositis, both generally tolerable in the 28-day regimen.

**MISCELLANEOUS ALKYLATING DRUGS**

Although nitrogen mustards containing chloroethyl groups constitute the most widely used class of alkylating agents, alternative alkylators with greater chemical stability and well-defined activity in specific types of cancer have value in clinical practice.
**Ethyleneimines and Methylmelamines**

**Altretamine**

**Pharmacology and Cytotoxic Effects.** Altretamine (HEXALEN), formerly known as hexamethylmelamine, is structurally similar to triethylenemelamine (tretamine). However, *in vitro* tests for alkylating activity of altretamine and its metabolites have been negative, and the precise mechanism of the cytotoxic action of altretamine is unknown. It is a palliative treatment for persistent or recurrent ovarian cancer following cisplatin-based combination therapy.

The usual dosage of altretamine as a single agent in ovarian cancer is 260 mg/m²/day in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

**Absorption, Fate, and Excretion.** Following oral administration, altretamine is well absorbed from the GI tract and undergoes rapid demethylation in the liver. The principal metabolites are pentamethylmelamine and tetramethyl melamine, and the elimination *t*₁/₂ is 4-10 hours.

**Clinical Toxicities.** The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity (ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo). Neurological symptoms abate upon discontinuation of therapy. Peripheral blood counts and a neurological examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days and subsequently restarted at a lower dosage of 200 mg/m²/day if the white cell count falls to <2000 cells/mm³ or the platelet count falls to <75,000 cells/mm³ or if neurotoxic or intolerable GI symptoms occur. If neurological symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued. Nausea and vomiting also are common side effects and may be dose limiting. Renal dysfunction may necessitate discontinuing the drug. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension may develop in patients who receive monoamine oxidase (MAO) inhibitors, amitriptyline, imipramine, or phenelzine concurrently with altretamine.

**Thiotepa**

**Pharmacological and Cytotoxic Effects.** Thiotepa (THIOPLEX, others) consists of three ethyleneimine groups stabilized by attachment to the nucleophilic thioephosphoryl base. Its current use primarily is for high-dose chemotherapy regimens.

Both thiotepa and its desulfurated primary metabolite, triethylene phosphoramide (TEPA), to which it is rapidly converted by hepatic CYPs, form DNA cross-links. The aziridine rings open after protonation of the ring-nitrogen, leading to a reactive molecule.

**Absorption, Fate, and Excretion.** TEPA becomes the predominant form of the drug present in plasma within hours of thiotepa administration. The parent compound has a plasma *t*₁/₂ of 1.2-2 hours, as compared to a longer *t*₁/₂ of 3-24 hours for TEPA. Thiotepa pharmacokinetics essentially are the same in children as in adults at conventional doses (<80 mg/m²), and drug and metabolite *t*₁/₂ are unchanged in children receiving high-dose therapy of 300 mg/m²/day for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite. Multiple secondary metabolites and chemical degradation products account for the remainder of the administered dose.

**Clinical Toxicities.** The toxicities of thiotepa essentially are the same as those of the other alkylating agents, namely myelosuppression, and to a lesser extent mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high-dose regimens, thiotepa may cause neurotoxic symptoms, including coma and seizures.

**Alkyl Sulfonates**

**Busulfan.** Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses and, prior to the advent of imatinib mesylate (GLEEVEC), was a standard agent for patients in the chronic phase of myelocytic leukemia and caused a severe and prolonged pancytopenia in some patients. Busulfan now is primarily used in high-dose regimens, in which pulmonary fibrosis, GI mucosal damage, and hepatic veno-occlusive disease (VOD) are important toxicities.

**Absorption, Fate, and Excretion.** Busulfan is well absorbed after oral administration in dosages of 2-6 mg/day and has a plasma *t*₁/₂ of 2-3 hours. The drug is conjugated to GSH by glutathione S-transferase A1A and further metabolized by CYP-dependent pathways; its major urinary metabolite is methane sulfonic acid. In high doses, children <18 years of age clear the drug two to four times faster than adults and tolerate higher doses (Vassal et al., 1993). An intravenous preparation is available for high-dose regimens. With doses of 1 mg/kg every 6 hours for 4 days, peak drug concentrations reach 10 μM in adults but only 1-5 μM in children 1-3 years of age, because of faster clearance. Busulfan clearance varies considerably among patients. VOD is associated with high area under the curve (AUC) (AUC >1500 μM × min) peak drug levels and slow clearance, leading to recommendations for dose adjustment based on drug level monitoring (Grochow, 1993). A target steady-state concentration of 600-900 ng/mL in plasma in adults or AUC <1000 μM × min in children achieves an appropriate balance between toxicity and therapeutic benefit (Witherspoon et al., 2001).

**Therapeutic Uses.** In treating chronic myelogenous leukemia (CML), the initial oral dose of busulfan (MYLERAN, BUSULFEX) varies with the total leukocyte count and the severity of the disease; daily doses of 2-8 mg for adults (~60 μg/kg or 1.8 mg/m² for children) are used to initiate therapy and are adjusted appropriately to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to ≤10,000 cells/mm³. A decrease in the leukocyte count usually is not seen during the first 10-15 days of treatment, and the leukocyte count may actually increase; during this period, an increase in leukocyte count should not be interpreted as drug resistance nor should the dose be increased. Because the leukocyte count may
fall for >1 month after discontinuing the drug, it is recommended
that busulfan be withdrawn when the total leukocyte count has
dropped to ~15,000 cells/mm³. A normal leukocyte count usually
is achieved within 12-20 weeks. During remission, daily treatment
resumes when the total leukocyte count reaches ~50,000 cells/mm³.
Daily maintenance doses are 1-3 mg. In high-dose therapy, doses of
1 mg/kg are given every 6 hours for 4 days, with adjustment based
on pharmacokinetics.

In high-dose regimens, busulfan is given at 0.8 mg/kg every
6 hours for 4 days. Anticonvulsants must be used concomitantly to
protect against acute CNS toxicities, including tonic-clonic seizures,
which may occur several hours after each dose. Busulfan induces
the metabolism of phenytoin. In patients requiring anti-seizure med-
ication, non-enzyme-inducing drugs such as lorazepam are recom-
manded as an alternative to phenytoin. When phenytoin is used
concurrently, plasma busulfan levels should be monitored and the
busulfan dose adjusted accordingly.

Clinical Toxicity. The major toxic effects of busulfan are related to
its myelosuppressive properties, and prolonged thrombocytopenia
may be a hazard. Occasionally, patients experience nausea, vomiting,
and diarrhea. Long-term use leads to impotence, sterility, amenor-
rea, and cataracts. The coincidence of VOD and hepatotoxicity is increased
by its co-administration with drugs that inhibit CYPs, including imi-
dazoles and metronidazole, possibly through inhibition of the clear-
ance of busulfan and/or its toxic metabolites (Nilsson et al., 2003).

Nitrosoureas

The nitrosoureas have an important role in the treatment of
brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow
reconstitution. They function as bifunctional alkylating agents but differ from conventional nitrogen mustards in both pharmacological and toxicological properties.

Carmustine (BCNU) and lomustine (CCNU) are highly
lipophilic and thus readily cross the blood-brain barrier, an important
property in the treatment of brain tumors. Unfortunately, with the
exception of streptozocin, nitrosoureas cause profound and delayed
myelosuppression with recovery 4-6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine
(methyl-CCNU), has resulted in renal failure. As with other alkylat-
ing agents, the nitrosoureas are highly carcinogenic and mutagenic.
They generate both alkylating and carbamylating moieties as illus-
trated in Figure 61–4.

Carmustine (BCNU). Carmustine’s major action is its
alkylation of DNA at the O⁶-guanine position, an
adduct repaired by MGMT. Methylation of the MGMT
promoter inhibits its expression in ~30% of primary gliomas and is associated with sensitivity to
nitrosoureas. In high doses with bone marrow rescue, it
produces hepatic VOD, pulmonary fibrosis, renal fail-
ure, and secondary leukemia (Tew et al., 2001).

Absorption, Fate, and Excretion. Carmustine is unstable in aque-
ous solution and in body fluids. After intravenous infusion, it dis-
appears from the plasma with a highly variable t₁/₂ of 15-90
minutes. Approximately 30-80% of the drug appears in the urine
within 24 hours as degradation products. The alkylating metabo-
lites enter rapidly into the cerebrospinal fluid (CSF), and their
concentrations in the CSF reach 15-30% of the concurrent plasma
values.

Therapeutic Uses. When used alone, carmustine (BCNU) is adminis-
tered intravenously at doses of 150-200 mg/m², given by infusion
over 1-2 hours and repeated every 6 weeks.

Because of its ability to cross the blood-brain barrier, car-
mustine has been used in the treatment of malignant gliomas but
has been increasingly replaced by temozolomide. An implantable
carmustine wafer (Gliadel) is available for use as an adjunct to surgery and radiation in newly diagnosed high-grade malignant
glioma patients and as an adjunct to surgery for recurrent glioblas-
toma multiforme.

Streptozocin. This antibiotic has a methylnitrosourea
(MNU) moiety attached to the 2-carbon of glucose. It
has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

Absorption, Fate, and Excretion. Streptozocin is rapidly degraded fol-

owing intravenous administration. The t₁/₂ of the drug is ~15 minutes. Only 10-20% of a dose is recovered intact in the urine.

Therapeutic Uses. Streptozocin (Zanosar) is used exclusively in the
treatment of human pancreatic islet cell carcinoma and malignant
carcinoid tumors. It is administered intravenously, 500 mg/m² once
daily for 5 days; this course is repeated every 6 weeks. Alternatively,
1000 mg/m² can be given weekly for 2 weeks, and the weekly dose
ten can be increased to a maximum of 1500 mg/m², depending on
tolerance and response.

Clinical Toxicity. Nausea is frequent. Mild, reversible renal or
hepatic toxicity occurs in approximately two-thirds of cases; in
<10% of patients, renal toxicity may be cumulative with each dose and may lead to irreversible renal failure. Proteinuria is an early
sign of tubular damage and impending renal failure. Streptozocin
should not be given with other nephrotoxic drugs. Hematological
toxicity—anemia, leukopenia, or thrombocytopenia—occurs in
20% of patients.

Triazenes

Dacarbazine (DTIC). Dacarbazine functions as a methyla-
lating agent after metabolic activation to the
monomethyl triazeno metabolite, MTIC. It kills cells
in all phases of the cell cycle. Resistance has been
ascribed to the removal of methyl groups from the O⁶-
guanine bases in DNA by MGMT.

Absorption, Fate, and Excretion. Dacarbazine is administered intrave-

ously. After an initial rapid phase of disappearance (t₁/₂ of ~20
minutes), dacarbazine is cleared from plasma with a terminal t₁/₂ of
~5 hours. The t₁/₂ is prolonged in the presence of hepatic or renal
disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion. Elevated urinary concentrations of 5-aminoimidazole-4-carboxamide reflect from the catabolism of dacarbazine, rather than inhibition of de novo purine biosynthesis.

**Therapeutic Uses.** Dacarbazine (DTIC-DOME) for malignant melanoma is given intravenously in dosages of 2–4.5 mg/kg/day for a 10-day period, repeated every 28 days. Alternatively, 250 mg/m² can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain. In combination with other drugs for Hodgkin’s disease, dacarbazine is given in dosages of 150 mg/m²/day for 5 days, repeated every 4 weeks, or a single dose of 375 mg/m² is given and repeated every 15 days.

At present, the primary clinical indication for dacarbazine is in the combination chemotherapy of Hodgkin’s disease. It is modestly effective against malignant melanoma and adult sarcomas.

**Clinical Toxicity.** DTIC induces nausea and vomiting in ≥90% of patients; vomiting usually develops 1–3 hours after treatment and may last up to 12 hours. Myelosuppression, with both leukopenia and thrombocytopenia, is mild and readily reversible within 1-2 weeks. A flu-like syndrome consisting of chills, fever, malaise, and myalgias may occur during treatment with DTIC. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatological reactions are less common adverse effects.

**Temozolomide.** Temozolomide (TEMODAR) is the standard agent in combination with radiation therapy for patients with malignant glioma and for astrocytoma. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle. Resistance arises by any of the common mechanisms attributed to other alkylating agents, but particularly the loss of MLH6, a component of MMR.

**Absorption, Fate, and Excretion.** Temozolomide is administered orally in dosages of ~200 mg/day; it has a bioavailability approaching 100%. Maximum drug concentration reaches 5 μg/mL, or ~10 μM in plasma, ~1 hour after administration of a dose of 200 mg and declines with an elimination t½ of 1-2 hours. The primary active metabolite MTIC reaches a maximum plasma concentration of 150 ng/mL 90 minutes after a dose and declines with a t½ of 2 hours. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamide (Baker et al., 1999).

**Clinical Toxicity.** Temozolomide is available for oral and intravenous administration. It is administered cyclically, and hematological monitoring is necessary to guide dosing adjustments. The toxicities of temozolomide mirror those of DTIC.

**Methylyhydrazines**

**Procarbazine.** The methylyhydrazine derivatives were synthesized in a search for inhibitors of monoamine neurotransmitters. Several compounds in this series had anticancer activity, but only procarbazine (N-isopropyl-α-(2-methylyhydrazino)-p-tolualamide), an agent formerly useful in Hodgkin’s disease and currently employed for second-line therapy in malignant brain tumors, has a role in clinical chemotherapy.

**PLATINUM COORDINATION COMPLEXES**

The platinum coordination complexes have broad anti-neoplastic activity and have become the foundation for treatment of ovarian, head and neck, bladder, esophagus, lung, and colon cancers. The analogs differ in their pharmacological properties, and oxaliplatin has mechanistic differences that may explain its unique activity in colorectal cancer (see “Mechanism of Action”) (Dolan and Fitch, 2007). Although cisplatin and other
platinum complexes do not form carbonium ion intermediates like other alkylating agents or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with alkylators.

**Chemistry.** Cisplatin and carboplatin are divalent, inorganic, water-soluble, platinum-containing complexes. Oxaliplatin, a tetravalent complex, does not display cross-resistance to the divalent compounds in some experimental tumors. The coordination of di- or tetravalent platinum with various organic adducts reduces its renal toxicity and stabilizes the metal ion, as compared to the inorganic divalent platinum ion.

**Mechanism of Action.** Cisplatin, carboplatin, and oxaliplatin enter cells by an active Cu$^{2+}$ transporter, CTR1, and in doing so rapidly degrade the transporter (Kruh, 2003). The compounds are actively extruded from cells by ATP7A and ATP7B copper transporters and by multidrug resistance protein 1 (MRP 1); variable expression of these transporters may contribute to clinical resistance (Dolan and Fitch, 2007). Inside the cell, the chloride, cyclohexane, or oxalate ligands of the three analogs are displaced by water molecules, yielding a positively charged and highly reactive molecule. In the primary cytotoxic reaction, the aquated species of the drug then reacts with nucleophiles on DNA and proteins.

Aquation of cisplatin is favored at the low concentrations of chloride inside the cell and in the urine. High concentrations of chloride stabilize the drug, explaining the effectiveness of chloride diuresis in preventing nephrotoxicity (see “Clinical Toxicities”). The activated platinum complexes can react with electron-rich molecules, such as sulfhydryls, and with various sites on DNA, forming both intrastrand and interstrand cross-links. The N-7 of guanine is a particularly reactive site, leading to platinum–DNA adducts. The oxaliplatin adducts inhibit replication and transcription, lead to single- and double-stranded breaks and miscoding, and if recognized by p53 and other checkpoint proteins, cause induction of apoptosis. Although no quantitative relationship between platinum–DNA adduct formation and efficacy has been documented, the ability of patients to form and sustain platinum adducts appears to be an important predictor of clinical response (Reed et al., 1988). The analogs differ in the formation of their adducts and the effects of adduct on DNA structure and function. Oxaliplatin and carboplatin are slower to form adducts. The oxaliplatin adducts are bulkier and less readily repaired, create a different pattern of distortion of the DNA helix, and differ from cisplatin adducts in the pattern of hydrogen bonding to adjacent segments of DNA (Sharma et al., 2007).

Unlike the other platinum analogs, oxaliplatin exhibits a cytotoxicity that does not depend on an active MMR system, which may explain its greater activity in colorectal cancer. It also seems less dependent on the presence of high mobility group (HMG) proteins that are required by the other platinum derivatives. Testicular cancers have a high concentration of HMG proteins and are quite sensitive to cisplatin. Basal-type breast cancers, such as those with BRCA1 and BRCA2 mutations, lack Her 2 amplification and hormone-receptor expression and appear to be uniquely susceptible to cisplatin through their upregulation of apoptotic pathways governed by p63 and p73 (Deyoung and Ellisen, 2007). The specificity of cisplatin with regard to phase of the cell cycle differs among cell types, although the effects of cross-linking are most pronounced during the S phase.

The platinum analogs are mutagenic, teratogenic, and carcinogenic. Cisplatin- or carboplatin-based chemotherapy for ovarian cancer is associated with a 4-fold increased risk of developing secondary leukemia.

**Resistance to Platinum Analogs.** Resistance to the platinum analogs likely is multifactorial, and the compounds differ in their degree of cross-resistance. Carboplatin shares cross-resistance with cisplatin in most experimental tumors, while oxaliplatin does not. A number of factors influence sensitivity to platinum analogs in experimental cells, including intracellular drug accumulation, as determined by the uptake and efflux transporters; intracellular levels of glutathione and other sulfhydryls such as metallothionein that bind to and inactivate the drug (Meijer et al., 1990); and rates of repair of DNA adducts. Repair of platinum–DNA adducts requires participation of the NER pathway. Inhibition or loss of NER increases sensitivity to cisplatin in ovarian cancer patients, while overexpression of NER components is associated with poor response to cisplatin or oxaliplatin-based therapy in lung, colon, and gastric cancer (Paré et al., 2008). Higher levels of expression of the NER component, ERCC1, in tumor cells and peripheral white blood cells are associated with a lower response rate in patients with solid tumors (Dolan and Fitch, 2007).

Resistance to cisplatin, but not oxaliplatin, appears to be partly mediated through loss of function in the MMR proteins (hMLH1, hMLH2, or hMSH6), which recognize platinum–DNA adducts and initiate apoptosis.

In the absence of effective repair of DNA–platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. However, it is clear that some DNA polymerases can bypass adducts, especially those created by cisplatin. Oxaliplatin adducts are less easily bypassed. It remains unproven whether these polymerases contribute to resistance. Cisplatin resistance related to loss of active uptake has been demonstrated in yeast; overexpression of copper efflux transporters, ATP7A and ATP7B, correlates with poor survival after cisplatin-based therapy for ovarian cancer (Kruh, 2003).
Cisplatin

Absorption, Fate, and Excretion. After intravenous administration, cisplatin has an initial plasma elimination $t_{1/2}$ of 25-50 minutes; concentrations of total (bound and unbound) drug fall thereafter, with a $t_{1/2}$ of ≥24 hours. More than 90% of the platinum in the blood is covalently bound to plasma proteins. The unbound fraction, composed predominantly of parent drug, diminishes within minutes. High concentrations of cisplatin are found in the tissues of the kidney, liver, intestine, and testes but poorly penetrate into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 hours; by 24 hours, up to 25% is excreted, and by 5 days, up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal.

Therapeutic Uses. Cisplatin (PLATINOL, others) is given only by the intravenous route. The usual dosage is 20 mg/m²/day for 5 days, 20-30 mg weekly for 3-4 weeks, or 100 mg/m² given once every 21-28 days. Instead, the dose-limiting toxicity is myelosuppression, primarily nausea, neurotoxicity, ototoxicity, and nephrotoxicity than cisplatin. Instead, the dose-limiting toxicity is myelosuppression, primarily thrombocytopenia. It is more likely to cause a hypersensitivity reaction; patients with a mild reaction, premedication, graded doses of drug, and more prolonged infusion lead to desensitization.

Carboplatin and cisplatin are equally effective in the treatment of suboptimally debulked ovarian cancer, non–small cell lung cancer, and extensive-stage small cell lung cancer; however, carboplatin may be less effective than cisplatin in germ cell, head and neck, and esophageal cancers (Go and Adjei, 1999). Carboplatin is an effective alternative for responsive tumors in patients unable to tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. The dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance (CrCl) for patients with a CrCl <60 mL/min. The following formula is useful for calculation of dose:

$$\text{Dose (mg)} = \text{AUC} \times (\text{GFR} + 25)$$

where the target AUC (area under the plasma concentration–time curve) is ~5-7 min/mg/mL for acceptable toxicity in patients receiving single-agent carboplatin (GFR = glomerular filtration rate).

Carboplatin (PARAPLATIN) is administered as an intravenous infusion over at least 15 minutes, using the above-mentioned formula for dose calculation, and is given once every 21-28 days.

Oxaliplatin

Absorption, Fate, and Excretion. Oxaliplatin, like cisplatin, has a very brief $t_{1/2}$ in plasma, probably as a result of its rapid uptake by tissues and its reactivity. Maximum concentrations in plasma range from 1-1.5 μg platinum/mL for patients receiving 80-130 mg/m²
intravenously and decline thereafter, with an initial \( t_{1/2} \) of 0.28 hour. Although the ultrafiltrable component has a slow terminal clearance from plasma, most of the low-molecular-weight platinum species represent inactive degradation products. These metabolites undergo renal excretion at a rate dependent on the CrCl. No dose adjustment is required for patients with a CrCl \( \geq 20 \) mL/min; decreased renal function does not affect the rapid chemical inactivation of the drug in the systemic circulation and tissues (Takimoto et al., 2007). Dose adjustment is not required for hepatic dysfunction (Synold et al., 2007).

**Therapeutic Uses.** Oxaliplatin exhibits a range of antitumor activity (colorectal and gastric cancer) that differs from other platinum agents. Oxaliplatin’s effectiveness in colorectal cancer is perhaps due to its MMR- and HMG-independent effects (see “Mechanism of Action” under “Platinum Coordination Complexes”). It also suppresses expression of thymidylate synthase (TS), the target enzyme of 5-fluorouracil (5-FU) action, which may promote synergy of these two drugs (Fischel et al., 2002). In combination with 5-FU, it is approved for treatment of patients with colorectal cancer.

**Clinical Toxicity.** The dose-limiting toxicity of oxaliplatin is a peripheral neuropathy. An acute form, often triggered by exposure to cold liquids, manifests as paresthesias and/or dysesthesias in the upper and lower extremities, mouth, and throat. It may be caused by rapid release of oxalate, with depletion of calcium and magnesium, and responds to infusion of these electrolytes. A second type of peripheral neuropathy is more closely related to cumulative dose and has features similar to cisplatin neuropathy; 75% of patients receiving a cumulative dose of 1560 mg/m\(^2\) experience some progressive sensory neurotoxicity, with dysesthesias, ataxia, and numbness of the extremities. Hematological toxicity is mild to moderate, except for rare immune-mediated cytopenias, and nausea is well controlled with 5-HT\(_3\)-receptor antagonists. Like other platinum analogs, oxaliplatin causes leukemia and pulmonary fibrosis months to years after administration. Oxaliplatin may cause an acute allergic response with urticaria, hypotension, and bronchoconstriction.

### FOLIC ACID ANALOGS

Folic acid is an essential dietary factor that is converted by enzymatic reduction to a series of tetrahydrofolate (FH\(_4\)) cofactors that provide methyl groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines). Interference with FH\(_4\) metabolism reduces the cellular capacity for one-carbon transfer and the necessary methylation reactions in the synthesis of purine ribonucleotides and thymidine monophosphate (TMP), thereby inhibiting DNA replication.

**History.** Antifolate chemotherapy occupies a special place in the history of cancer treatment: This class of drugs produced the first striking, although temporary, remissions in leukemia (Farber et al., 1948) and the first cure of a solid tumor, choriocarcinoma (Berlin et al., 1963). Interest in folate antagonists further increased with the development of curative combination therapy for childhood acute lymphocytic leukemia; in this therapy, methotrexate played a critical role in both systemic treatment and intrathecal therapy. Introduction of high-dose regimens with “rescue” of host toxicity by the reduced folate, leucovorin (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, \( \text{N}^5\)-formyl FH\(_4\)), further extended the effectiveness of this drug to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Most recently, pemetrexed, an analog that differs from methotrexate in its transport properties and sites of action, has proven useful in treating mesothelioma and lung cancer.

Recognition that methotrexate, an inhibitor of dihydrofolate reductase (DHFR), also directly inhibits the folate-dependent enzymes of *de novo* purine and thymidylate synthesis led to development of antifolate analogs that specifically target these other folate-dependent enzymes (Figure 61–5). New inhibitors have resulted from synthetic modifications of the basic folate molecule (replacement of the N5 and/or N8 nitrogens of the pteridine ring and the N10 nitrogen of the bridge between the pteridine and benzene rings of folate, as well as various side-chain substitutions). These

---

**Figure 61–5. Sites of action of methotrexate and its polyglutamates.** AICAR, aminoimidazole carboxamide; TMP, thymidine monophosphate; dUMP, deoxyuridine monophosphate; FH\(_2\)Glu\(_n\), dihydrofolate polyglutamate; FH\(_4\)Glu\(_n\), tetrahydrofolate polyglutamate; GAR, glycaminide ribonucleotide; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl-1-pyrophosphate.
new agents have greater capacity for transport into tumor cells (pralatrexate) and exert their primary inhibitory effect on TS (raltitrexed, TOMUDEX), early steps in purine biosynthesis (lometrexol), or both (the multitargeted antifolate, pemetrexed, ALIMTA) (Vogelzang et al., 2003; O’Connor et al., 2007).

Aside from its antineoplastic activity, methotrexate also has been used with benefit in the therapy of psoriasis (see Chapter 65). Additionally, methotrexate inhibits cell-mediated immune reactions and is employed to suppress graft-versus-host disease in allogeneic bone marrow and organ transplantation and for the treatment of dermatomyositis, rheumatoid arthritis, Wegener’s granulomatosis, and Crohn’s disease (see Chapters 35 and 47).

**Structure-Activity Relationship.** The primary target of methotrexate is the enzyme DHFR (Figure 61–5). Inhibition of DHFR leads to partial depletion of the FH₄ cofactors (5-10 methylene tetrahydrofolic acid and N-10 formyl tetrahydrofolic acid) required for the respective synthesis of thymidylate and purines. In addition, methotrexate, like its physiological counterparts (the folates), undergoes conversion to a series of polyglutamates (MTX-PGs) in both normal and tumor cells. These MTX-PGs constitute an intracellular storage form of folates and folate analogs and dramatically increase inhibitory potency of the analog for additional sites, including TS and two early enzymes in the purine biosynthetic pathway (Figure 61–5). Finally, the dihydrofolinic acid polyglutamates that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes (Figure 61–5) (Allegra et al., 1987b).

Because folic acid and many of its analogs are polar, they cross the blood-brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells: 1) a folate receptor, which has high affinity for folic acid but much reduced ability to transport methotrexate and other analogs; 2) the reduced folate transporter, the major transit protein for methotrexate, raltitrexed, pemetrexed, and most analogs (Westerhof et al., 1995); and 3) a transporter that is active at low pH. The importance of transport in determining drug sensitivity is illustrated by the finding that the reduced folate transporter is highly expressed in the hyperdiploid subtype of acute lymphoblastic leukemia, due to the presence of multiple copies of chromosome 21, on which its gene resides; these cells have extreme sensitivity to methotrexate (Pui et al., 2004). Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folylpolyglutamate synthetase. Intracellular methotrexate polyglutamates have been identified with up to six glutamyl residues. Because these higher polyglutamates are strongly charged and cross cellular membranes poorly, if at all, polyglutamation serves as a mechanism of entrapment and may account for the prolonged retention of methotrexate in chorionic epithelium (where it is a potent abortifacient); in tumors derived from this tissue, such as choriocarcinoma cells; and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamylated folates and analogs have substantially greater affinity than the monoglutamate form for folate-dependent enzymes that are required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

New folate antagonists that are better substrates for the reduced folate carrier have been identified. In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate (NEUTREXIN), a lipid-soluble analog that lacks a terminal glutamate, was one of the first to be tested for clinical activity. The analog has modest antitumor activity, primarily in combination with leucovorin rescue. However, it is beneficial in the treatment of P. jiroveci (Pneumocystis carinii) pneumonia (Allegra et al., 1987a), where leucovorin provides differential rescue of the host but not the parasite.

The most important new folate analog, MTA or pemetrexed (ALIMTA) (Figure 61–6), is a pyrrole–pyrimidine structure. It is avidly transported into cells via the reduced folate carrier. It readily is converted to polyglutamates that inhibit TS and glycine amide ribonucleotide transformylase, as well as DHFR. It has shown activity against ovarian cancer, mesothelioma, and non–small-cell adenocarcinomas of the lung (Vogelzang et al., 2003).

Inhibitors of DHFR differ in their relative potency for blocking enzymes from different species. Agents have been identified that have little effect on the human enzyme but have strong activity against bacterial and parasitic infections (see discussions of trimethoprim, Chapter 52, and pyrimethamine, Chapter 49). By contrast, methotrexate effectively inhibits DHFR in all species investigated. Crystallographic studies have revealed the structural basis for the high affinity of methotrexate for DHFR (Blakley and Sorrentino, 1998) and the species specificity of the various DHFR inhibitors.

**Mechanism of Action.** To function as a cofactor in one-carbon transfer reactions, folate must first be reduced by DHFR to FH₄. Single-carbon fragments are added enzymatically to FH₄ in various configurations and then may be transferred in specific synthetic reactions. In a key metabolic event catalyzed by TS (Figure 61–5), deoxyuridine monophosphate (dUMP) is converted to thymidine monophosphate (TMP), an essential component of DNA. In this reaction, a one-carbon group is transferred to dUMP from 5,10-methylene FH₄, and the reduced folate cofactor is oxidized to dihydrofolate (FH₂). To function again as a cofactor, FH₂ must be reduced to FH₄ by DHFR. Inhibitors such as methotrexate, with a high affinity for DHFR (Kᵢ ~0.01-0.2 nM), prevent the formation of FH₄ and allow an accumulation of the toxic inhibitory substrate, FH₂ polyglutamate, behind the blocked reaction. The absence of reduced folates shuts down the one-carbon transfer reactions crucial for the de novo synthesis of purine nucleotides and thymidylate and interrupts the synthesis of DNA and RNA. The toxic effects of methotrexate may be terminated by administering leucovorin, a fully reduced folate coenzyme, which repletes the intracellular pool of FH₄ cofactors.

As with most antimetabolites, methotrexate is only partially selective for tumor cells and kills rapidly
dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly.

Pemetrexed and its polyglutamates have a somewhat different spectrum of biochemical actions. Like methotrexate, pemetrexed inhibits DHFR, but as a polyglutamate, it even more potently inhibits glycinamide ribonucleotide formyltransferase (GART) and thymidylate synthase (TS). Unlike methotrexate, it produces little change in the pool of reduced folates, indicating that the distal sites of inhibition (TS and GART) predominate. Its pattern of deoxynucleotide depletion, as studied in cell lines, also differs from methotrexate, as it causes a greater fall in thymidine triphosphate (TTP) than in other triphosphates (Chen et al., 1998). Like methotrexate, it induces p53 and cell-cycle arrest, but this effect does not seem to depend on downstream induction of p21. Pralatrexate is more effectively taken up and polyglutamated than methotrexate. Pralatrexate is approved for treatment of cutaneous T-cell lymphoma (O’Connor et al, 2007).

Mechanisms of Resistance to Antifolates. In experimental and clinical chemotherapy, acquired resistance to methotrexate affects each known step in methotrexate action, including:

- Impaired transport of methotrexate into cells
- Production of altered forms of DHFR that have decreased affinity for the inhibitor
- Increased concentrations of intracellular DHFR through gene amplification or altered gene regulation
- Decreased ability to synthesize methotrexate polyglutamates
- Increased expression of a drug efflux transporter of the MRP class (see Chapter 5)

DHFR levels in leukemic cells increase within 24 hours after treatment of patients with methotrexate; this likely reflects induction of new enzyme synthesis. The unbound DHFR protein may bind to its own message and inhibit translational efficiency of its own synthesis, while the DHFR-MTX complex is ineffective in blocking the DHFR translation. With longer periods of drug exposure, tumor cell populations that contain markedly increased levels of DHFR emerge. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal...
elements formed by amplification of DHFR genes in response to methotrexate treatment) or in stably integrated, homogeneously staining chromosomal regions or amplicons. First identified as an explanation for resistance to methotrexate (Schimke et al., 1978), gene amplification of a target protein has since been implicated in the resistance to many antitumor agents, including 5-FU and pentostatin (2′-deoxycoformycin) and has been observed in patients with lung cancer (Curt et al., 1985) and leukemia. Impaired transport and polyglutamation have been implicated as mechanisms of resistance in childhood leukemia.

To overcome resistance, high doses of methotrexate may permit entry of the drug into transport-defective cells and may permit the intracellular accumulation of methotrexate in concentrations that inactivate high levels of DHFR.

The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance to this agent seems to arise from loss of influx transport, TS amplification, changes in purine biosynthetic pathways, or loss of polyglutamation.

Absorption, Fate, and Excretion. Methotrexate is readily absorbed from the GI tract at doses of <25 mg/m², but larger doses are absorbed incompletely and are routinely administered intravenously. Peak concentrations of 1-10 µM in the plasma are obtained after doses of 25-100 mg/m², and concentrations of 0.1-1 mM are achieved after high-dose infusions of 1.5-20 g/m². After intravenous administration, the drug disappears from plasma in a triphasic fashion (Sonneveld et al., 1986). The rapid distribution phase is followed by a second phase, which reflects renal clearance (t 1/2 of ~2-3 hours). A third phase has a t 1/2 of ~8-12 hours. Metabolism of methotrexate in humans usually is minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-methotrexate, which is potentially nephrotoxic. Renal excretion of methotrexate occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (e.g., nonsteroidal anti-inflammatory agents), that are nephrotoxic (e.g., cisplatin), or that are weak organic acids (e.g., aspirin, piperacillin) can delay drug excretion and lead to severe myelosuppression. Particular caution must be exercised in treating patients with renal insufficiency. In such patients, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided.

Methotrexate is retained in the form of polyglutamates for long periods—for example, for weeks in the kidneys and for several months in the liver.

It is important to emphasize that concentrations of methotrexate in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are not killed by standard dosage regimens. When high doses of methotrexate are given (>1.5 g/m²; see “Therapeutic Uses”), cytotoxic concentrations of methotrexate reach the CNS.

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates methylenetetrahydrofolate, the cofactor for TS, and thereby increases methotrexate toxicity (Pullarkat et al., 2001). The presence of this polymorphism in leukemic cells confers increased sensitivity to methotrexate and might also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS govern the translation efficiency of this message and, by governing the intracellular levels of TS, modulate the response and toxicity of both antifolates (Pui et al., 2004) and fluoropyrimidines.

Therapeutic Uses. Methotrexate (Amethopterin; RHEUMATREX, TRELALL, others) has been used in the treatment of severe, disabling psoriasis in doses of 2.5 mg orally for 5 days, followed by a rest period of at least 2 days, or 10-25 mg intravenously weekly. It also is used at low dosage to induce remission in refractory rheumatoid arthritis (Hoffmeister, 1983). Awareness of the pharmacology, toxic potential, and drug interactions associated with methotrexate is a prerequisite for its use in these non-neoplastic disorders.

Methotrexate is a critical drug in the management of acute lymphoblastic leukemia (ALL) in children. High-dose methotrexate is of great value in remission induction and consolidation and in the maintenance of remissions in this highly curable disease. A 6- to 24-hour infusion of relatively large doses of methotrexate may be employed every 2-4 weeks (≥1-7.5 g/m²) but only when leucovorin rescue follows within 24 hours of the methotrexate infusion. Such regimens produce cytotoxic concentrations of drug in the CSF and protect against leukemic meningitis. For maintenance therapy, it is administered weekly in doses of 20 mg/m² orally. Outcome of treatment in children correlates inversely with the rate of drug clearance. During methotrexate infusion, high steady-state levels are associated with a lower leukemia relapse rate (Pui et al., 2004). Methotrexate is of limited value in adults with AML, except for treatment and prevention of leukemic meningitis. The intrathecal administration of high concentrations of methotrexate has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of methotrexate in the CSF and also is effective in patients whose systemic disease has become resistant to methotrexate. The recommended intrathecal dose in all patients >3 years of age is 12 mg (Bleyer, 1978). The dose is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the potential toxicity of methotrexate that escapes into the systemic circulation, although this generally is not necessary. Because methotrexate administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be given via an intraventricular Ommaya reservoir in the treatment of active intrathecal disease. Methotrexate is of established value in choriocarcinoma and related trophoblastic tumors of women; cure is achieved in ~75% of advanced cases treated sequentially with methotrexate and dactinomycin and in >90% when early diagnosis is made. In the treatment of choriocarcinoma, 1 mg/kg of methotrexate is administered intramuscularly every other day for
four doses, alternating with leucovorin (0.1 mg/kg every other day). Courses are repeated at 3-week intervals, toxicity permitting, and urinary β-human choric gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt’s and other non-Hodgkin’s lymphomas. Methotrexate is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. High-dose methotrexate with leucovorin rescue (HDM-L) is a standard agent for adjuvant therapy of osteosarcoma and produces a high complete response rate in CNS lymphomas. The administration of HDM-L has the potential for renal toxicity, probably related to the precipitation of the drug, a weak acid, in the acidic tubular fluid. Thus, vigorous hydration and alkalization of urine pH are required prior to drug administration. HDM-L should be performed only by experienced clinicians who are familiar with hydration regimens and who have access to laboratories that monitor concentrations of methotrexate in plasma. If methotrexate values measured 48 hours after drug administration are 1 μM or higher, higher doses (100 mg/m²) of leucovorin must be given until the plasma concentration of methotrexate falls to <50 nM (Stoller et al., 1977). With appropriate hydration and urine alkalization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L is <2%. In patients who become oliguric, intermittent hemodialysis is ineffective in reducing methotrexate levels. Continuous-flow hemodialysis can eliminate methotrexate at ~50% of the clearance rate in patients with intact renal function (Wall et al., 1996). Alternatively, a methotrexate-cleaving enzyme, carboxypeptidase G2, can be obtained from the Cancer Therapy Evaluation Program at the National Cancer Institute. When administered intravenously, it rapidly clears the drug (DeAngelis et al., 1996). Methotrexate concentrations in plasma fall by ≥99% within 5-15 minutes following enzyme administration, with insignificant rebound. Systemically administered carboxypeptidase G2 has little effect on methotrexate levels in the CSF.

Clinical Toxicities. As previously stated, the primary toxicities of antifolates affect the bone marrow and the intestinal epithelium and correct within 10-14 days. Myelosuppressed patients may be at risk for spontaneous hemorrhage or life-threatening infection, and they may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed excretion of the drug. The dosage of methotrexate (and likely pemetrexed) must be reduced in proportion to any reduction in CrCl.

Additional toxicities of methotrexate include alopecia, dermatitis, an allergic interstitial pneumonitis, nephrotoxicity (after high-dose therapy), defective oogenesis or spermatogenesis, abortion, and teratogenesis. Low-dose methotrexate may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of methotrexate often causes meningismus and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Leucovorin does not reverse neurotoxicity.

A toxicity of particular significance in chronic administration to patients with psoriasis or rheumatoid arthritis is hepatic fibrosis and cirrhosis. Increased hepatic portal fibrosis is detected with higher frequency than in control patients after ≥6 months of continuous oral methotrexate treatment of psoriasis. Its presence mandates discontinuation of methotrexate. High-dose administration regularly causes acute elevation of hepatic transaminases, but these changes rapidly reverse and are not associated with permanent liver damage.

Folic acid antagonists are toxic to developing embryos. Methotrexate is highly effective when used with the prostaglandin analog misoprostol in inducing abortion in first-trimester pregnancy (Hausknecht, 1995).

Pemetrexed toxicity mirrors that of methotrexate, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. Dexamethasone, 4 mg twice daily on days –1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with pemetrexed, seen especially in patients with preexisting homocystinemia and possibly reflecting folate deficiency, largely is eliminated by concurrent administration of low dosages of folic acid, 350-1000 mg/day, beginning 1-2 weeks prior to pemetrexed and continuing while the drug is administered. Patients should receive intramuscular vitamin B₁₂ (1 mg) with the first dose of pemetrexed to correct possible B₁₂ deficiency. These small doses of folate and B₁₂ do not compromise the therapeutic effect.

PYRIMIDINE ANALOGS

The antimetabolites as a class encompass a diverse group of drugs that inhibit RNA and DNA function. The fluoropyrimidines and certain purine analogs (6-mercaptopurine and 6-thioguanine) inhibit the synthesis of essential precursors of DNA. Others, such as the cytidine and adenosine nucleoside analogs, become incorporated into DNA and block its further elongation and function. Other inhibitory effects of these analogs may contribute to their cytotoxicity and even their ability to induce differentiation.

To understand the role of these drugs, it is useful to review the nomenclature of the DNA bases and their metabolic intermediates. Four bases, shown in Figure 61–7, form DNA; these are two pyrimidines, thymine and cytosine, and two purines, guanine and adenine. Some bases (guanine) are found in mammalian cells as free bases, while others (the pyrimidines) are present in their active form only as nucleosides (a base attached to a ribose or deoxyribose). These precursor forms then are converted to a nucleoside triphosphate (base, sugar, and 5′-phosphate, also known as a nucleotide). Mammalian cells lack the ability to utilize cytosine, thymine, and adenine as bases, and so these bases are found in the bloodstream as nucleosides and in cells as nucleosides or nucleotides. The various purine and pyrimidine triphosphates form the intracellular pool of precursors for both RNA (with ribose sugars) and DNA (with deoxyribose sugars). The composition of RNA also differs from DNA in that RNA incorporates uracil instead of thymine as one of its bases.
Strategies for inhibiting DNA synthesis are based on the ability to create analogs of these precursors that readily enter tumor cells and become activated by intracellular enzyme. As an example, the first successful pyrimidine analog, 5-FU, is converted to a deoxynucleotide, fluoro-deoxyuridine monophosphate (FdUMP), which in turn blocks the enzyme; TS, required for the physiological conversion of dUMP to dTMP, a component of DNA. Other analogs incorporate into DNA itself and thereby block its function.

Cells can make the purine and pyrimidine bases de novo and convert them to their active triphosphates (dNTPs). The dNTPs then act as substrates for DNA polymerase and become linked in 3′-5′ phosphate ester bonds to form DNA strands; their base sequence provides the code for subsequent RNA and protein sequences.

As an alternative to synthesis of new precursor molecules, cells can salvage either free bases or their deoxynucleosides (Figure 61–7) from the bloodstream, presumably the products of degradation of DNA. Certain bases, such as uracil, guanine, and their analogs, can be taken up by cells and converted intracellularly to (deoxy) nucleotides by the addition of deoxyribose and phosphate groups. Antitumor analogs of these bases (5-FU, 6-thioguanine) can be formulated as simple substituted bases. Other bases, including cytosine, thymine, and adenine, and their analogs can only be utilized as deoxynucleosides, which are readily transported into cells and activated to deoxynucleotides by intracellular kinases. Thus, cytarabine (cytosine arabinoside; Ara-C), gemcitabine, 5-azacytidine, and adenine analogs (cladribine), are nucleosides readily taken up by cells, converted to nucleotides, and incorporated into DNA (Figure 61–8).

Fludarabine phosphate, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogs may differ from the physiological bases in a variety of ways: by altering in the purine or pyrimidine ring; by altering the sugar attached to the base, as in the arabinoside, Ara-C; or by altering both the base and sugar, as in fludarabine phosphate (Figure 61–7). These alterations produce inhibitory effects on vital enzymatic pathways and prevent DNA synthesis.

Fluorouracil, Capecitabine, and Floxuridine (Fluorodeoxyuridine)

5-fluorouracil (5-FU)

Mechanism of Action. 5-FU requires enzymatic conversion to the nucleotide status (ribosylation and phosphorylation) in order to exert its cytotoxic activity (Figure 61–9). Several routes are available for the formation of fluorouridine monophosphate (FUMP). 5-FU may be converted to fluorouridine by uridine phosphorylase and then to FUMP by uridine kinase, or it may react directly with 5-phosphoribosyl-1-pyrophosphate (PRPP), as catalyzed by orotate phosphoribosyltransferase, to form FUMP. Further metabolic pathways are available to FUMP. As the triphosphate FUTP, it is incorporated into RNA. In an alternative reaction sequence crucial for antineoplastic activity, it is reduced to FUDP by ribonucleotide reductase (RNR) to the deoxynucleotide level and forming of FdUMP. 5-FU also may be converted by thymidine phosphorylase to the deoxyriboside fluorodeoxyuridine (FUDR) and then by thymidine kinase to FdUMP; a potent inhibitor of thymidylate synthase. This complex metabolic pathway for the generation of FdUMP may be bypassed through administration of fluoruridine (fluorodeoxyuridine; FUDR), which is converted directly to FdUMP by thymidine kinase. FUDR rarely is used in clinical practice.

FdUMP inhibits TS and blocks the synthesis of TTP, a necessary constituent of DNA (Figure 61–10). The folate cofactor, 5,10-methylenetetrahydrofolate, and FdUMP form a covalently bound ternary complex with TS. This inhibited complex resembles the transition state formed during the enzymatic conversion of dUMP to
Fluoropyrimidine Analogs

CAPECITABINE

5-FLUOROURACIL (5-FU)

5-FLUORODEOXYURIDINE (FLOXURIDINE)

5-FLUORODEOXYURIDINE MONOPHOSPHATE (ACTIVE METABOLITE)

Figure 61–8. Structures of available pyrimidine analogs.

thymidylate. The physiological complex of TS-folate-dUMP progresses to the synthesis of thymidylate by transfer of the methylene group and two hydrogen atoms from folate to dUMP, but this reaction is blocked in the inhibited complex of TS-FdUMP-folate by the stability of the fluorine carbon bond on FdUMP; sustained inhibition of the enzyme results.

5-FU is incorporated into both RNA and DNA. In 5-FU-treated cells, both fluorodeoxyuridine triphosphate (FdUTP) and deoxyuridine triphosphate (dUTP) (the substrate that accumulates behind the blocked TS reaction) incorporate into DNA in place of the depleted physiological TTP. The significance of the incorporation of FdUTP and dUTP into DNA is unclear. Presumably, the incorporation of

Figure 61–9. Activation pathways for 5-fluorouracil (5-FU) and 5-floxuridine (FUR). deoxyxuridylic acid and/or fluorodeoxyxuridylic acid into DNA would call into action the excision-repair process. This process may result in DNA strand breakage because DNA repair requires thymidine, but this substrate is lacking as a result of TS inhibition. 5-FU incorporation into RNA also causes toxicity as the result of major effects on both the processing and functions of RNA.

Resistance to the cytotoxic effects of 5-FU or FUdR has been ascribed to loss or decreased activity of the enzymes necessary for activation of 5-FU, amplification of TS (Wasstein, 1982), mutation of TS to a form that is not inhibited by FDUMP (Barbour et al., 1990), and high levels of the degradative enzymes dihydouracil dehydrogenase and thymidine phosphorylase (Van Triest et al., 2000). TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FDUMP, inhibition of translation is relieved, and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5-FU (Chu et al., 1991).

Some malignant cells appear to have insufficient concentrations of 5,10-methylenetetrahydrofolate, and thus cannot form maximal levels of the inhibited ternary complex with TS. Addition of exogenous folate in the form of N5-formyl FH4 (leucovorin) increases formation of the complex and enhances responses to 5-FU in clinical trials (Grogan et al., 1993).

In addition to leucovorin, a number of other agents have been combined with 5-FU in attempts to enhance the cytotoxic activity through biochemical modulation. Methotrexate, by inhibiting purine synthesis and increasing cellular pools of PRPP, enhances the activation of 5-FU and increases antitumor activity of 5-FU when given prior to but not following 5-FU. In clinical trials, the combination of cisplatin and 5-FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is not well understood. Oxaliplatin, which downregulates TS expression, is commonly used with 5-FU and leucovorin for treating metastatic colorectal cancer. Perhaps the most important interaction is the enhancement of irradiation by fluoropyrimidines, the basis for which is unclear. 5-FU with simultaneous irradiation cures anal cancer and enhances local tumor control in head and neck, cervical, rectal, gastrointestinal, and pancreatic cancer.

Absorption, Fate, and Excretion. 5-FU is administered parenterally, because absorption after oral ingestion of the drug is unpredictable and incomplete. Metabolic degradation occurs in many tissues, particularly the liver. 5-FU is inactivated by reduction of the pyrimidine ring in a reaction carried out by dihydropyrimidine dehydrogenase (DPD), which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug (Milano et al., 1999). The rare individual who totally lacks this enzyme may experience profound drug toxicity following conventional doses of the drug. DPD deficiency can be detected either by enzymatic or molecular assays using peripheral white blood cells or by determining the plasma ratio of 5-FU to its metabolite, 5-fluoro-5,6-dihydroxymethyl.

Intravenous administration of 5-FU produces peak plasma concentrations of 0.1-0.5 mM; plasma clearance is rapid (with a t1/2 of 10-20 minutes). Only 5-10% of a single intravenous dose of 5-FU is excreted intact in the urine. Although the liver contains high concentrations of DPD, the dose does not have to be modified in patients with hepatic dysfunction, presumably because of degradation of the drug at extrahepatic sites. Given by continuous intravenous infusion for 24-120 hours, 5-FU achieves steady-state plasma concentrations in the range of 0.5-0.8 μM. 5-FU enters the CSF in minimal amounts.

Therapeutic Uses. 5-FU produces partial responses in 10-20% of patients with metastatic colon carcinomas, upper GI tract carcinomas, and breast carcinomas but rarely is used as a single agent. 5-FU in combination with leucovorin and oxaliplatin or irinotecan in the adjuvant setting is associated with a survival advantage for patients with colorectal cancers.

For average-risk patients in good nutritional status with adequate hematopoietic function, the weekly dosage regimen employs 500-600 mg/m2 with leucovorin once each week for 6 of 8 weeks. Other regimens use daily doses of 500 mg/m2 for 5 days, repeated in monthly cycles. When used with leucovorin, doses of daily 5-FU for 5 days must be reduced to 375-425 mg/m2 because of mucositis and diarrhea. 5-FU increasingly is used as a biweekly infusion, in which a loading dose is followed by a 48-hour continuous infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer (De Gramont et al., 1998).

Flouxuridine (FUDR). FUDR (fluorodeoxyuridine; FUdR, others) is used primarily by continuous infusion into the hepatic artery for treatment of metastatic carcinoma of the colon or following resection of hepatic metastases (Kemeny et al., 1999); the response rate to such infusion is 40-50%, or double that observed with intravenous administration.
Intrahepatic arterial infusion for 14-21 days causes minimal systemic toxicity; however, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7-14.

**Capecitabine (Xeloda).** Capecitabine, an orally administered produg of 5-FU, is approved for the treatment of 1) metastatic breast cancer in patients who have not responded to a regimen of paclitaxel and an anthracycline antibiotic; 2) metastatic breast cancer when used in combination with docetaxel in patients who have had a prior anthracycline-containing regimen; and 3) metastatic colorectal cancer.

The recommended dosage is 2500 mg/m²/day, given in two divided doses with food, for 2 weeks, followed by a rest period of 1 week. Capecitabine is well absorbed orally. It is rapidly de-esterified and deaminated, yielding high plasma concentrations of an inactive prodrug 5′-deoxyfluorodeoxyuridine (5′-dFdU), which disappears with a t½ of ~1 hour. The conversion of 5′-dFdU to 5-FU by thymidine phosphorylase occurs in liver tissues, peripheral tissues, and tumors. 5-FU levels are <10% of those of 5′-dFdU, reaching a maximum of 0.3 mg/L or 1 μM at 2 hours. Liver dysfunction delays the conversion of the parent compound to 5′-dFdU and 5-FU, but there is no consistent effect on toxicity (Twelves et al., 1999).

**Combination Therapy.** Higher response rates are seen when 5-FU or capecitabine is used in combination with other agents (e.g., with cisplatin in head and neck cancer, with oxaliplatin or irinotecan in colon cancer).

The combination of 5-FU and oxaliplatin or irinotecan has become the standard first-line treatment for patients with metastatic colorectal cancer, although equivalent results are reported for capecitabine and oxaliplatin. 5-FU in combination regimens has improved survival in the adjuvant treatment for breast cancer and, with oxaliplatin and leucovorin, for colorectal cancer. 5-FU also is a potent radiation sensitizer. Beneficial effects also have been reported when combined with irradiation as primary treatment for locally advanced cancers of the esophagus, pancreas, cervix, anus, and head and neck. 5-FU produces very favorable results for the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

**Clinical Toxicities.** The clinical manifestations of toxicity caused by 5-FU and fluorouracil are similar. The earliest untoward symptoms during a course of therapy are anorexia and nausea, followed by stomatitis and diarrhea, which constitute reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5-FU. The nadir of leukopenia usually is between days 9 and 14 after the first injection of drug. Thrombocytopenia and anemia also may occur. Loss of hair, occasionally progressing to total alopecia, nail changes, dermatitis, and increased pigmentation and atrophy of the skin may be encountered. Hand-foot syndrome, a particularly prominent adverse effect of capecitabine, consists of erythema, desquamation, pain, and sensitivity to touch of the palms and soles. Acute chest pain with evidence of ischemia in the electrocardiogram may result from coronary artery vasospasms during or shortly after 5-FU infusion. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional regimens than with bolus regimens, while hand-foot syndrome occurs more often with infusional regimens than with bolus regimens. The significant risk of toxicity with fluoropyrimidines emphasizes the need for very skillful supervision by physicians familiar with the action and possible hazards.

Capecitabine causes much the same spectrum of toxicities as 5-FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

### CYTIDINE ANALOGS

**Cytarabine (Cytosine Arabinoside; Ara-C)***

Cytarabine (1-β-D-arabinofuranosylcytosine; Ara-C) is the most important antimetabolite used in the therapy of AML. It is the single most effective agent for induction of remission in this disease.

**Mechanism of Action.** Ara-C is an analog of 2′-deoxyctydine with the 2′-hydroxyl in a position trans to the 3′-hydroxyl of the sugar (Figure 61–7). The 2′-hydroxyl hinders rotation of the pyrimidine base around the nucleoside bond and interferes with base pairing. The drug enters cells via a nucleoside transporter and is converted to its active form, the 5′-monophosphate ribonucleotide, by deoxycytidine kinase (CdK), an enzyme that shows polymorphic expression among patients, as detailed in the following paragraphs.

Ara-C penetrates cells by a carrier-mediated process shared by physiological nucleosides. Several candidate carriers bring nucleosides into cells, but the hENT1 transporter appears to be the primary mediator of Ara-C influx. In infants and adults with ALL and t(4;11) mixed-lineage leukemia (MLL) translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter, hENT1, is highly expressed (Pui et al., 2004), and its expression correlates with sensitivity to Ara-C. A single-point mutation in hENT1 conferred Ara-C resistance in a leukemic cell line (Cai et al., 2008). At extracellular drug concentrations >10 μM (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting.

Ara-C must be “activated” by conversion to the 5′-monophosphate nucleotide (Ara-CMP), a reaction catalyzed by CdK. Polymorphisms of CdK may influence the rate of activation in individual patients (Lamba et al., 2007). Ara-CMP then reacts with appropriate deoxynucleotide kinases to form diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with the physiological substrate deoxycytidine 5′-triphosphate (dCTP) for
incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, both in replication and repair synthesis, and blocks the further elongation of the nascent DNA molecule. The block in elongation activates checkpoint kinases (ATR and chk-1), which initiate attempts to remove the offending nucleotide. If DNA breaks are not repaired, apoptosis ensues. Ara-C cytotoxicity correlates with the total Ara-C incorporated into DNA. Thus, incorporation of about five molecules of Ara-C per 10⁶ bases of DNA decreases cellular clonogenicity by ~50% (Kufe et al., 1984).

Ara-C exposure activates a complex system of secondary intracellular signals that determine whether a cell survives or undergoes apoptosis. It activates the transcription factor AP-1 and stimulates the formation of ceramide, a potent inducer of apoptosis. It causes an increase in the cell damage response factor NF-kB in leukemic cells and activates checkpoint kinases. Additionally, the level of expression of the anti-apoptotic BCL-2 and BCL-Xₐ proteins correlates inversely with relative sensitivity to Ara-C (Ibrado et al., 1996). Thus, the lethality depends on the complex interplay of multiple factors, including transport, intracellular metabolism, and cellular response to DNA damage.

Low concentrations of Ara-C induce terminal differentiation of leukemic cells in tissue culture, an effect that is accompanied by decreased c-myc oncogene expression; molecular analysis of bone marrow specimens from some leukemic patients in remission after Ara-C therapy has revealed persistence of leukemic markers, suggesting that differentiation may have occurred.

Continuous inhibition of DNA synthesis for a duration equivalent to at least one cell cycle or 24 hours is necessary to expose most tumor cells during the S, or DNA-synthetic, phase of the cycle. The optimal interval between bolus doses of Ara-C is ~8-12 hours, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels during a multi-day cycle of treatment. Typical schedules for administration of Ara-C employ bolus doses every 12 hours or continuous drug infusion for 5-7 days.

Particular subtypes of AML derive benefit from high-dose Ara-C treatment; these include t(8;21), inv(16), t(9;16), and del(16), all of which involve core-binding factors that regulate hematopoiesis (Widemann et al., 1997). Approximately 20% of AML patients have leukemic cells with a k-RAS mutation, and these patients seem to derive greater benefit from high dose Ara-C regimens than do patients with wild type k-RAS (Neubauer et al., 2008).

Mechanisms of Resistance to Cytarabine. Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting activating enzyme, CdK, produces Ara-CMP. It is opposed by the degradative enzyme, cytidine deaminase, which converts Ara-C to a nontoxic metabolite, ara-uridine (Ara-U). Cytidine deaminase activity is high in many normal tissues, including intestinal mucosa, liver, and neutrophils, but lower in AML cells and other human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite, Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells leads to a longer duration of complete remission in patients with AML (Preisler et al., 1985). As discussed above, the ability of cells to transport Ara-C also may affect response. Clinical studies have implicated a loss of deoxycytidine kinase as the primary mechanism of resistance to Ara-C in AML (Cai et al., 2008), although 5’ nucleotidase, which degrades Ara-CMP, and possibly cytidine deaminase elevations, may play a role in AML resistance to Ara-C.

Absorption, Fate, and Excretion. Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only ~20% of the drug reaches the circulation after oral Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2-50 μM are measurable in plasma after intravenous injection of 30-300 mg/m² but disappear rapidly (t½ of 10 minutes) from plasma.

Less than 10% of the injected dose is excreted unchanged in the urine within 12-24 hours, while most appears as the inactive deaminated product, Ara-U. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection, but are far lower (~10%) than concentrations in plasma. After intrathecal administration of the drug at a dose of 50 mg/m², deamination proceeds slowly, with a t½ of 3-4 hours, and peak concentrations of 1-2 μM are achieved. CSF concentrations remain above the threshold for cytotoxicity (0.4 μM) for ≥24 hours. A depot liposomal formulation of Ara-C (DEPOCYT) provides sustained release into the CSF. After a standard 50-mg dose, liposomal Ara-C remains above cytotoxic levels for an average of 12 days, thus avoiding the need for frequent lumbar punctures (Cole et al., 2003).

Therapeutic Uses. Two dosage schedules are recommended for administration of cytarabine (CYTOSAR-U, TARABINE PFS, others): 1) rapid intravenous infusion of 100 mg/m² every 12 hours for 5-7 days or 2) continuous intravenous infusion of 100-200 mg/m²/day for 5-7 days. In general, children tolerate higher doses than adults. Intrathecal doses of 30 mg/m² every 4 days have been used to treat meningeal or lymphomatous leukemia. The intrathecal administration of 50 mg for adults (or 35 mg for children) of liposomal cytarabine (DEPOCYT) every 2 weeks seems equally effective as the every-4-days regimen with the standard drug.

Ara-C is indicated for induction and maintenance of remission in AML and is useful in the treatment of other leukemias, such as ALL, CML in the blast phase, acute promyelocytic leukemia, and high-grade lymphomas. Because drug concentration in plasma rapidly falls below the level needed to saturate transport and intercellular activation, clinicians have employed high-dose regimens (2-3 g/m² every 12 hours for 6-8 doses) to achieve 20-50 times higher serum levels, with improved results in remission induction and consolidation for AML. Injection of
the liposomal formulation is indicated for the intrathecal treatment of lymphomatous meningitis.

**Clinical Toxicities.** Cytarabine is a potent myelosuppressive agent capable of producing acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis.

Onset of dyspnea, fever, and pulmonary infiltrates on chest computed tomography scans may follow 1–2 weeks after high-dose Ara-C and may be fatal in 10–20% of patients, especially in patients being treated for relapsed leukemia (Forghieri et al., 2007). Infectious or other causes of pulmonary infiltrates must be excluded in evaluating such patients. No specific therapy, other than Ara-C discontinuation, is indicated. Intrathecal Ara-C, either the free drug or the liposomal preparation, may cause arachnoiditis, seizures, delirium, myelopathy, or coma, especially if given concomitantly with systemic high-dose methotrexate or systemic Ara-C (Jabbour et al., 2007).

Cerebellar toxicity, manifesting as ataxia and slurred speech, and cerebral toxicity (seizures, dementia, and coma) may follow intrathecal administration or high-dose systemic administration, especially in patients >40 years of age and/or patients with poor renal function.

**Azacitidine (5-Azacytidine)**

5-Azacytidine (Figure 61–8) and the closely related decitabine (2′,2′-deoxy-5-azacytidine) have antileukemic activity and induce differentiation by virtue of their inhibition of DNA cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15–20% of patients and reduce transfusion requirement in one-third of patients. 5-Azacytidine improves survival.

The aza-nucleosides enter cells by the human equilibrative transporter, the presence of which correlates with sensitivity of cell lines (Stresemann and Lyko, 2008). The drugs incorporate into DNA, where they become covalently bound to the methyltransferase through their N-5 position, depleting intracellular enzyme and leading to global demethylation of DNA and tumor cell differentiation and apoptosis. Decitabine also induces double-strand DNA breaks, perhaps as a consequence of the effort to repair the protein-DNA adduct. The azacytidine ring spontaneously opens in alkaline solution and has greater stability (t½ of 7 hours) at neutral pH. After subcutaneous administration of the standard dose of 75 mg/m², 5-azacytidine achieves peak drug levels of 10 μM and undergoes very rapid deamination by cytidine deaminase (plasma t½ of 20–40 minutes), with the product hydrolyzing to inactive metabolites. Due to the formation of intracellular nucleotides, which become incorporated into DNA, the effects of the aza-nucleosides persist for many hours.

The major toxicities of the aza-nucleosides include myelosuppression and mild GI symptoms. 5-Azacytidine produces rather severe nausea and vomiting when given intravenously in large doses (150–200 mg/m²/day for 5 days). The usual regimen for 5-azacytidine in myelodysplastic syndrome (MDS) is 75 mg/m²/day for 7 days every 28 days, while decitabine is given in a dose of 20 mg intravenously every day for 5 days every 4 weeks (Oki et al., 2007). Best responses may become apparent only after two to five courses of treatment.

**Gemcitabine**

Gemcitabine (2′,2′-difluoro-2-deoxycytidine; dFdC) (Figure 61–8), a difluoro analog of deoxycytidine, has become an important drug for patients with metastatic pancreatic; non-squamous, non–small cell lung; ovarian; and bladder cancer.

**Mechanism of Action.** Gemcitabine is carried into cells by three distinct nucleoside transporters: hENT, hCNT, and a nucleobase transporter found in malignant mesothelioma cells. The hENT transporter appears to be the major carrier. Intracellularly, deoxycytidine kinase phosphorylates gemcitabine to produce difluorodeoxycytidine monophosphate (dFdCMP), from which point it is converted to difluorodeoxycytidine di- and triphosphate (dFdCDP and dFdCTP). Although gemcitabine’s anabolism and effects on DNA in general mimic those of cytarabine, there are distinct differences in kinetics of inhibition, additional enzymatic sites of action, different effects of incorporation into DNA, and a distinct spectrum of clinical activity. Unlike that of cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle, and the drug is equally effective against confluent cells and cells in logarithmic growth phase. The cytotoxic activity may be a result of several actions on DNA synthesis. dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase. dFdCDP is a stoichiometric inhibitor of RNR (Wang et al., 2007). It forms a complex with the RNR subunits and with ATP, resulting in depletion of deoxyribonucleotide pools necessary for DNA synthesis. Most important, dFdCTP incorporates into DNA and, after the incorporation of one more nucleotide, causes DNA strand termination (Heinemann et al., 1988). This “extra” nucleotide may be important in hiding the dFdCTP from DNA repair enzymes, as the incorporated dFdCMP appears resistant to repair. The ability of cells to incorporate dFdCTP into DNA is critical for gemcitabine-induced apoptosis. Gemcitabine is inactivated by cytidine deaminase, which is found both in tumor cells and throughout the body.

Preliminary evidence suggests that response to gemcitabine in pancreatic carcinoma tumors correlates positively with high expression of hENT (Giovannetti et al., 2006) and low expression of subunits of RNR, but resistance is found in tumors with low levels of deoxycytidine kinase and high levels of cytidine deaminase, the inactivating enzyme (Ohashi et al., 2008). In mouse tumors, forced expression of the HMGA1 transcription factor also caused gemcitabine resistance (Liu and Whang, 2008), possibly through its effect on Akt-dependent survival pathways.

**Absorption, Fate, and Elimination.** Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination in liver, plasma, and other organs, and the predominant urinary elimination product is
difluorodeoxyuridine (dFdU). Although dFdU has modest toxicity at the usual concentrations found in plasma, in patients with significant renal dysfunction, dFdU and its triphosphate accumulate to high and potentially toxic levels (Koolen et al., 2009). Gemcitabine has a short plasma $t_{1/2}$ of ~15 minutes, with women and elderly patients clearing the drug more slowly (Abbruzzese et al., 1991). Peak levels reach 20-60 $\mu$M with doses of 1000 mg/m$^2$ given over 30 minutes intravenously. Clearance can vary widely among individuals but is not affected by renal failure.

Similar to that of cytarabine, conversion of gemcitabine to dFdCMP by deoxycytidine kinase is saturated at infusion rates of ~10 mg/m$^2$/min, which produce plasma drug concentrations of ~10-20 $\mu$M. In an attempt to increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 100-150 minutes at a fixed rate of 10 mg/min. The 150-minute infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells and increases the degree of myelosuppression but does not improve antitumor activity (Gandhi, 2007).

The inhibition of DNA repair by gemcitabine may increase cytotoxicity of other agents, particularly platinum compounds, and with radiation therapy. Preclinical studies of tumor cell lines show that gemcitabine enhances formation of cisplatin-DNA adducts, presumably through suppression of nuclear excision repair.

**Therapeutic Uses.** The standard dosing schedule for gemcitabine (GEMZAR) is a 30-minute intravenous infusion of 1-1.25 g/m$^2$ on days 1, 8, and 15 of each 21- to 28-day cycle, depending on the indication.

**Clinical Toxicities.** The principal toxicity of gemcitabine is myelosuppression. Longer-duration infusions lead to greater myelosuppression and hepatic toxicity. Nonhematological toxicities include a flu-like syndrome, asthenia, and rarely a posterior leukoencephalopathy syndrome. Mild elevation in liver transaminases may occur in ≥40% of patients and are reversible. Interstitial pneumonitis, at times progressing to acute respiratory distress syndrome (ARDS), may occur within the first two cycles of treatment and usually responds to corticosteroids. Rarely, patients on gemcitabine treatment for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation (Humphreys et al., 2004). Gemcitabine is a very potent radiosensitizer, likely the result of its inhibition of RNR, depletion of dATP, and inhibition of DNA repair (Flanagan et al., 2007) and should not be used with radiotherapy except in closely monitored clinical trials.

**PURINE ANALOGS**

The pioneering studies of Hitchings and Elion begun in 1942 who identified analogs of naturally occurring purine bases with antileukemic and immunosuppressant properties. Their work led to the development of drugs not only for treatment of malignant diseases (mercaptopurine, thioguanine) but also for immunosuppression in auto-immune disease and organ transplantation (azathioprine) and antiviral chemotherapy (acyclovir, ganciclovir, vidarabine, zidovudine) (Figure 61–11). The hypoxanthine analog allopurinol, a potent inhibitor of xanthine oxidase, is an important byproduct of this effort (see Chapter 34). Other purine analogs have valuable roles in cancer therapy. These include pentostatin (2’-deoxycoformycin), the first effective agent against hairy cell leukemia, cladribine (standard therapy for hairy cell leukemia), fludarabine phosphate (standard treatment for CLL) nelarabine (pediatric ALL), and clofarabine (T-cell leukemia/lymphoma). The apparent preferential activity of these agents in lymphoid malignancies may relate to their effective uptake, activation, and apoptotic effects in lymphoid tissue.

**6-Thiopurine Analogs**

6-Mercaptopurine (6-MP) and 6-thioguanine (6-TG) are approved agents for human leukemias and function as analogs of the natural purines, hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily transported into cells, including activated malignant cells. Nucleotides formed from 6-MP and 6-TG inhibit...
1702 de novo purine synthesis and also become incorporated into nucleic acids. The structural formula of 6-MP and other purine analogs is shown in Figure 61–11.

Mechanism of Action. Both 6-TG and 6-MP are excellent substrates for hypoxanthine guanine phosphoribosyl transferase (HGPRT) and are converted in a single step to the ribonucleotides 6-thioguanosine-5′-monophosphate (6-thioGMP) and 6-thiouridine-5′-monophosphate (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase, the enzyme that converts guanosine monophosphate (GMP) to guanosine diphosphate (GDP), T-IMP accumulates intracellularly and in a second step is converted to 6-TGMP. T-IMP inhibits the new formation of ribosyl-5-phosphate, as well as conversion of inosine-5′-monophosphate (IMP) to adenine and guanine nucleotides. Of these, the most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5-phosphate, the first committed step in the de novo pathway. 6-Thioguanine nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing. Strand breaks depend on the presence of an intact MMR system, the absence of which leads to resistance.

Mechanisms of Resistance to the Thiopurine Antimetabolites. The most common mechanism of 6-MP resistance observed in vitro is deficiency or complete lack of the activating enzyme, HGPRT, or increased alkaline phosphatase activity. Other mechanisms for resistance include 1) decreased drug uptake, or increased efflux due to one of several active transporters; 2) alteration in allosteric inhibition of ribosylamine 5-phosphate synthase; and 3) impaired recognition of DNA breaks and mismatches due to loss of a component (MSH6) of the new formation of ribosyl-5-phosphate, as well as conversion of inosine-5′-monophosphate (IMP) to adenine and guanine nucleotides. Of these, the most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5-phosphate, the first committed step in the de novo pathway. 6-Thioguanine nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing. Strand breaks depend on the presence of an intact MMR system, the absence of which leads to resistance.

Mercaptopurine Pharmacokinetics and Toxicity. Absorption of mercaptopurine is incomplete (10-50%) after oral ingestion; the drug is subject to first-pass metabolism by xanthine oxidase in the liver. Food or oral antibiotics decrease absorption. Oral bioavailability is increased when mercaptopurine is combined with high-dose methotrexate.

After an intravenous dose, the t1/2 of the drug in plasma is relatively short (~50 minutes in adults), due to rapid metabolic degradation by xanthine oxidase and by thiopurine methyltransferase (TPMT). Restricted brain distribution of mercaptopurine results from an efficient efflux transport system in the blood-brain barrier. In addition to the HGPRT-catalyzed anabolism of mercaptopurine, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Activity of the enzyme TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity. Low levels of erythrocyte TPMT activity are associated with increased drug toxicity in individual patients and a lower risk of relapse (Pui et al., 2004). In patients with auto-immune disease treated with mercaptopurine, those with polymorphic alleles may experience bone marrow aplasia and life-threatening toxicity. Testing for these polymorphisms prior to treatment is recommended in this patient population.

High concentrations of 6-methylmercaptopurine nucleotides are formed in white blood cells and bone marrow following 6-MP administration. They are less potent than 6-MP nucleotides as metabolic inhibitors, and their significance in contributing to the activity of 6-MP is not known.

A relatively large percentage of the administered sulfur appears in the urine as inorganic sulfate, the result of enzymatic desulfuration. The second major pathway for 6-MP metabolism involves its oxidation by xanthine oxidase to 6-thiouric acid, an inactive metabolite. Oral doses of 6-MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor, allopurinol. No dose adjustment is required for intravenous dosing.

Therapeutic Uses. In the maintenance therapy of ALL, the initial daily oral dose of mercaptopurine (6-MP; PURINETHOL, others) is 50–100 mg/m² and is thereafter adjusted according to white blood cell and platelet count. The combination of methotrexate and 6-MP appears to be synergistic. By inhibiting the earliest steps in purine synthesis, methotrexate elevates the intracellular concentration of PRPP, a cofactor required for 6-MP activation.

Clinical Toxicities. The principal toxicity of 6-MP is bone marrow depression, although in general, this side effect develops more gradually than with folic acid antagonists; accordingly, thrombocytopenia, granulocytopenia, or anemia may not become apparent for several weeks. When depression of normal bone marrow elements occurs, dose reduction usually results in prompt recovery, although myelosuppression may be severe and prolonged in patients with a polymorphism affecting TPMT. Anorexia, nausea, or vomiting is seen in ~25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6-MP and usually resolve upon discontinuation of therapy. Their appearance has been associated with biliary stasis and hepatic necrosis on biopsy. 6-MP and its derivative, azathioprine, predispose to opportunistic infection such as reactivation of hepatitis B, fungal infection, and Pneumocystis pneumonia and an increased incidence of squamous cell malignancies of the skin. 6-MP has teratogenic effects during the first trimester of pregnancy, and AML has been reported after prolonged 6-MP therapy for Crohn’s disease (Heizer and Peterson, 1998).

**Fludarabine Phosphate**

This compound is a fluorinated, deamination-resistant, phosphorylated analog of the antiviral agent vidarabine (9-β-D-arabinofuranosyl-adenine). It is active in CLL and low-grade lymphomas. It has found important uses as a cytotoxic drug and as a potent immunosuppressant.
Therapeutic Uses. Fludarabine phosphate (FLUDARA, OFORTA) is by renal excretion. Plasma is ~10 hours. The compound is primarily (40-50%) eliminated by the kidneys, with a terminal t1/2 in plasma of 6.7 hours. The nucleotide is an effective chain terminator when incorporated into DNA (Kamiya et al., 1996), and the incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation (Plunkett and Gandhi, 1993).

In experimental tumors, resistance to fludarabine is associated with decreased activity of deoxycytidine kinase (the enzyme that phosphorylates the drug) (Mansson et al., 2003), increased drug efflux, and increased RNR activity. Its mechanism of immunosuppression and paradoxical stimulation of auto-immunity stems from the particular susceptibility of lymphoid cells to purine analogs and the specific effects on the CD4+ subset of T cells, as well as its inhibition of regulatory T-cell responses.

Absorption, Fate, and Excretion. Fludarabine phosphate is administered both intravenously and orally and rapidly converts to fludarabine in the plasma. The median time to reach maximal concentrations of drug in plasma after oral administration is 1.5 hours, and oral bioavailability averages 55-60%. The terminal t1/2 of fludarabine in plasma is ~10 hours. The compound is primarily (40-50%) eliminated by renal excretion.

Therapeutic Uses. Fludarabine phosphate (FLUDARA, OFORTA) is approved for intravenous and oral use and is equally active by both routes (Forconi et al., 2008). The recommended dose of fludarabine phosphate is 25 mg/m2 daily for 5 days by intravenous infusion, or 40 mg/m2 daily for 5 days by mouth. The drug is administered intravenously over 30 minutes to 2 hours. Dosage should be reduced in patients with renal impairment in proportion to the reduction in CrCl. Treatment may be repeated every 4 weeks, and gradual improvement in CLL usually occurs within two to three cycles.

Fludarabine phosphate is highly active alone or with rituximab and cyclophosphamide for the treatment of patients with CLL. Activity in CLL as a single agent is equal by either the oral or intravenous routes, as overall response rates in previously untreated patients approximate 80% and the duration of response averages 22 months. The synergy of fludarabine with alkylators may stem from the observation that it blocks the repair of double-strand DNA breaks and interstrand cross-links induced by alkylating agents. It also is effective in follicular B-cell lymphomas refractory to standard therapy. It is increasingly used as a potent immunosuppressive agent in nonmyeloablative allogeneic bone marrow transplantation, where it suppresses the host response and may encourage alloreactive donor T cells.

Clinical Toxicities. Oral and intravenous therapy cause myelosuppression (World Health Organization grade 3 or 4) in about half of patients, nausea and vomiting in a minor fraction, and uncommonly chills and fever, malaise, anorexia, peripheral neuropathy, and weakness. Lymphopenia and thrombocytopenia and cumulative side effects are expected. Depletion of CD4+ T cells with therapy predisposes to opportunistic infections. Tumor lysis syndrome, a relatively infrequent complication, occurs primarily in previously untreated patients with CLL. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients.

Auto-immune events may occur after fludarabine treatment. CLL patients may develop an acute hemolytic anemia or pure red cell aplasia during or following fludarabine treatment. Prolonged cytopenias, probably mediated by auto-immunity, also complicate fludarabine treatment. Myelodysplasia and acute leukemias may arise as late complications (Tam et al., 2008). Pneumonitis is an occasional side effect and responds to corticosteroids. Because a significant fraction of drug is eliminated in the urine, patients with compromised renal function should be treated with caution, and initial doses should be reduced in proportion to the reduction in CrCl.

Cladribine

An adenosine deaminase-resistant purine analog, cladribine (2-chlorodeoxyadenosine; 2-CdA), has potent and probably curative activity in hairy cell leukemia, CLL, and low-grade lymphomas. It is taken up by active nucleoside transport. After intracellular phosphorylation by deoxycytidine kinase and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP, leading to apoptosis. It is a potent inhibitor of RNR. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme, deoxycytidine kinase; increased expression of RNR (Cardoen et al., 2001); or increased active efflux by ABCG2 or other members of the ABC cassette family of transporters (de Wolf et al., 2008).

Absorption, Fate, and Excretion. Cladribine is moderately well absorbed orally (55%) but is routinely administered intravenously. The drug is excreted by the kidneys, with a terminal t1/2 in plasma of 6.7 hours (Liliemark and Juliusson, 1991). Cladribine crosses the blood-brain barrier and reaches CSF concentrations of ~25% of those seen in plasma. Doses should be adjusted for renal dysfunction.

Therapeutic Uses. Cladribine (LEUSTATIN, others) is administered as a single course of 0.09 mg/kg/day for 7 days by continuous intravenous infusion.
Cladribine is considered the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL; low-grade lymphomas; Langerhans cell histiocytosis; CTCLs, including mycosis fungoides and the Sézary syndrome; and Waldenström macroglobulinemia.

**Clinical Toxicities.** The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and correlate with decreased CD4+ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome.

**Clofarabine (2-Chloro-2′-Fluoro-Arabinosyladenine)**

This analog resulted from incorporating the 2-chloro, glycosylase-resistant substituent of cladribine and a 2′-fluoro-arabinosyl substitution, which further strengthens stability and enhances uptake and phosphorylation. The resulting compound is approved for pediatric ALL after failure of two prior therapies.

For these patients, it produces complete remissions in 20-30% of patients. It has activity as well in pediatric and adult AML and in myelodysplasia. Its uptake and metabolic activation in tumor cells follow the same path as cladribine and the other purine nucleosides, although it is more readily phosphorylated by dCK. It incorporates into DNA, where it terminates DNA synthesis and leads to apoptosis.

**Absorption, Fate, and Distribution.** Clofarabine triphosphate has a long intracellular t½ of 24 hours. Its antitumor activity is ascribed to its incorporation into DNA, resulting in chain termination. Like cladribine, clofarabine inhibits RNR (Bonate et al., 2006). In children, following administration of usual doses of 52 mg/m² given as a 2-hour infusion daily for 5 days, clofarabine has a primary elimination t½ in plasma of 6.5 hours, and the majority of drug is excreted unchanged in the urine. Doses should be adjusted according to reductions in CrCl, although precise guidelines are not available.

**Clinical Toxicities.** The primary toxicities are myelosuppression; a clinical syndrome of hypotension, tachyphemia, pulmonary edema, organ dysfunction, and fever, all suggestive of capillary leak syndrome and cytokine release; elevated hepatic enzymes and increased bilirubin; nausea, vomiting, and diarrhea; and hypokalemia and hypophosphatemia. Evidence of capillary leak should lead to immediate discontinuation of the drug.

**Nelarabine (6-Methoxy-Arabinosyl-Guanine)**

The only guanine nucleoside in clinical use, this agent has selective activity against acute T-cell leukemia (20% complete responses) and the closely related T-cell lymphoblastic lymphoma and is approved for use in relapsed/refractory patients. Its basic mechanism of action closely resembles that of the other purine nucleosides, in that it is incorporated into DNA and terminates DNA synthesis. It has selective toxicity for T lymphocytes and T-cell malignancies.

**Absorption, Fate, and Distribution.** Following infusion, the parent methoxy compound is rapidly activated in blood and tissues by adenosine deaminase–mediated cleavage of the methyl group, yielding the phosphorylase resistant Ara-G, which has a longer plasma t½ of 3 hours. The active metabolite is transported into tumor cells, where it is activated by CdK to the monophosphate and thence to a triphosphate. Ara-G triphosphate (Ara-GTP) is incorporated into DNA and terminates DNA synthesis (Sanford and Lyseng-Williamson, 2008). The drug and its metabolite, Ara-G, are primarily eliminated by metabolism to guanine, and a smaller fraction is eliminated by renal excretion of Ara-G. The dose should not be adjusted for mild to moderate (CrCl >50 mg/mL) renal dysfunction (Sanford and Lyseng-Williamson, 2008), but the drug should be used with close clinical monitoring in patients with more severe renal impairment. Adults are given a dose of 1500 mg/m² intravenously as a 2-hour infusion on days 1, 3, and 5 of a 21-day cycle, and children are given a lower dose of 650 mg/m²/day intravenously for 5 days and repeated every 21 days.

**Clinical Toxicities.** Side effects include myelosuppression and liver function test abnormalities, as well as frequent, serious neurological sequelae, such as seizures, delirium, somnolence, peripheral neuropathy, or Guillain-Barré syndrome. Neurological side effects may not be reversible.

**Pentostatin (2′-Deoxycoformycin)**

Pentostatin (2′-deoxycoformycin; see Figure 61–11), a transition-state analog of the intermediate in the adenosine deaminase (ADA) reaction, potently inhibits ADA. Its effects mimic the phenotype of genetic ADA deficiency (severe immunodeficiency affecting both T- and B-cell functions). It was isolated from fermentation cultures of *Streptomyces antibioticus*. Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting RNR.
Deoxyadenosine also inactivates S-adenosyl homocysteine hydro-lase. The resulting accumulation of S-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

Absorption, Fate, and Excretion. Pentostatin is administered intravenously, and a single dose of 4 mg/m² has a mean terminal t₁/₂ of 5.7 hours. The drug is eliminated almost entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced CrCl.

Therapeutic Uses. The recommended dose is 4 mg/m² administered every other week intravenously. After hydration with 500-1000 mL of 5% dextrose in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion over a period of ≤30 minutes, followed by an additional 500 mL of fluids.

Pentostatin is extremely effective in producing complete remissions (58%) and partial responses (28%) in hairy cell leukemia (Grever et al., 2003). It largely has been superseded by cladribine.

Clinical Toxicities. Toxic manifestations include myelosuppression, GI symptoms, skin rashes, and abnormal liver function studies. Depletion of normal T cells occurs, and neutropenic fever and opportunistic infections may result. Immunosuppression may persist for several years after discontinuation of pentostatin therapy. At high doses (10 mg/m²), major renal and neurological complications are encountered. Pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

III. Natural Products

MICROTUBULE-DAMAGING AGENTS

Several anticancer agents act through the microtubules, either causing disorganized stabilization of microtubules in areas away from the centriole or causing destabilization of the mitotic spindle, interfering with mitosis. The vinca alkaloids are effective in the treatment of hematological malignancies, breast, germ cell, and lung cancers, whereas the taxanes have become leading agents in the treatment of ovarian, breast, head and neck, and lung cancers. A new class of agents, the epothilones, resembles the taxanes in their action but has limited cross-resistance with taxanes; the only approved epothilone in the U.S., ixabepilone, is indicated for metastatic breast cancer.

VINCA ALKALOIDS

History. The beneficial properties of the Madagascar periwinkle plant, Catharanthus roseus (formerly called Vinca rosea), a species of myrtle, have been described in medicinal folklore. Periwinkle extracts attracted interest because of their hypoglycemic effects in diabetes. Purified alkaloids, including vinblastine and vincristine, caused regression of an acute lymphocytic leukemia in mice and were among the earliest clinical agents for treatment of leukemias, lymphomas, and testicular cancer. A closely related derivative, vinorelbine, has important activity against lung and breast cancer.

Chemistry. The vinca alkaloids are asymmetrical dimeric compounds formed by condensation of the vindoline and catharanthine subunits.
throughout the cytoplasm (exploded mitosis) or may clump in unusual groupings, such as balls or stars. Cells blocked in mitosis undergo changes characteristic of apoptosis.

In addition to their key role in the formation of mitotic spindles, microtubules are found in high concentration in the brain and contribute to other cellular functions such as movement, phagocytosis, and axonal transport. Side effects of the vinca alkaloids, such as their neurotoxicity, may relate to disruption of these functions.

**Drug Resistance.** Despite their structural similarity, the vinca alkaloids have unique individual patterns of clinical effectiveness (see the individual vinca alkaloid sections). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance mediated by the mdr gene and its glycoprotein. Tumor cells become cross-resistant to a wide range of chemically dissimilar agents (the vinca alkaloids, epipodophyllotoxins, anthracyclines, and taxanes). Chromosomal abnormalities consistent with gene amplification have been observed in resistant cells in culture, and the cells contain markedly increased levels of the P-glycoprotein, a membrane efflux transporter (Endicott and Ling, 1989). Ca++ channel blockers such as verapamil can reverse resistance of this type in vitro; however, clinical trials of resistance-reversing agents have been disappointing. Other membrane transporters, such as the MRP and the closely related breast cancer resistance protein, may mediate multidrug resistance. Still other forms of resistance to vinca alkaloids stem from mutations in β tubulin or in the relative expression of isoforms of β tubulin; both changes prevent the inhibitors from effectively binding to their target.

**Cytotoxic Actions.** The very limited myelosuppressive action of vinblastine makes it a valuable component of several combination therapy regimens for leukemia and lymphoma, while the lack of severe neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes a mild neurotoxicity as well as myelosuppression, has an intermediate toxicity profile. Vincristine is a standard component of regimens for treating pediatric leukemias, lymphomas, and solid tumors, such as Wilms tumor, neuroblastoma, and rhabdomyosarcoma. In large-cell non-Hodgkin’s lymphomas, vincristine remains an important agent, particularly when used in the CHOP regimen with cyclophosphamide, doxorubicin, and prednisone. Vinblastine is employed in treating bladder cancer, testicular carcinomas, and Hodgkin’s disease. Vinorelbine has activity against non–small cell lung cancer and breast cancer.

**Absorption, Fate, and Excretion.** The liver cytochromes extensively metabolize all three agents, and the metabolites are excreted in the bile (Robieux et al., 1996). Only a small fraction of a dose (<15%) is found in the urine unchanged. In patients with hepatic dysfunction (bilirubin >3 mg/dL), a 50-75% reduction in dose of any of the vinca alkaloids is advisable, although firm guidelines for dose adjustment have not been established. The pharmacokinetics of each of the three drugs are similar, with an elimination t1/2 of 20 hours for vincristine, 23 hours for vinblastine, and 24 hours for vinorelbine.

**Vinblastine**

**Therapeutic Uses.** Vinblastine sulfate (VELBAN, others) is given intravenously; special precautions must be taken against subcutaneous extravasation, because this may cause painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose of 0.3 mg/kg of body weight, myelosuppression reaches its maximum in 7-10 days. If a moderate level of leukopenia (~3000 cells/mm³) is not attained, the weekly dose may be increased gradually by increments of 0.05 mg/kg of body weight. In regimens designed to cure testicular cancer, vinblastine is used in doses of 0.3 mg/kg every 3 weeks. Doses should be reduced by 50% for patients with plasma bilirubin >1.5 mg/dL.

One important clinical use of vinblastine is with bleomycin and cisplatin (see “Therapeutic Uses” under “Bleomycin”) in the curative therapy of metastatic testicular tumors, although it has been supplanted by etoposide or ifosfamide in this disease. It is a component of the standard curative regimen for Hodgkin’s disease [doxorubicin (ADRIAMYCIN), bleomycin, vinblastine, and dacarbazine (ABVD)]. It also is active in Kaposi sarcoma, neuroblastoma, Langerhans cell histiocytosis, carcinoma of the breast, and choriocarcinoma.

**Clinical Toxicities.** The nadir of the leukopenia that follows the administration of vinblastine usually occurs within 7–10 days, after which recovery ensues within 7 days. Other toxic effects of vinblastine include mild neurological manifestations. GI disturbances including nausea, vomiting, anorexia, and diarrhea may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Loss of hair, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis.

**Vincristine**

**Therapeutic Uses.** Vincristine sulfate (VINCASAR PFS, others) used together with glucocorticoids is the treatment of choice to induce remissions in childhood leukemia and in combination with alkylating agents and anthracycline for pediatric sarcomas; the common intravenous dosage for vincristine is 2 mg/m² of body surface area at weekly or longer intervals. Vincristine seems to be tolerated better by children than by adults, who may experience severe, progressive neurological toxicity and require a lower dose of 1.4 mg/m². Administration of the drug more frequently than every 7 days or at higher doses increases the toxic manifestations without proportional improvement in the response rate. Precautions also should be used to avoid extravasation during intravenous administration of vincristine. Doses should be reduced by 50% or 75% for patients with plasma bilirubin >1.5 mg/dL or >3 mg/dL, respectively.

**Clinical Toxicities.** The clinical toxicity of vincristine is mostly neurological. Early sensory changes do not warrant dose reduction. The more severe neurological manifestations may be avoided or reversed by either suspending therapy or reducing the dosage upon first evidence of motor dysfunction. Severe constipation,
sometimes resulting in colicky abdominal pain and obstruction, may be prevented by a prophylactic program of laxatives and hydrophilic (bulk-forming) agents and usually is a problem only with doses >2 mg/m².

Alopecia occurs in ~20% of patients given vincristine; however, the alopecia is always reversible, frequently without cessation of therapy. Modest leukopenia may follow vincristine administration. Thrombocytopenia, anemia, GI cholic and obstruction, and the syndrome of inappropriate secretion of antidiuretic hormone are less common adverse effects. Inadvertent injection of vincristine into the CSF causes a devastating and often fatal irreversible coma and seizures (Williams et al., 1983). CSF exchange has averted a fatal outcome in anecdotal reports.

Vinorelbine

Vinorelbine (NAVELbine, others) is administered in normal saline as an intravenous infusion over 6-10 minutes. When used alone, it is given at doses of 30 mg/m² either weekly or for 2 out of every 3 weeks. When used with cisplatin for the treatment of non–small cell lung cancer, it is given at doses of 25 mg/m² either weekly or for 3 out of every 4 weeks. A lower dose (20-25 mg/m²) may be required for patients who have received prior chemotherapy, and dosage adjustment is necessary for hematological toxicity. Its primary toxicity is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. Vinorelbine may cause allergic reactions and mild, reversible changes in liver enzymes. An oral formulation of vinorelbine is active in non–small cell lung carcinoma, and phase III studies are ongoing (Krzakowski et al., 2008). Similar to the other vincas, doses should be reduced by 50% or 75% in patients with plasma bilirubin 2.1-3 mg/dL or >3 mg/dL, respectively.

TAXANES

The first compound of this series, paclitaxel (TAXOL, others), was isolated from the bark of the Western yew tree in 1971 and presented significant problems in formulation because of its poor aqueous solubility. It was reformulated and approved by the U.S. Food and Drug Administration (FDA) in 2005 as an albumin-bound nanoparticle solution for infusion (nab-paclitaxel, ABRAXANE). Paclitaxel and its congenic, the semisynthetic docetaxel (TAXOTERE), exhibit unique pharmacological properties as inhibitors of mitosis, differing from the vinca alkaloids and colchicine derivatives in that they bind to a different β-tubulin site and promote rather than inhibit microtubule formation. The taxanes have a central role in the therapy of ovarian, breast, lung, GI, genitourinary, and head and neck cancers (Rowinsky and Donehower, 1995).

Chemistry. Paclitaxel is a diterpenoid compound that contains a complex eight-member taxane ring as its nucleus (Figure 61–12). The side chain linked to the taxane ring at C13 is essential for its antitumor activity. Modification of the side chain has led to identification of the more potent analog, docetaxel (Figure 61–12), which shares the same spectrum of clinical activity as paclitaxel, but differs in its toxicity. Originally purified as the parent molecule from yew bark, paclitaxel now can be obtained for commercial purposes by semisynthesis from 10-desacetylbaccatin, a precursor found in yew needles. It also has been successfully synthesized (Nicolaou et al., 1994) in a complex series of reactions. Paclitaxel has very limited water solubility and is administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil (CREMOPHOR EL); this vehicle likely is responsible for a high rate of hypersensitivity reactions. Patients receiving this formulation are protected by pretreatment with a histamine H₁-receptor antagonist such as diphenhydramine, an H₂-receptor antagonist such as cimetidine (see Chapter 32), and a glucocorticoid such as dexamethasone (see Chapter 42).

Nab-paclitaxel is soluble in aqueous solutions and can be administered safely without prophylactic antihistamines or steroids. This form of paclitaxel has increased cellular uptake via an albumin-specific mechanism.

Docetaxel, somewhat more soluble than paclitaxel, is administered in polysorbate 80 and is associated with a lower incidence of hypersensitivity reactions than paclitaxel dissolved in CREMOPHOR. However, pretreatment with dexamethasone for 3 days starting 1 day before therapy is required.

![Chemical structures of paclitaxel and its more potent analog, docetaxel.](image)
prior to therapy is required to prevent progressive fluid retention and minimize the severity of hypersensitivity reactions.

**Mechanism of Action.** Interest in paclitaxel was stimulated by the drug’s unique ability to promote microtubule formation at cold temperatures and in the absence of GTP. It binds specifically to the β-tubulin subunit of microtubules and antagonizes the disassembly of this key cytoskeletal protein, with the result that bundles of microtubules and aberrant structures derived from microtubules appear in the mitotic phase of the cell cycle. Arrest in mitosis follows. Cell killing is dependent on both drug concentration and duration of cell exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted; the sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule (Rowinsky and Donehower, 1995). Paclitaxel decreases doxorubicin clearance and enhances cardiotoxicity, while docetaxel has no apparent effect on anthracycline pharmacokinetics.

In cultured tumor cells, resistance to taxanes is associated in some lines with increased expression of the mdr-1 gene and its product, P-glycoprotein; other resistant cells have β-tubulin mutations, and these latter cells may display heightened sensitivity to vinca alkaloids (Cabral, 1983). Other resistant cell lines display an increase in survivin, an anti-apoptotic factor, α aurora kinase, an enzyme that promotes completion of mitosis. The taxanes preferentially bind to the βIII-tubulin subunit of microtubules; therefore, cells may become resistant by upregulating the βIII-isof orm of tubulin (Ranganathan et al., 1998). The basis of clinical drug resistance is not known. Cell death occurs by apoptosis, but the effectiveness of paclitaxel against experimental tumors does not depend on an intact p53 gene product.

Preclinical studies have suggested that nab-paclitaxel has an increased antitumor effect in breast cancer and a higher intratumoral drug concentration compared to cremophor-delivered paclitaxel. The reasons are not clear but may relate to maintenance of the drug in the nanoparticle micellar system or to increased expression of SPARC [Secreted Protein, Acidic and Rich in Cysteine; aka osteonectin, a matrix-cellular linkage protein expressed in pro-fibrotic states and linked to myriad pathologies (Kos and Wilding, 2010; Chlebowski and Cohn, 2010)] on tumor cells, leading to an increased drug uptake.

**Absorption, Fate, and Excretion.** Paclitaxel is administered as a 3-hour infusion of 135-175 mg/m² every 3 weeks or as a weekly 1-hour infusion of 80-100 mg/m². Prolonged infusions (96 hours) also have been evaluated in different tumor histologies and are active. The drug undergoes extensive metabolism by hepatic CYPs (primarily CYP2C8 with a contribution of CYP3A4); <10% of a dose is excreted in the urine intact. The primary metabolite identified thus far is 6-OH paclitaxel, which is inactive, but multiple additional hydroxylation products are found in plasma (Cresteil et al., 1994).

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate. In studies of 96-hour infusions of 140 mg/m² (35 mg/m²/day), the presence of hepatic metastases >2 cm in diameter decreased clearance and led to high drug concentrations in plasma and greater myelosuppression. Paclitaxel disappears from the plasma compartment with a t½ of 10-14 hours and a clearance of 15-18 L/hr/m². The critical plasma concentration for inhibiting bone marrow elements depends on duration of exposure but likely lies at ~50-100 nM (Huizing et al., 1993).

Nab-paclitaxel achieves a higher serum concentration of paclitaxel compared to CREMOPHOR-solubilized paclitaxel, but the increased clearance of nab-paclitaxel results in a similar drug exposure (Gardner et al., 2008). Nab-paclitaxel is most often administered intravenously over 30 minutes at 260 mg/m² every 3 weeks; however, alternate dosing regimens are being evaluated. Like the other taxanes, nab-paclitaxel should not be given to patients with an absolute neutrophil count <1500 cells/mm³. Docetaxel pharmacokinetics are similar to those of paclitaxel, with an elimination t½ of ~12 hours. Clearance is primarily through CYP3A4 and CYP3A5-mediated hydroxylation, leading to inactive metabolites (Clarke and Rivory, 1999). In contrast to paclitaxel, the pharmacokinetics of docetaxel are linear for doses ≤115 mg/m².

Dose reductions in patients with abnormal hepatic function have been suggested, and 50-75% doses of taxanes should be used in the presence of hepatic metastases >2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as phenytoin and phenobarbital, or those that inhibit the same cytochromes, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is markedly delayed by cyclosporine A and a number of other drugs employed experimentally as inhibitors of the P-glycoprotein. This inhibition may be due to a block of CYP-mediated metabolism or effects on biliary excretion of the parent drug or metabolites.

**Therapeutic Uses.** The taxanes have become central components of regimens for treating metastatic ovarian, breast, lung, GI, genitourinary, and head and neck cancers. In current regimens, these drugs are administered once weekly or once every 3 weeks. The appropriate use of the steroid-sparing nab-paclitaxel still is being evaluated in clinical trials; in a randomized phase III study comparing 175 mg/m² of paclitaxel to 260 mg/m² of nab-paclitaxel in women with metastatic breast cancer, the nab-paclitaxel arm had a higher response rate and longer time to progression compared to the paclitaxel arm (Gradishar et al., 2005).

**Clinical Toxicities.** Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8-11 days after a dose and reverses rapidly by days 15-21. Used with filgrastim [granulocyte-colony stimulating factor (G-CSF)], doses as high as 250 mg/m² over 24 hours are well tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias for several days after receiving paclitaxel. In high-dose schedules, or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-hour infusions and in the weekly schedule.

Hypersensitivity reactions occurred in patients receiving paclitaxel infusions of short duration (1-6 hours) but have largely been averted by pretreatment with dexamethasone, diphenhydramine, and histamine H₁-receptor antagonists, as noted above. Premedication is not necessary with 96-hour infusions. Many patients experience asymptomatic bradycardia, and occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-hour infusions.

Nab-paclitaxel produces increased rates of peripheral neuropathy compared to CREMOPHOR-delivered paclitaxel but rarely causes hypersensitivity reactions.
Docetaxel causes greater degrees of neutropenia than paclitaxel but less peripheral neuropathy and asthenia and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of docetaxel therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, 8 mg/day, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause a progressive interstitial pneumonitis, with respiratory failure supervening if the drug is not discontinued (Read et al., 2002).

**ESTRAMUSTINE**

Estramustine (EMCYT) is a combination of estradiol coupled to normustine (nornitrogen mustard) through a carbamate link. Estramustine has weaker estrogenic and antineoplastic activity than estradiol and other alkylating agents. Although the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not function *in vivo* as an alkylating agent but rather binds to β-tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions.

Estramustine is used solely for the treatment of metastatic or locally advanced hormone refractory prostate cancer (Kitamura, 2001) at an initial dosage of 14 mg/kg/day in three or four divided doses.

**Absorption, Fate, and Excretion.** Following oral administration, at least 75% of a dose of estramustine is absorbed from the GI tract and rapidly dephosphorylated. Estramustine undergoes extensive first-pass metabolism by CYP1A2 and CYP3A4 to an active oxidized 17-keto derivative, estramustine, and to multiple inactive products; both active forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have a plasma t1/2 of 10 and 14 hours, respectively, and are excreted as inactive metabolites, mainly in the feces (Bergenheim and Henriksson, 1998). Estramustine inhibits the clearance of taxanes.

**Clinical Toxicities.** In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, elevated risk of thrombosis, and fluid retention), hypercalcemia, acute attacks of porphyria, impaired glucose tolerance, and hypersensitivity reactions, including angioedema.

**EPOTHILONES**

Microtubule-damaging compounds are limited by difficulties in formulation, drug delivery, and susceptibility to multidrug resistance. A new group of microtubule-targeting drugs, the epothilones, overcomes these problems in experimental systems. Several epothilones currently are in various stages of clinical development. Ixabepilone (IXEMPRA) is approved for breast cancer treatment. Others in the pipeline include the epothilone B analogs patupilone (EPO906) and 21-aminoepothilone B (BMS-310705), the epothilone D analog KOS-1584 (R1645), and the synthetic sagopilone.

**Chemistry.** The epothilones are 16-membered polyketides discovered as cytotoxic metabolites from a strain of *Sorangium cellulosum*, a myxobacterium originally isolated from soil on the bank of the Zambezi River in southern Africa (Gerth et al., 1996).

Six natural epothilones (A-F), and synthetic and semisynthetic analogs are in various stages of development (Lee and Swain, 2008). Most trials of epothilones to date have evaluated compounds of the subtypes A, B, and D, which differ in their functional groups at carbon 12.

Initial studies of the natural epothilone compounds A, B, and D showed good *in vitro* cytotoxic activity at nanomolar concentrations, epothilone B having roughly twice the potency as epothilones A and D (Lee and Swain, 2008). The early *in vivo* activity in animals, however, was disappointing due to instability of their lactone ring. Modification of epothilone B by substituting a nitrogen for the lactone oxygen yielded ixabepilone, which is not susceptible to esterases.

**Mechanism of Action.** The epothilones resemble taxanes in that they bind to β-tubulin and trigger microtubule nucleation at multiple sites away from the centriole. This chaotic microtubule stabilization triggers cell-cycle arrest at the G2-M interface and apoptosis. Epothilones bind to a site distinct from that of taxanes. In colon cancer cell lines, p53 and Bax trigger apoptosis in ixabepilone-treated cells.

*In vitro* studies suggest that ixabepilone is less susceptible to P-glycoprotein-mediated multidrug resistance when compared to taxanes. Other mechanisms implicated in epothilone resistance include mutation of the β-tubulin binding site and upregulation of isoforms of β tubulin.

**Absorption, Distribution, and Excretion.** Ixabepilone is administered intravenously. Because of its minimal aqueous solubility, it is delivered in the solubilizing agent, polyoxyethylated castor oil/ethanol (CREMOPHOR EL). CREMOPHOR has been implicated as the cause of infusion reactions associated with paclitaxel and with other drug formulations, but such reactions are infrequent when administration is preceded by premedication with H1 and H2 antagonists. The drug is cleared by hepatic CYPs and has a plasma t1/2 of 52 hours.

**Therapeutic Uses.** In a phase III study for registration, patients with metastatic breast cancer resistant to or pretreated with anthracyclines and resistant to taxanes had an improved progression-free survival of
1.6 months with ixabepilone plus capecitabine compared to capecitabine alone (p = .0003) (Thomas et al., 2007).

Ixabepilone also is indicated as monotherapy for metastatic breast cancer in patients who have previously progressed through treatment with anthracyclines, taxanes, and capecitabine.

The recommended dose of ixabepilone as monotherapy or in combination with capecitabine is 40 mg/m² administered over 3 hours every 3 weeks. Note that because of additive myelosuppression, the phase III trial used an attenuated dose of capecitabine (2000 mg/m²) administered with ixabepilone compared to 2500 mg/m² when capecitabine was administered alone. Patients should be pretreated with both an H₁ and H₂ antagonist before receiving ixabepilone to minimize hypersensitivity reactions.

The combination of ixabepilone and capecitabine is contraindicated in patients with a baseline neutrophil count <1500 cells/mm³, a platelet count <100,000 cells/mm³, serum transaminases >2.5 × ULN or bilirubin above normal. In patients receiving ixabepilone monotherapy with mild to moderate hepatic dysfunction (bilirubin <1.5 × ULN or 1.5-3 × ULN, respectively), starting doses of 32 and 20 mg/m² are recommended due to delayed drug clearance.

Toxicities. Epothilones have toxicities similar to those of the taxanes, namely neutropenia peripheral sensory neuropathy, fatigue, diarrhea, and asthenia. Grade 3/4 peripheral sensory neuropathy was seen in 21% of patients receiving combined therapy with ixabepilone and capecitabine and in 14% of patients receiving monotherapy. Ixabepilone in combination with capecitabine causes a 68% rate of grade 3/4 neutropenia compared to 2500 mg/m² when capecitabine was administered alone. Patients should be pretreated with both an H₁ and H₂ antagonist before receiving ixabepilone to minimize hypersensitivity reactions.

The combination of ixabepilone and capecitabine is contraindicated in patients with a baseline neutrophil count <1500 cells/mm³, a platelet count <100,000 cells/mm³, serum transaminases >2.5 × ULN or bilirubin above normal. In patients receiving ixabepilone monotherapy with mild to moderate hepatic dysfunction (bilirubin <1.5 × ULN or 1.5-3 × ULN, respectively), starting doses of 32 and 20 mg/m² are recommended due to delayed drug clearance.

**CAMPTOTHECIN ANALOGS**

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme topoisomerase I. The lead compound in this class, camptothecin, was isolated from the Chinese tree *Camptotheca acuminata* in 1966. Initial efforts to develop the compound as a sodium salt were compromised by severe and unpredictable toxicity, principally myelosuppression and hemorrhagic cystitis. Elucidation of the mechanism of action and a better understanding of its physicochemical properties during the 1980s led to the development of more soluble and less toxic analogs. Irinotecan and topotecan, currently the only camptothecin analogs approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer.

**Chemistry.** All camptothecins have a fused five-ring backbone that includes a labile lactone ring (Figure 61–13). The hydroxyl group and S-conformation of the chiral center at C20 in the lactone ring are required for biological activity. Appropriate substitutions on the A and B rings of the quinoline subunit enhance water solubility and increase potency for inhibiting topoisomerase I. Topotecan [(S)-9-dimethylaminooctyl-10-hydroxycamptothecin hydrochloride] is a semisynthetic molecule with a basic dimethylamino group that increases its water solubility. Irinotecan (7-ethyl-10-[4-(1-piperidino)-1-piperidino]carbonyloxycapecitabine, or CPT-11) differs from topotecan in that it is a prodrug. The carbamate bond between the camptothecin moiety and the dibasic bispiperidine side chain at position C10 (which makes the molecule water soluble) is cleaved by a carboxylesterase to form the active metabolite, SN-38 (see Chapter 6).

**Mechanism of Action.** The DNA topoisomerases are nuclear enzymes that reduce torsional stress in supercoiled DNA, allowing selected regions of DNA to become sufficiently untangled and relaxed to permit replication, repair, and transcription. Two classes of topoisomerase (I and II) mediate DNA strand breakage and resealing, and both have become the target of cancer chemotherapies. Camptothecin analogs inhibit the function of topoisomerase I, while a number of different chemical entities (e.g., anthracyclines, epipodophyllotoxins, acridines) inhibit topoisomerase II. Topoisomerase I binds covalently to double-stranded DNA through a reversible transsterification reaction. This reaction yields an intermediate complex in which the tyrosine of the enzyme is bound to the 3′-phosphate end of the DNA strand, creating a single-strand DNA break. This “cleavable complex” allows for relaxation of the DNA torsional strain, either by passage of the intact single-strand through the nick or by free rotation of the DNA about the noncleaved strand. Once the DNA torsional strain has been relieved, the topoisomerase I reseals the cleavage and dissociates from the newly relaxed double helix.

The camptothecins bind to and stabilize the normally transient DNA-topoisomerase I cleavable complex. Although the initial cleavage action of topoisomerase I is not affected, the re-ligation step is inhibited, leading to the accumulation of single-stranded breaks in DNA. These lesions are reversible and not by themselves toxic to the cell. However, the collision of a DNA replication fork with this cleaved strand of DNA causes an irreversible double-strand DNA break, ultimately leading to cell death (Tsao et al., 1993). Camptothecins are therefore S phase–specific drugs, because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications. S phase–specific cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold to optimize therapeutic efficacy. In fact, preclinical studies of low-dose, protracted administration of camptothecin analogs have less toxicity, and equal or greater antitumor activity, than shorter, more intense courses.
The precise sequence of events that leads from drug-induced DNA damage to cell death has not been fully elucidated. *In vitro*, camptothecin-induced DNA damage abolishes the activation of the p34^cdc2/cyclin B complex, leading to cell-cycle arrest at the G2 phase (Tsao et al., 1993). Treatment with camptothecins can induce the transcription of *c-fos* and *c-jun* early-response genes, and this occurs in association with internucleosomal DNA fragmentation, a characteristic of programmed cell death.

**Mechanisms of Resistance.** A variety of mechanisms of resistance to topoisomerase I–targeted agents have been characterized *in vitro*, although little is known about their significance in the clinical setting. Decreased intracellular drug accumulation may underlie resistance in cell lines. Topotecan, but not SN-38 or irinotecan, is a substrate for P-glycoprotein. However, the clinical relevance of P-glycoprotein-mediated efflux as a mechanism of resistance against topotecan remains unclear, as the magnitude of the effect in preclinical studies was found to be substantially lower than that observed with other MDR substrates, such as etoposide or doxorubicin. Other reports have associated topotecan and irinotecan resistance with the MRP class of transporters (Miyake et al., 1999). Cell lines that lack carboxylesterase activity demonstrate resistance to irinotecan (Van Ark-Otte et al., 1998), but in patients, the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. Although a good correlation has been found in certain tumor cell lines between sensitivity to camptothecin analogs and topoisomerase I levels (Sugimoto et al., 1990), clinical studies have not confirmed this association. Chromosomal deletions or hypermethylation of the topoisomerase I gene are possible mechanisms of decreased topoisomerase I expression in resistant cells. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins *in vitro* and *in vivo*. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA-binding affinity have been associated with experimental camptothecin resistance (Tamura et al., 1991). In addition, enzyme phosphorylation or polyADP-ribosylation may reduce the activity of topoisomerase I and its susceptibility to inhibition. Finally, exposure of cells to topoisomerase I–targeted agents upregulates topoisomerase II, an alternative enzyme for DNA strand passage.

Very little is known about how the cell deals with the stabilized DNA-topoisomerase complexes. Cellular repair processes may not readily recognize the drug-enzyme-DNA complex. However, an enzyme with specific tyrosyl-DNA phosphodiesterase activity may be involved in the disassembly of topoisomerase I–DNA complexes (Yang et al., 1996).

**Absorption, Fate, and Excretion**

**Topotecan.** Topotecan is approved for intravenous administration. However, there has been interest in developing an oral dosage form for the drug, which has a bioavailability of 30-40% in cancer patients. Topotecan exhibits linear pharmacokinetics, and it is rapidly eliminated from systemic circulation. The biological t_{1/2} of total topotecan, which ranges from 3.5-4.1 hours, is relatively short compared to that of other camptothecins. Only 20-35% of the total drug in plasma is found to be in the active lactone form. Within 24 hours, 30-40% of the administered dose appears in the urine. Doses should be reduced in proportion to reductions in CrCl. Although several oxidative metabolites have been identified, hepatic metabolism appears to be a relatively minor route of drug elimination. Unlike most other camptothecins considered for clinical development, plasma protein binding of topotecan is low, at only 7-35%, which may explain its relatively greater CNS penetration.

**Irinotecan.** The conversion of irinotecan to SN-38 is mediated predominantly by carboxylesterases in the liver. Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only ~4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics at doses evaluated in cancer patients. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. Another potential advantage of this analog is that the t_{1/2} of SN-38 is 11.5 hours, which is much longer than the t_{1/2} of topotecan. CSF penetration of SN-38 in humans has not been characterized yet, although in rhesus monkeys, it is only 14%, significantly lower than that observed for topotecan.

In contrast to topotecan, hepatic metabolism represents an important route of elimination for both irinotecan and SN-38. Oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bispiperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be two times greater in brain cancer patients taking antiseizure drugs that induce hepatic CYPs, further attesting to the importance of oxidative hepatic metabolism as a route of elimination for this drug (Gilbert et al., 2003).

Glucuronidation of the hydroxyl group at position C10 (resulting from cleavage of the bispiperidine promoiety) produces the only known metabolite of SN-38. Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and their metabolites, although urinary excretion also contributes significantly (14-37%). Uridine diphosphate-glucuronosyltransferase 1A1 (UGT1A1), converts SN-38 to its inactive derivative (Iyer et al., 1998). The extent of SN-38 glucuronidation inversely correlates with the risk of severe diarrhea after irinotecan therapy. UGT1A1 also glucuronidates bilirubin. Polymorphisms of this enzyme are associated with familial hyperbilirubinemia syndromes such as Crigler-Najjar syndrome and Gilbert syndrome. Crigler-Najjar syndrome is rare (one in a million births), but Gilbert syndrome occurs in up to 15% of the general population and results in a mild hyperbilirubinemia that may be clinically silent. The presence of UGT enzyme polymorphisms may have a major impact on the clinical use of irinotecan. A positive correlation has been found between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38 in patients treated with irinotecan. Moreover, severe irinotecan toxicity has been observed in cancer patients with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38. The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to irinotecan’s GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite excreted in the bile.

**Therapeutic Uses**

**Topotecan.** Topotecan (HYCAMTIN) is indicated for previously treated patients with ovarian and small cell lung cancer. Its significant hematological toxicity has limited its use in combination with other active agents in these diseases (e.g., cisplatin).
The recommended dosing regimen of topotecan for ovarian cancer and small cell lung cancer is a 30-minute infusion of 1.5 mg/m²/day for 5 consecutive days every 3 weeks. For cervical cancer in conjunction with cisplatin, the dose of topotecan is 0.75 mg/m² on days 1, 2, and 3, repeated every 21 days. Because a significant fraction of the topotecan administered is excreted in the urine, patients with decreased CrCl may experience increased toxicity (O’Reilly et al., 1996). Therefore, the dose of topotecan should be reduced to 0.75 mg/m²/day in patients with moderate renal dysfunction (CrCl of 20–40 mL/min), and topotecan should not be administered to patients with severe renal impairment (CrCl <20 mL/min). Hepatic dysfunction does not alter topotecan clearance and toxicity. A baseline neutrophil count >1500 cells/mm³ and a platelet count >100,000 is necessary prior to topotecan administration. For small cell lung cancer, oral therapy can be used at a dosage of 2.3 mg/m²/day for 5 consecutive days repeated every 21 days. The oral dose is reduced to 1.8 mg/m² for patients with a CrCl of 30–49 mL/min.

**Irinotecan.** Approved single-agent dosage schedules of irinotecan (CAMPTOSAR, others) in the U.S. include 125 mg/m² as a 90-minute infusion administered weekly (on days 1, 8, 15, and 22) for 4 out of 6 weeks, and 350 mg/m² given every 3 weeks. In patients with advanced colorectal cancer, irinotecan is used as first-line therapy in combination with fluoropyrimidines or as a single agent or in combination with cetuximab following failure of a 5-FU/oxaliplatin regimen.

### Clinical Toxicities

**Topotecan.** The dose-limiting toxicity with all dosing schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at the recommended phase II dose of 1.5 mg/m² daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

**Irinotecan.** The dose-limiting toxicity with all dosing schedules is delayed diarrhea, with or without neutropenia. In the initial studies, up to 35% of patients experienced severe diarrhea. Adoption of an intensive regimen of loperamide (4 mg of loperamide starting at the onset of any loose stool more than a few hours after receiving therapy, followed by 2 mg every 2 hours) (see Chapter 47) has effectively reduced this incidence by more than half. However, once severe diarrhea occurs, standard doses of anti-diarrheal agents tend to be ineffective. Diarrhea generally resolves within a week and, unless associated with fever and neutropenia, rarely is fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14–47% of the patients treated with the every-3-weeks schedule and is less frequently encountered among patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients and may be fatal, particularly when associated with concomitant diarrhea. A cholinergic syndrome resulting from the inhibition of acetylcholinesterase activity by irinotecan may occur within the first 24 hours after irinotecan administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to atropine. Atropine may be prophylactically administered to patients who have previously experienced a cholinergic reaction. Other common and generally manageable toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. Finally, there have been case reports of dyspnea and interstitial pneumonitis associated with irinotecan therapy in Japanese patients with lung cancer (Fukuoka et al., 1992).

### ANTIBIOTICS

**Dactinomycin (Actinomycin D)**

The first anticancer antibiotics were the series of actinomycins discovered by Waksman and colleagues in 1940. The most important of these, actinomycin D, has beneficial effects in the treatment of solid tumors in children and choriocarcinoma in adult women.

**Chemistry and Structure-Activity Relationships.** The actinomycins are chromopeptides. Most contain the same chromophore, the planar phenoxazone actinosin, which is responsible for their yellow-red color. The differences among naturally occurring actinomycins are confined to variations in the structure of the amino acids of the peptide side chains.

**Mechanism of Action.** The capacity of actinomycins to bind with double-helical DNA is responsible for their biological activity and cytotoxicity. X-ray studies of a crystalline complex between dactinomycin and deoxyguanosine permitted formulation of a model that explains the binding of the drug to DNA (Sobell, 1973). The planar phenoxazone ring intercalates between adjacent guanine–cytosine base pairs of DNA, while the polypeptide chains extend along the minor groove of the helix. The summation of these interactions provides great stability to the dactinomycin-DNA complex, and as a result of the binding of dactinomycin, the transcription of DNA by RNA polymerase is blocked. The DNA-dependent RNA polymerases are much more sensitive to the effects of dactinomycin than are the DNA polymerases. In addition, dactinomycin causes single-strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II.

**Cytotoxic Action.** Dactinomycin inhibits rapidly proliferating cells of normal and neoplastic origin and, on a molar basis, is among the...
most potent antitumor agents known. The drug may produce alopecia and, when extravasated subcutaneously, causes marked local inflammation. Erythema, sometimes progressing to necrosis, has been noted in areas of the skin exposed to X-ray radiation before, during, or after administration of dactinomycin.

Absorption, Fate, and Excretion. Dactinomycin is administered by intravenous injection. Metabolism of the drug is minimal. The drug is excreted in both bile and urine and disappears from plasma with a terminal t₁/₂ of 36 hours. Dactinomycin does not cross the blood-brain barrier.

Therapeutic Uses. A wide variety of single-agent and combination chemotherapy regimens with dactinomycin (actinomycin D; COSMEGEN) are employed. The usual daily dose of dactinomycin is 10-15 μg/kg; this is given intravenously for 5 days; if no manifestations of toxicity are encountered, additional courses may be given at intervals of 2-4 weeks. In other regimens, 3-6 μg/kg/day, for a total of 125 μg/kg, and weekly maintenance doses of 7.5 μg/kg have been used. If infiltrated during administration, the drug is extremely corrosive to soft tissues.

The most important clinical use of dactinomycin is in the treatment of rhabdomyosarcoma and Wilm’s tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly vincristine and cyclophosphamide. Ewing, Kaposi, and soft-tissue sarcomas also respond. Dactinomycin and methotrexate form a curative therapy for chorioderma.

Clinical Toxicities. Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local drug extravasation.

Anthrycyclines and Anthracenediones

Anthrycyclines are derived from the fungus *Streptomyces peucetius* var. *caesius*. Idarubicin and epirubicin are analogs of the naturally produced anthrycyclines doxorubicin and daunorubicin, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. Daunorubicin and idarubicin primarily have been used in the acute leukemias, whereas doxorubicin and epirubicin display broader activity against human solid tumors. These agents, which all possess potential for generating free radicals, cause an unusual and often irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent mitoxantrone has useful activity against prostate cancer and AML, and is used in high-dose chemotherapy, but has less cardiotoxicity.

Chemistry. The anthracycline antibiotics have a tetracyclic ring structure attached to an unusual sugar, daunosamine. Cytotoxic agents of this class all have quinone and hydroquinone moieties on adjacent rings that permit the gain and loss of electrons. Although there are marked differences in the clinical uses of daunorubicin and doxorubicin, their chemical structures differ only by a single hydroxyl group on C-14 (substituent R₄, on the diagram below). Idarubicin is 4-demethoxydaunorubicin (alteration in substituent R₃), a synthetic derivative of daunorubicin; epirubicin is an epimer at the 4’ position of the sugar. Mitoxantrone, an anthracenedione, lacks a glycosidic side group.

**DOXORUBICIN**  **DAUNORUBICIN**  **EPIRUBICIN**  **IDARUBICIN**

Mechanism of Action. A number of important biochemical effects have been described for the anthracyclines and anthracenediones, all of which could contribute to their therapeutic and toxic effects. These compounds can intercalate with DNA, directly affecting transcription and replication. A more important action is the ability to form a tripartite complex with topoisomerase II and DNA. Topoisomerase II is an ATP-dependent enzyme that binds to DNA and produces double-strand breaks at the 3′-phosphate backbone, allowing strand passage and uncoiling of super-coiled DNA. Following strand passage, topoisomerase II re-ligates the DNA strands. This enzymatic function is essential for DNA replication and repair. Formation of the tripartite complex with anthracyclines or with etoposide inhibits the re-ligation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while overexpression of transcription-linked DNA repair may contribute to resistance.

Anthrycyclines, by virtue of their quinone groups, also generate free radicals in solution and in both normal and malignant tissues (Myers, 1988). Anthracyclines can form semiquinone radical intermediates that can react with O₂ to produce superoxide anion radicals. These can generate both hydrogen peroxide and hydroxyl radicals, which attack DNA (Serrano et al., 1999) and oxidize DNA bases. The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron (Myers, 1988). Enzymatic defenses such as superoxide dismutase and catalase protect cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as alpha tocopherol or by an iron chelator, dexrazoxane (ZINECARD, others), which protects against cardiac toxicity (Swain et al., 1997). Exposure of cells to anthracyclines leads to apoptosis; mediators of this process include the p53 DNA-damage sensor and activated caspases (proteases), although ceramide, a lipid breakdown product, and the Fas receptor-ligand system also have been implicated (Friesen et al., 1996).
As discussed in “Drug Resistance” under “Vinca Alkaloids,” multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Attempts to reverse or prevent the emergence of resistance through the simultaneous use of inhibitors of the P-glycoprotein (Ca++ channel blockers, steroidal compounds, and others) have yielded inconclusive results, primarily due to confounding effects of these inhibitors on anthracycline pharmacokinetics and metabolism. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by the breast cancer resistance protein, a “half” transporter (Doyle et al., 1998). Other biochemical changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

**Absorption, Fate, and Excretion.** Daunorubicin, doxorubicin, epirubicin, and idarubicin usually are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. The plasma disappearance curves for doxorubicin and daunorubicin are multiphasic, with a terminal $t_{1/2}$ of 30 hours. All anthracyclines are converted to an active alcohol intermediate that plays a variable role in their therapeutic activity. Idarubicin has a $t_{1/2}$ of 15 hours, and its active metabolite, idarubicinol, has a $t_{1/2}$ of 40 hours. The drugs rapidly enter the heart, kidneys, lungs, liver, and spleen. They do not cross the blood-brain barrier.

Daunorubicin and doxorubicin are eliminated by metabolic conversion to a variety of aglycones and other inactive products. Idarubicin is primarily metabolized to idarubicinol, which accumulates in plasma and likely contributes significantly to its activity. Clearance of anthracyclines and their active alcohol metabolites is delayed in the presence of hepatic dysfunction, and at least a 50% initial reduction in dose should be considered in patients with abnormal serum bilirubin levels (Twelves et al., 1998).

**Therapeutic Use**

**Idarubicin.** The recommended dosage for idarubicin (IDAMYCIN PFS) is 12 mg/m²/day for 3 days by intravenous injection in combination with cytarabine. Slow injection over 10-15 minutes is recommended to avoid extravasation, as with other anthracyclines. It has less cardiotoxicity than the other anthracyclines.

**Daunorubicin.** Daunorubicin (daunomycin, rubidomycin; CERUBIDINE, others) is available for intravenous use. The recommended dosage is 25-45 mg/m²/day for 3 days. The agent is administered with appropriate care to prevent extravasation, because severe local vesicant action may result. Total doses of $>1000$ mg/m² are associated with a high risk of cardiotoxicity. Patients should be advised that daunorubicin may impart a red color to the urine.

Daunorubicin and idarubicin also are used in the treatment of AML, in combination with Ara-C.

**Clinical Toxicities.** The toxic manifestations of daunorubicin as well as idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, and rash. Cardiac toxicity is a peculiar adverse effect observed with these agents. It is characterized by tachycardia, arrhythmias, dyspnea, hypotension, pericardial effusion, and congestive heart failure poorly responsive to digitalis (see “Clinical Toxicities” under “Doxorubicin”).

**Doxorubicin**

**Therapeutic Uses.** Doxorubicin is available for intravenous use. The recommended dose is 60-75 mg/m², administered as a single rapid intravenous infusion that is repeated after 21 days. Care should be taken to avoid extravasation, because severe local vesicant action and tissue necrosis may result. A doxorubicin liposomal product (DOXIL) is available for treatment of AIDS-related Kaposi sarcoma and is given intravenously in a dose of 20 mg/m² over 60 minutes and repeated every 3 weeks. The liposomal formulation also is approved for ovarian cancer at a dose of 50 mg/m² every 4 weeks and as a treatment for multiple myeloma (in conjunction with bortezomib), where it is given as a 30-mg/m² dose on day 4 of each 21-day cycle. Patients should be advised that the drug may impart a red color to the urine.

Doxorubicin is effective in malignant lymphomas. In combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens of chemotherapy for adjuvant and metastatic carcinoma of the breast. The drug also is particularly beneficial in pediatric and adult sarcomas, including osteogenic, Ewing, and soft-tissue sarcomas.

**Clinical Toxicities.** The toxic manifestations of doxorubicin are similar to those of daunorubicin. Myelosuppression is a major dose-limiting complication, with leukopenia usually reaching a nadir during the second week of therapy and recovering by the fourth week; thrombocytopenia and anemia follow a similar pattern but usually are less pronounced. Stomatitis, mucositis, diarrhea, and alopecia are common but reversible. Erythematous streaking near the site of infusion (“ADRIAMYCIN flare”) is a benign local allergic reaction and should not be confused with extravasation. Facial flushing, conjunctivitis, and lacrimation may occur rarely. The drug may produce severe local toxicity in irradiated tissues (e.g., the skin, heart, lung, esophagus, and GI mucosa) even when the two therapies are not administered concomitantly.

Cardiomyopathy is the most important long-term toxicity. Two types of cardiomyopathies may occur:

- An acute form is characterized by abnormal electrocardiographic changes, including ST- and T-wave alterations and arrhythmias. This is brief and rarely a serious problem. An acute reversible reduction in ejection fraction is observed in some patients in the 24 hours after a single dose, and plasma troponin T, a cardiac enzyme released with myocardial damage, may increase in a minority of patients in the first few days following drug administration (Lipschultz et al., 2004). Acute myocardial damage, the “pericarditis–myocarditis syndrome,” may begin in the days following drug infusion and is characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.

- Chronic, cumulative dose-related toxicity (usually total doses of ≥550 mg/m²) progress to congestive heart failure. The mortality rate in patients with congestive failure approaches 50%. Total doses of doxorubicin as low as 250 mg/m² can cause pathological changes in the myocardium, as demonstrated by subendocardial biopsies. Nonspecific alterations, including a decrease in the number of myocardial fibrils, mitochondrial changes, and cellular degeneration, are visible by electron microscopy. The most promising noninvasive techniques used to detect the early development of drug-induced congestive heart failure are radionuclide cineangiography, which assesses ejection fraction, and
echocardiography, which reveals abnormalities in contractility and ventricular dimensions. Sequential echocardiograms have detected structural abnormalities in 25% of children who received up to 300 mg/m² of doxorubicin, although <10% have clinical manifestations of cardiac disease in long-term follow-up. Although no completely practical and reliable predictive tests are available, the frequency of clinically apparent cardiomyopathy is 1-10% at total doses <450 mg/m². The risk increases markedly, with estimates as high as 20% at total doses of 550 mg/m². This total dosage should be exceeded only under exceptional circumstances or with the concomitant use of dexrazoxane, a cardioprotective iron-chelating agent that appears not to compromise the anticancer activity of the drug (Swain et al., 1997). Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant trastuzumab (Slamon et al., 2001) increases the risk of cardiotoxicity. Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In children treated with anthracyclines, there is a 3- to 10-fold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. A total dose limit of 300 mg/m² is advised for pediatric cases. Concomitant administration of dexrazoxane may reduce troponin T elevations and avert later cardiotoxicity (Lipshultz et al., 2004).

Epirubicin (Ellence, others)
This anthracycline is indicated as a component of adjunctive therapy for treatment of breast cancer. It is administered in doses of 100-120 mg/m² intravenously every 3-4 weeks. Total doses >900 mg/m² sharply increase the risk of cardiotoxicity. Its toxicity profile is the same as that of doxorubicin.

Valrubicin (Valstar)
Valrubicin is a semi-synthetic analog of doxorubicin, used exclusively for intravesicular treatment of bladder cancer. Eight hundred mg are instilled into the bladder once a week for 6 weeks. Less than 10% of instilled drug is absorbed systemically. Side effects relate to bladder irritation (Kuznetsov et al., 2001).

Mitoxantrone
Mitoxantrone has been approved for use in AML, prostate cancer, and late-stage, secondary progressive multiple sclerosis. Mitoxantrone has limited ability to produce quinone-type free radicals and causes less cardiac toxicity than does doxorubicin. It produces acute myelosuppression, cardiac toxicity, and mucositis as its major toxicities; the drug causes less nausea, vomiting, and alopecia than does doxorubicin.

Mitoxantrone (Novantrone, others) is administered by intravenous infusion. To induce remission in acute nonlymphocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m² for 3 days with cytarabine. It also is used in advanced hormone-resistant prostate cancer in a dose of 12-14 mg/m² every 21 days.

EPIPODOPHYLLOTOXINS
Podophyllotoxin, extracted from the mandrake plant (mayapple; Podophyllum peltatum), was used as a folk remedy by the American Indians and early colonists for its emetic, cathartic, and anthelmintic effects. Two synthetic derivatives have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin’s disease, and large cell lymphomas.

These derivatives, shown below, are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin, etoposide and teniposide have no effect on microtubular structure or function at usual concentrations.

Mechanism of Action. Etoposide and teniposide are similar in their actions and in the spectrum of human tumors affected. Like the anthracyclines, they form a ternary complex with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G₂ phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate 1) amplification of the mdr-1 gene that encodes the P-glycoprotein drug efflux transporter, 2) mutation or decreased expression of topoisomerase II, or 3) mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe et al., 1993).

Etoposide
Absorption, Fate, and Excretion. Oral administration of etoposide results in variable absorption that averages ~50%. After intravenous injection, peak plasma concentrations of 30 μg/mL are achieved; there is a biphasic pattern of clearance with a terminal t₁/₂ of ~6-8 hours in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with
compromised renal function, dosage should be reduced in proportion to the reduction in CrCl (Arbuck et al., 1986). In patients with advanced liver disease, increased toxicity may result from a low serum albumin (decreased drug binding) and elevated bilirubin (which displaces etoposide from albumin). However, guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1-10% of those in plasma.

**Therapeutic Uses.** The intravenous dose of etoposide (VEPESID, others) for testicular cancer in combination therapy is 50-100 mg/m² for 5 days, or 100 mg/m² on alternate days for three doses. For small cell carcinoma of the lung, the dosage in combination therapy is 35 mg/m²/day intravenously for 4 days or 50 mg/m²/day intravenously for 5 days. The oral dose for small cell lung cancer is twice the IV dose. Cycles of therapy usually are repeated every 3-4 weeks. When given intravenously, the drug should be administered slowly over a 30- to 60-minute period to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve etoposide, a relatively insoluble compound.

A disturbing complication of etoposide therapy has emerged in long-term follow-up of patients with childhood acute lymphoblastic leukemia, who develop an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11q23. At this locus is a gene (the MLL gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia but may express lymphoid surface markers. Another distinguishing feature of etoposide-related leukemia is the short time interval between the end of treatment and the onset of leukemia (1-3 years), compared to the 4- to 5-year interval for secondary leukemias related to alkylating agents, and the absence of a myelodysplastic period preceding leukemia (Pui et al., 1995). Patients receiving weekly or twice-weekly doses of etoposide, with cumulative doses >2000 mg/m², seem to be at higher risk of leukemia.

Etoposide primarily is used for treatment of testicular tumors, in combination with bleomycin and cisplatin, and in combination with cisplatin and ifosfamide for small cell carcinoma of the lung. It also is active against non-Hodgkin’s lymphomas, acute nonlymphocytic leukemia, and Kaposi sarcoma associated with acquired immunodeficiency syndrome (AIDS). Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it frequently is used for high-dose chemotherapy in total doses of 1500-2000 mg/m² (Josting et al., 2000).

**Clinical Toxicities.** The dose-limiting toxicity of etoposide is leukopenia, with a nadir at 10-14 days and recovery by 3 weeks. Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea complicate treatment in ~15% of patients. Alopecia is a common but reversible adverse effect. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity increases in patients with decreased serum albumin, an effect related to decreased protein binding of the drug.

**Teniposide**

Teniposide (VUMON) is administered intravenously. It has a multiphasic pattern of clearance from plasma; after distribution, a t₁/₂ of 4 hours and another t₁/₂ of 40-40 hours are observed. Approximately 45% of the drug is excreted in the urine, but in contrast to etoposide, as much as 80% is recovered as metabolites. Anticonvulsants such as phenytoin increase the hepatic metabolism of teniposide and reduce systemic exposure (Baker et al., 1992). Dosage need not be reduced for patients with impaired renal function. Less than 1% of the drug crosses the blood-brain barrier. Teniposide is available for treatment of refractory ALL in children and is synergistic with cytarabine. It is administered by intravenous infusion in dosages that range from 50 mg/m²/day for 5 days to 165 mg/m²/day twice weekly. The drug has limited utility and primarily is given for acute leukemia in children and monocytic leukemia in infants, as well as glioblastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting are its primary toxic effects.

**DRUGS OF DIVERSE MECHANISM OF ACTION**

**Bleomycin**

The bleomycins, a unique group of DNA-cleaving antibiotics, were discovered by Umezawa and colleagues as fermentation products of *Streptomyces verticillus*. The drug currently employed clinically is a mixture of the two copper-chelating peptides, bleomycins A₂ and B₂. The various bleomycins differ only in their terminal amino acid (Figure 61-14).

Bleomycins have attracted interest because of their significant antitumor activity against both Hodgkin’s lymphoma and testicular tumors. They are minimally myelo- and immunosuppressive but cause unusual cutaneous side effects and pulmonary fibrosis. Because their toxicities do not overlap with those of other cytotoxic drugs, and because of their unique mechanism of action, bleomycin maintains an important role in treating Hodgkin’s disease and testicular cancer.

**Chemistry.** The bleomycins are water-soluble, basic glycopeptides (Figure 61-14). The core of the bleomycin molecule assumes a metal-binding cage consisting of a pyrimidine chromophore linked to propionate and another aminoalanine amide side chain, and the sugars, l-gulose and 3-O-carbamoyl-d-mannose. Bound to the metal ion binding core are a tripeptide chain and a terminal, DNA-binding bithiazole carboxylic acid.

**Mechanism of Action.** Bleomycin’s cytotoxicity results from its ability to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA. Studies *in vitro* indicate that bleomycin causes accumulation of cells in the G2 phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, and fragments, as well as translocations (Twortman, 1983).

Bleomycin cleaves DNA by generating free radicals. In the presence of O₂ and a reducing agent, such as dithiothreitol, the metal–drug complex becomes activated and functions as a ferrous oxidase, transferring electrons from Fe²⁺ to molecular oxygen to
produce oxygen radicals (Burger, 1998). Metallobleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-cytochrome P450 reductase. Bleomycin binds to DNA, and the activated complex generates free radicals that are responsible for abstraction of a proton at the 3’ position of the deoxyribose backbone of the DNA chain, opening the deoxyribose ring and generating a strand break in DNA. The process for repair of this break is poorly understood, but an excess of breaks generates apoptosis.

Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. Hydrolase activity is low in skin and lung, perhaps contributing to the serious toxicity at those sites. Some bleomycin-resistant cells contain high levels of hydrolase activity (Sebti et al., 1991). In other cell lines, resistance has been attributed to decreased uptake, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins. A polymorphism of the hydrolase gene, SNP A1450G, has been identified in 10% of patients with testicular cancer, with the G/G genotype is associated with a 20% decreased survival in patients treated with bleomycin combination therapy, suggesting that this single nucleotide polymorphism is associated with increased hydrolase activity (de Haas et al., 2008).

Absorption, Fate, and Excretion. Bleomycin is administered intravenously, intramuscularly, or subcutaneously or instilled into the bladder for local treatment of bladder cancer. After intravenous infusion, relatively high drug concentrations are detected in the skin and lungs of experimental animals, and these organs become major sites of toxicity. Having a high molecular mass, bleomycin crosses the blood-brain barrier poorly.

After intravenous administration of a bolus dose of 15 mg/m², peak concentrations of 1-5 mg/mL are achieved in plasma. The half-time for elimination is ~3 hours. About two-thirds of the drug are excreted intact in the urine. Concentrations in plasma are greatly elevated if usual doses are given to patients with renal impairment and if such patients are at high risk of developing pulmonary toxicity. Doses of bleomycin should be reduced in the presence of a CrCl <60 mL/min (Dalgleish et al., 1984).

Therapeutic Uses. The recommended dose of bleomycin (BLENOX-AN®, others) is 10-20 units/m² given weekly or twice weekly by the intravenous, intramuscular, or subcutaneous route. A test dose of ≤2 units before the first two doses is recommended for lymphoma patients. A variety of regimens are employed clinically, with bleomycin doses expressed in units. In treating testicular cancer, a standard total dose of 30 mg is given weekly for 3 consecutive weeks, and for three to four cycles of treatment. Total courses exceeding 250 mg should be given with caution, and usually only in high-risk testicular cancer treatment, because of a marked increase in the risk of pulmonary toxicity above this total dose. Bleomycin also may be instilled into the pleural cavity in doses of 5-60 mg (depending on the technique) to ablate the pleural space in patients with malignant effusions.

Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer, it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is a component of the standard curative ABVD regimen (doxorubicin [adriamycin], bleomycin, vinblastine, and dacarbazine) for Hodgkin’s lymphoma.

Clinical Toxicities. Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause a constellation of cutaneous toxicities, including hyperpigmentation, hyperkeratosis, erythema, and even ulceration. Rarely, patients with severe skin toxicity may experience Raynaud’s phenomenon. Skin changes may begin with tenderness and swelling of the distal digits and progress to erythematous, ulcerating lesions over the elbows, knuckles, and other pressure areas. Healing of these lesions often leaves a residual hyperpigmentation, and lesions may recur when patients are treated with other antineoplastic drugs. Rarely, bleomycin causes a flagellate dermatitis consisting of bands of puritic erythema on the arms, back, scalp, and hands. This rash responds readily to topical corticosteroids.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse
basilar infiltrates on X-ray and may progress to life-threatening pulmonary fibrosis. Radiological changes of bleomycin-induced lung disease may be indistinguishable from interstitial infection or tumor, and show strong PET-positivity, but may progress from patchy infiltrates to dense fibrosis, cavitation and pneumothorax, atelectasis, or lobar collapse. Approximately 5-10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and ~1% die of this complication (O’Sullivan et al., 2003). Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests are not of predictive value for detecting early onset of this complication. The CO diffusion capacity declines in patients receiving doses >250 mg. The risk of pulmonary toxicity is related to total dose, with a significant increase in risk in total doses >250 mg and in patients >40 years of age, in those with a CrCl of <80 mL/min, and in those with underlying pulmonary disease; single doses of ≥30 mg/m² also are associated with an increased risk of pulmonary toxicity. Administration of high inspired O₂ concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known specific therapy for bleomycin lung injury except for symptomatic management and standard pulmonary care. Steroids are of variable benefit, with greatest effectiveness in the earliest inflammatory stages of the lesion.

The etiology of bleomycin pulmonary toxicity has been investigated in rodent models (Moeller et al., 2008). These studies implicate various factors secreted by macrophages, including cytokines (such as transforming growth factor β [TGFβ] and tumor necrosis factor α [TNFα]), chemokines (such as CCL2 and CXCL12), as causative factors in leading to fibrosis in response to epithelial damage. Other contributing factors may be disordered coagulation cascades and imbalances in eicosanoids, leading to overproduction of profibrotic leukotrienes and underproduction of antifibrotic prostaglandins. Fibroblasts are recruited to the site of injury by release of lysophosphatide acid from inflammatory cells and contribute to the development of fibrosis (Tager et al., 2008). Various agents (e.g., thalidomide, anti-Her 2 antibodies, PPAR-γ agonists, N-acetylcysteine, anticoagulants, pirfenidone, and bosentan) have attenuated bleomycin toxicity in the animal model, given either before or after the toxic agent. The last four agents are being evaluated in clinical trials for the treatment of idiopathic pulmonary fibrosis (Walter et al., 2006), for which bleomycin lung disease in rodents is the primary disease model.

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This reaction is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and possibly may be related to release of an endogenous pyrogen. This reaction has occurred in ~1% of patients with lymphomas or testicular cancer.

**Mitomycin**

This antibiotic was isolated from *Streptococcus caespi- tosus* by Wakaki and associates in 1958. It has limited clinical utility, having been replaced by less toxic and more effective drugs in most settings, with the exception of anal cancers, for which it is curative.

Mitomycin contains an azauridine group and a quinone group in its structure, as well as a mitosane ring, and each of these participates in the alkylation reactions with DNA.

**Mechanism of Action.** After intracellular enzymatic or spontaneous chemical reduction of the quinone and loss of the methoxy group, mitomycin becomes a bifunctional or trifunctional alkylating agent. Reduction occurs preferentially in hypoxic cells in some experimental systems. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6 and N7 positions of guanine. Attempts to repair DNA lead to strand breaks. Mitomycin is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced quinone, and P-glycoprotein-mediated drug efflux (Dorr, 1988).

**Absorption, Fate, and Excretion.** Mitomycin is administered intravenously. It disappears rapidly from the blood after injection, with a t½ of 25-90 minutes. Peak concentrations in plasma are 0.4 µg/mL after doses of 20 mg/m² (Dorr, 1988). The drug distributes widely throughout the body but is not detected in the CNS. Inactivation occurs by hepatic metabolism or chemical conjugation with sulphydryls. Less than 10% of the active drug is excreted in the urine or the bile.

**Therapeutic Uses.** Mitomycin (mitomycin-C; MUTAMYCIN, others) is administered by intravenous infusion; extravasation may result in severe local injury. The usual dose (6-20 mg/m²) is given as a single bolus every 6-8 weeks. Dosage is modified based on hematological recovery. Mitomycin also may be used by direct instillation into the bladder to treat superficial carcinomas (Boccardo et al., 1994).

Mitomycin is used in combination with 5-FU and cisplatin, for anal cancer. Mitomycin is used off label (in the form of an extemporaneously compounded eye drop) as an adjunct to surgery to inhibit wound healing and reduce scarring; it appears to have benefit in the management of malignant and nonmalignant ophthalmic pathologies (see the review by Abraham, 2006).

**Clinical Toxicities.** The major toxic effect is myelosuppression, characterized by marked leukopenia and thrombocytopenia; after higher doses, the nadirs may be delayed and cumulative, with recovery only after 6-8 weeks of pancytopenia. Nausea, vomiting, diarrhea, stomatitis, rash, fever, and malaise also are observed. A hemolytic uremic syndrome represents the most dangerous toxic manifestation of mitomycin and is believed to result from drug-induced endothelial damage. Patients who have received >50 mg/m² total dose may acutely develop hemolysis, neurological abnormalities, interstitial pneumonia, and glomerular damage resulting in renal failure. The incidence of renal failure increases to 28% in patients who receive total doses of ≥70 mg/m². There is no effective treatment for the disorder. It must be recognized early,
and mitomycin must be discontinued immediately. Mitomycin causes interstitial pulmonary fibrosis, and total doses >30 mg/m² have infrequently led to congestive heart failure. It also may potentiate the cardiotoxicity of doxorubicin when used in combination with this drug.

Mitotane

Mitotane (\(o,p'\)-DDD), a compound chemically similar to the insecticides DDT and DDD, is used in the treatment of neoplasms derived from the adrenal cortex. In studies of the toxicology of related insecticides in dogs, it was noted that the adrenal cortex was severely damaged, an effect caused by the presence of the \(o,p'\) isomer of DDD.

MITOTANE (\(o,p'\) DDD)

Cytotoxic Action. The mechanism of action of mitotane has not been elucidated, but its relatively selective destruction of adrenocortical cells, normal or neoplastic, is well established. Thus, administration of the drug causes a rapid reduction in the levels of adrenocorticos-teroids and their metabolites in blood and urine, a response that is useful in both guiding dosage and following the course of hyperadrenocorticism (Cushing’s syndrome) resulting from an adrenal tumor or adrenal hyperplasia. It does not damage other organs.

Absorption, Fate, and Excretion. Approximately 40% of mitotane is absorbed after oral administration. After daily doses of 5-15 g, concentrations of 10-90 μg/mL of unchanged drug and 30-50 μg/mL of a metabolite are present in the blood. After discontinuation of therapy, plasma concentrations of mitotane are still measurable for 6-9 weeks. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane found in the urine constitutes 25% of an oral or parenteral dose. About 60% of an oral dose is excreted unchanged in the stool.

Therapeutic Uses. Mitotane (LYSODREN) is administered in initial daily oral doses of 2-6 g, usually in three or four divided portions, and usually increased to 9-10 g/day if tolerated. The maximal tolerated dose may vary from 2-16 g/day. Treatment should continue for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. Spironolactone should not be administered concomitantly, because it interferes with the adrenal suppression produced by mitotane (Wortsman and Soler, 1977).

Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30-50% of such patients.

Clinical Toxicity. Although the administration of mitotane produces anorexia and nausea in most patients, somnolence and lethargy in ~34%, and dermatitis in 15-20%, these effects do not contraindicate the use of the drug at lower doses. Because this drug damages the adrenal cortex, administration of replacement doses of adrenocorticosteroids is necessary (Hogan et al., 1978).

Trabectedin

Trabectedin (YONDELIS) is the only drug used clinically that is derived from a sea animal. It was isolated from the marine tunicate, Ecteinascidin turbinate, as part of the National Cancer Institute’s natural products discovery program. Trabectedin is designated as an orphan drug in the U.S. for ovarian cancer, sarcoma, and pancreatic cancer and is approved in the E.U. for secondline treatment of soft-tissue sarcomas and ovarian cancer.

MECHANISM OF ACTION. This large structure binds to the minor groove of DNA, allowing the alkylation of the N2 position of guanine and bending the helix toward the major groove (Tavecchio et al., 2008). A portion of the molecule protrudes from the minor groove and may play a role in attracting repair or transcription complexes. The bulky DNA adduct is recognized by the transcription-coupled nucleotide excision repair complex, and these proteins initiate attempts to repair the damaged strand, converting the adduct to a double-stranded break. Tumor cell sensitivity to trabectedin exhibits interesting molecular features. Trabectedin has particular cytotoxic effects on cells that lack components of the Fanconi anemia complex or those that lack the ability to repair
double-strand DNA breaks through homologous recombination (Soares et al., 2007). Unlike cisplatin and other DNA adduct–forming drugs, its activity requires the presence of intact components of NER, including XPG, which may be important for initiation of single breaks and attempts at adduct removal (Stevens et al., 2008).

Absorption, Fate, and Excretion. Trabectedin is administered as a 24-hour infusion of 1.3 mg/m² every 3 weeks. Its approval in Europe was based on a trial in soft-tissue sarcoma in which a superior time to progression was found with the longer infusion, as compared to a more convenient 3-hour infusion. It is administered with dexamethasone, 4 mg BID, starting 24 hours before drug infusion to diminish hepatic toxicity. The drug is slowly cleared by CYP3A4, with a plasma t½ of ~24-40 hours.

Therapeutic Uses. Trabectedin is approved outside the U.S. for second-line treatment of soft-tissue sarcomas and for ovarian cancer in combination with a doxorubicin formulation (DOXIL®). It produces a very high (>50%) disease control rate in myxoid liposarcomas, a tumor characterized by a particular genomic translocation, although the reasons for this sensitivity are unclear (Grosso et al., 2009). Tumor characterized by a particular genomic translocation, although the reasons for this sensitivity are unclear (Grosso et al., 2009). Other toxicities include mild myelosuppression and, rarely, rhabdomyolysis.

ENZYMES

L-Asparaginase

In 1953, Kidd reported that guinea pig serum had anti-leukemic effects and identified L-asparaginase (L-ASP) as the source of this activity (Kidd, 1953). Fifteen years later, the purified enzyme from Escherichia coli proved to have dramatic antitumor activity against malignant lymphoid cells, based on the dependence of those tumors on exogenous sources of L-asparagine (Broome, 1981). The enzyme has become a standard agent for treating ALL.

Mechanism of Action. Most normal tissues are able to synthesize L-asparagine in amounts sufficient for protein synthesis, but lymphocytic leukemias lack adequate amounts of asparagine synthetase, and derive the required amino acid from plasma. L-ASP, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of asparagine, leading to cell death. L-ASP is used in combination with other agents, including methotrexate, doxorubicin, vincristine, and prednisone for the treatment of ALL and for high-grade lymphomas.

Resistance arises through induction of asparaginase synthetase in tumor cells. For unknown reasons, hyperdiploid ALL cells or those with translocations involving the TEL oncogene are particularly sensitive to L-ASP (Pui et al., 2004), while cells containing the bcr-abl translocation, more common in adult ALL, are more resistant.

Absorption, Fate, Excretion, and Therapeutic Use. L-Asparaginase (ELSPAR), a 144-kDa tetramer, is given intramuscularly or intravenously, but usually by the former route. After intravenous administration, E. coli–derived L-ASP has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma in humans, and a t½ of 24 hours (Asselin et al., 1993). It is given in doses of 6000-10,000 IU every third day for 3-4 weeks, although doses up to 25,000 IU once per week may be more effective in childhood ALL (Moghrabi et al., 2007). Enzyme levels must be maintained at >0.2 IU/mL in plasma to deplete asparagine in the bloodstream. Pegaspargase (PEG-L-ASPARAGINASE; ONCASPAR) a preparation in which the enzyme is conjugated to 5000-Da units of monomethoxy polyethylene glycol, has much slower clearance from plasma (t½ of 6-7 days), and it is administered in doses of 2500 IU/m² intramuscularly no more frequently than every 14 days, producing rapid and complete depletion of plasma and tumor cell asparagine for 21 days in most patients (Appel et al., 2008). Pegaspargase has much reduced immunogenicity (<20% of patients develop antibodies) (Hawkins et al., 2004) and has been approved for first-line ALL therapy.

Intermittent dosage regimens and longer durations of treatment increase the risk of inducing hypersensitivity. In hypersensitive patients, neutralizing antibodies inactivate L-ASP. Not all patients with neutralizing antibodies experience clinical hypersensitivity, although enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegaspargase produces more rapid clearance of lymphoblasts from bone marrow than does the E. coli preparation and circumvents the rapid antibody-mediated clearance seen with E. coli enzyme in relapsed patients (Avramis et al., 2002). Asparaginase preparations only partially deplete CSF asparagine.

Clinical Toxicity. L-ASP toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions, including urticaria and full-blown anaphylaxis, occur in 5-20% of patients and may be fatal. These reactions usually are heralded by the earlier appearance of circulating neutralizing antibody and accelerated enzyme clearance from plasma. In these patients, pegaspargase is a safe and effective alternative. So-called “silent” enzyme inactivation by antibodies occurs in a higher percentage of patients than overt hypersensitivity and may be associated with a negative clinical outcome, especially in high-risk ALL patients (Mann et al., 2007).

Other toxicities result from inhibition of protein synthesis in normal tissues (e.g., hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, hypertriglyceridemia due to effects on lipoprotein production, hypoalbuminemia). Pancreatitis may result from extreme triglyceridemia and has been treated by plasma exchange. The clotting problems may take the form of spontaneous thrombosis—more frequent in thrombophlic patients with underlying deficiencies in factor S, factor C, antithrombin III mutation, or factor V Leiden—or, less frequently, hemorrhagic episodes (Caruso et al., 2006). Thrombosis of cortical sinus vessels frequently goes unrecognized. Brain magnetic resonance imaging studies should be considered in patients treated with L-ASP who present with seizures, headache, or altered mental status. Intracranial hemorrhage in the first week of L-ASP treatment is an infrequent but devastating complication. L-ASP suppresses immune function as well.
HDAC (histone deacetylase) inhibitors inhibit the p21 cell-cycle checkpoint and thereby enhances the effects of itabine, and fludarabine into DNA. It also promotes degradation of an inducer of fetal hemoglobin in patients with sickle cell disease. The drug is orally administered, and its toxicity in most patients is modest and limited to myelosuppression.

**HYDROXYUREA**

The syntheses of hydroxyurea (HU) was first reported in 1869, but its potential anticancer activity was not recognized until 90 years later, when the drug was found to inhibit the growth of both leukemia and solid tumors. This drug has unique and surprisingly diverse biological effects as an antileukemic drug, radiation sensitizer, and an inducer of fetal hemoglobin in patients with sickle cell disease. The drug is orally administered, and its toxicity in most patients is modest and limited to myelosuppression.

**Cytotoxic Action.** HU inhibits the enzyme ribonucleoside diphosphate reductase, which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, a rate-limiting step in the biosynthesis of DNA. HU binds the iron molecules that are essential for activation of a tyrosyl radical in the catalytic subunit (hRRM2) of RNR. The drug is specific for the S phase of the cell cycle, during which RNR concentrations are maximal. It causes cells to arrest at or near the G1–S interface through both p53-dependent and -independent mechanisms.

Because cells are highly sensitive to irradiation at the G1–S boundary, HU and irradiation cause synergistic antitumor effects. Through depletion of physiological deoxynucleotides, HU potentiates the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoiso-merase II inhibitors and facilitates the incorporation of antimitabolites such as Ara-C, gemcitabine, and fludarabine into DNA. It also promotes degradation of the p21 cell-cycle checkpoint and thereby enhances the effects of HDAC (histone deacetylase) inhibitors in vitro (Kramer et al., 2008). The role of nitric oxide release in its differentiating activity and in its antitumor effects is uncertain but intriguing (Cokic et al., 2003).

HU has become the primary drug for improving the control of sickle cell (HbS) disease in adults and is also used for inducing fetal hemoglobin (HbF) in thalassemia HbC and HbC/S patients (Brawley et al., 2008). It reduces vaso-occlusive events, painful crises, hospitalizations, and the need for blood transfusions in patients with sickle cell disease. It does so via several potential mechanisms. Increased synthesis of HbF promotes solubility of hemoglobin and prevents sickling. The mechanism of HbF production is uncertain. It may simply result from suppression of erythroid precursor proliferation with compensatory stimulation of a distinct set of fetal Hb-producing cells. Sar1a, a specific promoter that upregulates in response to HU, induces HbF synthesis (Kumkhaek, 2008). Polymorphisms in this promoter may explain differential responses to HU. An alternative mechanism for HbF production has been offered because of the ability of HU to generate nitric oxide both in vitro and in vivo, causing nitrosylation of small-molecular-weight GTPases, a process that stimulate γ-globin production in erythroid precursors. Another property of HU that may be relevant is its ability to reduce L-selectin expression and thereby to inhibit adhesion of red cells and neutrophils to vascular endothelium. Also, by suppressing the production of neutrophils, it decreases their contribution to vascular occlusion.

Tumor cells become resistant to HU through increased synthesis of the hRRM2 subunit of ribonucleoside diphosphate reductase, thus restoring enzyme activity.

**Absorption, Fate, and Excretion.** The oral bioavailability of HU is excellent (80-100%), and comparable plasma concentrations are seen after oral or intravenous dosing. Peak plasma concentrations are reached 1-1.5 hours after oral doses of 15-80 mg/kg. HU disappears from plasma with a t1/2 of 3.5-4.5 hours. The drug readily crosses the blood-brain barrier, and it appears in significant quantities in human breast milk. From 40-80% of the drug is recovered in the urine within 12 hours after either intravenous or oral administration. Although precise guidelines are not available, it is advisable to modify initial doses for patients with abnormal renal function until individual tolerance can be assessed. Animal studies suggest that metabolism of HU does occur, but the extent and significance of its metabolism in humans have not been established.

**Therapeutic Uses.** In cancer treatment, two dosage schedules for HU (HYDREA, DROXIA, others), alone or in combination with other drugs, are most commonly used in a variety of solid tumors: 1) intermittent therapy with 80 mg/kg administered orally as a single dose every third day or 2) continuous therapy with 20-30 mg/kg administered as a single daily dose. In patients with essential thrombocytopenia and in sickle cell disease, HU is given in a daily dose of 15 mg/kg, adjusting that dose upward or downward according to blood counts. The neutrophil count responds within 1-2 weeks to discontinuation of the drug. In treating subjects with sickle cell and related diseases, a neutrophil count of at least 2500 cells/mL should be maintained (Platt, 2008). Treatment typically is continued for 6 weeks in malignant diseases to determine its effectiveness; if satisfactory results are obtained, therapy can be continued indefinitely, although leukocyte counts at weekly intervals are advisable.

The principal use of HU has been as a myelosuppressive agent in various myeloproliferative syndromes, particularly CML, polycythemia vera, myeloid metaplasia, and essential thrombocytosis, for controlling high platelet or white cell counts. Many of the myeloproliferative syndromes harbor activating mutations of JAK2, a gene that is downregulated by HU. In essential thrombocytopenia, it is the drug of choice for patients with a platelet count >1.5 million cells/mm³ or with a history of arterial or venous thrombosis. In this disease, it dramatically lowers the risk of thrombosis by lowering the platelet, neutrophil, and red cell counts and by reducing expression of L-selectin and increasing nitric oxide production by neutrophils.

In CML, HU has been largely replaced by imatinib. Although it has produced anecdotal, temporary remissions in patients with solid tumors (e.g., head and neck cancers, cervical cancers), HU rarely is used in such patients as a single agent. HU
A number of chemical entities (vitamin D and its analogs, retinoids, benzamides and other inhibitors of histone deacetylase, various cytotoxics and biological agents, and inhibitors of DNA methylation) can induce differentiation in tumor cell lines in vitro. Fittingly, the first and best example of differentiating therapy was discovered in the treatment of APL (Wang and Chen, 2008).

Retinoids

Tretinoin. The biology and pharmacology of retinoids and related compounds are discussed in detail in Chapter 65. The most important of these for cancer treatment is tretinoin (all-trans retinoic acid; ATRA), which induces a high rate of complete remission in APL as a single agent and, in combination with anthracyclines, cures most patients with this disease.

Under physiological conditions, the RAR-α receptor dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly. ATRA binding displaces a repressor from the complex and promotes differentiation of cells of multiple lineages. In APL cells, physiological concentrations of retinoid are inadequate to displace the repressor. Pharmacological concentrations, however, are effective in activating the differentiation program and in promoting degradation of the PML–RAR-α fusion gene (Collins, 2008). ATRA also binds and activates RAR-γ and thereby promotes stem-cell renewal, perhaps through its effects on the microenvironment (Drumea et al., 2008), and this action may help restore normal bone marrow renewal. Resistance to ATRA arises by further mutation of the fusion gene, abolishing ATRA binding; by induction of the CYP26A1 in liver or leukemic cells; or by loss of expression of the PML–RAR-α fusion gene (Roussel and Lanotte, 2001). Sensitivity can be restored by transfection of a functional PML–RAR-α gene.

Clinical Pharmacology. The usual dosing regimen of orally administered ATRA (VESANOID, others) is 45 mg/m2/day until 30 days after remission is achieved (maximum course of therapy is 90 days). ATRA as a single agent reverses the hemorrhagic diathesis associated with APL and induces a high rate of temporary remission. However, clinical trials have clearly established the benefit of giving ATRA in combination with an anthracycline for remission induction, achieving ≥80% relapse-free long-term survival.

ATRA concentrations reach 400 ng/mL in plasma. ATRA is cleared by a CYP3A4-mediated elimination with a t1/2 of <1 hour. Treatment with inducers of CYP3A4 leads to more rapid drug disappearance and, in some patients, resistance to ATRA (Gallagher, 2002). Inhibitors, such as antifungal imidazoles, block its degradation and may lead to hypercalcemia and renal failure (Cordoba et al., 2008), which responds to diuresis, bisphosphonates, and ATRA.

SECTION VIII
CHEMOTHERAPY OF NEOPLASTIC DISEASES

DIFFERENTIATING AGENTS

One of the hallmarks of malignant transformation is a block in differentiation. It is not clear whether the block is complete or partial, in that tumor cells with the features of stem cells can be found in most tumors, while the greater bulk of tumor cells do not carry the markers or the biological potential of continuous proliferation. Nonetheless, there is growing evidence that many human tumors are generated by mutations that block specific steps in differentiation, an example being the t(15;17) translocation in APL (acute promyelocytic leukemia). This translocation joins the retinoic acid receptor-α (RAR-α, a dimerizing protein critical for differentiation) and the PML gene, which encodes a transcription factor important in inhibiting proliferation and promoting myeloid differentiation. Four other translocation partners for APL have been identified in less common varieties of APL. Under physiological conditions, RAR-α binds retinoic acid and regulates the expression of a number of specific genes that control myeloid differentiation. The oncogenic PML–RAR-α gene produces a protein that binds retinoids with much decreased affinity, lacks PML regulatory function, and fails to upregulate transcription factors (C/EBP and PU.1) that promote myeloid differentiation (Collins, 2008). The fusion protein forms homo- and heterodimers that regulate expression of genes that increase leukemic stem cell renewal, suppress checkpoint and apoptotic signals, and suppress expression of DNA repair functions, thereby enhancing mutability of APL cells. Epigenetic regulation of gene expression by histone acetylation and methylation also is disrupted by the fusion protein.

Clinical Toxicity. Leukopenia, anemia, and occasionally thrombocytopenia—are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, and mild dermatological reactions; more rarely, statitis, alopecia, and neurological manifestations have been encountered. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in all animal species tested and should not be used in women with childbearing potential (Platt, 2008).

Clinical Toxicity. Leukopenia, anemia, and occasionally thrombocytopenia—are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, and mild dermatological reactions; more rarely, statitis, alopecia, and neurological manifestations have been encountered. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in all animal species tested and should not be used in women with childbearing potential (Platt, 2008).
discontinuation. Corticosteroids and chemotherapy sharply decrease the occurrence of “retinoic acid syndrome,” which is characterized by fever, dyspnea, weight gain, pulmonary infiltrates, and pleural or pericardial effusions. When used as a single agent for remission induction, especially in patients with >5000 leukemic cells/mm³ in the peripheral blood, ATRA induces an outpouring of cytokines and mature-appearing neutrophils of leukemic origin. These cells express high concentrations of integrins and other adhesion molecules on their surface and clog small vessels in the pulmonary circulation, leading to significant morbidity in 15-20% of patients. The syndrome of respiratory distress, pleural and pericardial effusions, and mental status changes may have a fatal outcome. Pretreatment dexamethasone should be given to patients with leukemic cell counts of >5,000/mL to counteract “retinoic acid syndrome”.

Toxicity. Retinoids as a class, including ATRA, cause dry skin, cheilitis, reversible hepatic enzyme abnormalities, bone tenderness, pseudotumor cerebri, hypercalcemia, and hyperlipidemia, and as mentioned in the previous paragraph, the retinoic acid syndrome.

**Arsenic Trioxide (ATO)**

Although recognized as a heavy metal toxin for centuries, arsenicals attracted interest as a medicinal agent nearly a century ago for syphilis and parasitic disease, and eventually CML. Arsenic trioxide has become a highly effective treatment for relapsed APL, producing complete responses in >85% of such patients (Wang and Chen, 2008). It now is a standard treatment for patients who relapse after ATRA and chemotherapy, cures a significant fraction of these patients, and has entered trials as primary therapy in combination with ATRA and chemotherapy. The chemistry and toxicity of arsenic is considered in detail in Chapter 67.

The basis for its antitumor activity remains uncertain. APL cells have high levels of reactive oxygen species (ROS) and are quite sensitive to further ROS induction. ATO inhibits thioredoxin reductase and thereby generates ROS. It inactivates glutathione and other sulfhydryls that scavenge ROS and thereby aggravates ROS damage. Cells exposed to ATO also upregulate p53, Jun kinase, and caspases associated with the intrinsic pathway of apoptosis and downregulate anti-apoptotic proteins such as bcl-2. Of particular relevance to APL, it promotes the phosphorylation, sumoylation, and degradation of the APL fusion protein (Lallemand-Breitenbach et al., 2008), as well as the degradation of NF-κB, a transcription factor that stimulates angiogenesis and dampens apoptotic responses in cells with DNA damage. ATO’s cytotoxic effects are antagonized by cell survival signals emanating from activation of components of the PI3 kinase cell survival pathway, including Akt kinase, S6 kinase, and mammalian target of rapamycin (mTOR). Inhibition of mTOR by rapamycin enhances its cytotoxic activity in culture systems.

It induces differentiation of leukemic cell lines in vitro, and in both experimental and human leukemias in vivo, but the mechanisms of differentiation and their relationship to the above pharmacological activities are not known.

**Clinical Pharmacology.** ATO (TRISENOX) is well absorbed orally, but in cancer treatment is administered as a 2-hour intravenous infusion in dosages of 0.15 mg/kg/day for up to 60 days, until remission is documented. Consolidation therapy begins after a 3-week break. It enters cells via one of several glucose transporters. The primary mechanism of elimination is through enzymatic methylation. Methyalted metabolites have uncertain biological effects. Peak steady-state concentrations of arsenic in plasma reached 5-7 μM in one study in adults, while 20-fold lower levels were reported in children using more specific atomic absorption methods (Fox, 2008). Multiple methylated metabolites form rapidly and are excreted in urine. Less than 20% of administered drug is excreted unchanged in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

**Toxicity.** Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects, including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and light-headedness. Ten percent or fewer of patients will experience a leukocyte maturation syndrome similar to that seen with ATRA, including pulmonary distress, effusions, and mental status changes. Oxygen, corticosteroids, and temporary discontinuation of ATO lead to full reversal of this syndrome (Soignet et al., 1998). Another important and potentially dangerous side effect is lengthening of the QT interval on the electrocardiogram in 40% of patients, but rarely do patients develop torsades de pointes, a dangerous form of ventricular tachycardia. Simultaneous treatment with other QT-prolonging drugs, such as macrolide antibiotics, quinidine, or methadone, should be avoided. QT prolongation by ATO results from inhibition of the rapid K⁺ efflux channels in myocardial tissue by As₂O₃. This change leads to slow repolarization of myocardium, and ventricular arrhythmias. Monitoring of serum electrolytes and repletion of serum K⁺ in patients with hypokalemia are precautionary measures in patients receiving ATO therapy. In patients exhibiting a significantly prolonged QT (>470 milliseconds), treatment should be suspended, K⁺ supplemented, and therapy resumed only if the QT returns to normal. Torsades de pointes requires treatment with intravenous magnesium sulfate, K⁺ repletion, and defibrillation if the arrhythmia persists (Gupta et al., 2007) (see Chapter 29).

**Histone Deacetylase Inhibitors**

**Vorinostat.** A new field of cancer research, called epigenetics, concerns the control of cell proliferation and differentiation by processes beyond pure genetic alterations. These processes include cellular modification of expression of genes by microRNAs, histones, and proteins, and post-translational modification of proteins. Vorinostat (ZOLINZA), also known as suberoylanilide hydroxamic acid (SAHA), is unique as an epigenetic modifier that directly affects histone function (Figure 61–15). To understand its action, it is important to review the complex structure of DNA, which wraps itself around histone proteins to form the nucleosome. This higher-order packaging controls gene expression. Acetylation of lysine residues on histones increases the spatial distance between DNA strands and the protein...
core, allowing access for transcription factor complexes, and thereby enhancing transcriptional activity. Acetyl groups are added by histone acetyltransferases and removed by histone deacyetylases (HDACs). HDAC inhibitors such as vorinostat increase histone acetylation and thus enhance gene transcription. Many nonhistone proteins also are subject to lysine acetylation and thus are affected by treatment with HDAC inhibitors. The role of their acetylation status in the antitumor action of HDAC inhibitors is unclear.

**Mechanism of Action.** Vorinostat is a hydroxamic acid modeled after hybrid polar compounds, such as hexamethylene bisacetamide (HMBA); as a class, these compounds cause differentiation of malignant cells in vitro, as do other classes of compounds with HDAC-inhibitory activity, including cyclic tetrapeptides, benzamides, and short-chain aliphatic acids. These compounds bind to a critical Zn^{++} ion in the active site of HDAC enzymes. Vorinostat inhibits the enzymatic activity of HDACs at micromolar concentrations. An important distinction between vorinostat and other HDAC inhibitors is that vorinostat and the hydroxamates are pan-HDAC inhibitors, whereas other compounds have selectivity for HDAC isoenzyme subsets. The biological and clinical implications of this specificity are not clear, and the specific mechanism by which HDAC inhibitors exert their antitumor activity is uncertain. They induce cell-cycle arrest, differentiation, and apoptosis of cancer cells; nonmalignant cells are relatively resistant to these effects. They increase transcription of cell-cycle regulators, affect levels of nuclear transcription factors, and induce pro-apoptotic genes. HDAC inhibition directly blocks activity of the chaperone HSP90 and stabilizes the tumor suppressor p53 (Bolden et al., 2006).

**Absorption, Fate, and Excretion.** Vorinostat is administered as a once-daily oral dose of 400 mg. It is inactivated by glucuronidation of the hydroxyl amine group, followed by hydrolysis of the terminal carboxamide bond and further oxidation of the aliphatic side chain (Figure 61–15). The metabolites are pharmacologically inactive. The terminal t_{1/2} of vorinostat in plasma is ~2 hours. Interestingly, histones remain hyperacetylated up to 10 hours after an oral dose of vorinostat, suggesting that its effects persist beyond drug metabolism and elimination.

**Therapeutic Uses.** Vorinostat is approved for use in refractory cutaneous T-cell lymphoma (CTCL). In patients with refractory CTCL, vorinostat produced an overall response rate of 30%, with a median time to progression of 5 months (Duvic et al., 2007). Vorinostat and other HDAC inhibitors, including romidepsin (depsipeptide; FK228) and MGCD 0103, have shown activity in CTCL, other B- and T-cell lymphomas, and myeloid leukemia.

**Toxicity.** The most common side effects of vorinostat are fatigue, nausea, diarrhea, and thrombocytopenia. Deep venous thrombosis and pulmonary embolism were infrequent but serious adverse events in CTCL patients receiving vorinostat. Most HDAC inhibitors in development cause QTc prolongation, although no serious cardiac toxicity has been reported with vorinostat. A small number of patients receiving infusional depsipeptide romidepsin (see below) and the hydroxamate dacinostat (NVP-LAQ 824) have developed ventricular arrhythmias while on treatment, but the causal relationship to the drugs has not been clearly established, and the cardiac risk may be lower with orally administered and/or less potent HDAC inhibitors (Piekarz et al., 2006). Caution is advised when using HDAC inhibitors in patients with underlying cardiac abnormalities, and careful monitoring of the QTc interval and correction of electrolyte (K^+, Mg^{++}) abnormalities is necessary.

**Romidepsin.** Romidepsin, a bicyclic polypeptide derived from a soil bacterium, inhibits HDAC at low nanomolar concentrations and is approved for treatment of CTCL and for peripheral T-cell lymphomas. In a Phase II trial it produced complete responses in 4 patients with CTCL, and partial responses in 20, from a total of 71 patients treated. Its primary toxicities include GI complaints (nausea vomiting) and transient myelosuppression. Its administration leads to T-wave flattening, but without clear cardiac toxicity (Piekarz et al., 2009).

**BIBLIOGRAPHY**

Serrano J, Palmeira CM, Kuehl DW, Wallace KB. Cardiodefective and cumulative oxidation of mitochondrial...

Strategies for cancer drug discovery have evolved in step with the explosion of knowledge about the molecular underpinnings of cancer. Many new drugs either recently approved or in late stages of evaluation were designed to block the fundamental mutations that cause specific cancers: aberrant growth factor receptors, dysregulated intracellular signaling pathways, defective DNA repair and apoptosis, and tumor angiogenesis. The primary tools for inhibiting these new targets are either monoclonal antibodies that attack cell surface receptors and antigens, or synthetic small molecules that enter cells and engage critical enzymes. These two classes of drugs have very different pharmacological properties.

Monoclonal antibodies kill tumor cells by blocking cell surface receptor function and by recruiting immune cells and complement to the antigen–antibody complex. They may be armed to carry toxins or radionuclides to the cells of interest, thereby enhancing their cytotoxic effects. They generally are specific for a single receptor, have a long plasma $t_{1/2}$, and require only intermittent administration. Small molecules may attack the same targets and pathways as the monoclonals, but may also exert their effect by entering cells and inhibiting enzymatic functions (usually tyrosine kinase reactions). The small molecules often inhibit multiple enzymatic sites, have a broad spectrum of target kinases, and tend to be substrates of hepatic CYPs with a $t_{1/2}$ of 12-24 hours, and thus require daily oral administration. The two classes of drug, when targeted against the same pathway, may have significantly different spectra of antitumor activity. Thus, monoclonal antibodies to the epidermal growth factor receptor (EGFR) are effective in the treatment of head and neck and colon cancers, while small molecules, such as erlotinib and gefitinib, attack the intracellular tyrosine kinase function of the same receptor and have a different spectrum of antitumor activity (non–small cell lung cancer).

Because of the central importance of the specific target in cancer chemotherapy, we will center this discussion around the target rather than the specific type of drug.

**PROTEIN TYROSINE KINASE INHIBITORS**

Protein kinases are critical components of signal transduction pathways that regulate cell growth and adaptation to the extracellular environment. These signaling pathways influence gene transcription and/or DNA synthesis, as well as cytoplasmic events. The human genome contains ~550 protein kinases and 130 phosphoprotein phosphatases that regulate the phosphorylation states of key signaling molecules. Protein kinases can be classified into three different categories: kinases that specifically phosphorylate tyrosine residues, kinases that phosphorylate serine and threonine residues, and kinases with activity toward all three residues. Tyrosine kinases can be further subdivided into proteins that have an extracellular ligand-binding domain (receptor tyrosine kinases) and enzymes that are confined to the cytoplasm or nuclear cellular compartment (nonreceptor tyrosine kinases). Growth factors and other ligands bind to and activate the receptor
tyrosine kinases under physiological conditions. In a growing number of human malignancies, mutations that constitutively activate protein tyrosine kinases are implicated in malignant transformation; thus, protein tyrosine kinases are targets for cancer therapy.

**Inhibitors of the BCR-ABL Kinase: Imatinib, Dasatinib, and Nilotinib**

Imatinib mesylate (STI 571, GLEEVEC, GLIVEC) was the first molecularly targeted protein kinase inhibitor to receive FDA approval. It targets the BCR-ABL tyrosine kinase, which underlies chronic myelogenous leukemia (CML). A single molecular event, in this case the 9:22 translocation, leads to expression of the Abelson proto-oncogene kinase ABL fused to BCR (breakpoint cluster region), yielding a constitutively activated protein kinase, BCR-ABL, and then the malignant phenotype. Imatinib and the related compounds dasatinib and nilotinib induce clinical and molecular remissions in >90% of CML patients in the chronic phase of disease. Imatinib effectively treats other tumors that carry related tyrosine kinase mutations, including GI stromal tumors (driven by c-KIT mutation) (Blanke et al., 2008), and hypereosinophilia syndrome, chronic myelomonocytic leukemia, and dermatofibrosarcoma protuberans (all driven by mutations that activate the platelet-derived growth factor receptor, PDGFR) (Sirvent et al., 2003).

**Chemistry.** Imatinib was identified through high-throughput screening against the BCR-ABL kinase. The lead compound of this series, a 2-phenylaminopyrimidine, had low potency and poor specificity, inhibiting both serine/threonine and tyrosine kinases (Buchdunger et al., 2001). The addition of a 3′-pyridyl group at the 3′ position of the pyrimidine enhanced its potency. Further modifications resulted in improved activity against PDGFR and c-KIT and loss of serine/threonine kinase inhibition. Introduction of N-methylpiperazine as a polar side chain greatly improved water solubility and oral bioavailability, yielding imatinib, an inhibitor of the closed, or inactive, configuration of the kinase:

Dasatinib (BMS-354825, SPRYCE), a second-generation BCR-ABL inhibitor, was developed using a series of substituted 2-(aminopyridyl) and 2-(aminopyrimidinyl) thiazol-5-carboxamides. It inhibits the Src kinase, and unlike imatinib, it binds both the open and closed configurations of the BCR-ABL kinase (Shah et al., 2004).

Nilotinib (AMN107, TASIGNA) was designed to have increased potency and specificity compared to imatinib. Its structure, based on crystallographic studies of the BCR-ABL kinase, promotes hydrogen bonding to Glu286 and Asp381 (Weisberg et al., 2005) and overcomes mutations that cause imatinib resistance.

**Mechanism of Action.** Crystallographic and mutagenesis studies indicate that imatinib and nilotinib bind to a segment of the kinase domain that fixes the enzyme in a closed or nonfunctional state, in which the protein is unable to bind its substrate/phosphate donor, ATP (Weisberg et al., 2005). The three BCR-ABL kinase inhibitors differ in their potency of inhibition, their binding specificities, and their susceptibility to resistance mutations in the target enzyme. Dasatinib ([IC_{50}] = <1 nM) and nilotinib ([IC_{50}] = <20 nM) (Weisberg, 2005) inhibit BCR-ABL kinase more potently than does imatinib ([IC_{50}] = 100 nM).

**Mechanisms of Resistance.** Resistance to the tyrosine kinase inhibitors arises from point mutations in three separate segments of the kinase domain (Figure 62–1). The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate. Most such mutations hold the enzyme in its open and enzymatically active confirmation. The most common resistance mutations affect amino acids 255 and 315, both of which serve as contact points for imatinib; these mutations confer high-level resistance to imatinib and nilotinib. Dasatinib is unaffected by mutation at 255 but is ineffective in the presence of mutation at 315. Nilotinib retains inhibitory activity in the presence of most point mutations (except at 315) that confer resistance to imatinib (Weisberg et al., 2005; O’Hare et al., 2005).

Other mutations affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as at amino acids 351 and 355, do not affect response to dasatinib or nilotinib but confer low levels of resistance to imatinib (O’Hare et al., 2005; Corbin et al., 2003).
This finding may explain the clinical response of some resistant patients to dose escalation of imatinib.

Molecular studies of circulating tumor cells have detected resistance-mediating kinase mutations prior to initiation of therapy, particularly in patients with Ph+ acute lymphoblastic leukemia (ALL) (Roche-Lestienne et al., 2003) or CML in blastic crisis. This finding strongly supports the hypothesis that drug-resistant cells arise through spontaneous mutation and expand under the selective pressure of drug exposure. Mutations may become detectable in the peripheral blood of patients receiving imatinib in the accelerated phase and in the late (>4 years from diagnosis) chronic phase of CML (Branford et al., 2003), heralding the onset of drug resistance.

Mechanisms other than BCR-ABL kinase mutation play a minor role in resistance to imatinib. Amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from patients resistant to treatment (Morel et al., 2003). The multidrug resistant (MDR) gene, which codes for a drug efflux protein, confers resistance experimentally but has not been implicated in clinical resistance.

Finally, Philadelphia chromosome-negative clones lacking the BCR-ABL translocation and displaying the karyotype of myelodysplastic cells may emerge in patients receiving imatinib for CML and may progress to myelodysplasia (MDS) and to acute myelocytic leukemia (AML). Their origin is unclear.

Pharmacokinetics

Imatinib. Imatinib is well absorbed after oral administration and reaches maximal plasma concentrations within 2-4 hours. The elimination t1/2 of imatinib and its major active metabolite, the N-desmethyl derivative, are ~18 and 40 hours, respectively. Mean imatinib area under the curve (AUC) increases proportionally with increasing dose in the range 25-1000 mg (Peng et al., 2004). Food does not change the pharmacokinetic profile of imatinib. Doses >300 mg/day achieve trough levels of 1 μM, which correspond to in vitro levels required to kill BCR-ABL–expressing cells. Inhibition of the BCR-ABL tyrosine kinase in white blood cells from patients with CML reaches a maximum in the dose range of 250-750 mg/day. Nonrandomized studies suggest that response may be restored in a minority of resistant patients with doses of 600 or 800 mg/day, as opposed to the standard 400 mg/day (Kantarjian et al., 2004). In the treatment of GI stromal cell tumors (GIST), higher doses (600 mg/day) may improve response rates.

CYP3A4 is the major enzyme responsible for metabolism of imatinib. CYPs 1A2, 2D6, 2C9, and 2C19 play minor roles in its metabolism. Clinicians must be cautious in introducing drugs that might interact with imatinib and CYP3A4. A single dose of ketoconazole, an inhibitor of CYP3A4, increases the maximal imatinib concentration in plasma and its plasma AUC by 26% and 40%, respectively. Co-administration of imatinib and rifampin, an inducer of CYP3A4, lowers the plasma imatinib AUC by 70%.
imatinib, as a competitive CYP3A4 substrate, inhibits the metabolism of simvastatin and increases its plasma AUC by 3.5-fold (O’Brien et al., 2003).

**Dasatinib.** Dasatinib also is well absorbed after oral administration. As for other BCR-ABL kinase inhibitors, the bioavailability of dasatinib is significantly reduced at neutral gastric pH, resulting from antacids and H2 blockers, but is unaffected by food. The plasma t½ of dasatinib is 3-5 hours, and clearance depends on CYP3A4 metabolism. Its metabolites are inactive. Dasatinib exhibits dose proportional increases in AUC, and its clearance is constant over the dose range of 15-240 mg/day. No significant changes in dasatinib pharmacokinetics were observed on repeated dosing or administration of food. Dasatinib was originally approved at a dose of 70 mg twice a day. A randomized phase III trial comparing 50 mg twice daily, 70 mg twice daily, 100 mg daily, and 140 mg daily concluded that all four schedules were equally effective in patients with CML, although the 100-mg daily dose improved progression-free survival (Shah et al., 2008).

Dasatinib is metabolized primarily by CYP3A4, although FMO3 and UGT also contribute to a minor degree. Dasatinib plasma concentrations are affected by inducers and inhibitors of CYP3A4 in a similar fashion to imatinib.

**Nilotinib.** Approximately 30% of an oral dose of nilotinib (400 mg twice daily) is absorbed after administration, and the drug achieves peak concentrations in plasma 3 hours after dosing. Unlike the other BCR-ABL inhibitors, nilotinib’s bioavailability increases significantly in the presence of food (Kantarjian et al., 2006). The drug has a long plasma t½ (~17 hours), and plasma concentrations reach a steady state only after 8 days of daily dosing. Doses >400 mg/day are associated with nonlinear increases in median serum concentrations, indicating saturation of GI absorption.

Like dasatinib and imatinib, nilotinib undergoes elimination through metabolism by CYP3A4; metabolism is affected by inducers, inhibitors, and competitors of the CYP3A4 pathway. Nilotinib is a substrate and inhibitor of P-glycoprotein.

**Pharmacokinetics and Clinical Uses.** These protein tyrosine kinase inhibitors have efficacy in diseases in which the ABL, kit, or PDGFR have dominant roles in driving the proliferation of the tumor, reflecting the presence of a mutation that results in constitutive activation of the kinase, either by fusion with another protein or via point mutations. Thus, imatinib shows remarkable therapeutic benefits in patients with chronic-phase CML (BCR-ABL), GIST (kit mutation positive), chronic myelomonocytic leukemia (EVT6-PDGFR translocation), hypereosinophilic syndrome (FIP1L1-PDGFR), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGFR) (Druker, 2004). It is the agent of choice for GIST patients with metastatic disease and as adjuvant therapy of c-kit–positive GIST (DeMatteo et al., 2009). GIST biology is particularly instructive, as patients with an exon 11 mutation of kit have a significantly higher partial response rate (72%) than those with no detectable kit mutations (9%) (Heinrich et al., 2003). The currently recommended dose of imatinib is 400-600 mg/day. Dasatinib is approved for patients with CML resistant or intolerant to imatinib in both chronic (100 mg/day) and advanced phases of disease (70 mg twice daily), and for use combined with cytotoxic chemotherapy in patients with Ph+ ALL who are resistant or intolerant to prior therapies. Nilotinib is approved for patients with CML resistant to or intolerant of prior imatinib therapy.

**Toxicity.** Imatinib, dasatinib, and nilotinib cause GI distress (diarrhea, nausea, and vomiting), but these symptoms usually are easily controlled. All three drugs promote fluid retention, which may lead to dependent edema, and peri-orbital swelling. Dasatinib may cause pleural effusions. Nilotinib may prolong the QT interval, and should be used with caution in patients with underlying heart disease or arrhythmias, although ventricular arrhythmias have not been reported. Significant myelosuppression occurs infrequently but may require transfusion support, dose reduction, or discontinuation of the drug. All three drugs in this class can be associated with hepatotoxicity. Most nonhematological adverse reactions are self limited and respond to dose adjustments. After the adverse reactions, such as edema, myelosuppression, or GI symptoms have resolved, the drug may be reintiated and titrated back to effective doses.

**EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS**

The EGFR belongs to the ErbB family of transmembrane receptor tyrosine kinases. EGFR, also known as ErbB1 or HER1, is essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues in the C-terminal domain. Recognition of the phosphotyrosines by other proteins initiates protein-protein interactions that result in stimulation of a variety of signaling pathways, including MAPK, PI3K/Akt, and STAT pathways (Figure 62–2) (Schlessinger, 2000). In epithelial cancers, overexpression (or mutational activations) of the EGFR is a common finding and, to some extent, creates a dependence on EGFR signaling in these tumors (Hynes and Lane, 2005).

Two separate classes of drugs that target the EGFR pathway have become important agents in the therapy of solid tumors. The EGFR tyrosine kinase inhibitors erlotinib and gefitinib bind to the kinase domain and block the enzymatic function of EGFR. The monoclonal antibodies cetuximab and panitumumab bind specifically to the extracellular domain of EGFR. They inhibit EGFR-dependent signaling through inhibition of ligand-dependent activation and receptor dimerization, downregulation of EGFR expression, and induction of antibody-dependent cell-mediated cytotoxicity (Ciardiello and Tortora, 2008).

**Gefitinib**

**Chemistry.** Gefitinib was identified through screens that demonstrated its inhibition of EGFR tyrosine...
kinase activity and ability to kill EGFR-dependent cell lines.

**Mechanism of Action.** Gefitinib inhibits the EGFR tyrosine kinase by virtue of competitive blockade of ATP binding. Gefitinib has an IC\textsubscript{50} of 20-80 nM for the EGFR enzyme but is significantly less potent against HER2 (ErbB2/neu). Gefitinib has antitumor activity in human xenograft tumors that exhibit high levels of EGFR expression.

**Absorption, Distribution, and Elimination.** Following oral administration of gefitinib, peak plasma concentrations are achieved within 3-7 hours, and oral bioavailability approaches 60%. Administration of 225 mg/day orally results in steady-state levels of 200 ng/mL after 7-10 doses. The mean terminal t\textsubscript{1/2} is 41 hours. Elimination of gefitinib primarily occurs by hepatic CYP3A4 metabolism.

**Therapeutic Uses.** Gefitinib initially was approved for the third-line treatment of patients with non–small cell lung cancer based on promising results in two small clinical trials. However, a larger, randomized, placebo-controlled trial failed to show an effect on survival, leading the FDA to restrict its use to patients who have previously received clinical benefit from the drug (Thatcher et al., 2005). Gefitinib continues to be widely used outside the U.S. Two large trials have failed to demonstrate a benefit of gefitinib in combination with chemotherapy. The standard dose is 250 mg daily.

Retroactive analysis of multiple studies revealed that patients who were nonsmokers, Asians, or women were most likely to respond to gefitinib. Tumors from these patients frequently have characteristic activating mutations in *EGFR* (Sequist and Lynch, 2008). These mutations mostly fall into two groups: 1) small in-frame deletions within exon 19 and 2) the L858R point mutation. Trials that randomized never- and light-smoking patients to first-line gefitinib or to chemotherapy demonstrated a 70% response rate to gefitinib in patients with an activating *EGFR* mutation, compared with responses in only 1% in patients without an *EGFR* mutation. In patients with *EGFR*-mutant tumors, the response rate to gefitinib was double the response to standard chemotherapy. Therefore, mounting evidence supports the use of gefitinib, and potentially erlotinib, as first-line therapy in patients selected for the presence of sensitizing *EGFR* mutations.

**Adverse Effects and Drug Interactions.** Diarrhea and pustular/papular rash occur in ~50% of patients taking gefitinib. Other side effects include dry skin, nausea, vomiting, pruritus, anorexia, and fatigue. Most adverse effects occur within the first month of therapy and are tolerable when managed with supportive medications and dose reductions. Asymptomatic increases in liver transaminases may necessitate dose reduction or discontinuation of therapy. Interstitial lung disease, often associated with symptoms of cough and dyspnea, occurs in <2% of patients receiving gefitinib but may have a fatal outcome.

Exposure to gefitinib is not significantly altered by food; however, co-administration of drugs that cause sustained elevations in gastric pH reduce mean gefitinib AUC by 47%. Metabolism of gefitinib is predominantly via CYP3A4. Substances that induce CYP3A4 activity (e.g., phenytoin, carbamazepine, rifampin, barbiturates, St. John’s wort) decrease gefitinib plasma concentrations and efficacy; conversely, inhibitors of CYP3A4 (e.g., itraconazole, ketoconazole) increase plasma concentrations. Patients using warfarin should be monitored closely for elevation of the INR while taking gefitinib.

**Erlotinib**

Erlotinib (TARCEVA) is a quinazolinamine inhibitor of HER1/EGFR tyrosine kinase.
Mechanism of Action. Erlotinib is a potent inhibitor of the EGFR tyrosine kinase. Like gefitinib, erlotinib competitively inhibits ATP binding at the active site of the kinase. Erlotinib has an IC₅₀ of 2 nM for the EGFR kinase. Tumors harboring k-ras mutations and EML4-ALK translocations do not respond to EGFR kinase inhibitors.

Absorption, Distribution, and Excretion. Erlotinib is ~60% absorbed after oral administration but should not be taken with food, which increases its bioavailability to ~100%. Peak plasma levels occur 4 hours after an oral dose. Erlotinib has a t½ of 36 hours and is metabolized by CYP3A4 and to a lesser extent by CYPs 1A2 and 1A1. The standard daily dose of erlotinib results in a plasma AUC approximately one order of magnitude greater than the AUC of gefitinib.

Therapeutic Uses. Erlotinib is approved for second-line treatment of patients with locally advanced or metastatic non–small cell lung cancer. FDA approval was based on an improvement in overall survival in a large multi-national trial comparing oral erlotinib, 150 mg daily, to placebo (Shepherd et al., 2005). Results from two subsequent trials showed no clinical benefit from the combination of erlotinib with platinum-based chemotherapy as compared to chemotherapy alone.

Erlotinib also is approved for first-line treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer in combination with gemcitabine. A large double-blinded study of 569 patients demonstrated a modest 2-week improvement in overall survival in patients who received 100 mg of erlotinib plus gemcitabine, as compared with patients who received gemcitabine alone (Moore et al., 2007). The recommended dose of erlotinib in non–small cell lung cancer is a 150-mg tablet daily. In pancreatic cancer, the dose is a 100-mg tablet daily. It should be taken at least 1 hour before or 2 hours after a meal.

Adverse Effects and Drug Interactions. As with gefitinib, the most common adverse reactions in patients receiving erlotinib are diarrhea, an acneform rash, anorexia, and fatigue. Serious or fatal interstitial lung disease occurs with a frequency of 0.7-2.5%. Hepatic function deserves close monitoring because serious or fatal hepatic failure due to erlotinib has been reported, particularly in patients with baseline hepatic dysfunction. Other rare but serious toxicities include GI perforation, renal failure, arterial thrombosis, microangiopathic hemolytic anemia, hand-foot skin reaction, and corneal perforation or ulceration. Erlotinib therapy may cause rare cases of Stevens-Johnson syndrome/toxic epidermal necrolysis.

Concurrent use of proton-pump inhibitors decreases the bioavailability of erlotinib by 50%. As with gefitinib, plasma levels can vary dramatically due to drug interactions with inducers or inhibitors of CYP3A4. Patients using warfarin may experience elevations of the international normalized ratio (INR) while taking erlotinib. Smoking accelerates metabolic clearance of erlotinib by 24% and may decrease its antitumor effects.

Resistance to Gefitinib and Erlotinib

Patients with non–small cell lung cancer who initially respond to erlotinib or gefitinib have tumors that are dependent on the EGFR signaling pathway. Clinical response to these agents is strongly associated with the presence of sensitizing mutations in EGFR as described in “Therapeutic Uses” under “Gefitinib,” but response is less strongly correlated with overexpression or amplification of EGFR (Sequist and Lynch, 2008). Therapy directed at the EGFR may delay disease progression in patients with non–small cell lung cancers that lack activating EGFR mutations, although response rates approach zero in these patients. The subset of non–small cell lung tumors harboring k-ras mutations and EML4-ALK translocations do not respond to EGFR inhibitors.

Tumors containing mutations in EGFR initially respond to erlotinib and gefitinib but eventually progress. Resistance arises through several different mechanisms. A secondary mutation in the EGFR gatekeeper residue, T790M, prevents binding of drug to the kinase domain and confers resistance (Kobayashi et al., 2005). Irreversible EGFR inhibitors currently are in clinical development to overcome this mechanism. Amplification of the met oncogene provides an alternative pathway to clinical resistance by activating cell growth signals downstream of EGFR (Engelman et al., 2007). MET-amplified tumors respond in vitro to the simultaneous inhibition of EGFR and MET. Other potential mechanisms of resistance include activation of downstream mediators, efflux of drug, and altered receptor trafficking.

Cetuximab

Cetuximab is a monoclonal antibody to the extracellular domain of the EGFR. Such antibodies, although sharing the same target with erlotinib and gefitinib and having a similar side effect profile, have a different spectrum of antitumor activity.

Chemistry. Cetuximab (ERBITUX) is a recombinant chimeric human/mouse immunoglobulin G1 (IgG1) antibody that binds to the extracellular domain of EGFR. It consists of the Fv regions of a murine anti-EGFR antibody with human IgG1 heavy- and κ light-chain constant regions.

Mechanism of Action. Cetuximab binds specifically to the extracellular domain of EGFR and prevents ligand-dependent signaling and receptor dimerization, thereby blocking cell growth and survival signals. Cetuximab also may mediate antibody-dependent cellular cytotoxicity against tumor cells.

Absorption, Distribution, and Elimination. Cetuximab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration, steady-state levels are achieved by the third weekly infusion. The volume of distribution approximates the intravascular space of 2-3 L/m². Therapeutic doses that saturate total body receptor pools of EGFR follow zero-order kinetics for elimination. Clearance occurs via EGFR binding and internalization and by degradation in the reticuloendothelial system.

Therapeutic Uses

Head and Neck Cancer. Cetuximab won FDA approval based on an improvement in overall survival when used in combination with radiation therapy for locally or regionally advanced squamous cell carcinoma of the head and neck (HNSCC). It received a second indication as monotherapy for patients with metastatic or recurrent HNSCC who had failed platinum-based chemotherapy. It has become a useful agent in combination with cisplatin-based chemotherapy, where it has shown an improvement in survival compared to chemotherapy alone (Vermorken et al., 2008).
**Metastatic Colon Cancer.** Cetuximab received approval as a single agent for the treatment of EGFR-positive metastatic colorectal cancer; cetuximab is used in patients who cannot tolerate irinotecan-based therapy and in combination with irinotecan for patients refractory to oxaliplatin, irinotecan, and 5-fluorouracil (5-FU). In the first-line setting, cetuximab may improve survival in combination with 5-FU/leucovorin and irinotecan or oxaliplatin (Bokemeyer et al., 2009). Numerous trials now have shown that the 40-50% of colorectal tumors carrying mutations in the \( k\)-ras oncogene are resistant to the effects of cetuximab. The antibody yields a response rate of 1% in patients with mutant tumors, compared to 12% in \( k\)-ras wild-type tumors (Karapetis et al., 2008). Cetuximab enhances the effectiveness of chemotherapy in patients with \( k\)-ras mutant tumors but not \( k\)-ras wild-type tumors (Bokemeyer et al., 2009).

The standard dose of cetuximab is a single loading dose of 400 mg/m\(^2\) intravenously, followed by weekly doses of 250 mg/m\(^2\) intravenously for the duration of treatment.

**Adverse Effects.** Side effects associated with cetuximab treatment include an acneform rash in the majority of patients. Patients also may experience pruritus, nail changes, headache, and diarrhea. Other rare but serious adverse effects include cardiopulmonary arrest, interstitial lung disease, and hypomagnesemia. In addition, patients can develop anaphylactoid reactions during infusion, which may be related to pre-existing IgE antibodies that are more prevalent in patients from the southern U.S.

**Panitumumab**

**Chemistry.** Panitumumab (VECTIBIX) is a recombinant, fully humanized IgG\(_{2}\) antibody that binds specifically to the extracellular domain of EGFR. Unlike cetuximab, it does not mediate antibody-dependent cell-mediated cytotoxicity.

**Absorption, Distribution, and Elimination.** Panitumumab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration every 2 weeks, steady-state levels are achieved by the third infusion. The mean elimination \( t_{1/2} \) is 7.5 days.

**Therapeutic Uses.** Panitumumab improves progression-free survival in patients with metastatic colorectal carcinoma, as demonstrated in patients with EGFR-expressing tumors who had two or more previous therapies (Van Cutsem et al., 2008). The dose of panitumumab is 6 mg/kg intravenously given once every 2 weeks.

**Adverse Effects.** The adverse effects with panitumumab are similar to cetuximab and include rash and dermatological toxicity, severe infusion reactions, pulmonary fibrosis, and electrolyte abnormalities.

**HER2/neu Inhibitors**

Both antibodies (trastuzumab) and small molecules (lapatinib and others in clinical trial) have striking antitumor effects in patients with HER2-positive breast cancer, and have become essential therapeutic agents in combination with cytotoxic chemotherapy for this aggressive malignancy.

**Trastuzumab.** Trastuzumab (HERCEPTIN) is a humanized monoclonal antibody that binds to the external domain of HER2/neu (ErbB2).

**Chemistry.** Trastuzumab has dose-dependent pharmacokinetics with a mean \( t_{1/2} \) of 5.8 days on the 2-mg/kg maintenance dose. Steady-state levels are achieved between 16 and 32 weeks, with mean trough and peak concentrations of ~79 and 123 \( \mu \)g/mL, respectively (Baselga, 2000). The infusional effects of trastuzumab are typical of other monoclonal antibodies and include fever, chills, nausea, dyspnea, and rashes. Premedication with diphenhydramine and acetaminophen is indicated. The most serious toxicity of trastuzumab is cardiac failure; reasons for cardiotoxicity are poorly understood, although the HER2 antigen is highly expressed in the developing heart during embryogenesis, and HER2 knockout mice fail to survive because of cardiomyopathy (Crone et al., 2002). Cardiac failure is a potentially disabling or fatal side effect unless it is recognized early and the drug is discontinued (Seidman et al., 2002). Before initializing therapy, baseline electrocardiogram and cardiac ejection fraction measurement should be obtained to rule out underlying heart disease, and patients deserve careful clinical follow-up thereafter for signs or symptoms of congestive heart failure, such as cough, weight gain, or edema. When trastuzumab is used as a single agent, <5% of patients will experience a decrease in left-ventricular ejection fraction, and 1% will have clinical signs of congestive failure. However, left-ventricular dysfunction occurs in up to 20% of patients who received the antibody in combination with doxorubicin and cyclophosphamide. The risk of cardiac toxicity is greatly reduced with taxane–trastuzumab combinations.

**Lapatinib.** Small molecules can inhibit receptor tyrosine kinase activity of ErbB2 (HER2/neu) and have antitumor activity in patients who have developed progressive disease on trastuzumab (Moy and Goss, 2007). Lapatinib and other pan-HER inhibitors block both
ErbB1 and ErbB2 and bind to an internal site on the receptor (usually the ATP-binding pocket), compared to the external binding site of trastuzumab. Lapatinib also inhibits a truncated form of the HER2 receptor that lacks a trastuzumab-binding domain. These differences may account for the activity of lapatinib in trastuzumab-resistant patients.

Lapatinib (TYKERB) is FDA-approved for HER2-amplified, trastuzumab-refractory breast cancer, in combination with the fluoro-opyrimidine analog, capecitabine. In its critical phase III trial, lapatinib plus capecitabine improved disease-free survival by 4.4 months and increased the disease response rate to 22% versus 14% in the control group treated with capecitabine alone. As a small molecule, lapatinib crosses the blood-brain barrier more readily than inhibitor antibodies and has produced anecdotal responses in patients with brain metastases and decreased the incidence of brain metastases in trastuzumab-refractory breast cancer, in combination with the fluoropyrimidine analog, capecitabine. In its critical phase III trial, lapatinib plus capecitabine improved disease-free survival by 4.4 months and increased the disease response rate to 22% versus 14% in the control group treated with capecitabine alone. As a small molecule, lapatinib crosses the blood-brain barrier more readily than inhibitor antibodies and has produced anecdotal responses in patients with brain metastases and decreased the incidence of brain metastases in its phase III trial (Geyer et al., 2006).

**Pharmacokinetics and Toxicity.** The drug is administered orally, 1250 mg/day. It is metabolized by CYP3A4 to a number of inactive products, as well as to an oxidized intermediate that has activity against ErbB1 but not ErbB2. The plasma t₁/₂ of 14 hours allows parent drug accumulation over the period of treatment. Concurrent administration of inducers and inhibitors of CYP3A4 shorten and prolong the drug’s t₁/₂, respectively, and may necessitate adjustment of the dose. Lapatinib toxicities include mild diarrhea, cramping, and exacerbation of gastro-esophageal reflux. When lapatinib is combined with capecitabine, diarrhea becomes a significant side effect in one-third of patients. Lapatinib’s inhibition of ErbB1 (EGFR) causes an acneform rash in one-third of patients; the rash can be effectively controlled in most cases with topical or oral antibiotics and topical benzoyl peroxide gel. Unlike trastuzumab, lapatinib has not produced a clear signal of cardiac toxicity (Medina and Goodin, 2008); nonetheless, because it targets ErbB2, lapatinib should be used with caution in combination with other cardiotoxic drugs and with careful surveillance in patients who have underlying heart disease.

**INHIBITORS OF ANGIOGENESIS**

In 1971, Judah Folkman opened the field of angiogenesis therapy when he hypothesized that the induction of new blood vessel formation—angiogenesis—is an essential property of cancers (Folkman, 1971). Although this revolutionary hypothesis was initially greeted with skepticism, angiogenesis now is firmly established as one of the hallmarks of cancer.

Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells. Angiogenic factors secreted by tumors include VEGF (vascular endothelial growth factor), FGF (fibroblast growth factor), TGF-β (transforming growth factor β) and PDGF (platelet-derived growth factor). Multiple tumor types overexpress these angiogenic factors. Several animal models have demonstrated that tumor secretion of pro-angiogenic factors turns on an “angiogenic switch,” a process essential to tumor growth and metastasis. Strikingly, in multiple experimental models, blockade of these pro-angiogenic molecules halts tumor growth, and in human cancers, anti-angiogenic drugs also have inhibitory effects.

Jain has proposed an additional mechanism for the efficacy of angiogenesis inhibitors (Jain, 2009), based on the observation that the leaky capillaries within tumors have increased permeability and cause an increase in tumor interstitial pressure. This increased pressure inhibits blood flow, decreases oxygenation, and prevents drug delivery within the tumor. Antibodies directed at the primary angiogenic factor, VEGF, decrease interstitial pressure within tumors and reverse the changes in oxygenation and blood flow. By “normalizing” interstitial pressure and improving blood flow, anti-angiogenic agents enhance the ability of chemotherapeutic agents to reach the tumor. Hence, an additional benefit of anti-angiogenic molecules may be their ability to increase the delivery of chemotherapy to the tumor. This hypothesis seems to be validated in the synergy observed when cytotoxic chemotherapy is combined with anti-VEGF antibodies.

The best studied of the angiogenic factors is VEGF. VEGF initiates endothelial cell proliferation when it binds to a member of the VEGF receptor (VEGFR) family, a group of highly homologous receptors with intracellular tyrosine kinase domains that includes VEGFR1 (FLT1), VEGFR2 (KDR), and VEGFR3 (FLT4). The binding of VEGF to its receptor activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and anti-apoptotic signaling pathways within the endothelial cell.

The cognate interaction between VEGF and its receptor creates several opportunities for pharmacological inhibition of this pathway. Antibodies targeting VEGF, such as bevacizumab, sterically hinder the interaction of VEGF with its receptor. As an alternative to VEGF antibody therapy, the investigational drug...
Aflibercept (VEGF Trap), a recombinant molecule that utilizes the VEGFR1-binding domain to sequester VEGF, acts as a “soluble decoy receptor” for VEGF.

Alternatively, the propagation of pro-angiogenic signals can be abrogated by the inhibition of the tyrosine kinase activity of VEGFR. Three small molecules (pazopanib, sorafenib, and sunitinib) that inhibit the kinase function of VEGFR-2 have been approved for clinical use. Although bevacizumab and the small molecules share a similar spectrum of toxicities, they have somewhat different spectra of clinical activity and significant differences in pharmacokinetics.

**Bevacizumab.** Bevacizumab (Avastin), a humanized antibody directed against VEGF-A, was the first FDA-approved molecule that specifically targeted angiogenesis. As a single agent, it delays progression of renal-cell cancer, and, in combination with cytotoxic chemotherapy, effectively treats lung, colorectal, and breast cancers.

In clear-cell renal-cell carcinoma, a cancer notoriously resistant to traditional chemotherapeutic agents, single-agent bevacizumab increases survival by 3 months (Yang et al., 2003). Clear-cell renal-cell cancer, a highly vascular tumor, presents a particularly attractive target for bevacizumab and other anti-angiogenic agents because mutations or DNA methylation affecting the von Hippel-Lindau (VHL) gene are a constant feature of renal-cell carcinomas. The VHL gene product functions as an inhibitor of the angiogenic pathway. Thus, a loss of VHL protein activates hypoxia inducible factor 2 (HIF-2), a transcription factor that promotes synthesis of VEGF and other hypoxic response proteins. In 2009, the FDA approved bevacizumab in combination with interferon-α for the treatment of metastatic renal-cell carcinoma.

Bevacizumab is approved as a single agent following prior therapy for glioblastoma. In all other cancers, bevacizumab has little apparent single-agent activity but improves survival in epithelial cancers in combination with standard chemotherapeutic agents (Sandler et al., 2006). Bevacizumab with carboplatin and paclitaxel increases survival in non–small lung cancer by 2 months. Likewise, bevacizumab combined with FOLFOX (5-FU, leucovorin, and oxaliplatin) or FOLFIRI (5-FU, leucovorin, and irinotecan) improves survival by 5 months in metastatic colorectal cancer. Finally, the combination of bevacizumab with docetaxel increases progression-free survival in patients with metastatic breast cancer (Miller et al., 2007). Trials testing bevacizumab in glioblastoma multiforme have yielded promising results with minimal evidence of intracranial hemorrhage.

Clinical uses of bevacizumab now have expanded beyond the realm of oncology. In wet age-related macular degeneration, abnormal choroidal neovascularization often leads to rapid visual loss. A slightly altered version of bevacizumab called ranibizumab (Lucentis), in which the Fc region has been deleted, effectively treats wet macular degeneration. Bevacizumab restores hearing in patients with progressive deafness due to neurofibromatosis type 2–related tumors (Plotkin et al., 2009).

Clinical Pharmacology. Bevacizumab is administered intravenously as a 30- to 90-minute infusion. In metastatic colon cancer, in conjunction with combination chemotherapy, the dose of bevacizumab is 5 mg/kg every 2 weeks. In metastatic non–small cell lung cancer, doses of 15 mg/kg are given every 3 weeks with chemotherapy. For treatment of metastatic breast cancer, patients receive 10 mg/kg of bevacizumab every 2 weeks in combination with paclitaxel or docetaxel. The differing doses of bevacizumab reflect the varying designs of approval-directed trials. The optimal dosage in each case has not yet been defined. The antibody has a plasma t1/2 of 4 weeks.

**Toxicity.** Bevacizumab causes a wide range of class-related adverse effects. A prominent concern with this class of agents was the potential for vessel injury and bleeding, noticed in patients with squamous-cell lung cancer (Johnson et al., 2004). Bevacizumab is contraindicated for patients who have a history of hemoptysis, brain metastasis, or a bleeding diathesis, but in appropriately selected patients, the rate of life-threatening pulmonary hemorrhage is <2% (Sandler et al., 2006).

The safety of operating on patients treated with bevacizumab continues to be a major concern because of the risk of bleeding and poor wound healing. In a pooled analysis of two large clinical trials of colon cancer, patients who needed surgery while being treated with bevacizumab had a higher rate (13% versus 3.4%) of serious wound healing complications than patients treated with placebo (Scappaticci et al., 2007). In light of these data and because of the long t1/2 of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should be not resumed for at least 4 weeks after surgery.

Other toxicities characteristic of anti-angiogenic drugs include hypertension and proteinuria. A majority of patients receiving the drug require antihypertensive therapy, particularly those receiving higher doses and more prolonged treatment (Sandler et al., 2006; Hurwitz et al., 2004; Miller et al., 2007). The mechanism driving this hypertension is still unclear but may relate, in part, to decreased endothelial nitric oxide production. Physicians should carefully monitor the blood pressure of all patients on bevacizumab and intervene with antihypertensives when appropriate. Case reports describe patients with poorly controlled hypertension developing a reversible posterior leukoencephalopathy during bevacizumab treatment. Bevacizumab also is rarely associated with congestive heart failure, probably secondary to hypertension (Miller et al., 2007).

Patients often develop proteinuria during bevacizumab treatment, but it usually is an asymptomatic finding and rarely associated with nephrotic syndrome (Gressett and Shah, 2009).

The most dreaded vascular toxicity of anti-angiogenic agents is an arterial thromboembolic event (i.e., stroke or myocardial infarction). A meta-analysis found that the rate of arterial thromboembolic events in patients receiving bevacizumab-containing regimens reached 3.8% compared to the control rate of 1.7% (Scappaticci et al., 2007). To reduce the risk of arterial thromboembolic events, clinicians should carefully evaluate a patient’s risk factors (age >65 years, clotting diathesis, a past history of arterial thromboembolic events) before starting the drug.

GI perforation, a potentially life-threatening complication of bevacizumab, has been observed with particular frequency (up to 11%) in patients with ovarian cancer, perhaps related to the presence of peritoneal carcinomatosis and to prior abdominal surgery.
In colon cancer patients, colonic perforation occurs infrequently during bevacizumab treatment but increases in frequency in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or prior abdominal radiation treatment (Gressett and Shah, 2009). The rate of colon perforation is <1% in breast and lung cancer patients receiving the antibody.

**Sunitinib.** Sunitinib (SUTENT) competitively inhibits the binding of ATP to the tyrosine kinase domain on the VEGF receptor-2, a mechanism it shares with sorafenib (see “Sorafenib”). Sunitinib also inhibits other protein tyrosine kinases (FLT3, PDGFR-α, PDGFR-β, RET, CSF-1R, and c-KIT) at concentrations of 5-100 nM (Fabian et al., 2005).

Sunitinib has activity in metastatic renal-cell cancer, producing a higher response rate (31%) and a longer progression-free survival than any other approved angiogenic drug (Motzer et al., 2007). Sunitinib also is approved for treatment of advanced renal-cell carcinoma and GIST that have developed resistance to imatinib as a consequence of c-KIT mutations (Heinrich et al., 2008). Specific c-KIT mutations correlate with response to sunitinib. For example, patients with c-KIT exon 9 mutations have a response rate of 37%, whereas patients with c-KIT exon 11 mutations have only a 5% response rate.

**Pharmacokinetics and Dosing.** Sunitinib is administered orally in doses of 50 mg once a day. The typical cycle of sunitinib is 4 weeks on treatment followed by 2 weeks off treatment. The dosage and schedule of sunitinib can be increased or decreased according to toxicity (hypertension, fatigue). Dosages <25 mg/day typically are ineffective. Sunitinib is metabolized by CYP3A4 to produce an active metabolite, SU12662, the t_{1/2} of which is 80-110 hours; steady-state levels of the metabolite are reached after ~2 weeks of repeated administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of sunitinib are not affected by food intake.

**Toxicity.** The main toxicities of bevacizumab are shared by all anti-angiogenic inhibitors, including sunitinib and sorafenib. Specifically, patients taking sunitinib can experience bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multi-targeted tyrosine kinase inhibitor, it has a broader side-effect profile than bevacizumab.

Fatigue, the most common side effect of sunitinib, affects 50-70% of patients and may be disabling. Hypothyroidism occurs in 40-60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils <1000/mL) develop in 10% of patients. Less common side effects include congestive heart failure (usually in association with hypertension) and hand-foot syndrome. To monitor for these side effects, it is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.

**Sorafenib.** Sorafenib (NEXAVAR), like sunitinib, targets multiple protein tyrosine kinases (VEGFR1, VEGFR2, VEGFR3, PDGFR-β, c-KIT, FLT-3, and b-RAF) and inhibits their catalytic activities at concentrations of 20-90 nM (Fabian et al., 2005).

**Absorption, Distribution, and Elimination.** Sorafenib, an oral medication, is given in daily doses of 400 mg twice a day. Patients typically begin treatment taking 200 mg once a day and increase dosage as tolerated. Unlike sunitinib, sorafenib is given every day without treatment breaks. Sorafenib is metabolized to inactive products by CYP3A4 with a t_{1/2} of 20-27 hours; with repeated administration, steady-state concentrations are reached within 1 week.

**Therapeutic Uses.** Sorafenib is the only drug currently approved for treatment of hepatocellular carcinoma. In these otherwise refractory patients, sorafenib increased median survival by 3 months compared to placebo (10.7 versus 7.9 months) (Llovet et al., 2008). The response rate to sorafenib was low (2%), suggesting that sorafenib primarily has a cytostatic effect. Sorafenib also is approved in metastatic renal-cell cancer, based on improvement in progression-free survival in patients with previously treated disease (Escudier et al., 2007). Because of its higher initial response rate, sorafenib generally is the preferred first-line therapy in this disease.

**Adverse Effects.** Sorafenib patients can experience the vascular toxicities (bleeding, hypertension, and arterial thromboembolic events) seen with other anti-angiogenic medications. More common adverse effects include fatigue, nausea, diarrhea, anorexia, and rash; uncommonly, one may notice bone marrow suppression and GI perforation (Escudier et al., 2007).

**THALIDOMIDE**

Among agents with anti-angiogenic activity, the immunomodulatory analogs (IMiDs), thalidomide and lenalidomide, have a most unusual history and a multiplicity of biological and immunological effects. Their
classification as anti-angiogenics is convenient but tentative. Thalidomide originally entered development in the 1950s for the treatment of pregnancy-associated morning sickness but was withdrawn from the market due to the tragic consequences of teratogenicity and dysmelia (stunted limb growth) (Franks et al., 2004). It re-entered clinical practice, initially because of its clinical efficacy in erythema nodosum leprosum, for which it received approval in 1998 (see Chapter 56). Further research revealed its anti-angiogenic and immunomodulatory effects, and these findings triggered experimental trials in cancer, most notably against multiple myeloma (MM). Both thalidomide and lenalidomide possess potent activity in newly diagnosed and heavily pretreated relapsed/refractory MM patients (Richardson et al., 2007). Lenalidomide also has striking clinical activity in the 5q− subset of myelodysplastic syndrome (MDS) and has been approved for this indication. A specific gene array profile identifies MDS patients who lack the 5q− abnormality but respond to lenalidomide (Ebert et al., 2008).

**Mechanisms of Action.** The precise mechanisms responsible for these drugs’ clinical effects are unclear. Thalidomide’s enantiomeric interconversion and spontaneous cleavage to multiple short-lived and poorly characterized metabolites, as well as its species-specific in vivo metabolic activation, confound the interpretation of preclinical in vitro and in vivo mechanistic studies. At least four distinct, but potentially complementary, mechanisms have been proposed to explain the antitumor activity of IMiDs (Figure 62–3):

- **Direct anti-proliferative/pro-apoptotic antitumor effects.** They inhibit the anti-apoptotic effects of NF-κB and the anti-apoptotic Bcl-2 family member A1/Bfl-1 (Mitsiades et al., 2002a).
- **Indirect inhibition of tumor cell growth and survival** by abrogation of cell interactions with adhesion molecules (Hideshima et al., 2000).
- **Inhibition of interleukin-6 (IL-6) and tumor necrosis factor α (TNF α) production, release, and signaling,** leading to anti-angiogenic effects.
- **Immunomodulation through enhancement of natural killer (NK) and T cell–mediated cytotoxicity.** Their antagonism of anti-apoptotic pathways and their anti-angiogenic effects could account for the clinical synergy with glucocorticoids and bortezomib against MM (Mitsiades et al., 2002b).

**Figure 62–3. Schematic overview of proposed mechanisms of antitumor activity (targeted therapies: tyrosine kinase inhibitors, monoclonal antibodies, and cytokines).**

**Thalidomide**

**Pharmacokinetics and Therapeutic Use.** Thalidomide (THALOMID) exists at physiological pH as a racemic mixture of cell-permeable
and rapidly interconverting non-polar S(−) and R(+) isomers, the equilibrium favoring the R product. The R-enantiomer is associated with the teratogenic and biological activities, while the S accounts for the sedative properties of thalidomide.

Thalidomide is given in dosages of 200-1200 mg/day. In treating MM, doses usually are escalated by 200 mg/day every 2 weeks until dose-limiting side effects (sedation, fatigue, constipation, or a sensory neuropathy) supervene. With extended treatment, the neuropathy may necessitate dose reduction or discontinuation of treatment for a period of time. Thalidomide absorption from the GI tract is slow and highly variable [4 hours mean time to reach peak concentration (T\text{max}), with a range of 1-7 hours]. It distributes throughout most tissues and organs, without significant binding to plasma proteins. Peak levels are achieved in 3-4 hours, and the t\text{1/2} of disappearance of the enantiomers is ~6 hours. Elimination of thalidomide is mainly by spontaneous hydrolysis in all body fluids; the S-enantiomer is cleared more rapidly than the R-enantiomer. Thalidomide and its metabolites are excreted in the urine, while the non-absorbed portion of the drug is excreted unchanged in feces, but clearance of active drug is primarily attributable to hydrolysis. The inactive hydrolysis products undergo a complex pattern of CYP-mediated metabolism. Studies in elderly prostate cancer patients showed a significantly longer plasma t\text{1/2} at highest doses (1200 mg daily) versus lowest doses (200 mg daily) (Figg et al., 1999). No dose adjustment is necessary in the presence of renal failure.

Thalidomide enhances the sedative effects of barbiturates and alcohol and the catatonic effects of chlorpromazine and reserpine. Conversely, CNS stimulants (such as methamphetamine and methylphenidate) counteract the depressant effects of thalidomide.

**Lenalidomide.** Lenalidomide (REVLIMID) constitutes the lead compound in the new class of immunomodulatory thalidomide derivatives and exhibits a panoply of pharmacological properties (direct suppression of the tumor cell growth in culture, T-cell and NK-cell activation, suppression of TNF α and other cytokines, antiangiogenesis, and promotion of hematopoietic stem cell differentiation) (List, 2007).

**Pharmacokinetics and Therapeutic Use.** The standard dosage of lenalidomide is 25 mg/day for 21 days of a 28-day cycle. The drug is rapidly absorbed following oral administration, reaching peak plasma levels within 1.5 hours. The C\text{max} and AUC values increase proportionately with increasing dose, over a single-dose range of 5-400 mg. The t\text{1/2} of parent drug in plasma is 9 hours at the 400-mg dose. Approximately 70% of the orally administered dose of lenalidomide is excreted intact by the kidney. The AUC progressively rises in patients with moderate to severe renal failure (creatinine clearance <50 mL/min). Based on pharmacokinetic considerations, downward dose adjustments to 10 mg/day for creatinine clearance of 30-50 mL/h and to the same dose every 2 days for creatinine clearance <30 mL/h are recommended for patients with renal failure. The safety and efficacy of these adjusted doses have not been established in prospective studies (Chen et al., 2007).

This orally administered agent has exhibited potent antitumor activity in MM, MDS, and chronic lymphocytic leukemia (CLL); causes fewer adverse side effects; and lacks the teratogenicity of thalidomide.

**Adverse Effects of Thalidomide and Lenalidomide**

Thalidomide is well tolerated at doses <200 mg daily. The most common adverse effects reported in cancer patients are sedation and constipation, while the most serious one is peripheral sensory neuropathy, which occurs in 10-30% of patients with MM or other malignancies in a dose- and time-dependent manner (Richardson et al., 2004). Thalidomide-related neuropathy is an asymmetrical, painful, peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. The incidence of peripheral neuropathy increases with higher cumulative doses of thalidomide, especially in elderly patients. Although symptoms improve upon drug discontinuation, long-standing sensory loss may not reverse. Particular caution should apply in cancer patients with pre-existing neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids, bortezomib), especially because there has been little progress in defining effective strategies to alleviate neuropathic symptoms.

Adverse effects of lenalidomide are much less severe, as it causes little sedation, constipation, or neuropathy. The drug depresses bone marrow function and is associated with significant leukopenia in 20% of patients. In rare instances, patients develop hepatotoxicity and renal dysfunction. In some CLL patients, lenalidomide causes dramatic lymph node swelling and tumor lysis, a syndrome called the tumor flare reaction. Patients with renal dysfunction receiving the standard dose of 25 mg/day are particularly prone to this reaction; thus, clinical trials in CLL are proceeding at much lower doses of 10 mg/day, with escalation as tolerated. CLL patients should receive pretreatment hydration and allopurinol to avoid the consequences of tumor swelling and tumor lysis. A negative interaction with rituximab, an anti-CD20 antibody, may result from lenalidomide’s downregulation of CD20, an interaction that has clinical implications for their combined use in lymphoid malignancies (Lapalombella et al., 2008).

Thromboembolic events occur with increased frequency in patients receiving thalidomide or lenalidomide, but particularly in combination with glucocorticoids and with anthracyclines (Musallam et al., 2008). Anticoagulation reduces this risk and seems indicated in patients presenting with risk factors for clotting, but anticoagulant prophylaxis has not been evaluated prospectively.

**PROTEASOME INHIBITION: BORTEZOMIB**

Bortezomib (VELCADE), an inhibitor of proteasome-mediated protein degradation, has earned a central role in the treatment of MM.

**Chemistry.** Bortezomib, [(1R)-3-methyl-1-[[[(2S)-1-oxo-3-phenyl-2-[[pyrazinylcarbonyl]amino]propyl]amino]butyl]boronic acid, has a unique boron-containing structure:
Mechanism of Action. Bortezomib binds to the β5 subunit of the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity (Adams, 2004). This event disrupts multiple intracellular signaling cascades, leading to apoptosis. A most important consequence of proteasome inhibition is its effect on NF-κB, a key transcription factor that promotes cell damage response and cell survival. Most NF-κB is found in the cytosol bound to IκB; in this form, NF-κB is restricted to the cytosol and cannot enter to the nucleus to regulate transcription. In response to stress signals resulting from hypoxia, chemotherapy, and DNA damage, IκB becomes ubiquitinated and then degraded via the proteasome. Its degradation releases NF-κB, which enters the nucleus, where it transcriptionally activates a host of genes involved in cell survival (e.g., cell adhesion proteins E-selectin, ICAM-1, and VCAM-1), as well as proliferative (e.g., cyclin-D1) or anti-apoptotic molecules (e.g., clAPs, BCL-2). NF-κB is highly expressed in many human tumors, including MM, and may be a key factor in tumor cell survival in a hypoxic environment and during chemotherapy. Bortezomib blocks proteasomal degradation of IκB, thereby preventing the transcriptional activity of NF-κB and downregulating survival responses.

NF-κB inhibition may not account for the full spectrum of effects triggered by proteasome inhibition, because bortezomib also disrupts the ubiquitin–proteasomal degradation of p21, p27, p53, and other key regulators of the cell cycle and initiators of apoptosis. Bortezomib activates the cell’s stereotypical “unfolded protein response” or UPR, in which abnormal protein conformation activates adaptive signaling pathways in the cell. The composite effect leads to irreversible commitment of MM cells to apoptosis (Mitsiades et al., 2002). In clinical trials, bortezomib also sensitizes tumor cells to cytotoxic drugs, including alkylators and anthracyclines, and to IMiDs and inhibitors of histone deacetylase (Orlowski et al., 2007).

Absorption, Fate, and Excretion. The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus on days 1, 4, 8, and 11 of every 21-day cycle (with a 10-day rest period per cycle). At least 72 hours should elapse between doses. Drug administration should be withheld until resolution of any grade 3 nonhematological toxicity or grade 4 hematological toxicity, and subsequent doses should be reduced 25%.

After intravenous administration of 1–1.3 mg/m² of bortezomib, the drug exhibits a terminal t1/2 in plasma of 5.5 hours (Papandreou et al., 2004). The median peak plasma concentration averages 509 ng/mL after a 1.3-mg/m² bolus injection. Peak proteasome inhibition reaches 60% within 1 hour and declines thereafter, with a t1/2 of ~24 hours.

Bortezomib clearance results from the deboronation of 90% of the parent compound, followed by hydroxylation of the boron-free product by CYPs 3A4 and 2D6; administration of this drug with potent inducers or inhibitors/substrates of CYP3A4 requires caution. No dose adjustment is required for patients with renal dysfunction.

Therapeutic Uses and Toxicity. Bortezomib is FDA approved as initial therapy for MM and as therapy for MM after relapse from other drugs (Kane et al., 2003). It also has received approval for relapsed or refractory mantle cell lymphoma. The drug is active in myeloma, including the induction of complete responses in up to 30% of patients when used in combination with other drugs (i.e., thalidomide, lenalidomide, liposomal doxorubicin, or dexamethasone) (San Miguel et al., 2008).

Bortezomib toxicities include thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), and neutropenia, anemia, vomiting, diarrhea, limb pain, dehydration, nausea, or weakness. Peripheral neuropathy, the most chronic of the toxicities, develops most frequently in patients with a prior history of neuropathy secondary to prior drug treatment (e.g., thalidomide) or diabetes or with prolonged use. Dose reductions or discontinuation of bortezomib ameliorates the neuropathic symptoms. Injection of bortezomib may precipitate hypotension, especially in volume-depleted patients, in those who have a history of syncope, or in patients taking antihypertensive medications. High-dose bortezomib causes hypotension and congestive heart failure in animals; cardiac toxicity occurs rarely in humans, but congestive failure and prolonged QT-interval have been reported.

mTOR INHIBITORS: RAPAMYCIN ANALOGS

Rapamycin (sirolimus) is a fungal fermentation product that inhibits the proper functioning of a serine/threonine protein kinase in mammalian cells eponymously named mammalian target of rapamycin, or mTOR, an effector PI3 kinase signaling. The PI3K/PKB(Akt)/mTOR pathway responds to a variety of signals from growth factors (e.g., insulin, interleukins, EGF) that modulate cell growth, translation, metabolism, and apoptosis. The activation of the PI3K pathway is opposed by the phosphatase activity of the tumor suppressor, PTEN. Activating mutations and amplification of genes in the receptor-PI3K pathway, and loss of function alterations in PTEN, occur frequently in cancer cells, with the result that PI3K signaling is exaggerated and cells lose growth control and exhibit enhanced survival (decreased apoptosis).

Rapamycin and its congeners, temsirolimus and everolimus, are well-established first-line drugs in post-transplant immunosuppression. More recently, mTOR inhibitors have found important applications in oncology for treatment of renal and hepatocellular cancer and mantle cell lymphomas.
Mechanisms of Action and Resistance. The rapamycins inhibit an enzyme complex, mTORC1, which occupies a downstream position in the PI3 kinase pathway (Figure 62–4). mTOR forms the mTORC1 complex with a member of the FK506-binding protein family, FKBP12. Among other actions, mTORC1 phosphorylates S6 kinase and also relieves the inhibitory effect of 4EBP on initiation factor elf-4E, thereby promoting protein synthesis and metabolism. The antitumor actions of the rapamycins result from their binding to FKBP12 and inhibition of mTORC1. Rapamycin and its congeners have immunosuppressant effects, inhibit cell-cycle progression and angiogenesis, and promote apoptosis.

Resistance to mTOR inhibitors is incompletely understood but may arise through the action of a second mTOR complex, mTORC2, which is unaffected by rapamycins and which regulates AKT kinase. Experimental work suggests that inhibition of mTORC1 leads to mTORC2 activation of AKT kinase and the MAP kinase pathway, and these actions may be responsible for incomplete responses or resistance of rapamycins (Carracedo et al., 2008). Dual mTORC1 and mTORC2 inhibitors are in clinical development.

Absorption, Fate, and Excretion. The FDA has approved both temsirolimus and everolimus for treatment of renal cancer. Temsirolimus prolongs survival and delays disease progression in patients with advanced and poor- or intermediate-risk renal cancer, as compared to standard interferon-α treatment. Everolimus, as compared to placebo, prolongs survival in patients who had failed initial treatment with anti-angiogenic drugs (Motzer et al., 2008). mTOR inhibitors also have antitumor activity against mantle cell lymphomas (Ansell et al., 2008) and are under active investigation in combination with hormonal therapies, EGFR inhibitors, and cytotoxic drugs.

For renal-cell cancer, temsirolimus is given in weekly doses of 25 mg, intravenously, while everolimus is administered orally in doses of 10 mg daily. Both drugs should be administered in the fasting state at least 1 hour before a meal. Both parent molecules are metabolized by CYP3A4. Temsirolimus has a plasma t_{1/2} of 30 hours; its primary metabolite, sirolimus, has a longer t_{1/2} of 53 hours. Because sirolimus has equivalent activity as an inhibitor of mTORC1, and has a greater AUC, sirolimus is likely the more important contributor to antitumor action in patients (Hutson et al., 2008). Everolimus has a plasma t_{1/2} of 30 hours, and on a weekly schedule at doses of 20 mg, it maintains inhibition of mTORC1 for 7 days in white blood cells (O’Donnell et al., 2008). At their usual clinical doses, both agents provide peak drug levels of ~1 μM.

Both drugs are susceptible to interactions with other agents that affect CYP3A4 activity. Ketoconazole, a CYP3A4 inhibitor, causes a 2- to 3-fold increase in the AUCs of both temsirolimus and sirolimus, while inducers of metabolism such as rifampin or phenytoin can decrease the C_{Pmax} of temsirolimus by 36% and decrease the AUC of its metabolite by >50%. The dose of temsirolimus should be doubled in the presence of inducers and reduced by half in the presence of ketoconazole (Hutson et al., 2008). Hepatic dysfunction delays drug clearance; for everolimus, the dose should be...
reduced to 5 mg daily for patients with moderate hepatic impairment (Child-Pugh class B); guidelines for dose reduction of temsirolimus in such patients have not been established. The drugs’ pharmacokinetics do not depend on renal function, and hemodialysis does not hasten temsirolimus clearance.

Higher-dose intravenous temsirolimus regimens, up to 175 mg/week, have been explored in mantle cell lymphoma and in other diseases, as has oral temsirolimus administration. Poor oral bioavailability hampers the oral route of administration, as <20% of drug or active metabolite reaches the plasma (Buckner et al., 2010).

Clinical Toxicity. The rapamycin analogs have very similar patterns of toxicity. The most prominent side effects are a mild maculopapular rash, mucositis, anemia, and fatigue, each occurring in 30-50% of patients. A minority of patients will develop leukopenia or thrombocytopenia with progressive cycles of treatment, and these effects are reversed if therapy is discontinued. Less common side effects include hyperglycemia, hypertriglyceridemia, and, rarely, pulmonary infiltrates and interstitial lung disease. Pulmonary infiltrates emerge in 8% of patients receiving everolimus and in a smaller percentage of those treated with temsirolimus. In patients showing minor radiological changes, but without symptoms, drug administration may be continued. If symptoms such as cough or shortness of breath develop or radiological changes progress, the drug should be discontinued. Prednisone may hasten the resolution of radiological changes and symptoms (Hutson et al., 2008).

BIOLOGICAL RESPONSE MODIFIERS

Biological response modifiers include cytokines or monoclonal antibodies that beneficially affect the patient’s biological response to a neoplasm. Included are agents that act indirectly to mediate their antitumor effects (e.g., by enhancing the immunological response to neoplastic cells) or directly, binding to receptors on the tumor cells and delivering toxins or radionuclides. Recombinant DNA technology has greatly facilitated the identification and production of a number of human proteins with potent effects on the function and growth of both normal and neoplastic cells. Proteins that currently are in clinical use include the interferons (see Chapters 35 and 58); interleukins (see Chapter 35); hematopoietic growth factors such as erythropoietin, filgrastim [granulocyte-colony-stimulating factor (G-CSF)], and sargramostim [granulocyte-macrophage colony-stimulating factor (GM-CSF)] (see Chapter 37); and monoclonal antibodies.

Monoclonal Antibodies

Since the discovery of methods for fusing mouse myeloma cells with B lymphocytes, it has been possible to produce a single species of murine antibody that recognizes a specific antigen. Cancer cells express antigens that are attractive targets for monoclonal antibody–based therapy (Table 62–1). Immunization of mice with human tumor cell extracts has led to the isolation of monoclonal Abs reactive against unique or highly expressed target antigens, and a few of these monoclonals possess antitumor activity. Because murine antibodies have a short t1/2 in humans, activate human immune effector mechanisms poorly, and induce a human anti–mouse antibody immune response, they usually are chimerized by substituting major portions of the human IgG molecule. Presently, monoclonal antibodies have received FDA approval for lymphoid and solid tumor malignancies. Available agents include rituximab (Coiffier et al., 2002) and alemtuzumab (Keating et al., 2002) for lymphoid malignancies, trastuzumab (Vogel et al., 2002) for breast cancer, bevacizumab (Sandler et al., 2006) for colon and lung cancer, and cetuximab and panitumumab (Van Cutsem et al., 2007) for colorectal cancer and head and neck cancer. The nomenclature adopted for naming therapeutic monoclonal antibodies is to terminate the name in -ximab for chimeric antibodies and -umab for fully humanized antibodies.

Unmodified monoclonal antibodies may kill tumor cells by a variety of mechanisms [e.g., antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), and direct induction of apoptosis by antigen binding], but the clinically relevant mechanisms for most antibodies are uncertain (Villamor et al., 2003). Monoclonal antibodies also may be linked to a toxin (immunotoxins), such as gemtuzumab ozogamicin (MYLOTARG) (Larson et al., 2005) or denileukin difitox (ONTAK) (Negro-Vilar et al., 2007), or conjugated to a radioactive isotope, as in the case of 90Yttrium (90Y)-ibritumomab tiuxetan (ZEVALIN) (Witzig et al., 2002) (Table 62–1). Genetic polymorphisms affecting the target antigen or complement receptors may influence response (Cartron et al., 2002).

Unarmed Monoclonal Antibodies

Rituximab. Rituximab (RITUXAN) is a chimeric monoclonal antibody that targets the CD20 B-cell antigen (Tables 62–1 and 62–2) (Maloney et al., 1997). CD20 is found on cells from the pre–B cell stage through its terminal differentiation to plasma cells and is expressed on 90% of B-cell neoplasms. The biological functions of CD20 are uncertain, although incubation of B cells with anti-CD20 antibody has variable effects on cell-cycle progression, depending on the monoclonal antibody type. Monoclonal antibody binding to CD20 generates transmembrane signals that produce autophosphorylation and activation of serine/tyrosine protein kinases, induction of c-myc oncogene expression,
and expression of major histocompatibility complex class II molecules. CD20 also may regulate transmembrane Ca\(^{2+}\) conductance through its function as a Ca\(^{2+}\) channel. It is unclear which of these actions relates to the pharmacological effect of rituximab.

Rituximab is approved as a single agent for relapsed indolent lymphomas and significantly enhances response and survival in combination with chemotherapy for the initial treatment of diffuse large B-cell lymphoma. It remains effective in patients who relapse after initial treatment with rituximab-based combinations. Rituximab improves response rates when added to combination chemotherapy for other indolent B-cell non-Hodgkin’s lymphomas (NHLs), including CLL, mantle cell lymphoma, Waldenström macroglobulinemia, and marginal zone lymphomas (Cheson and Leonard, 2008). Maintenance of remission with rituximab delays time to progression and improves overall survival in indolent NHL (van Oers et al., 2006). It is increasingly used for treatment of autoimmune diseases such as rheumatological disease, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemias, cryoglobulin-induced renal disease and multiple sclerosis.

**Pharmacokinetics and Dosing.** Rituximab has a \(t_{1/2}\) of ~22 days (Maloney et al., 1997). The drug is administered by intravenous infusion both as a single agent and in combination with chemotherapy at a dose of 375 mg/m\(^2\). As a single agent, it is given weekly for 4 weeks, with maintenance dosing every 3-6 months. In combination regimens, the drug may be administered every 3-4 weeks, with chemotherapy, for up to eight doses. As maintenance therapy following 6-8 cycles of combination chemotherapy, rituximab may be given once weekly for four doses, at 6-month intervals, for up to 16 doses.

During the first administration, the rate of infusion should be increased slowly to prevent serious hypersensitivity reactions. Infusions should begin at 50 mg/h, and in the absence of infusion reactions, the rate can increase in 50-mg/h increments every 30 minutes to a maximum rate of 400 mg/h. On subsequent infusion in the absence of reactions, infusions may start at 100 mg/hr and increase to 100-mg/hr increments every 30 minutes to a maximum rate of 400 mg/h. Pretreatment with antihistamines, acetaminophen, and glucocorticoids decreases the risk of hypersensitivity reactions.

Patients with large numbers of circulating tumor cells (as in CLL) are at increased risk for tumor lysis syndrome; in these patients, the initial dose should be no more than 50 mg/m\(^2\) on day 1.

of treatment, and patients should receive standard tumor lysis prophylaxis. The remainder of the dose can then be given on day 3.

**Resistance and Toxicity.** Resistance to rituximab may emerge through downregulation of CD20, impaired antibody-dependent cellular cytotoxicity, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels (Maloney et al., 2002). Polymorphisms in two of the receptors for the antibody Fc region responsible for complement activation, FcγRIIIa and FcγRIIa, may predict the clinical response to rituximab monotherapy in patients with follicular lymphoma but not in CLL (Cartron et al., 2002).

Rituximab infusional reactions can be life-threatening, but with pretreatment are usually mild and limited to fever, chills, throat itching, urticaria, and mild hypotension. All respond to decreased infusion rates and antihistamines. Uncommonly, patients may develop severe mucocutaneous skin reactions, including Stevens-Johnson syndrome. Rituximab may cause reactivation of hepatitis B virus or rarely, JC virus (with progressive multifocal leukoencephalopathy) (Kranick et al., 2007). Patients should be screened for hepatitis B before initiation of therapy. Hypogammaglobulinemia and autoimmune syndromes (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, pure red cell aplasia, and delayed neutropenia) may supervene 1-5 months after administration (Cattaneo et al., 2006).

**Ofatumumab.** Ofatumumab (ARZERRA) is a second monoclonal antibody that binds to sites on the major and minor extracellular loops of CD20, distinct
from the site targeted by rituximab. Binding of the drug results in B-cell lysis (both CDC and ADCC). Ofatumumab is approved for treating patients with CLL after failure of fludarabine and alemtuzumab.

A complex dosing scheme is used, beginning with small (300 mg) doses on day 1, followed by higher doses (up to 2 g/week) for 7 weeks, followed by 2 g every 4 weeks for four additional doses. Slow rates of infusion are recommended for the initial dose and for the first 2 hours of subsequent infusions.

Ofatumumab’s primary toxicities consist of immunosuppression and opportunistic infection, hypersensitivity reactions during antibody infusion, and myelosuppression, which may be prolonged. Blood counts should be monitored during treatment. Rarely, patients may develop reactivation of viral infections, leading to progressive multifocal leukoencephalopathy or hepatitis B progression. The drug should not be administered to patients with active hepatitis B infection; liver function should be monitored closely in hepatitis B carriers.

Alemtuzumab. Alemtuzumab (CAMPATH) is a humanized IgG-κ monoclonal antibody, composed of a rat antigen–binding region within human constant regions and variable framework. The drug binds to CD52 antigen present on the surface of a subset of normal neutrophils and on all B and T lymphocytes, on testicular elements and sperm, and on most B- and T-cell lymphomas (Kumar et al., 2003). Consistently high levels of CD52 expression on lymphoid tumor cells and the lack of CD52 modulation with antibody binding make this antigen a favorable target for unconjugated monoclonal antibodies. Alemtuzumab can induce tumor cell death through ADCC and CDC.

Pharmacokinetics and Dosing. Alemtuzumab is administered intravenously in dosages of 30 mg/day three times per week. Premedication with diphenhydramine (50 mg) and acetaminophen (650 mg) should precede drug infusion. Because of hypersensitivity, dosing begins with a 3-mg infusion, followed by a 10-mg dose 2 days later and, if well tolerated, a 30-mg dose 2 days later. The drug has an initial mean t½ of 1 hour, but after multiple doses, the t½ extends to 12 days, and steady-state plasma levels are reached at approximately week 6 of treatment, presumably through saturation of CD52-binding sites. Clinical activity has been demonstrated in both B- and T-cell low-grade lymphomas and CLL, including patients with disease refractory to purine analogs (Hillmen et al., 2007). In chemotherapy-refractory CLL, overall response rates are ~40%, with complete responses of 6% in multiple series. Response rates in patients with untreated CLL are higher (overall response rates of 83% and complete responses of 24%).

Toxicity. The most concerning toxicities include acute infusion reactions and depletion of normal neutrophils and T cells (Table 62–2). Serious myelosuppression, with depletion of all blood lineages, occurs in the majority of patients and may represent either direct marrow toxicity or auto-immune responses. Immunosuppression by the antibody leads to a significant risk of fungal, viral, and other opportunistic infections (Listeria), particularly in patients who have previously received purine analogs (Keating et al., 2002; Hillmen et al., 2007). Patients should receive antibiotic prophylaxis against Pneumocystis carinii and herpes virus during treatment and for at least 2 months following therapy with alemtuzumab. Because reactivation of cytomegalovirus (CMV) infections may follow antibody use, patients should be monitored for symptoms and signs of viremia, hepatitis, and pneumonia. CD4+ T-cell counts may remain profoundly depleted (<200 cells/μL) for 1 year. Alemtuzumab does not combine well with chemotherapy in standard regimens because of significant infectious complications (Gallamini et al., 2007).

Monoclonal Antibody–Cytotoxic Conjugates

Gemtuzumab Ozogamicin. Gemtuzumab ozogamicin (MYLOTARG) consists of a humanized monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of calicheamicin, a potent enediyne antitumor antibiotic (Bernstein, 2000). The CD33 antigen is present on most hematopoietic cells, on >80% of AMLs, and on most myeloid cells in patients with myelodysplasias. However, other normal cell types lack CD33 expression, making this antigen attractive for targeted therapy. CD33 has no known biological function, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation. Following its binding to CD33, gemtuzumab ozogamicin undergoes endocytosis, and cleavage of calicheamicin from the antibody takes place within the lysosome. The potent toxin then enters the nucleus, binds in the minor groove of DNA, and causes double-strand DNA breaks and cell death (Zein et al., 1988).

Clinical Pharmacology. The antibody conjugate produces a 30% complete response rate in relapsed AML, when administered at a dose of 9 mg/m² for up to 3 doses at 2-week intervals (Sievers et al., 2001). Pharmacokinetics of gemtuzumab ozogamicin at the standard 9-mg/m² dose are described by a t½ of total and unconjugated calicheamicin of 41 and 143 hours, respectively (Dowell et al., 2001). Following a second dose, the t½ of drug-antibody conjugate increases to 64 hours and the AUC increases to twice that of the initial dose. Most patients require two to three doses to achieve remission. The drug currently is approved in patients >60 years of age with AML in first relapse.

The primary toxicities of gemtuzumab ozogamicin include myelosuppression in all patients treated and hepatocellular damage in 30-40% of patients, manifested by hyperbilirubinemia and enzyme elevations. It also causes a syndrome that resembles hepatic veno-occlusive disease (tender, enlarged liver and rising serum bilirubin) when patients subsequently undergo myeloablative therapy or when gemtuzumab ozogamicin follows high-dose chemotherapy (Wadleigh et al., 2003). This syndrome reflects injury to hepatic sinusoids rather than venules. Defibrotide, an orphan drug, may prevent severe or fatal hepatic injury in patients who develop signs of hepatic failure while receiving a stem cell transplant following gemtuzumab ozogamicin (Verslyus et al., 2004). Prolonged myelosuppression, particularly delayed recovery of platelet counts, may
complicate the patient’s course following remission induction with gemtuzumab ozogamicin.

### Radioimmunoconjugates

Radioimmunoconjugates provide targeted delivery of radionuclides to tumor cells (Tables 62–1 and 62–2) (Witzig et al., 2002; Horning et al., 2005). $^{131}$Iodine ($^{131}$I) is a favored radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The $\gamma$ particles emitted by $^{131}$I can be used for both imaging and therapy, but protein-iodine conjugates have the drawback of releasing free $^{131}$I and $^{131}$I-tyrosine into the blood, and thus present a health hazard to caregivers, family, and others in contact with the patient. The $\beta$-emitter $^{90}$Y has emerged as an attractive alternative to $^{131}$I, based on its higher energy and longer path length. These features suggest that it may be more effective in tumors with larger diameters. It also has a short $t_{1/2}$ and remains conjugated, even after endocytosis, providing a safer profile for outpatient use.

Currently available radioimmunoconjugates consist of murine monoclonal antibodies against CD20 conjugated with $^{131}$I [tosilomab (BEXXAR)] or $^{90}$Y [ibrutinomab tiuxetan (ZEVALIN)]. Both drugs have shown responses rates in relapsed lymphoma of 65-80%. They require significant collaboration between medical oncologists and nuclear medicine departments for administration. When using Zevalin, an initial dose of unlabeled rituximab is administered, followed by an imaging dose of Indium-111-labeled Zevalin. Biodistribution is determined, allowing calculation of a therapeutic dose of $^{90}$Y Zevalin. A pretreatment dose of rituximab then is administered to saturate nonspecific binding sites, followed by the therapeutic dose of $^{90}$Y Zevalin. The steps in Bexxar administration closely follow those of Zevalin. An imaging dose precedes the therapeutic dose given 1 week later. These agents cause antibody-related hypersensitivity, bone marrow suppression, and secondary leukemias.

### Interleukin-2

IL-2 is a 133-amino acid glycoprotein encoded by a gene on chromosome 4q26–27; its molecular weight is 15 kDa (Smith, 1988). It bears structural homology to IL-4, IL-15, and GM-CSF. IL-2 is produced by activated T cells and NK cells; it acts to promote activated T-cell proliferation and enhanced killing by NK cells. Responsiveness depends on expression of the IL-2 receptor. Resting T cells and nearly all types of tumor cells lack receptor expression and are unresponsive to IL-2.

The IL-2 receptor has three components: 1) an $\alpha$ chain, a 55-kDa protein (CD25) involved mainly in IL-2 binding; 2) a $\beta$ chain, a 75-kDa protein involved in intracellular signaling; and 3) a $\gamma$ chain, a 64-kDa protein that is a component of many cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21) and also is involved in signaling (Waldmann, 1991). IL-2 affinity for the three-component receptor is 10 pM; in the absence of the $\alpha$ chain, IL-2–binding affinity is reduced by a factor of 100.

**Mechanism of Action.** IL-2 stimulates the proliferation of activated T cells and the secretion of cytokines from NK cells and monocytes. IL-2 stimulation increases cytotoxic killing by T cells and NK cells. The mechanism of tumor cell killing has not been precisely defined but is presumed to be the result of enhanced killing by immune effector cells.

**Pharmacokinetics.** The serum $t_{1/2}$ of IL-2 after intravenous administration has an $\alpha$ phase of about 13 minutes and a $\beta$ phase of about 90 minutes (Konrad et al., 1990). After a bolus dose of 6 million IU/m$^2$, peak serum levels are nearly 2,000 IU/mL. The same dose given subcutaneously achieves peak levels of 32-42 IU/mL in 2-6 hours. Six million IU/m$^2$ given by continuous intravenous infusion reaches a steady-state level of 123 IU/mL within 2 hours. IL-2 is excreted in the urine as an inactive metabolite. Encapsulation of IL-2 in liposomes or conjugation of IL-2 to polyethylene glycol alters its distribution and $t_{1/2}$; these forms are not FDA-approved.

**Clinical Use.** Aldesleukin (PROLEUKIN) possess the biological activities of human native IL-2. The drug is approved for use in metastatic renal-cell cancer (Rosenberg, 2000) and metastatic melanoma (McDermott, 2009). High-dose IL-2 produces an overall response rate of ~19% in patients with renal-cell cancer, and 8% achieve a complete response. Responses last a median of 8-9 years. Patients whose tumors express carbonic anhydrase IX have a higher likelihood of response (Atkins, 2009). High-dose IL-2 induces an overall response rate of ~16% in patients with metastatic melanoma, and 6% achieve a complete response. Responses last a median of ~5 years. Low-dose IL-2 also produces responses, but the duration of the responses may be less than with high-dose IL-2. The issue of appropriate dosage is controversial.

Aldesleukin may be administered in several ways. High-dose IL-2 is 600,000–720,000 IU/kg administered by intravenous bolus every 8 hours until dose-limiting toxicity appears or 14 total doses have been given; the schedule may be repeated after 9 days of rest for a maximum of 28 doses. Low-dose IL-2 is 60,000 or 72,000 IU/kg given by intravenous bolus every 8 hours for 15 doses. A third regimen involves delivery of 18 million units/m$^2$ daily by continuous intravenous infusion for 5 days. Chronic administration doses are 250,000 IU/kg subcutaneously daily for 5 days followed by 125,000 IU/kg daily for 6 weeks.

**Toxicity.** IL-2 toxicities are dominated by the capillary leak syndrome (Schwartz et al., 2002). Intravascular fluid leaks into the extracellular space, tissues, and lung, producing hypotension, edema, respiratory difficulties, confusion, tachycardia, oliguric renal failure, and electrolyte problems, including hypokalemia, hypomagnesemia, hypocalcemia, and hypophosphatemia. Symptoms include fever, chills, malaise, nausea, vomiting, and diarrhea. Laboratory abnormalities include thrombocytopenia, abnormal liver function tests, and neutropenia. Most patients develop a pruritic skin rash over most of the body surface. Hypothyroidism may occur. Arrhythmias are a rare complication.

These toxicities can be variable in grade but are often life-threatening, yet nearly all are reversible within 24-48 hours of discontinuing therapy. In view of the toxicities, patients should have a
good performance status and normal renal and hepatic function before beginning therapy and should be closely supervised during drug administration.

**Denileukin Diftitox.** Denileukin diftitox (ONTAK) is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphtheria toxin (Foss et al., 2001). The limited tissue expression of the high-affinity IL-2R makes this an attractive target for an immunotoxin, as cells that do not express the IL-2R or express only the intermediate- or low-affinity receptor types are significantly less sensitive to this agent. Introduction of the diphtheria toxin fragment into cells leads to ADP-ribosylation and inactivation of eukaryotic elongation factor EF-2, inhibition of protein synthesis, and hence, cell death.

Denileukin diftitox is FDA-approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. It should be administered at 9 or 18 μg/kg/day by intravenous infusion over 30–60 minutes for 5 consecutive days every 21 days for eight cycles. Response rates of 30–37% have been achieved in such patients with denileukin diftitox, with a median response duration of 6.9 months (Olsen et al., 2001). Additional patients derived clinical benefit but did not meet the objective criteria for response. The systemic exposure to denileukin diftitox is variable but proportional to dose. The drug has a distribution t 1/2 of 2–5 minutes with a terminal t 1/2 of ~70 minutes. Immunological reactivity to denileukin diftitox can be detected in virtually all patients after treatment but does not preclude clinical benefit with continued treatment. Denileukin diftitox clearance in later cycles of treatment accelerates by 2- to 3-fold as a result of development of antibodies, but serum levels exceed those required to produce cell death in IL-2R-expressing cell lines (1-10 ng/mL for >90 minutes). Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities associated with denileukin diftitox typically are acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity (Foss et al., 2001).

**Colony-Stimulating Factors**

As noted in the preceding sections, many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression often has limited the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., G-CSF), and granulocytes and macrophages (i.e., GM-CSF) have advanced the ability to use combination therapy or high-dose therapy with diminished complications such as febrile neutropenia. The individual growth factors and specifics of supportive use of these agents are described in detail in Chapter 37.

**BIBLIOGRAPHY**

Bernstein ID. Monoclonal antibodies to the myeloid stem cells: Therapeutic implications of CMA-676, a humanized anti-CD33 antibody calicheamicin conjugate. Leukemia, 2000, 14:474–475.

Larson RA, Sievers EL, Stadtmauer EA, et al. Final report of the efficacy and safety of gemtuzumab ozogamicin (mylotarg) in

The growth of a number of cancers is hormone dependent or regulated by hormones. Research in the fields of fertility, birth control, and menopause has yielded valuable hormone analogs and antagonists for the treatment of both breast and prostate cancer. These molecules interrupt the stimulatory axis created by systemic pools of androgens and estrogens, inhibit hormone production or binding to receptors, and ultimately block the complex expression of genes that promotes tumor growth and survival. These drugs have proven effective in extending survival and delaying or preventing tumor recurrence in breast cancer and prostate cancer.

**GLUCOCORTICOIDs**

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapter 42. Only the applications of these drugs in the treatment of neoplastic disease are considered here. Glucocorticoids act through their binding to a specific physiological receptor that translocates to the nucleus and induces anti-proliferative and apoptotic responses in sensitive cells. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, glucocorticoids are used as cytotoxic agents in the treatment of acute leukemia in children and malignant lymphoma in children and adults.

In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in \( \leq 30\% \) of children. Although these responses frequently are characterized by complete disappearance of all detectable leukemic cells from the peripheral blood and bone marrow, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. For these reasons, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and L-asparaginase. Glucocorticoids are a valuable component of curative regimens for other lymphoid malignancies, including Hodgkin’s disease, non-Hodgkin’s lymphoma, multiple myeloma, and chronic lymphocytic leukemia (CLL). Glucocorticoids are extremely helpful in controlling auto-immune hemolytic anemia and thrombocytopenia associated with CLL.

The glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Doses of 4-6 mg every 6 hours have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. Acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dexamethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Gradual tapering of the dosage may be undertaken if a clinical response to definitive antitumor therapy has been achieved. The antitumor effects of glucocorticoids are mediated by their binding to the glucocorticoid receptor, which activates a program of gene expression that leads to apoptosis.

Several glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 42). Prednisone, e.g., usually is administered orally in doses as high as 60-100 mg, or even higher, for the first few days and gradually reduced to levels of 20-40 mg/day. A continuous attempt should be made to establish the lowest possible dosage required to control the manifestations of the disease. These agents, when used chronically, exert a wide range of side effects, including glucose intolerance, immunosuppression, osteoporosis, and psychosis (see Chapter 42). Dexamethasone is the preferred agent for remission induction in multiple myeloma, usually in combination with melphalan, anthracyclines, vincristine, bortezomib, or thalidomide.

**PROGESTINS**

Progestational agents (see Chapters 40 and 66) have been used as second-line hormonal therapy for metastatic...
hormone-dependent breast cancer and in the management of endometrial carcinoma previously treated by surgery and radiotherapy. In addition, progestins stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and acquired immunodeficiency syndrome (AIDS). Although progesterone itself is poorly absorbed when given orally and must be used with an oil carrier when given intramuscularly, there are synthetic progesterone preparations.

Medroxyprogesterone (DEPO-PROVERA, others) can be administered intramuscularly in doses of 400-1000 mg weekly. An alternative and more commonly used oral agent is megestrol acetate (MEGACE, others; 40-320 mg daily in divided doses). Hydroxyprogesterone (not available in the U.S.) usually is administered intramuscularly in doses of 1000 mg one or more times weekly. Beneficial effects have been observed in approximately one-third of patients with endometrial cancer. The response of breast cancer to megestrol is predicted by both the presence of estrogen receptors (ERs) and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose dependent, with some patients demonstrating second responses following escalation of megestrol to 1600 mg/day. Clinical use of progestins in breast cancer has been largely superseded by the advent of tamoxifen and the aromatase inhibitors (AIs). Responses to progesterational agents also have been reported in metastatic carcinomas of the prostate and kidney.

**ESTROGENS AND ANDROGENS**

Discussions of the pharmacology of the estrogens and androgens appear in Chapters 40, 41, and 66. These agents are of value in certain neoplastic diseases, notably those of the prostate and mammary gland, because these organs are dependent on hormones for their growth, function, and morphological integrity. Carcinomas arising from these organs often retain the hormonal responsiveness of their normal counterpart tissues. By changing the hormonal environment of such tumors, it is possible to alter the course of the neoplastic process.

**Estrogens and Androgens in the Treatment of Mammary Carcinoma**

High doses of estrogen have long been recognized as effective treatment of breast cancer. However, serious side effects such as thromboembolism prompted the development of alternate strategies. Paradoxically, anti-estrogens also are effective, as seen by remission of disease achieved with oophorectomy. Thus, because of equivalent efficacy and more favorable side effects, anti-estrogens such as tamoxifen and the AIs have replaced estrogens or androgens for breast cancer. The presence of the ERs and progesterone receptors (PRs) on tumor tissue serves as a biomarker for response to hormonal therapy in breast cancer and identifies the subset of patients with a ≥60% likelihood of responding. The response rate to anti-estrogen treatment is somewhat lower in the subset of patients with tumors that are ER+ or PR+ but also positive for human epidermal growth factor receptors HER1/neu amplification. In contrast, ER-negative and PR-negative carcinomas do not respond to hormonal therapy.

Responses to hormonal therapy may not be apparent clinically or by imaging for 8-12 weeks. If the disease responds or remains stable on a given treatment, the medication typically should be continued until the disease progresses or unwanted toxicities develop. The duration of an induced remission in patients with metastatic disease averages 6-12 months but sometimes can last for many years.

**Anti-Estrogen Therapy**

Anti-estrogen approaches for the therapy of hormone receptor–positive breast cancer include the use of selective estrogen-receptor modulators (SERMs), selective estrogen-receptor downregulators (SERDs), and AIs (Table 63–1).

**Selective Estrogen-Receptor Modulators.** SERMs bind to the ER and exert either estrogenic or anti-estrogenic effects, depending on the specific organ. Tamoxifen citrate is the most widely studied anti-estrogenic treatment in breast cancer. The recent decline in breast cancer mortality in Western countries is believed to be partly due to the common use of tamoxifen, especially in the adjuvant setting. However, in addition to its estrogen antagonistic effects in breast cancer, tamoxifen also exerts estrogen agonist effects on non-breast tissues, thus influencing the overall therapeutic index of the drug. Therefore, several novel anti-estrogen compounds that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen have been developed. These novel anti-estrogens can be divided into tamoxifen analogs [e.g., toremifene (FARESTON), droloxifene, idoxifene], “fixed ring” compounds [e.g., raloxifene (EVISTA), lasofoxifene, arzoxifene, miproxifene, levormeloxifene, EM652], and the SERDs [e.g., fulvestrant (FASLODEX), SR 16234, and ZK 191703, the latter also termed “pure anti-estrogens”] (Howell et al., 2004a).

**Tamoxifen.** Tamoxifen was first synthesized in 1966 and initially developed as an oral contraceptive but instead was found to induce ovulation and proved to have anti-proliferative effects on estrogen-dependent breast cancer cell lines. For >3 decades, tamoxifen has been studied
for use in various stages of breast cancer. It has become a standard agent as a result of its anticancer activity and good tolerability profile. Tamoxifen is prescribed for the prevention of breast cancer in high-risk patients, for the adjuvant therapy of early-stage breast cancer, and for the therapy of advanced breast cancer. It also prevents the development of breast cancer in women at high risk based on a strong family history, prior nonmalignant breast pathology, or inheritance of the BRCA1 or BRCA2 genes.

**Mechanism of Action.** Tamoxifen is a competitive inhibitor of estradiol binding to the ER.

There are two subtypes of estrogen receptors: ERα and ERβ, which have different tissue distributions and can either homo- or heterodimerize. Binding of estradiol and SERMs to the estrogen-binding sites of the ERs initiates a change in conformation of the ER, dissociation of the ER from heat-shock proteins, and inhibition of ER dimerization. Dimerization facilitates the binding of the ER to specific DNA estrogen-response elements (EREs) in the vicinity of estrogen-regulated genes. Co-regulator proteins interact with the receptor to act as co-repressors or co-activators of gene expression. At least 50 transcriptional activating factors transduce and modulate the effects of estrogen on target genes. Differences in tissue distribution of ER subtypes, the function of co-regulator proteins, and the various transcriptional activating factors likely explain the variability of response to tamoxifen in hormone receptor–positive (ER+) breast cancer and its agonist and antagonist activities in noncancerous tissues. Other organs displaying agonist effects of tamoxifen include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer), the coagulation system (thromboembolism), bone metabolism (increase in bone mineral density [BMD]), and liver (alterations of blood lipid profile).

**Absorption, Fate, and Excretion.** The usual oral dose of tamoxifen in the U.S. is 20 mg once a day. Doses as high as 200 mg/day have been used in the therapy of breast cancer, but high doses are associated with retinal degeneration.

Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3-7 hours and steady-state levels being reached at 4-6 weeks. Metabolism of tamoxifen is complex and principally involves CYPs 3A4/5, and 2D6 in the formation of N-desmethyl tamoxifen, and CYP2D6 to form 4-hydroxytamoxifen, a more potent metabolite (Figure 63–1). Both metabolites can be further converted to 4-hydroxy-N-desmethyltamoxifen, which retains high affinity for the ER. The parent drug has a terminal t1/2 of 7 days; the t1/2 of N-desmethy1tamoxifen and 4-hydroxytamoxifen are significantly longer (14 days). After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal.

**Therapeutic Uses.** The usual oral dose of tamoxifen in the U.S. is 20 mg once a day.

Tamoxifen is used for the endocrine treatment of women with ER+ metastatic breast cancer or following primary tumor excision as adjuvant therapy. For the adjuvant treatment of premenopausal women, tamoxifen is given for 5 years, or in postmenopausal women, for 2 years, followed by an AI. In patients with high risk of recurrence, it may be sequenced after adjuvant chemotherapy. Tamoxifen is used in premenopausal women with ER+ tumors. Disease response rates are similar to those seen in postmenopausal patients. Alternative or additional anti-estrogen strategies in premenopausal women include oophorectomy or gonadotropin-releasing hormone analogs.

Premen, premenopausal; Postmen, postmenopausal; AI, aromatase inhibitor; PD, progressive disease; TAM, tamoxifen; ER, estrogen receptor.
The combination of tamoxifen and a gonadotropin-releasing hormone analog in premenopausal women (to reduce high estrogen levels resulting from tamoxifen effects on the gonadal-pituitary axis) yields better response rates and improved overall survival than either drug alone (Klijn et al., 2000).

The Nolvadex Adjuvant Trial Organization (NATO) study indicated an overall disease-free survival advantage for patients receiving tamoxifen versus placebo. Five years of adjuvant therapy with tamoxifen yielded superior results compared to 1 or 2 years of therapy (Swedish Breast Cancer Cooperative Group, 1996; Early Breast Cancer Trialists’ Collaborative Group, 1998). Therefore, although the optimal duration of tamoxifen has not been fully determined, randomized trials have demonstrated superiority of 5 years over shorter durations. One clinical trial evaluating the administration of tamoxifen for >5 years failed to show benefit of continued therapy and a trend toward worse outcomes in women who received tamoxifen therapy over a longer duration (Fisher et al., 2001).

Tamoxifen also has shown effectiveness (a 40-50% reduction in tumor incidence) in initial trials for preventing breast cancer in women at increased risk (Vogel et al, 2010). These studies were prompted by preclinical experiments showing prevention of tumors in animal models and also by the observation of reduced contralateral new primary breast tumors in women receiving adjuvant tamoxifen for early-stage breast cancer (Early Breast Cancer Trialists’ Collaborative Group, 1998; Fisher et al., 2001). Tamoxifen only reduces ER+ tumors without affecting ER-negative tumors, which contribute disproportionately to breast cancer mortality.

**Toxicity.** The common adverse reactions to tamoxifen include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, hair loss, nausea, and vomiting. These may occur in ≤25% of patients and rarely are sufficiently severe to require discontinuation of therapy. Menstrual irregularities, vaginal bleeding and discharge, pruritus vulvae, and dermatitis occur with increasing severity in postmenopausal women.

Tamoxifen also increases the incidence of endometrial cancer by 2- to 3-fold, particularly in postmenopausal women who receive 20 mg/day for ≥2 years. In general, tamoxifen-associated endometrial cancers are reported as low-grade and early-stage tumors. Standard practice guidelines from the National Comprehensive Cancer Network alert physicians to the evaluation of abnormal vaginal bleeding in women with an intact uterus.

Tamoxifen increases the risk of thromboembolic events, which increase with the age of a patient and also in the perioperative period. Hence, it often is recommended to discontinue tamoxifen prior to elective surgery. Because tamoxifen is associated with thromboembolism, some authorities suggest that the pretreatment evaluation of breast cancer patients should include screening for coagulation abnormalities (factor V Leiden, protein C, antithrombin III defects) and for a history of thromboembolic disease. Presence of these risk factors should lead to exclusion of women from treatment. Note that no clear causative association between the presence of the
factor V Leiden mutation and tamoxifen-induced thromboembolism has been found (Abramson, 2006).

Like estrogen, tamoxifen is a hepatic carcinogen in animals, although increases in primary hepatocellular carcinoma have not been reported in patients on the drug. Tamoxifen causes retinal deposits, decreased visual acuity, and cataracts in occasional patients, although the frequency of these changes is more common in patients on high doses of drug.

In addition to its ability to prevent recurrence or the development of primary breast cancer, tamoxifen has other end-organ benefits related to its partial estrogenic action. For example, it may slow the development of osteoporosis in postmenopausal women. Like certain estrogens, tamoxifen lowers total serum cholesterol, low-density-lipoprotein cholesterol, and lipoproteins and raises apolipoprotein A-I levels, potentially decreasing the risk of myocardial infarction.

**Tamoxifen Resistance.** Despite its benefits, initial or acquired resistance to tamoxifen frequently occurs (Moy and Goss, 2006). Polymorphisms in CYP2D6 that reduce its activity lead to lower plasma levels of 4-OH tamoxifen, a potent metabolite, and are associated with higher risks of disease relapse and a lower incidence of hot flashes (Goetz et al., 2005). CYP2D6 is responsible for the activation of tamoxifen to its active metabolite endoxifen (Figure 63–1). Cross-talk between the ER and HER2/neu pathway also has been implicated in tamoxifen resistance. The paired box 2 gene product (PAX2) has been identified as a crucial mediator of ER repression of ErbB2 by tamoxifen (Hurtado et al., 2008). Interactions between PAX2 and the ER co-activator AIB-1/SRC-3 determine tamoxifen response in breast cancer cells.

**Toremifene.** Toremifene (FARESTON) is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile (Figure 63–2). Toremifene is indicated for the treatment of breast cancer in women with tumors that are ER+ or of unknown receptor status.

In preclinical models, toremifene has activity against breast cancer cells in vitro and in vivo similar to that of tamoxifen. Unlike tamoxifen, however, toremifene is not hepatocarcinogenic in experimental animals. Two adjuvant studies have compared efficacy of these two agents and, in particular, long-term tolerability and safety, in early-stage breast cancer. There were no significant differences in efficacy or tolerability after a median follow-up of 4.4 years, and the number of subsequent second cancers was similar (Howell et al., 2004a). However, in vitro in a low-estrogen environment, toremifene has less estrogen agonist effect than tamoxifen. This may make toremifene more effective in combination with an AI than tamoxifen, and this possibility is the subject of ongoing clinical trials.

**Selective Estrogen Receptor Downregulators**

SERDs, unlike SERMs, are devoid of any estrogen agonist activity.

**Fulvestrant.** Fulvestrant (FASLODEX) is the first agent approved by the U.S. Food and Drug Administration (FDA) in the class of ER downregulators (Figure 63–2). This new class of hormone antagonists was hypothesized to have an improved safety profile, faster onset, and longer duration of action than the SERMs due to their pure ER antagonist activity (Robertson, 2002). Fulvestrant is approved for postmenopausal women with hormone receptor–positive metastatic breast cancer that has progressed on tamoxifen.

**Mechanism of Action.** Fulvestrant is a steroidal anti-estrogen that binds to the ER with an affinity >100 times that of tamoxifen. The drug inhibits the binding of estrogen but also alters the receptor structure such that the receptor is targeted for proteasomal degradation; fulvestrant also may inhibit receptor dimerization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells, both in vitro and in vivo; as a consequence of this ER downregulation, the drug abolishes ER-mediated transcription of estrogen-dependent genes (Howell et al., 2004b).

**Absorption, Fate, and Excretion.** Maximum plasma concentrations are reached ~7 days after intramuscular administration of fulvestrant and are maintained over 1 month. The plasma t½ is ~40 days.
Steady-state concentrations are reached after three to six monthly injections. There is extensive and rapid distribution and extensive protein binding of this highly lipophilic drug.

Various pathways, similar to those of steroid metabolism (oxidation, aromatic hydroxylation, and conjugation), extensively metabolize fulvestrant. CYP3A4 appears to be the only CYP isoenzyme involved in the metabolism of fulvestrant. However, several preclinical and clinical studies indicate that fulvestrant is not subject to CYP3A4 interactions that might affect its pharmacokinetics, safety, or efficacy; however, the effects of strong CYP3A4 inhibitors have not been studied. The putative metabolites possess no estrogenic activity, and only the 17-keto compound demonstrates a level of anti-estrogenic activity, which is ~22% that of fulvestrant. Less than 1% of the parent drug is excreted intact in the urine.

**Dosing.** The approved dosing for fulvestrant is 250 mg by intramuscular injection monthly. Because pharmacokinetic data have shown that it takes ~3-6 months for fulvestrant to reach steady-state levels with monthly dosing, alternative regimens have been studied. A loading dose regimen of 500 mg on day 0, 250 mg on days 14 and 28, and then 250 mg each month (McCormack and Sapunar, 2008) yields maximum fulvestrant concentrations in plasma an average of 12 days after the first dose and maintains those levels thereafter.

**Therapeutic Uses.** Fulvestrant is used in postmenopausal women as anti-estrogen therapy of hormone receptor–positive metastatic breast cancer after progression on first-line anti-estrogen therapy such as tamoxifen (Strasser-Weippl and Goss, 2004). Fulvestrant is at least as effective in this setting as the third-generation AI anastrozole.

Fulvestrant 250 mg (administered as a once-monthly 5-mL intramuscular injection) also has been compared with tamoxifen 20 mg (orally once daily) in a trial of postmenopausal women with ER+ and/or PR+ or ER/PR-unknown metastatic breast cancer who had not previously received endocrine or chemotherapy. In patients with ER+ and/or PR+ disease, there was no difference between fulvestrant and tamoxifen in time to disease progression or overall response rate (Vergote and Robertson, 2004). The long time to steady-state plasma levels for fulvestrant has brought into question the results of studies that lacked a loading dose, and trials are in progress to test the relative efficacy of giving an initial loading dose followed by regular monthly injections.

**Toxicity and Adverse Effects.** Fulvestrant generally is well tolerated, the most common adverse effects being nausea, asthenia, pain, vasodilation (hot flashes), and headache. The risk of injection site reactions, seen in ~7% of patients, is reduced by giving the injection slowly. In the study comparing anastrozole and fulvestrant in tamoxifen-resistant patients, the drugs had equivalent quality-of-life outcome measures (Vergote and Robertson, 2004).

**AROMATASE INHIBITORS**

Aromatase inhibitors (AIs; Figure 63–3) block the function of the aromatase enzyme that converts androgens to estrogens. AIs now are considered the standard of care for adjuvant treatment of postmenopausal women with hormone receptor–positive breast cancer, either as initial therapy or sequenced after tamoxifen.

![Figure 63–3. Structure of the main aromatase inhibitors and the natural substrate androstenedione.](image-url)
Aromatase activity is the product of the CYP19 gene. CYP19 is highly expressed in human placenta and in granulosa cells of ovarian follicles, where its expression depends on cyclical gonadotropin stimulation. Aromatase also is present, at lower levels, in several nonglandular tissues, including subcutaneous fat, liver, muscle, brain, and normal breast and in breast-cancer tissue. The aromatase enzyme is responsible for the conversion of adrenal androgens and gonadal androstenedione and testosterone to the estrogens, estrone (E1) and estradiol (E2), respectively (Figure 63–4). In postmenopausal women, this conversion is the primary source of circulating estrogens, while estrogen production in premenopausal women primarily is from the ovaries.

In postmenopausal women, AIs can suppress most peripheral aromatase activity, leading to profound estrogen deprivation. This strategy of estrogen deprivation of ER+ breast cancer cells stands in contrast to the ER antagonist activity that SERMs and SERDs exert.

Based on their sequence of development, AIs are classified as first, second, or third generation. In addition, they are further classified as type 1 (steroidal) or type 2 (nonsteroidal) AIs according to their structure and mechanism of action. Type 1 inhibitors are steroidal analogs of androstenedione (Figure 63–3). Androstenedione analogs bind covalently to the same site on the aromatase molecule, but unlike androstenedione, they bind irreversibly because of their conversion to reactive intermediates by aromatase. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme.

### Third-Generation Aromatase Inhibitors

The third-generation inhibitors, developed in the 1990s, include the type 1 steroidal agent exemestane and the type 2 nonsteroidal imidazoles anastrozole and letrozole. Currently, third-generation AIs are used as part of the standard of care for treatment of early-stage and advanced breast cancer in postmenopausal women.

**Anastrozole.** Anastrozole is a potent and selective triazole AI.

**Mechanism of Action.** Anastrozole, like letrozole, binds competitively and specifically to the heme of the CYP19. Anastrozole, 1 mg or 10 mg.

---

**Figure 63–4.** Steroid synthesis pathways. The enclosed area contains the pathways used by the adrenal glands and gonads. Enzymes are labeled in green, inhibitors in red. 11β: 11β-hydroxylase; 17,20: C-17,20-lyase (also CYP17); 17α: 17α-hydroxylase (CYP17); 17βR: 17β-reductase; 18: aldosterone synthase; 21: 21-hydroxylase; 3β: 3β-hydroxysteroid dehydrogenase; 5αR: 5α-reductase; A: aromatase.
administered once daily for 28 days, reduces total body androgen aromatization by 96.7% or 98.1%, respectively. In addition, anastrozole reduces aromatization in large, ER+ breast tumors.

Absorption, Fate, and Excretion. Anastrozole is absorbed rapidly after oral administration, reaching maximal plasma concentrations after 2 hours. Repeated dosing increases plasma concentrations of anastrozole, and steady-state is attained after 7 days. Although a high-fat breakfast slows absorption, the meal does not significantly alter the ultimate steady-state concentration achieved with multiple dosing. Anastrozole is metabolized by N-dealkylation, hydroxylation, and glucuronidation. The main metabolite of anastrozole is a triazole. In addition, several other metabolites with no pharmacological activity are formed. Less than 10% of the drug is excreted as the unmetabolized parent compound. The principal excretory pathway is via the liver and biliary tract. The elimination t½ is ~50 hours. The pharmacokinetics of anastrozole, which can be affected by drug interactions via the CYP system, are not altered by co-administration of tamoxifen or cimetidine (Köberle and Thürlimann, 2001).

Therapeutic Uses. Anastrozole (ARIMIDEX), 1 mg administered orally once daily, is approved for upfront adjuvant hormonal therapy in postmenopausal women with early-stage breast cancer and as treatment for advanced breast cancer. In early-stage breast cancer, anastrozole is significantly more effective than tamoxifen in delaying time to tumor recurrence and decreasing the odds of a primary contralateral tumor (Baum et al., 2002). In advanced breast cancer, the results of two large, randomized trials in postmenopausal women with disease progression while taking tamoxifen showed a statistically significant survival advantage with anastrozole 1 mg/day versus megestrol acetate 40 mg four times daily. In another phase III clinical trial on women with ER+ or PR+ metastatic breast cancer, anastrozole showed a statistically significant advantage over tamoxifen in median time to disease progression (Bonneterre et al., 2001).

Adverse Effects and Toxicity. Compared to tamoxifen, anastrozole has been associated with a significantly lower incidence of vaginal bleeding, vaginal discharge, hot flashes, endometrial cancer, ischemic cerebrovascular events, venous thromboembolic events, and deep venous thrombosis, including pulmonary embolism. Anastrozole is associated with a higher incidence of musculoskeletal disorders and fracture than tamoxifen. In the advanced disease setting, anastrozole is as well tolerated as megestrol and causes less weight gain. In addition, anastrozole is as well tolerated as tamoxifen, with a low rate of withdrawal due to drug-related adverse events (2%).

The estrogen depletion caused by anastrozole and other AIs raises the concern of bone loss. Compared with tamoxifen, treatment with anastrozole results in significantly lower BMD in the lumbar spine and total hip (Eastell et al., 2008). Bisphosphonates prevent AI-induced bone loss in postmenopausal women (Bruksky et al., 2007).

Anastrozole has no clinically significant effect on adrenal glucocorticoid or mineralocorticoid synthesis in postmenopausal women. Anastrozole also does not affect ACTH-stimulated release of cortisol or aldosterone, plasma concentrations of FSH or LH in postmenopausal women, or TSH levels.

Letrozole. Letrozole is approved for upfront adjuvant hormonal therapy in postmenopausal women with early-stage breast cancer and as treatment for advanced breast cancer.

Actions. In postmenopausal women with primary breast cancer, letrozole inhibits estrogen aromatization by 99% and reduces local aromatization within the tumors. The drug has no significant effect on the synthesis of adrenal steroids or thyroid hormone and does not alter levels of a range of other hormones. Letrozole also reduces cellular markers of proliferation to a significantly greater extent than tamoxifen in human estrogen-dependent tumors that overexpress HER1 and HER2/neu.

Letrozole increases the levels of bone resorption markers in healthy postmenopausal women and in those with a history of breast disease but without current active disease. Letrozole has not demonstrated a consistent effect on serum lipid levels in healthy women or postmenopausal women with breast cancer.

Absorption, Fate, and Excretion. Letrozole is rapidly absorbed after oral administration, and maximum plasma levels are reached ~1 hour after ingestion. Letrozole has a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2-6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive carbinol metabolite mainly via the kidneys. The total body clearance is low (2.2 L/h); the elimination t½ is ~41 hours.

Therapeutic Uses. The usual dose of letrozole (FEMARA) is 2.5 mg administered orally once daily. In early-stage breast cancer, extending adjuvant endocrine therapy with letrozole (beyond the standard 5-year period of tamoxifen) improves disease-free survival compared with placebo and improves overall survival in the subset of patients with positive axillary nodes (Goss et al., 2004). Furthermore, upfront letrozole is significantly more effective than upfront tamoxifen in terms of time to tumor recurrence and odds of a primary contralateral tumor (Thürlimann et al., 2005).

In advanced breast cancer, letrozole is superior to tamoxifen as first-line treatment; time to disease progression is significantly longer and objective response rate is significantly greater with letrozole, but median overall survival is similar between groups (Mouridsen et al., 2003). As second-line therapy of advanced breast cancer that has progressed on tamoxifen or after oophorectomy, letrozole has efficacy equal to that of anastrozole and similar to or better than that of megestrol.

Adverse Effects and Toxicity. Letrozole is well tolerated; the most common treatment-related adverse events are hot flashes, nausea, and hair thinning. In patients with tumors that progressed on anti-estrogen therapy, letrozole was tolerated at least as well as, or better than, megestrol. In the trial of extended adjuvant therapy, adverse events reported more frequently with letrozole than placebo were hot flashes, arthralgia, myalgia, and arthritis, but patients discontinued letrozole no more frequently than placebo in this double-blind trial. Letrozole has a low overall incidence of cardiovascular side effects (Mouridsen et al., 2007).

A greater number of new diagnoses of osteoporosis occurred among women receiving letrozole. Compared with tamoxifen, the use of upfront letrozole results in significantly more clinical fractures. Bisphosphonates prevent letrozole-induced bone loss in postmenopausal women (Bruksky et al., 2007).

Exemestane. Exemestane (AROMASIN) is a more potent, orally administered analog of the natural aromatase substrate, androstenedione, and lowers estrogen levels more effectively than does its predecessor, formestane.
Mechanism of Action. In contrast to the reversible competitive inhibitors of aromatase (anastrozole and letrozole), exemestane irreversibly inactivates the enzyme and is referred to as a “suicide substrate.” Doses of 25 mg/day inhibit aromatase activity by 98% and lower plasma estrone and estradiol levels by ~90% in postmenopausal women.

Absorption, Fate, and Excretion. Exemestane is rapidly absorbed from the GI tract, reaching maximum plasma levels after 2 hours. Its absorption is increased by 40% after a high-fat meal. Exemestane is highly protein bound in plasma and has a terminal t1/2 of ~24 hours. It is extensively metabolized in the liver to inactive metabolites. A key metabolite, 17-hydroxyexemestane, which is formed by reduction of the 17-oxo group via 17-β-hydroxysteroid dehydrogenase, has weak androgenic activity, which also could contribute to antitumor activity. The elimination t1/2 of the parent drug is 24 hours. Although significant quantities of active metabolites are excreted in the urine, no dosage adjustments are recommended in patients with renal dysfunction.

Therapeutic Uses. Exemestane (AROMASIN), 25 mg administered orally once daily, is approved for disease progression in postmenopausal women who completed 2-3 years of adjuvant tamoxifen based on results from a randomized clinical trial in women with ER+ breast cancer. Women who had completed 2-3 years of adjuvant tamoxifen were randomized to complete a total of 5 years of adjuvant treatment with tamoxifen or exemestane (Coombes et al., 2004). The unadjusted hazard ratio in the exemestane group versus the tamoxifen group was 0.68, representing a 32% reduction in risk and corresponding to an absolute benefit in terms of disease-free survival of 4.7% at 3 years after randomization. Overall survival was not significantly different in the two groups.

In advanced breast cancer, exemestane improves time to disease progression compared with tamoxifen as first-line treatment (Paridaens et al., 2008). Exemestane also has been evaluated in a phase III trial against megestrol in women with disease progressing on prior anti-estrogen therapy. Patients receiving exemestane had a similar response rate but improved time to disease progression and time to treatment failure and had a longer duration of survival compared with those taking megestrol acetate. Responses to treatment also have been reported in women with disease progressing on prior nonsteroidal AIs.

Clinical Toxicity. Exemestane generally is well tolerated. Discontinuations due to toxicity are uncommon (2.8%). Hot flashes, nausea, fatigue, increased sweating, peripheral edema, and increased appetite have been reported. In the trial comparing exemestane to tamoxifen in early-stage breast cancer, exemestane caused more frequent arthralgia and diarrhea but less frequent vaginal bleeding and muscle cramps. Visual disturbances and clinical fractures were more common with exemestane (Coombes et al., 2004).

Whether exemestane negatively affects long-term bone metabolism remains to be determined. The drug has less androgenic activity than formestane but otherwise has a similar toxicity profile.

HORMONE THERAPY IN PROSTATE CANCER

Androgens stimulate the growth of normal and cancerous prostate cells. The critical role of androgens for prostate cancer growth was established in 1941 and led to the awarding of a Nobel Prize in 1966 to Dr. Charles Huggins (Huggins and Hodges, 1941; Huggins et al., 1941). These findings established androgen deprivation therapy as the mainstay of treatment for patients with advanced prostate cancer.

Localized prostate cancer frequently is curable with surgery or radiation therapy. However, when distant metastases are present, hormone therapy is the primary treatment. Standard approaches either reduce the concentration of endogenous androgens or inhibit their effects. Androgen deprivation therapy (ADT) is the standard first-line treatment (Sharifi et al., 2005). ADT is accomplished via surgical castration (bilateral orchiectomy) or medical castration (using gonadotropin-releasing hormone [GnRH] agonists or antagonists). Other hormone therapy approaches are used in second-line treatment and include anti-androgens, estrogens, and inhibitors of steroidogenesis (see the discussion later in this section).

ADT is considered palliative, not curative, treatment (Walsh et al., 2001). ADT can alleviate cancer-related symptoms, produce objective responses, and normalize serum prostate-specific antigen (PSA) in >90% of patients. ADT provides important quality-of-life benefits, including reduction of bone pain and reduction of rates of pathological fracture, spinal cord compression, and ureteral obstruction (Huggins et al., 1941). It also prolongs survival (Sharifi et al., 2005).

The duration of response to ADT for patients with metastatic disease is variable but typically lasts 14-20 months (Crawford et al., 1989; Eisenberger et al., 1998). Disease progression despite ADT signifies a castration-resistant state. However, many men respond to secondary hormonal manipulations. Despite castrate levels of testosterone, low-level androgen (DHEA) synthesis from the adrenal glands may permit the continued androgen-driven growth of prostate cancer cells. Therefore, anti-androgens (which competitively bind the androgen receptor [AR]), inhibitors of steroidogenesis (such as ketoconazole), and estrogens frequently are employed as secondary hormone therapies. Unlike the nearly universal response to ADT, only the minority of patients experience symptomatic relief or tumor regression when treated with secondary hormone therapies. When patients become refractory to further hormonal therapies, their disease is considered androgen independent. In these patients, the next treatment option usually is cytotoxic chemotherapy; docetaxel has a proven survival benefit, with average overall survival of 18 months (Petrylak et al., 2004; Tannock et al., 2004).

Common side effects of androgen deprivation include vaso-motor flushing, loss of libido, impotence, gynecomastia, fatigue, anemia, weight gain, decreased insulin sensitivity, altered lipid profiles, osteoporosis and fractures, and loss of muscle mass (Saylor and Smith, 2009). The spectrum of side effects of GnRH agonists is distinct from the metabolic syndrome (Smith, 2008). ADT is associated with an increased risk of diabetes and coronary heart disease.
(Keating et al., 2006). However, retrospective analyses have not revealed a compelling increase in cardiovascular mortality due to GnRH agonists (Efstathiou et al., 2008; Efstathiou et al., 2009). Skeletal-related events due to ADT, including fractures, may be mitigated by bisphosphonate therapy, such as zoledronic acid (ZOMETA) (Saad et al., 2002) or inhibitors of osteoclast activation, such as denosumab (Smith et al., 2009).

Anti-androgens, when compared with GnRH agonists, cause more gynecomastia, mastodynia, and hepatotoxicity but less vaso-motor flushing, and loss of bone mineral density (BMD) (McLeod, 1997). Estrogens cause a hypercoagulable state and increase cardiovascular mortality in prostate cancer patients and are no longer standard treatment options (Byar and Corle, 1988).

**Gonadotropin-Releasing Hormone Agonists and Antagonists**

The biosynthesis of androgens, primarily in the testes and adrenals, is described in Chapter 41, and the regulation of Leydig cell synthetic activity by the hypothalamic–pituitary axis is considered there as well. Pharmacological castration was first reported in 1982 (Tolis et al., 1982). In the U.S., the most common form of ADT involves chemical suppression of the pituitary gland with GnRH agonists. Synthetic GnRH analogs (Table 63–2) have greater receptor affinity and reduced susceptibility to enzymatic degradation than the naturally occurring GnRH molecule and are 100-fold more potent (Schally et al., 1980). GnRH (also termed luteinizing hormone–releasing hormone, LHRH) agonists bind to GnRH receptors on pituitary gonadotropin-producing cells, causing an initial release of both LH and FSH and a subsequent increase in testosterone production from testicular Leydig cells. After ~1 week of therapy, GnRH receptors are downregulated on the gonadotropin-producing cells, causing a decline in the pituitary response (Conn and Crowley, 1991). The fall in serum LH leads to a decrease in testosterone production to castrate levels within 3-4 weeks of the first treatment. Subsequent treatments maintain testosterone at castrate levels (Limonta et al., 2001).

During the transient rise in LH, the resultant testosterone surge may induce an acute stimulation of prostate cancer growth and a “flare” of symptoms from metastatic deposits. Patients may experience an increase in bone pain or obstructive bladder symptoms lasting for 2-3 weeks (Waxman et al., 1985). The flare phenomenon can be effectively counteracted with concurrent administration of 2-4 weeks of oral anti-androgen therapy, which may inhibit the action of the increased serum testosterone levels (Kuhn et al., 1989).

Current depot forms of GnRH agonists are the result of progressive improvements in drug development. GnRH agonists in common use include leuprolide (LUPRON, others), goserelin (ZOLADEX), triptorelin (Trelstar), histrelin (Vantas), and buserelin (Suprefact; not available in the U.S.). Long-acting preparations of both leuprolide and goserelin are available in doses that are approved for 3-, 4-, and 6-month administrations.

Leuprolide and goserelin have been compared with orchietomy in randomized trials. A meta-analysis of 10 such randomized trials found equivalence in overall survival, progression-related outcomes, and time to treatment failure (Kaisary et al., 1991; Seidenfeld et al., 2000; Turkes et al., 1987; Vogelzang et al., 1995).

Combined androgen blockade (CAB) requires administration of ADT with an anti-androgen. The theoretical advantage is that the GnRH agonist will deplete testicular androgens, while the anti-androgen component competes at the receptor with residual androgens made by the adrenal glands. CAB provides maximal relief of androgen stimulation. Numerous large trials have compared CAB with ADT monotherapy, with variable results. Several meta-analyses of these trials suggest a benefit for CAB in 5-year survival but not at earlier time points (Samson et al., 2002; Schmitt et al., 1999). Toxicity and costs associated with CAB are higher than with ADT alone.

GnRH antagonists have been developed to suppress testosterone while avoiding the flare phenomenon of GnRH agonists. Other than avoidance of the initial flare, GnRH antagonist therapy offers no apparent advantage compared with GnRH agonists. The first available GnRH antagonist, abarelix (Plenaxis), rapidly achieves medical castration (Trachtenberg et al., 2002). However, local reactions and anaphylaxis have discouraged its clinical acceptance and have led to its withdrawal from the market. A second GnRH antagonist, degarelix, is not associated with systemic allergic reactions and is approved for prostate cancer in the U.S. (Klotz et al., 2008).

**Anti-Androgens**

Anti-androgens bind to ARs and competitively inhibit the binding of testosterone and dihydrotestosterone. Unlike castration, anti-androgen therapy by itself does not decrease LH production; therefore, testosterone levels are normal or increased. Men treated with anti-androgen monotherapy maintain some degree of potency and libido and do not have the same spectrum of side effects seen with castration.

Currently, anti-androgen monotherapy is not indicated as first-line treatment for patients with advanced prostate cancer. Numerous studies have examined the effectiveness of anti-androgens compared with surgical castration, GnRH agonists, or treatment with diethylstilbestrol (DES; discontinued in the U.S.). A meta-analysis of eight trials indicated that nonsteroidal anti-androgens had equivalent overall survival relative to castration, although the association between nonsteroidal anti-androgens and decreased survival approached statistical significance (Seidenfeld et al., 2000). Anti-androgens most commonly are used in clinical practice as secondary hormone therapy or in CAB.

Available Anti-Androgens. Anti-androgens are classified as steroidal, including cyproterone and megestrol, or non-steroidal, including flutamide, bicalutamide (CASODEX, others), and nilutamide (NILADRON) (Figure 63–5). Cyproterone is associated with liver toxicity and has inferior efficacy compared with other forms of ADT (Schroder et al., 1999; Thorpe et al., 1996). Cyproterone is used in the E.U. for treatment of men with metastatic prostate cancer but is not available in the U.S. Neither bicalutamide nor flutamide is approved as monotherapy at any dose for treatment of prostate cancer in the U.S.

Mechanism of Action of Nonsteroidal Anti-Androgens. The non-steroidal anti-androgens are taken orally and inhibit ligand binding and consequent AR translocation from the cytoplasm to the nucleus.

Flutamide. Flutamide has a t₁/₂ of 5 hours and therefore is given as a 250-mg dose every 8 hours. Its major metabolite, hydroxyflutamide, is biologically active; there are at least five other minor metabolites (Luo et al., 1997). The common side effects include diarrhea, breast tenderness, and nipple tenderness. Less commonly, nausea, vomiting, and hepatotoxicity occur (Wysowski and Fourcroy, 1996; Wysowski et al., 1993).

Bicalutamide. Bicalutamide (CASODEX, others) has a serum t₁/₂ of 5-6 days and is taken once daily at a dosage of 50 mg/day when given with a GnRH agonist. Both enantiomers of bicalutamide undergo glucuronidation to inactive metabolites, and the parent compounds and metabolites are eliminated in bile and urine. The elimination t₁/₂ of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency.

Bicalutamide is well tolerated at higher doses with rare additional side effects. Daily bicalutamide (either low or high dose) is significantly inferior compared with surgical or medical castration (Bales and Chodak, 1996; Tyrrell et al., 1998). Although the ease of administration and favorable toxicity are attractive, concerns about inferior survival have limited the use of bicalutamide monotherapy.

Nilutamide. Nilutamide (NILADRON) is a second-generation anti-androgen with an elimination t₁/₂ of 45 hours, allowing once-daily administration at 150 mg/day. Common side effects include mild nausea, alcohol intolerance (5-20%), and diminished ocular adaptation to darkness (25-40%); rarely, interstitial pneumonitis occurs (Decensi et al., 1991; Pfitzenmeyer et al., 1992). It is metabolized to five known products that are all excreted in the urine. Nilutamide appears to offer no benefit over the first-generation drugs above and has the least favorable toxicity profile (Dole and Holdsworth, 1997).

Estrogens. High estrogen levels can reduce testosterone to castrate levels in 1-2 weeks via negative feedback on the hypothalamic–pituitary axis. Estrogen also may compete with androgens for steroid hormone receptors and may thereby exert a cytotoxic effect on prostate cancer cells (Landström et al., 1994). Numerous estrogenic compounds have been tested in prostate cancer. Estrogens are associated with increased myocardial infarctions, strokes, and pulmonary emboli and increased mortality, as well as impotence, loss of libido, and lethargy. One benefit is that estrogens prevent bone loss (Scherr et al., 2002).

Most early studies on the use of estrogens used DES and were conducted between 1960 and 1975 by the Veterans Administration Cooperative Urological Research Group (VACURG). Two studies compared orchiectomy to different doses of DES to placebo (Byar, 1973; Byar and Corle, 1988). DES was as effective as orchiectomy for metastatic prostate cancer but was associated with an increase in cardiovascular events, including myocardial infarction, cerebrovascular accident, and pulmonary embolism (Bailar and Byar, 1970; Byar, 1973; de Voogt et al., 1986; Waymont et al., 1992). Due to its cardiovascular toxicity and unacceptable mortality at any dose level, DES is not indicated for prostate cancer treatment and is not available in North America for that purpose. Other synthetic estrogens have a similar associated cardiovascular toxicity to that of DES but without the efficacy. These compounds include conjugated estrogens (PREMARIN, others), ethinyl estradiol, medroxyprogesterone acetate (PROVERA, others), and chlorotrianisene (no longer marketed in the U.S.).

Inhibitors of Steroidogenesis. In the castrate state, AR signaling, despite low steroid levels, supports continued prostate cancer growth. AR signaling may occur due to androgens produced from nongonadal sources, AR gene mutations, or AR gene amplification. Nongonadal sources of androgens include the adrenal glands and the prostate cancer cells themselves (Figure 63–4). Androstenedione, produced by the adrenal glands, is converted to testosterone in peripheral tissues and tumors (Stanbrough et al., 2006). Intratumoral de novo androgen synthesis also may provide sufficient androgen for AR-driven cell proliferation (Montgomery et al., 2008).

Ketoconazole is an antifungal agent that interrupts the synthesis of an essential fungal membrane sterol. In an unrelated action,
ketoconazole inhibits both testicular and adrenal steroidogenesis by blocking CYPs, primarily CYP17 (17α-hydroxylase). Ketoconazole is administered off label as secondary hormone therapy to reduce adrenal androgen synthesis in castration-resistant prostate cancer (Small et al., 2004). Ketoconazole causes significant diarrhea and hepatic enzyme elevations that limit its use as initial hormone therapy. Consequent poor patient adherence deters from its efficacy. Ketoconazole is given in doses of 200 mg or 400 mg three times daily. Hydrocortisone supplementation is co-administered to compensate for inhibition of adrenal steroidogenesis at the 400-mg dose level. A related compound, itraconazole, inhibits the activation of Smoothened (SMO), a component of the Hedgehog (Hh) signaling pathway (Kim et al., 2010), which is overly active in certain cancers. Thus, this class of antifungal agents may act by several distinct mechanisms and prove useful in treating other cancers.

Abiraterone is an irreversible inhibitor of both 17α-hydroxylase and C-17,20-lyase CYP17 activity, with greater potency and selectivity compared with ketoconazole. The parent compound, abiraterone acetate, is orally bioavailable and has been well tolerated in castration-resistant prostate cancer patients as secondary hormone therapy in phase I and II studies (Attard et al., 2009; Attard et al., 2008). With continuous administration, abiraterone increases ACTH levels, resulting in mineralocorticoid excess. Therefore, abiraterone acetate is administered with daily low-dose glucocorticoids, such as prednisone. Ongoing phase III trials will evaluate the efficacy and appropriate timing of abiraterone therapy for prostate cancer patients.

OVERVIEW OF OCULAR ANATOMY, PHYSIOLOGY, AND BIOCHEMISTRY

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers; as a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties. Because of its anatomical isolation, the eye offers a unique, organ-specific pharmacological laboratory in which to study the autonomic nervous system and the effects of inflammation and infectious diseases. No other organ in the body is so readily accessible or as visible for observation; however, the eye also presents some unique challenges as well as opportunities for drug delivery (Robinson, 1993).

Extraocular Structures

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 64–1). In the orbit, connective (i.e., Tenon’s capsule) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or globe). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon’s, and retrobulbar injections.

The eyelids serve several functions. Foremost, their dense sensory innervation and eyelashes protect the eye from mechanical and chemical injuries. Blinking, a coordinated movement of the orbicularis oculi, levator palpebrae, and Müller’s muscles, serves to distribute tears over the cornea and conjunctiva. In humans, the average blink rate is 15-20 times/minute. The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the fornix, located superiorly and inferiorly behind the upper and lower lids, respectively. Topical medications usually are placed in the inferior fornix, also known as the inferior cul-de-sac.

The lacrimal system consists of secretory glandular and excretory ductal elements (Figure 64–2). The secretory system is composed of the main lacrimal gland, which is located in the temporal outer portion of the orbit, and accessory glands, also known as the glands of Krause and Wolfring, located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 64–1 and Chapter 8). The parasympathetic innervation is clinically relevant because a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (Chapter 15), antihistamines (Chapter 32), and drugs used in the management of Parkinson disease (Chapter 22). Located just posterior to the eyelashes are meibomian glands, which secrete oils that retard evaporation of the tear film. Abnormalities in gland function, as in acne rosacea and meibomitis, can greatly affect tear film stability.

Conceptually, tears constitute a trilaminar lubrication barrier covering the conjunctiva and cornea. The anterior layer is composed primarily of lipids secreted by the meibomian glands. The middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands, constitutes ~98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucins produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea.

The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids (Figure 64–2). With blinking, tears
enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nose. The nose is lined by a highly vascular mucosal epithelium; consequently, topically applied medications that pass through this nasolacrimal system have direct access to the systemic circulation.

Ocular Structures
The eye is divided into anterior and posterior segments (Figure 64–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, canal of Schlemm (Schlemm’s canal), iris, lens, zonule, and ciliary body. The posterior segment includes the vitreous, retina, choroid, sclera, and optic nerve.

Anterior Segment
Cornea. The cornea is a transparent and avascular tissue organized into five layers: epithelium, Bowman’s membrane, stroma, Descemet’s membrane, and endothelium (Figure 64–3B). Representing an important barrier to foreign matter, including drugs, the hydrophobic...
epithelial layer comprises five to six cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman’s membrane, a layer of collagen fibers. Constituting ~90% of the corneal thickness, the stroma, a hydrophilic layer, is uniquely organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet’s membrane, the basement membrane of the corneal endothelium. Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal integrity by active transport processes and serve as a hydrophilic barrier. Hence, drug absorption across the cornea requires penetration of the trilaminar hydrophilic–hydrophilic–hydrophilic domains of the various anatomical layers.

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1-2 mm wide) called the limbus. Limbal structures include the conjunctival epithelium, which contains the corneal epithelial stem cells, Tenon’s capsule, episclera, corneoscleral stroma, canal of Schlemm, and trabecular meshwork (Figure 64–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds ~250 μL of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, which holds ~50 μL of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

### Aqueous Humor Dynamics and Regulation of Intraocular Pressure

Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, and into the anterior chamber and leaves the eye primarily by the trabecular meshwork and canal of Schlemm. From the canal of Schlemm, aqueous humor drains into an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80-95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanoids (see “Glaucoma” and Chapter 33).

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: open-angle glaucoma, which is by far the most common form of glaucoma in the U.S., and angle-closure glaucoma. Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production and/or increasing aqueous outflow. The preferred management for angle-closure glaucoma is surgical iridectomy, by either laser or incision, but short-term medical management may be necessary to reduce the acute intraocular pressure (IOP) elevation and to clear the cornea prior to surgery. Long-term IOP reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork. In anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing through the pupil from the posterior chamber to the anterior chamber. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing the iris base to be pushed against the angle wall, thereby covering the trabecular meshwork and closing the filtration angle and markedly elevating the IOP. The result is known as an acute attack of pupillary-block angle-closure glaucoma. Unfortunately, individuals with susceptible angles usually are not aware of a risk of angle-closure glaucoma. Furthermore, drug warning labels do not always specify the type of glaucoma for which this rare risk exists. Thus, unwarranted concern is raised among patients who have open-angle glaucoma who need not be concerned about taking these drugs.

### Iris and Pupil

The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and

¹Although acetylcholine and choline acetyltransferase are abundant in the corneal epithelium of most species, the function of this neurotransmitter in this tissue is unknown. ²The ciliary epithelium also is the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium. ³Although β₂ adrenergic receptors mediate ciliary body smooth muscle relaxation, there is no clinically significant effect on accommodation.
parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see “Distribution”). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 64–4), which causes mydriasis (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which, when stimulated, causes miosis (constriction). The use of pharmacological agents to dilate normal pupils (i.e., for clinical purposes such as examining the ocular fundus) and to evaluate the pharmacological response of the pupil (e.g., unequal pupils, or anisocoria, seen in Horner’s syndrome or Adie’s pupil) is summarized in Table 64–2. Figure 64–5 provides a flowchart for the diagnostic evaluation of anisocoria.

Ciliary Body. The ciliary body serves two very specialized roles in the eye:

- secretion of aqueous humor by the epithelial bilayer
- accommodation by the ciliary muscle

The anterior portion of the ciliary body, called the pars plicata, is composed of 70-80 ciliary processes with intricate folds. The posterior portion is the pars plana. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonule suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as accommodation, permits focusing on near objects and may be pharmacologically blocked by muscarinic cholinergic antagonists, through the process called cycloplegia. Contraction of the ciliary muscle also puts traction on the scleral spur and hence widens the spaces within the trabecular meshwork. This latter effect accounts for at least some of the IOP-lowering effect of both directly acting and indirectly acting parasympathomimetic drugs.

Lens. The lens, a transparent biconvex structure, is suspended by zonules, specialized fibers emanating from the ciliary body. The lens is ~10 mm in diameter and is enclosed in a capsule. The bulk of the
The lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a cataract.

**Posterior Segment.** Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye’s posterior pole is particularly challenging.

**Sclera.** The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is

Topically applied ophthalmic drugs unless otherwise noted. “This percentage of pilocarpine is not commercially available and usually is prepared by the physician administering the test or by a pharmacist. This test also requires that no prior manipulation of the cornea (i.e., tonometry for measuring intraocular pressure or testing corneal sensation) be done so that the normal integrity of the corneal barrier is intact. Normal pupils will not respond to this weak dilution of pilocarpine; however, an Adie’s pupil manifests a denervation supersensitivity and is, therefore, pharmacodynamically responsive to this dilute cholinergic agonist.

Figure 64–5. Anisocoria evaluation flowsheet. (Adapted with permission from Thompson and Pilley, 1976. Copyright © Elsevier.)
covered by an episcleral vascular coat, by Tenon’s capsule, and by the conjunctiva. The tendons of the six extraocular muscles insert collagen fibers into the superficial scleral. Numerous blood vessels pierce the sclera through emissaria to both supply and drain the choroid, ciliary body, optic nerve, and iris.

Inside the scleral shell, the vascular choroid nourishes the outer retina by a capillary system in the choriocapillaris. Between the outer retina and the choriocapillaris lie Bruch’s membrane and the retinal pigment epithelium, whose tight junctions provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

**Retina.** The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels. Of all structures within the eye, the neurosensory retina has been the most widely studied. The unique organization and biochemistry of the photoreceptors have provided a superb system for investigating signal transduction mechanisms. The wealth of information about rhodopsin has made it an excellent model for the G protein–coupled signal transduction. Such detailed understanding holds promise for targeted therapy for some of the hereditary retinal diseases.

**Vitreous.** Approximately 80% of the eye’s volume is the vitreous, which is a clear medium containing collagen type II, hyaluronic acid, proteoglycans, and a variety of macromolecules, including glucose, ascorbic acid, amino acids, and a number of inorganic salts. Glutamate in the vitreous has been suspected to have a possible relationship to glaucoma. The ganglion cells appear to die in glaucoma via a process of apoptosis (Quigley et al., 1995; Wax et al., 1998), and glutamate has been shown to induce apoptosis via NMDA receptor excitotoxicity (Sucher et al., 1997). Elevated glutamate levels have been noted in experimental animal models (Dreyer et al., 1996; Yoles and Schwartz, 1998) and in humans with glaucoma (Dreyer et al., 1996), although this has been questioned (Levkovitch-Verbin et al., 2002). Memantine, a noncompetitive NMDA receptor antagonist (Vorwerk et al., 1996; Seki and Lipton, 2008; Ju et al., 2008), is currently being investigated clinically as a possible treatment for glaucoma.

**Optic Nerve.** The optic nerve is a myelinated nerve conducting the retinal output to the central nervous system (CNS). It is composed of:

- an intraocular portion, which is visible as the optic disk in the retina
- an intraorbital portion
- an intracanalicular portion
- an intracranial portion

The nerve is ensheathed in meninges continuous with the brain. At present, pharmacological treatment of optic neuropathies usually is based on management of the underlying disease. For example, nonarteritic ischemic optic neuropathy might be treated with intravitreal glucocorticoids (Kaderli et al., 2007) and optic neuritis may be best treated with intravenous glucocorticoids (Atkins et al., 2007; Beck and Gal, 2008; Volpe, 2008). Unfortunately, these guidelines have not yet become routine clinical practice (Biousse et al., 2009). Glaucomatous optic neuropathy is medically managed by decreasing IOP.

### PHARMACOKINETICS AND TOXICOLOGY OF OCULAR THERAPEUTIC AGENTS

#### Drug-Delivery Strategies

Properties of varying ocular routes of administration are outlined in Table 64–3. A number of delivery systems have been developed for treating ocular diseases. Most ophthalmic drugs are delivered in solutions, but...
for compounds with limited solubility, a suspension form facilitates delivery.

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. Prolonging the time in the cul-de-sac facilitates drug absorption. Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. The polymers used include cellulosic ethers, polyvinyl alcohol, carbopol, polyacrylamide, polymethylvinyl ether–maleic anhydride, poloxamer 407, and pluronic acid. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the ganciclovir intravitreal implant, provide a zero-order rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a finite period of time rather than as a bolus. This surgical implant has been used to deliver cytomegalovirus (CMV) medication in proximity to the retinal infection (Marx et al., 1996). The intent is to deliver a sustained dose of medication over several months with reduced spikes in drug delivery (Kunou et al., 2000) independent of patient compliance.

Pharmacokinetics

Classical pharmacokinetic theory based on studies of systemically administered drugs (see Chapter 2) does not fully apply to all ophthalmic drugs (Kaur and Kanwar, 2002). Although similar principles of absorption, distribution, metabolism, and excretion determine the fate of drug disposition in the eye, alternative routes of drug administration, in addition to oral and intravenous routes, introduce other variables in compartmental analysis (Table 64–3 and Figure 64–6). Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon’s, and retrobulbar routes (Figure 64–1 and Table 64–3).

For example, anesthetic agents commonly are administered by injection for surgical procedures, and antibiotics and glucocorticoids also may be injected to enhance their delivery to local tissues. The antimetabolite 5-fluorouracil and the DNA alkylating agent mitomycin C may be extemporaneously compounded for subconjunctival administration to retard the fibroblast proliferation related to scarring after glaucoma surgery. Mitomycin C also can be applied to the cornea to prevent scarring after corneal surgery. Intraocular (i.e., intravitreal) injections of antibiotics are considered in instances of endophthalmitis, a severe intraocular infection. The sensitivities of the organisms to the antibiotic and the retinal toxicity threshold may be nearly the same for some antibiotics; hence, the antibiotic dose injected intravitreally must be carefully titrated. Intraocular inserts are used to treat intraocular viral infections. The ganciclovir implant is indicated to treat CMV retinitis in patients with acquired immunodeficiency syndrome (AIDS).

Unlike clinical pharmacokinetic studies on systemic drugs, where data are collected relatively easily from blood samples, there is significant risk in obtaining tissue and fluid samples from the human eye. Consequently, animal models, frequently rabbits, are studied to provide pharmacokinetic data on ophthalmic drugs.

Absorption. After topical instillation of a drug, the rate and extent of absorption are determined by the time the drug remains in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva (Lee, 1993). A drug’s residence time may be prolonged by changing its formulation. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs (HERRICK LACRIMAL PLUG, PUNCTUM PLUG) or cautery. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver, and consequently, significant systemic side effects may be caused by topical medications, especially when used chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 64–6.
Transcorneal and transconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The time period between drug instillation and its appearance in the aqueous humor is defined as the lag time. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug’s diffusion capacity are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is conceptualized as a differential solubility process; the cornea may be thought of as a trilaminar “fat-water-fat” structure corresponding to the epithelial, stromal, and endothelial layers. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, a drug with both hydrophilic and lipophilic properties is best suited for transcorneal absorption.

Drug penetration into the eye is approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal epithelial defects and corneal ulcers, may alter drug penetration. Medication absorption usually is increased when an anatomical barrier is compromised or removed. Experimentally, drugs may be screened for their potential clinical utility by assessing their corneal permeability coefficients. These pharmacokinetic data combined with the drug’s octanol/water partition coefficient (for lipophilic drugs) or distribution coefficient (for ionizable drugs) yield a parabolic relationship that is a useful parameter for predicting ocular absorption. Of course, such in vitro studies do not account for other factors that affect corneal absorption, such as epithelial integrity, blink rate, dilution by tear flow, nasolacrimal drainage, drug binding to proteins and tissue, and transconjunctival absorption; hence, these studies have limitations in predicting ocular drug absorption in vivo.

**Distribution.** Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly by local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures as well as potentially to the systemic circulation via the trabecular meshwork pathway (Figure 64–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of α-adrenergic–receptor agonists is slower in onset in human volunteers with darkly pigmented irides compared to those with lightly pigmented irides. In rabbits, radiolabeled atropine binds significantly to melanin granules in irides of non-albino animals. This finding correlates with the fact that atropine’s mydriatic effect lasts longer in non-albino rabbits than in albino rabbits and suggests that drug-melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug-melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of chloroquine (see Chapter 49) causes a toxic retinal lesion known as a “bull’s-eye” maculopathy, which is associated with a decrease in visual acuity.

**Metabolism.** Enzymatic biotransformation of ocular drugs may be significant because a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronidases, and sulfate transferases, glutathione-conjugating enzymes, catechol-O-methyl-transferase, monoamine oxidase, and 11β-hydroxysteroid dehydrogenase are found in the eye. The esterases have been of particular interest because of the development of prodrugs for enhanced corneal permeability; e.g., dipivefrin hydrochloride is a prodrug for epinephrine, and latanoprost is a prodrug for prostaglandin F2α (PGF2α); both drugs are used for glaucoma management. Topically applied ocular drugs are eliminated by the liver and kidney after systemic absorption, but enzymatic transformation of systemically administered drugs also is important in ophthalmology.

**Toxicology.** All ophthalmic medications are potentially absorbed into the systemic circulation (Figure 64–6), so undesirable systemic side effects may occur. Most ophthalmic drugs are delivered locally to the eye, and the potential local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periocular skin, and nasal mucosa. Eyedrops and contact lens solutions commonly contain preservatives such as benzalkonium chloride, chlorobutanol, chelating agents, and thimerosal for their antimicrobial effectiveness. In particular, benzalkonium chloride may cause a punctate keratopathy or toxic ulcerative keratopathy (Grant and Schuman, 1993). Thimerosal is used rarely due to a high incidence of hypersensitivity reactions.

### THERAPEUTIC AND DIAGNOSTIC APPLICATIONS OF DRUGS IN OPHTHALMOLOGY

#### Chemotherapy of Microbial Diseases in the Eye

**Antibacterial Agents**

**General Considerations.** A number of antibiotics have been formulated for topical ocular use (Table 64–4). The pharmacology, structures, and kinetics of individual drugs have been presented in detail in Section VI. Appropriate selection of antibiotic and route of administration is dependent on the patient’s symptoms, the clinical examination, and the culture/sensitivity results. Specially formulated antibiotics also may be extemporaneously prepared by qualified pharmacists for serious eye infections such as corneal infiltrates or ulcers and endophthalmitis.

**Therapeutic Uses.** Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly in clinical practice. Periocular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (i.e., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics are administered. The microbiological spectrum for orbital cellulitis is changing; e.g., there has been a sharp decline in *Haemophilus influenzae* after the introduction in 1985 of the *H. influenzae* vaccine (Ambati et al., 2000).

*Dacryoadenitis,* an infection of the lacrimal gland, is most common in children and young adults. It may be bacterial (typically...

a For specific information on dosing, formulation, and trade names, refer to the Physicians’ Desk Reference for Ophthalmic Medicines, which is published annually. b Polymyxin B is formulated for delivery to the eye in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 52-55 for further discussion of these antibacterial agents. c Tobramycin is formulated for delivery to the eye in combination with dexamethasone or loteprednol etabonate. H, hypersensitivity; BD, blood dyscrasia; D-RCD, drug-related corneal deposits.

Staphylococcus aureus, Streptococcus spp.) or viral (most commonly seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

Dacyrocystitis is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacyrocystitis and canalicular infections may be caused by S. aureus, Streptococcus spp., diphtheroids, Candida spp., and Actinomyces israelii. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the lids include hordeolum and blepharitis. A hordeolum, or stye, is an infection of the meibomian, Zeis, or Moll glands at the eyelid margins. The typical offending bacterium is S. aureus, and the usual treatment consists of warm compresses and topical antibiotic gel, drops, or ointment. Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, and it also usually is associated with a Staphylococcus sp. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used, usually in gel, drop, or ointment form, particularly when the disease is accompanied by conjunctivitis and keratitis. Systemic tetracycline, doxycycline, minocycline, and erythromycin often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

Conjunctivitis is an inflammatory process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. The less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid.
The more commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus, vaccinia variola virus) and bacterial sources (e.g., Neisseria spp., Streptococcus pneumoniae, Haemophilus spp., S. aureus, Moraxella lacunata, and chlamydial spp.). Rickettsia, fungi, and parasites, in both cyst and trophozoite form, are rare causes of conjunctivitis. Effective management is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

Keratitis, or corneal inflammation, can occur at any level of the cornea (e.g., epithelium, subepithelium, stroma, endothelium). It can be due to non-infectious or infectious causes. Numerous microbial agents have been identified as causes of infectious keratitis, including bacteria, viruses, fungi, spirochetes, and cysts and trophozoites. Severe infections with tissue loss (corneal ulcers) generally are treated more aggressively than infections without tissue loss (corneal infiltrates).

The mild, small, more peripheral infections usually are not cultured, and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for smears, cultures, and sensitivities are performed, and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. The goal of treatment is to eradicate the infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture and sensitivity results.

Endophthalmitis is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called panophthalmitis. Endophthalmitis usually is caused by bacteria or fungi, or rarely by spirochetes. The typical case occurs during the early postoperative course (e.g., after cataract, glaucoma, cornea, or retinal surgery), following trauma, or by endogenous seeding in an immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics.

Immediate vitrectomy (i.e., specialized surgical removal of the vitreous) is beneficial for patients who have light perception–only vision (Endophthalmitis Vitrectomy Study Group, 1995). Vitrectomy for other causes of endophthalmitis (e.g., glaucoma bleb related, post-traumatic, or endogenous) may be beneficial (Schiedler et al., 2004). In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source, but the efficacy of systemic antibiotics with trauma is not well established.

Antiviral Agents

General Considerations. The various antiviral drugs currently used in ophthalmology are summarized in Table 64–5 (see Chapter 58 for additional details about these agents).

Therapeutic Uses. The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus (Liesegang, 1999; Chern and Margolis, 1998), and retinitis. There currently are no antiviral agents for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and typically is treated by symptomatic relief of irritation.

Viral keratitis, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and CMV. Topical antiviral agents are indicated for the treatment of epithelial disease due to herpes simplex infection. When treating viral keratitis topically, there is a very narrow margin between the therapeutic topical antiviral activity and the toxic effect on the cornea; hence, patients must be followed very closely. The role of oral acyclovir and glucocorticoids in herpetic corneal and external eye disease has been examined in the Herpetic Eye Disease Study (Herpetic Eye Disease Study Group, 1997; Herpetic Eye Disease Study Group, 1998). Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis, which predominantly is presumed to involve a cell-mediated immune reaction, topical glucocorticoids accelerate recovery (Wilhelmus et al., 1994). For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral acyclovir in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1998). An ophthalmic formulation of trifluridine (VIROPTIC) is available for treatment of keratoconjunctivitis and epithelial keratitis due to herpes simplex viruses.

Herpes zoster ophthalmicus is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, valacyclovir, and famciclovir are effective in reducing the severity and complications of herpes zoster ophthalmicus (Colin et al., 2000). Currently, there are no ophthalmic preparations of acyclovir approved by the FDA, although an ophthalmic ointment is available for investigational use.

Viral retinitis may be caused by herpes simplex virus, CMV, adenovirus, and varicella zoster virus. With the highly active antiretroviral therapy (HAART; see Chapter 59), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis (Jacobson et al., 2000; Whitcup, 2000). Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal administration of ganciclovir has been found to be an effective alternative to the systemic route (Sanborn et al., 1992). Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by various combinations of oral, intravenous, intravitreal injection of, and intravitreal implantation of antiviral medications (Roig-Melo et al., 2001).
Antifungal Agents

General Considerations. The only currently available topical ophthalmic antifungal preparation is a polyene, natamycin (NATACYN), which has the following structure:

Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, or intravitreal routes of administration (Table 64–6). The pharmacology and structures of available antifungal agents are given in Chapter 57.

Therapeutic Uses. As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Ophthalmic indications for antifungal medications include fungal keratitis, scleritis, endophthalmitis, mucormycosis, and canaliculitis. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, contact lens wear, and immunosuppression (including topical steroid use).

In 2005-2006, there was a worldwide epidemic of *Fusarium* fungal keratitis related to a specific contact lens solution, which resolved when it was removed from the market (Chang et al., 2007). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection.

Antiprotozoal Agents

General Considerations. Parasitic infections involving the eye usually manifest themselves as a form of uveitis, an inflammatory process of either the anterior or posterior segments and, less commonly, as conjunctivitis, keratitis, and retinitis.

Therapeutic Uses. In the U.S., the most commonly encountered protozoal infections include *Acanthamoeba* and *Toxoplasma gondii*. In contact lens wearers who develop keratitis, physicians should be highly suspicious of the presence of *Acanthamoeba* (McCulley et al., 2000).

Additional risk factors for *Acanthamoeba* keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination of topical agents. The aromatic diamidines (i.e., propamidine isethionate in both topical aqueous and ointment forms [BROLENE]) have been used successfully to treat this relatively resistant infectious keratitis (Hargrave et al., 1999), although it is not available in the U.S. The cationic
antiseptic agent polyhexamethylene biguanide (PHMB) also is used in drop form for *Acanthamoeba* keratitis, although this is not an FDA-approved antiprotozoal agent. Oral imidazoles (e.g., itraconazole, fluconazole, ketoconazole, voriconazole) often are used in addition to the topical medications. Resolution of *Acanthamoeba* keratitis often requires many months of treatment.

Toxoplasmosis may present as a posterior (e.g., focal retinochoroiditis, papillitis, vitritis, retinitis) or occasionally as an anterior uveitis. Treatment is indicated when inflammatory lesions encroach upon the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids:

- pyrimethamine, sulfadiazine, and folinic acid (leucovorin)
- pyrimethamine, sulfadiazine, clindamycin, and folinic acid
- sulfadiazine and clindamycin
- clindamycin
- trimethoprim-sulfamethoxazole with or without clindamycin

Other protozoal infections (e.g., giardiasis, leishmaniasis, malaria) and helminths are less common eye pathogens in the U.S. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections.

In the eye, infections can occur in a variety of locations, such as the cornea, sclera, vitreous, and retina and can be caused by bacteria, viruses, fungi, and parasites. Treatment is based on the severity of infection, the location, and the class of infectious agent. Within each group of microbial cause, different organisms are treated with different medications. Gram-positive bacteria respond to certain antibiotics and Gram-negative bacteria to others. Some organisms are quite susceptible to many antimicrobial agents, while others are not. Still others may have been susceptible in the past but have become resistant. The task of staying ahead of the rapidly developing resistances is becoming increasingly difficult. In ophthalmology, fortunately, newer-generation topical fluoroquinolones recently were brought to market, which has at least temporarily helped stem the tide of resistant infections. Additional topical fluoroquinolones are in development.

While the selection of topical antiviral agents is rather limited, several new systemic antiviral agents have become available in the past decade. Similarly, there is only one commercially available topical antifungal medication, but there are numerous systemic agents, several of them new in the past few years. Potentially, some of these systemic medications could be modified for topical use or even formulated as intraocular implants, greatly expanding our options in the treatment of many ophthalmic infectious diseases.

*Off-label use. Only natamycin (NATACYN) is commercially available and labeled for ophthalmic use. All other antifungal drugs are not labeled for ophthalmic use and must be formulated for the given method of administration. For further dosing information, refer to the Physicians’ Desk Reference for Ophthalmic Medicines. For additional discussion of these antifungal agents, see Chapter 57.*
Use of Autonomic Agents in the Eye

General Considerations. General autonomic pharmacology has been discussed extensively in Chapters 8-12. The autonomic agents used in ophthalmology as well as the responses (i.e., mydriasis, cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 64–7.

Therapeutic Uses. Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus.

Glaucoma. In the U.S., glaucoma is the second leading cause of blindness in African-Americans, the third leading cause in Caucasians, and the leading cause in Hispanic Americans (Congdon et al., 2004). African Americans have three times the age-adjusted prevalence of glaucoma compared to Caucasians (Friedman et al., 2004). Characterized by progressive optic nerve cupping and visual field loss, glaucoma is responsible for the bilateral blindness of 90,000 Americans (half of whom are African-American or Hispanic) (Congdon et al., 2004), and ~2.2 million have the disease (1.86% of the population >40 years of age). This number is expected to increase by 50% by the year 2020 (Friedman et al., 2004). Risk factors associated with glaucomatous nerve damage include increased IOP, positive family history of glaucoma, African-American heritage, and possibly myopia and hypertension. The production and regulation of aqueous humor were discussed earlier in “Aqueous Humor Dynamics and Regulation of Intraocular Pressure.” Previously, an IOP of >21 mm Hg was considered abnormal. This, however, is incorrect, as IOP is not an accurate indicator of disease. Nonetheless, elevated IOP is a risk factor for glaucoma. Several randomized, controlled trials have determined that reducing IOP can delay glaucomatous nerve or field damage (Fluorouracil Filtering Surgery Study Group, 1996; AGIS Investigators, 2000; Heijl et al., 2002). Although markedly elevated IOPs (e.g., >30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients apparently can tolerate IOPs in the mid- to high 20s. These patients are referred to as ocular hypertensives. The Ocular Hypertension Treatment Study found that prophylactic medical reduction of IOP reduced the risk of progression to glaucoma from ~10-5% (Kass et al., 2002). Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range, and this form of the disease sometimes is called normal- or low-tension glaucoma. A reduction of IOP by 30% reduces disease progression from ~35-10%, even for normal-tension glaucoma patients (Collaborative Normal-Tension Glaucoma

*Off-label use. Refer to the Physicians' Desk Reference for Ophthalmic Medicines for specific indications and dosing information. *Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within 2 diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are: for atropine, 30-40 minutes and 7-10 days; for scopolamine, 20-130 minutes and 3-7 days; for homatropine, 40-60 minutes and 1-3 days; for cyclopentolate, 30-60 minutes and 1 day; for tropicamide, 20-40 minutes and 6 hours. Times to development of maximal cycloplegia and to recovery, respectively, are: for atropine, 60-180 minutes and 6-12 days; for scopolamine, 30-60 minutes and 3-7 days; for homatropine, 30-60 minutes and 1-3 days; for cyclopentolate, 25-75 minutes and 6 hours to 1 day; for tropicamide, 30 minutes and 6 hours.

Study Group, 1998a; Collaborative Normal-Tension Glaucoma Study Group, 1998b). Despite overwhelming evidence that IOP reduction is a helpful treatment, at present the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood.

Current pharmacotherapies are targeted at decreasing the production of aqueous humor at the ciliary body and increasing outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best IOP-lowering technique for glaucoma therapy. Currently, a National Eye Institute–sponsored clinical trial, the Collaborative Initial Glaucoma Treatment Study (CIGTS), aims to determine whether it is best, in terms of preservation of visual function and quality of life, to treat patients newly diagnosed with open-angle glaucoma with filtering surgery or medication. Initial results showed no difference in disease progression rates between the two treatment groups at 5 years (Lichter et al., 2001), but after 9 years, more subjects (25.5% versus 21.3%) had visual field loss in the medicine arm than in the surgery arm of the trial (Musch et al., 2009).

The CIGTS study aside, a stepped medical approach depends on the patient’s health, age, and ocular status, with knowledge of systemic effects and contraindications for all medications. Recall that:

- young patients usually are intolerant of miotic therapy secondary to visual blurring from induced myopia
- direct miotic agents are preferred over cholinesterase inhibitors in “phakic” patients (i.e., those patients who have their own crystalline lens) because the latter drugs can promote cataract formation
• in patients who have an increased risk of retinal detachment, miotics should be used with caution because they have been implicated in promoting retinal tears in susceptible individuals (such tears are thought to be due to altered forces at the vitreous base produced by ciliary body contraction induced by the drug)

The goal is to prevent progressive glaucomatous optic-nerve damage with minimum risk and side effects from either topical or systemic therapy. With these general principles in mind, a stepped medical approach may begin with a topical prostaglandin (PG) analog. Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP-lowering effect, PG analogs have largely replaced β adrenergic–receptor antagonists as first-line medical therapy for glaucoma. The PG analogs consist of latanoprost (XALATAN), travoprost (TRAVATAN, TRAVATAN Z), and bimatoprost (LUMIGAN, LATISSE). The chemical structure of latanoprost is shown below:

\[
\text{PGF}_{2\alpha}\text{ reduces IOP but has intolerable local side effects. Modifications to the chemical structure of PGF}_{2\alpha}\text{ have produced analogs with a more acceptable side-effect profile. In primates and humans, PGF}_{2\alpha}\text{ analogs appear to lower IOP by facilitating aqueous outflow through the accessory uveoscleral outflow pathway. The mechanism by which this occurs is unclear. PGF}_{2\alpha}\text{ and its analogs (prodrugs that are hydrolyzed to PGF}_{2\alpha}\text{) bind to FP receptors that link to G}_{41}\text{ and then to the PLC–IP}_{3.–Ca^{2+}}\text{ pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by PGF}_{2\alpha}\text{ range from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteinases and digestion of extracellular matrix materials that may impede outflow tracts. There also is less myocilin protein noted in monkey smooth muscle after PGF}_{2\alpha}\text{ treatment (Lindsey et al., 2001). The \(\beta\) receptor antagonists now are the next most common topical medical treatment. There are two classes of topical \(\beta\) blockers. The nonselective ones bind to both \(\beta_1\) and \(\beta_2\) receptors and include timolol maleate and hemihydrate (hemihydrate is not available in the U.S.), levobunolol, metipranolol, and carteolol. There is one \(\beta_1\)-selective antagonist, betaxolol, available for ophthalmic use, but it is less efficacious than the nonselective \(\beta\) blockers because the \(\beta\) receptors of the eye are largely of the \(\beta_2\) subtype. However, because the \(\beta_1\) receptors are found preferentially in the heart while the \(\beta_2\) receptors are found in the lung, betaxolol is less likely to cause breathing difficulty. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where \(\beta_2\) receptors account for 75-90% of the total population. How \(\beta\) blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a \(\beta\) receptor–mediated cyclic AMP–PKA pathway; \(\beta\) blockade blunts adrenergic activation of this pathway by preventing catecholamine stimulation of the \(\beta\) receptor, thereby decreasing intracellular cyclic AMP. Another hypothesis is that \(\beta\) blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production (Juzych and Zimmerman, 1997). When there are medical contraindications to the use of PG analogs or \(\beta\) receptor antagonists, other agents, such as a \(\beta_2\) adrenergic–receptor agonist or topical carbonic anhydrase inhibitor (CAI), may be used as first-line therapy. The \(\beta_2\) adrenergic agonists improve the pharmacological profile of the nonselective sympathomimetic agent epinephrine and its derivative, dipivefrin (PROPINE, others). Epinephrine stimulates both \(\alpha\) and \(\beta\) adrenergic receptors. The drug appears to decrease IOP by enhancing both conventional (via a \(\beta_2\) receptor mechanism) and uveoscleral outflow (perhaps via PG production) from the eye. Although effective, epinephrine is poorly tolerated, principally due to localized irritation and hyperemia. Dipivefrin is an epinephrine prodrug that is converted into epinephrine by esterases in the cornea. It is much better tolerated but is still prone to cause epinephrine-like side effects (Fang and Kass, 1997). The \(\beta_2\) adrenergic agonist clonidine is effective at reducing IOP but also readily crosses the blood-brain barrier and causes systemic hypotension; as a result, it no longer is used for glaucoma. In contrast, apraclonidine (IOPIDINE) is a relatively selective \(\beta_2\) adrenergic agonist that is highly ionized at physiological pH and therefore does not cross the blood-brain barrier. Brimonidine (ALPHAGAN, others) also is a selective \(\alpha_2\) adrenergic agonist but is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic \(\alpha_2\) receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic \(\alpha_2\) receptors, these drugs stimulate the G\(_i\) pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production (Juzych et al., 1997).

The development of a topical CAI took many years but was an important event because of the poor side-effect profile of oral CAIs. Dorzolamide (TRUSOPT, others) and brinzolamide (AZOPT) both work by inhibiting carbonic anhydrase (isoenzyme II), which is found in the ciliary body epithelium. This reduces the formation of bicarbonate ions, which reduces fluid transport and, thus, IOP (Sharir, 1997).

Any of these four drug classes can be used as additive second- or third-line therapy. In fact, the \(\beta\) receptor antagonist timolol has been combined with the CAI dorzolamide (see the structure below) in a single medication (COSOPT, others) and with the \(\alpha_2\) adrenergic agonist brimonidine (COMBIGAN).
Such combinations reduce the number of drops needed and may improve compliance. Other combination products involving PG analogs and β blockers are in development.

Topical miotic agents are historically important glaucoma medications but are less commonly used today. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Multiple miotic agents have been developed. Pilocarpine and carbachol are cholinomimetics that stimulate muscarinic receptors. Ectotheophosphate (PHOSPHOLINE IODIDE) is an organophosphate inhibitor of acetylcholinesterase; it is relatively stable in aqueous solution and, by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. The usefulness of these medicines is lessened by their numerous side effects and the need to use them three to four times a day (Kaufman and Gabelt, 1997).

If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then systemic therapy with CAI is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see Chapter 25), followed by methazolamide. The least well tolerated are acetazolamide tablets.

Toxicity of Agents in the Treatment of Glaucoma. Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. Epinephrine-related compounds, effective in IOP reduction, can cause a vasoconstriction–vasodilation rebound phenomenon leading to a red eye. Ocular and skin allergies from topical epinephrine, related produg formulations, apraclonidine, and brimonidine are common. Brimonidine is less likely to cause ocular allergy and therefore is more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children <2 years of age.

Systemic absorption of epinephrine-related drugs and β adrenergic antagonists can induce all the side effects found with direct systemic administration. The use of CAIs systemically may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects. These medical strategies for managing glaucoma do help to slow the progression of this disease, yet there are potential risks from treatment-related side effects, and treatment effects on quality of life must be recognized.

Uveitis. Inflammation of the uvea, or uveitis, has both infectious and non-infectious causes, and medical treatment of the underlying cause (if known), in addition to the use of topical therapy, is essential. Cyclopentolate (CYCLOGYL, others), tropicamide (MYDRIACYL) or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine (ISOPTO HYOSCINE), and homatropine frequently are used to prevent posterior synechiae formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis.

If posterior synechiae already have formed, an α adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. A solution containing scopolamine 0.3% in combination with 10% phenylephrine (MURCOLL-2) is available for this purpose. Two others, 1% hydroxyamphetamine hydrobromide combined with 0.25% tropicamide (PAREMYD) and 1% phenylephrine in combination with 0.2% cyclopentolate (CYCLOMYDRIL) are only indicated for induction of mydriasis. Topical steroids usually are adequate to decrease inflammation, but sometimes they must be supplemented with systemic steroids.

Strabismus. Strabismus, or ocular misalignment, has numerous causes and may occur at any age. Besides causing diplopia (double vision), strabismus in children may lead to amblyopia (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents.

An eye with hyperopia, or farsightedness, must constantly accommodate to focus on distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest esotropia (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by ~7 years of age, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. Unfortunately, this is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002; Pediatric Eye Disease Investigator Group, 2003). Ectotheophosphate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as ectotheophosphate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

Surgery and Diagnostic Purposes. For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and sympathomimetic agents frequently are used singly or in combination for this purpose (Table 64–7).

Intraoperatively, there are circumstances in which miosis is preferred, and two cholinergic agonists are available for intraocular use, acetycholine (MIOCHOL-E) and carbachol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or lid droop (ptosis); the edrophonium test is helpful in diagnosing these patients (see Chapter 10). For surgical visualization of the lens, trypan blue (VISIONBLUE) is marketed to facilitate visualization of the lens and for staining during surgical vitrectomy procedures to guide the excision of tissue (MEMBRANEBLUE).

Use of Immunomodulatory and Antimitotic Drugs for Ophthalmic Therapy

Glucocorticoids. Glucocorticoids have an important role in managing ocular inflammatory diseases;
their chemistry and pharmacology are described in Chapter 42.

**Therapeutic Uses.** Currently, the glucocorticoids formulated for topical administration to the eye are dexamethasone (DEXASOL, others), prednisolone (PRED FORTE, others), fluorometholone (FML, others), loteprednol (ALREX, LOTEMAX), rimexolone (VEXOL), and difluprednate (DUREZOL). Because of their anti-inflammatory effects, topical corticosteroids are used in managing significant ocular allergy, anterior uveitis, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, and postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site (Araujo et al., 1995). Steroids commonly are given systemically and by sub-Tenon’s capsule injection to manage posterior uveitis. Intravitreal injection of steroids now is being used to treat a variety of retinal conditions including age-related macular degeneration (ARMD), diabetic retinopathy, and cataract macular edema. Two intravitreal triamcinolone formulations, TRIVARIS and TRIESENCE, are approved for ocular inflammatory conditions unresponsive to topical corticosteroids and visualization during vitrectomy, respectively. Parenteral steroids followed by tapering oral doses is the preferred treatment for optic neuritis (Kauffman et al., 2000; Trobe et al., 1999). An ophthalmic implant of fluocinolone (RETIsert) is marketed for the treatment of chronic, non-infectious uveitis.

**Toxicity of Steroids.** Steroid drops, pills, and creams are associated with ocular problems, as are intravital and intravenous steroids. Ocular complications include the development of posterior subcapsular cataracts, secondary infections (see Chapter 42), and secondary open-angle glaucoma (Becker and Mills, 1963). There is a significant increase in the risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only ~5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, however, moderate to marked steroid-induced IOP elevations may occur in up to 90% of patients. The pathophysiology of steroid-induced glaucoma is not fully understood, but there is evidence that the GLCIA gene may be involved (Stone et al., 1997). Typically, steroid-induced elevation of IOP is reversible once administration of the steroid ceases. However, intraocular or sub-Tenon’s steroid-related pressure elevation may persist for months and may require treatment with glaucoma medication or even filtering surgery. Newer topical steroids, so-called “soft steroids” (e.g., loteprednol), have been developed that reduce, but do not eliminate, the risk of elevated IOP.

**Nonsteroidal Anti-Inflammatory Agents General Considerations.** Nonsteroidal drug therapy for inflammation is discussed in Chapter 34. Nonsteroidal anti-inflammatory drugs (NSAIDs) now are being applied to the treatment of ocular disease.

**Therapeutic Uses.** Currently, there are five topical NSAIDs (see Chapter 34) approved for ocular use: flurbiprofen (OCUFEN, others), ketorolac (ACULAR, others), diclofenac (VOLTAREN, others), bromfenac (XIBROM), and nepafenac (NEVANAC). Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. Diclofenac is used for postoperative inflammation. Both ketorolac (Weisz et al., 1999; Almeida et al., 2008) and diclofenac (Asano et al., 2008) have been found to be effective in treating cystoid macular edema occurring after cataract surgery. Bromfenac and nepafenac are indicated for treating postoperative pain and inflammation after cataract surgery. In patients treated with PG analogs such as latanoprost or bimatoprost, ketorolac and diclofenac may help decrease postoperative inflammation. They also are useful in decreasing pain after corneal refractive surgery. Topical and systemic NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

**Antihistamines and Mast-Cell Stabilizers.** Pheniramine (Chapter 32) and antazoline, both H1 receptor antagonists, are formulated in combination with naphazoline, a vasoconstrictor, for relief of allergic conjunctivitis; emedastine difumarate (EMADINE) also is used. Cromolyn sodium (CROLOM, others), which reportedly prevents the release of histamine and other autacoids from mast cells, has found limited use in treating conjunctivitis that is thought to be allergen mediated, such as vernal conjunctivitis. Lodoxamide tromethamine (ALOMIDE) and pemirolast (ALAMAST), mast-cell stabilizers, also are available for ophthalmic use. Nedocromil (ALOCRIL) also is primarily a mast-cell stabilizer with some antihistamine properties. Olopatadine hydrochloride (PATAKOL, PATAKAD), ketotifen fumarate (ZADITOR, ALAWAY), bepotastine (BEPREVE), and azelastine (OPTIVAR) are H1 antagonists with mast cell–stabilizing properties. Epinastine (ELESTAT) antagonizes H1 and H3 receptors and exhibits mast cell–stabilizing activity.

**Immunosuppressive and Antimitotic Agents General Considerations.** The principal application of immunosuppressive and antimitotic agents to ophthalmology relates to the use of 5-fluorouracil and mitomycin C in corneal and glaucoma surgeries. Interferon-α2b also has occasionally been used. Certain systemic diseases with serious vision-threatening ocular manifestations—such as Behçet’s disease, Wegener’s granulomatosis, rheumatoid arthritis, and reactive arthritis (Reiter’s syndrome)—require systemic immunosuppression (see Chapter 35).

**Therapeutic Uses.** In glaucoma surgery, both fluorouracil and mitomycin (MUTAMYCIN), which also are anti-neoplastic agents (see Chapter 61), improve the success of filtration surgery by limiting the postoperative wound-healing process. Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. Meticulous care is used to avoid intraocular penetration, because mitomycin is extremely toxic to intraocular structures. Fluorouracil may be used intraoperatively at the trabeculectomy site and/or...
subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1989). Although both agents work by limiting the healing process, sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection.

In corneal surgery, mitomycin has been used topically after excision of pterygium, a fibrovascular membrane that can grow onto the cornea. Mitomycin can be used to reduce the risk of scarring after certain procedures to remove corneal opacities and also prophylactically to prevent corneal scarring after excimer laser surface ablation (photorefractive and phototherapeutic keratectomy). Mitomycin also is used to treat certain conjunctival and corneal tumors. Interferon α-2b has been used in the treatment of conjunctival papilloma and certain conjunctival tumors. Although the use of mitomycin for both corneal surgery and glaucoma filtration surgeries augments the success of these surgical procedures, caution is advocated in light of the potentially serious delayed ocular complications (Rubinfeld et al., 1992; Hardten and Samuelson, 1999; Bahar et al., 2009).

Intraocular methotrexate (see Chapter 61) is used to treat uveitis and uveitic cystoid macular edema. It also has been used to treat the uncommon complication of lymphoma in the vitreous, which is an inaccessible compartment for most anti-neoplastic drugs (Taylor et al., 2009).

**Immunomodulatory Agent.** Topical cyclosporine (cyclosporin A; RESTASIS) is approved for the treatment of chronic dry eye associated with inflammation. Cyclosporine is an immunomodulatory agent that inhibits activation of T cells. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort (Sall et al., 2000; Perry et al., 2008).

**Drugs and Biological Agents Used in Ophthalmic Surgery**

**Presurgical Antiseptics.** Povidone iodine (BETADINE) is formulated as a 5% sterile ophthalmic solution for use prior to surgery to prep periocular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Following irrigation, the exposed tissues are flushed with sterile saline. As for other povidone iodine uses, hypersensitivity to iodine is a contraindication.

**Adjuncts in Anterior Segment Surgery.** Viscoelastic substances assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate (HEALON, others), chondroitin sulfate (VISCOAT), or hydroxypropylmethylcellulose and share the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Various viscoelastic agents emphasize certain features that are broadly characterized as dispersive or cohesive. They are used almost exclusively in anterior segment surgery. Complications associated with viscoelastic substances are related to transient elevation of IOP after the surgical procedure.

**Ophthalmic Glue.** Cyanoacrylate tissue adhesive (ISODENT, DERMABOND, HISTOACRYL), while not FDA approved for the eye, is widely used in the management of corneal ulcerations and perforations. It is applied in liquid form and polymerized into a solid plug.

Fibrinogen glue (TISSEEL, EVICEL) is increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts. These are FDA approved for use in cardiac, vascular, and general surgery but not for the eye.

**Anterior Segment Gases.** Sulfur hexafluoride (SF₆) and perfluoropropane gases have long been used as vitreous substitutes during retinal surgery. In the anterior segment, they are used in non-expansile concentrations to treat Descemet’s detachments, typically after cataract surgery. These detachments can cause mild to severe corneal edema. The gas is injected into the anterior chamber to push Descemet’s membrane up against the stroma, where ideally it reattaches and clears the corneal edema.

**Vitreous Substitutes.** The primary use of vitreous substitutes is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. Several compounds, including gases, perfluorocarbon liquids, and silicone oil (Table 64–8), are available. With the exception of air, the gases expand because of interaction with systemic oxygen, carbon dioxide, and nitrogen, and this property makes them desirable to temporarily tamponade areas of the retina. However, use of these expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons, with specific gravities between 1.76 and 1.94, are denser than vitreous and are helpful in flattening the retina when vitreous is present. Silicone oil (polydimethylsiloxanes; ADATOSIL, 5000) has had extensive use in both Europe and the U.S. for long-term tamponade of the retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

**Surgical Hemostasis and Thrombolytic Agents.** Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. In some intraocular surgeries, thrombin has a valuable role in hemostasis. Intravitreal administration

*a See Parel and Villain, 1994, and Chang, 1994, for further details. cs, centistoke (unit of viscosity).
of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur, but this reaction can be minimized by thorough irrigation after hemostasis is achieved. This coagulation factor also may be applied topically via soaked sponges to exposed conjunctiva and sclera, where hemostasis may be a challenge due to the rich vascular supply.

Topical aminocaproic acid (CAPROGEL) has been investigated to prevent rebleeding after traumatic hyphema (blood in the anterior chamber), but clinical trials report mixed success, and the drug is not marketed in the U.S. (Karkhaneh et al., 2003; Pieramici et al., 2003).

Depending on the intraocular location of a clot, there may be significant problems relating to IOP, retinal degeneration, and persistent poor vision. Recombinant tissue plasminogen activator (t-PA; alteplase) (Chapter 30) has been used during intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage. Alteplase also has been administered subconjunctivally and intracamerally (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of t-PA is bleeding.

**Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders.** Botulinum toxin type A is FDA-approved for the treatment of strabismus and blepharospasm associated with dystonia, facial wrinkles (glabellar lines), axillary hyperhidrosis, and spasmodic torticollis (cervical dystonia). It also has been used off label for Meige’s syndrome, hemifacial spasm, and certain migraine headaches (Tsui, 1996; Price et al., 1997) (see also Chapter 11). Two botulinum toxin type A preparations are marketed in the U.S.: onabotulinumtoxinA (BOTOX, BOTOX COSMETIC) and abobotulinumtoxinA (DYSPORT). By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles.

The variability in duration of paralysis may be related to the rate of developing antibodies to the toxin, upregulation of nicotinic cholinergic postsynaptic receptors, and aberrant regeneration of motor nerve fibers at the neuromuscular junction. Complications related to this toxin include double vision (diplopia) and lid droop (ptosis) and potentially life-threatening distant spread of toxin effect from the injection site (asthenia, generalized muscle weakness, diplopia, blurred vision, ptosis, dysphagia, dysphonia, dysarthria, urinary incontinence, and breathing difficulties) within hours to weeks after administration.

**Agents Used to Treat Blind and Painful Eye.** Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraocular muscles, including those in the eyelids, or neurotrophic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

**Systemic Agents with Ocular Side Effects.** Just as certain systemic diseases have ocular manifestations, certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening. Examples are listed in the following sections. A review of these drugs recently has been published (Santaella and Fraunfelder, 2007).

**Glaucoma.** The anti-seizure drug topiramate (TOPAMAX, others) frequently has been reported to cause choroidal effusions, thereby anterioaly rotating the ciliary body and causing an angle-closure glaucoma (Banta et al., 2001).

**Retina.** Numerous drugs have toxic side effects on the retina. The anti-arthritis and antimalarial medicines hydroxychloroquine (PLAQUENIL, others) and chloroquine can cause a central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until ~6 years after the drug is started. Stopping the drug will not reverse the damage but will prevent further toxicity (Tehrani et al., 2008). Tamoxifen is known to cause a crystalline maculopathy. The anti-seizure drug vigabatrin (SABRIL) causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients. The mechanism is not known, but vigabatrin is more effectively transported into the retina than into the brain, and consequently, elevations of retinal GABA concentrations may contribute to the vision loss.

**Optic Nerve.** The three phosphodiesterase (PDE) inhibitors, sildenafil (VIAGRA, REVATIO), vardenafil (LEVITRA), and tadalafil (CIALIS, ADCIRCA), inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection. The drug also mildly inhibits PDE6, which controls the levels of cyclic GMP in the retina. Visually, this can result in seeing a bluish haze or experiencing light sensitivity. There have been several reports of nonarteritic ischemic optic neuropathy (NAION) in patients using these drugs. Despite these reports, there is little conclusive evidence that these drugs caused this problem, but patients should stop using the medications if they experience vision problems (Latties, 2009). Multiple medications can cause a toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. There can be accompanying optic nerve pallor. These medicines include ethambutol, chloramphenicol, and rifampin (Lloyd and Fraunfelder, 2007). Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

**Anterior Segment.** Steroids also have been implicated in cataract formation. If vision is reduced, cataract surgery may be
necessary. Rifabutin, if used in conjunction with clarithromycin or fluconazole for treatment of Mycobacterium avium complex (MAC) opportunistic infections in human immunodeficiency virus (HIV)-positive persons, is associated with an iridocyclitis and even hypopyon. This will resolve with steroids or by stopping the medication.

**Ocular Surface.** Isotretinoin (Accutane, others) has a drying effect on mucous membranes and is associated with dry eye and meibomian gland dysfunction.

**Cornea Coryanghiva and Eyclids.** The cornea, the conjunctiva, and even the eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed cornea verticillata. It appears as fine tan or brown pigment in the epithelium. Fortunately, the deposits seldom affect vision, and therefore, this rarely is a cause to discontinue the medication. The deposits disappear slowly if the medication is stopped. Other medications, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine, can cause a similar pattern.

The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmented deposits in the cornea, conjunctiva, and eyelids. The deposits generally are found in Descemet’s membrane and the posterior cornea. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen, perhaps because the medication deposits in the skin are slowly released and accumulate in the eye.

Gold treatments for arthritis (now rarely used) can lead to gold deposition in the cornea and conjunctiva, which are termed chryiasis and are gold to violet in color. With lower cumulative doses (1-2 g), the deposits are found primarily in the epithelium and anterior stroma. These deposits usually disappear with discontinuation of the medication. With higher doses, the gold is deposited in Descemet’s membrane and posterior stroma and can involve the entire stroma. These changes can be permanent. The deposits generally do not affect vision and are not a reason to stop gold therapy.

Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone (Morrow and Abbott, 1998).

**Agents Used to Assist in Ocular Diagnosis**

A number of agents are used in an ocular examination (e.g., mydriatic agents, topical anesthetics, dyes to evaluate corneal surface integrity), to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics), and to help in making a diagnosis in cases of anisocoria (Figure 64–5) and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed earlier. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed in “Anterior Segment and External Diagnostic Uses” and “Posterior Segment Diagnostic Uses.”

**Anterior Segment and External Diagnostic Uses.** Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes fluorescein, rose bengal, and lissamine green are used in evaluating these problems. Available as a 2% alkaline solution, 10% and 25% solutions for injection, and an impregnated paper strip, fluorescein reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to help determine the patency of the nasolacrimal system. In addition, this dye is used as part of the procedure of applanation tonometry (IOP measurement) and to assist in determining the proper fit of rigid and semi-rigid contact lenses. Fluorescein in combination with proparacaine or benoxinate is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. Fluoresxon (Fluoresent), a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place).

Rose bengal and lissamine green, available as saturated paper strips, stain devitalized tissue on the cornea and conjunctiva.

**Posterior Segment Diagnostic Uses.** The integrity of the blood-retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either fluorescein sodium or indocyanine green. These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

**Agents Used to Treat Retinal Neovascularization and Macular Degeneration**

Verteporfin (Visudyne) is approved for photodynamic therapy of the exudative form of ARMD with predominantly classic choroidal neovascular membranes (Fine et al., 2000; Jager et al., 2008). Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological...
myopia and presumed ocular histoplasmosis syndrome. Verteporfin is a mixture of two regioisomers (I and II):

Verteporfin is administered intravenously, and once it reaches the choroidal circulation, the drug is light activated by a nonthermal laser source. Depending on the size of the neovascular membrane and concerns of occult membranes and recurrence, multiple photodynamic treatments may be necessary. Activation of the drug in the presence of oxygen generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The $t_{1/2}$ of the drug is 5-6 hours. It is eliminated predominantly in the feces. The potential side effects include headache, injection-site reactions, and visual disturbances. The drug causes temporary photosensitization, and patients must avoid exposure of the skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving it.

Pegaptanib (MACUGEN) is approved for neovascular (wet) ARMD. Pegaptanib is a selective vascular endothelial growth factor (VEGF) antagonist. It is a pegylated anti-VEGF aptamer, a single strand of nucleic acid that binds to the major pathological VEGF isoform, extracellular VEGF$_{165}$, thereby inhibiting VEGF$_{165}$ binding to VEGF receptors. VEGF$_{165}$ induces angiogenesis and increases vascular permeability and inflammation, all of which are thought to contribute to the progression of the neovascular (wet) form of ARMD, a leading cause of blindness. Pegaptanib reduced vision loss in patients with wet ARMD (Gragoudas et al., 2004). Dose levels >0.3 mg did not demonstrate any additional benefit.

Pegaptanib (0.3 mg) is administered once every 6 weeks by intravitreal injection into the eye to be treated. Side effects are largely related to the injection. Following the injection, patients should be monitored for elevation in IOP and for endophthalmitis. Rare cases of anaphylaxis/anaphylactoid reactions have been reported. No special dosage modification is required for any of the populations that have been studied (i.e., gender, elderly).

Bevacizumab (AVASTIN) is a monoclonal murine antibody that targets VEGF-A and thereby inhibits vascular proliferation and tumor growth (see Chapter 62). Ranibizumab (LUCENTIS) is a variant of bevacizumab that has had the Fab domain affinity matured (Lien and Lowman, 2008).

In the eye, several diseases that involve neovascularization such as proliferative diabetic retinopathy, macular edema, retinopathy of prematurity (Hubbard, 2008), ARMD (Patel et al., 2008), and neovascular glaucoma have been treated off label with bevacizumab, while ranibizumab generally has been reserved for both classic (Brown et al., 2009) and occult (Chang et al., 2007) choroidal neovascular membranes associated with ARMD. Both drugs are delivered by intravitreal injection and often are used on a weekly or monthly basis for maintenance therapy. Aside from the risks of hemorrhage and infection from intravitreal injections, both drugs have been associated with the risk of cerebral vascular accidents (Dafer et al., 2007; Shima et al., 2008). A multicenter clinical trial evaluating the effectiveness of the two medications for treating ARMD is currently under way.

Use of Anesthetics in Ophthalmic Procedures

Topical anesthetic agents used clinically in ophthalmology include proparacaine and tetracaine drops, lidocaine gel (see Chapter 20), and intranasal cocaine. Proparacaine and tetracaine are used topically to perform tonometry, to remove foreign bodies on the conjunctiva and cornea, to perform superficial corneal surgery, and to manipulate the nasolacrimal canalicular system. They also are used topically to anesthetize the ocular surface for refractive surgery using either the excimer laser or placement of intrastromal corneal rings. Cocaine may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system.

Lidocaine and bupivacaine are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and vascular and subdural injections. Both preservative-free lidocaine (1%), which is introduced into the anterior chamber, and lidocaine jelly (2%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. This form of anesthesia eliminates the risks of the anesthetic injection and allows for more rapid visual recovery after surgery. General anesthetics and sedation are important adjuncts for patient care for surgery and examination of the eye, especially in children and uncooperative adults. Most inhalational agents and CNS depressants are associated with a reduction in IOP. An exception is ketamine, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extracellular muscles, which may result in expulsion of intraocular contents.

Other Agents for Ophthalmic Therapy

Vitamins and Trace Elements

General Considerations. Table 64–9 summarizes the current understanding of vitamins related to eye function and disease, especially the biochemistry of vitamin A.

Although vitamin A must be supplied from the environment, most actions of vitamin A, like those of vitamin D, are exerted through hormone-like receptors. Vitamin A has diverse actions in cellular regulation and differentiation that go far beyond its classically defined function in vision. Analogs of vitamin A, because of their prominent effects on epithelial differentiation, have found important therapeutic applications in the treatment of a variety of dermatological conditions and are being evaluated in cancer chemoprevention.

**History.** The relationship of night blindness to nutritional deficiency was definitively recognized in the 1800s. Ophthalmia brasiliana (keratomalacia), a disease of the eyes that afflicted primarily poorly nourished slaves, was first described in 1865. Later, it was observed that the nurselings of mothers who fasted were prone to develop spontaneous sloughing of the cornea. Other reports of nutritional keratomalacia soon followed from all parts of the world.

Experimental rather than clinical observations, however, led to the discovery of vitamin A. In 1913, McCollum and Davis, and Osborne and Mendel independently reported that animals fed artificial diets with lard as the sole source of fat developed a nutritional deficiency that could be corrected by the addition to the diet of a factor contained in butter, egg yolk, and cod liver oil. An outstanding symptom of this experimental nutritional deficiency was xerophthalmia (dryness and thickening of the conjunctiva). Clinical and experimental vitamin A deficiencies were recognized to be related during World War I, when it became apparent that xerophthalmia in humans was a result of a decrease in the amount of butterfat in the diet.

**Chemistry and Terminology.** Retinoid refers to the chemical entity retinol and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogs that need not have retinol-like (vitamin A) activity (Evans and Kaye, 1999).

The purified plant pigment carotene (provitamin A) is a remarkably potent source of vitamin A. β-Carotene, the most active carotenoid found in plants, has the structural formula shown in Figure 64–7A. The structural formulas for the vitamin A family of retinoids are shown in Figure 64–7B.

Retinol, a primary alcohol, is present in esterified form in the tissues of animals and saltwater fish, mainly in the liver.

A number of cis-trans isomers exist because of the unsaturated carbons in the retinol side chain. Fish liver oils contain mixtures of the stereoisomers; synthetic retinol is the all-trans isomer. Interconversion between isomers readily takes place in the body. In the visual cycle, the reaction between retinal (vitamin A aldehyde) and opsin to form rhodopsin occurs only with the 11-cis isomer. Ethers and esters derived from the alcohol also show activity in vivo. The ring structure of retinol (β-ionone), or the more unsaturated ring in 3-dehydroretinol (dehydro-β-ionone), is essential for activity; hydrogenation destroys biological activity. Of all known derivatives, all-trans-retinol and its aldehyde, retinal, exhibit the greatest biological potency in vivo; 3-dehydroretinol has ~40% of the potency of all-trans-retinol.

Retinoic acid, in which the alcohol moiety has been oxidized, shares some but not all of the actions of retinol. Retinoic acid is ineffective in restoring visual or reproductive function in certain species in which retinol is effective. However, retinoic acid is very potent in promoting growth and controlling differentiation and maintenance of epithelial tissue in vitamin A–deficient animals. Indeed, all-trans-retinoic acid (tretinoin) appears to be the active form of vitamin A in all tissues except the retina, and is 10- to 100-fold more potent than retinol in various systems in vitro. Isomerization of this compound in the body yields 13-cis-retinoic acid (isotretinoin), which is nearly as potent as tretinoin in many of its actions on epithelial tissues but may be only one-fifth as potent in producing the toxic symptoms of hypervitaminosis A. Retinoic acid analogs used clinically are discussed in detail in Chapter 65.
Physiological Functions and Pharmacological Actions. Vitamin A plays an essential role in the function of the retina, is necessary for growth and differentiation of epithelial tissue, and is required for growth of bone, reproduction, and embryonic development. Together with certain carotenoids, vitamin A enhances immune function, reduces the consequences of some infectious diseases, and may protect against the development of certain malignancies. As a result, there is considerable interest in the pharmacological use of retinoids for cancer prophylaxis and for treating various premalignant conditions. Because of the effects of vitamin A on epithelial tissues, retinoids and their analogs are used to treat a number of skin diseases, including some of the consequences of aging and prolonged exposure to the sun (see Chapter 65).

The functions of vitamin A are mediated by different forms of the molecule. In vision, the functional vitamin is retinal. Retinoic acid appears to be the active form in functions associated with growth, differentiation, and transformation.

Retinal and the Visual Cycle. Vitamin A deficiency interferes with vision in dim light, a condition known as night blindness (nyctalopia).

Photoreception is accomplished by two types of specialized retinal cells, termed rods and cones. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The initial step is the absorption of light by a chromophore attached to the receptor protein. The chromophore of both rods and cones is 11-cis-retinal. The holoreceptor in rods is termed rhodopsin—a combination of the protein opsin and 11-cis-retinal attached as a prosthetic group. The three different types of cone cells (red, green, and blue) contain individual, related photoreceptor proteins and respond optimally to light of different wavelengths.

In the synthesis of rhodopsin, 11-cis-retinal is converted to 11-cis-retinal in a reversible reaction that requires pyridine nucleotides. 11-cis-Retinal then combines with the ε amino group of a specific lysine residue in opsin to form rhodopsin. Most rhodopsin is located in the membranes of the discs situated in the outer segments of the rods. The protein has seven membrane-spanning domains, a characteristic shared by all receptors whose functions are transduced via G proteins.
The visual cycle (Figure 64–8) is initiated by the absorption of a photon of light, leading to the isomerization of 11-cis-retinal to the all-trans form covalently bound to rhodopsin, a G protein–coupled receptor (GPCR). Activated rhodopsin interacts with the heterotrimeric G protein transducin (Gt), initiating GDP–GTP exchange and formation of the activated α,GTP subunit. α,GTP binds to and activates a cyclic GMP phosphodiesterase (PDE6), resulting in a rapid drop in the local concentration of cyclic GMP. The decline in cyclic GMP permits dissociation of cyclic GMP from open cyclic GMP–gated ion channels (open in the dark), causing channel closure and hyperpolarization. This is followed by a stimulation of GC (guanylyl cyclase) activity, re-opening of the ion channel, and restoration of initial cellular Ca2+. A series of reactions involving rhodopsin kinase, arrestin, recoverin, and the GTPase activity of α,GTP also help to restore the system to the ground state, with re-formation of the heterotrimeric form of G,GDP (Cote, 2007).

**Vitamin A Deficiency and Vision.** Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. Upon depletion of retinol from liver and blood, usually at plasma concentrations of retinol of <0.2 mg/L (0.70 μM), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency is overcome, opsins, lacking the stabilizing effect of retinal, decays, and anatomical deterioration of the rod outer segment occurs. In rats maintained on a vitamin A–deficient diet, irreversible ultrastructural changes leading to blindness then supervene, a process that takes ~10 months.

Following short-term deprivation of vitamin A, dark adaptation can be restored to normal by the addition of retinol to the diet. However, vision does not return to normal for several weeks after adequate amounts of retinol have been supplied. The reason for this delay is unknown.

**Vitamin A and Epithelial Structures.** The functional and structural integrity of epithelial cells throughout the body is dependent on an adequate supply of vitamin A. The vitamin plays a major role in the induction and control of epithelial differentiation in mucus-secreting or keratinizing tissues. In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucus, the inhibition of keratinization, and the display of goblet cells.

In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness. Common causes of vitamin A deficiency include malnutrition and bariatric surgery. Worldwide, xerophthalmia remains one of the most common causes of blindness.

**Mechanism of Action.** In isolated fibroblasts or epithelial tissue, retinoids enhance the synthesis of some proteins (e.g., fibronectin)
and reduce the synthesis of others (e.g., collagenase, certain species of keratin), and molecular evidence suggests that these actions can be entirely accounted for by changes in nuclear transcription (Mangelsdorf et al., 1994). Retinoic acid appears to be considerably more potent than retinol in mediating these effects.

Retinoic acid influences gene expression by combining with nuclear receptors. Multiple retinoid receptors have been described. These are grouped into two families. One family, the retinoic acid receptors (RARs), designated α, β, and γ, are derived from genes localized to human chromosomes 17, 3, and 12, respectively. The second family, the retinoid X receptors (RXRs), also is composed of α, β, and γ receptor isoforms (Chambon, 1995). The retinoid receptors show extensive sequence homology to each other in both their DNA and hormone-binding domains and belong to a receptor superfamily that includes receptors for steroid and thyroid hormones and calcitriol (Mangelsdorf et al., 1994). Cellular responses to thyroid hormones, calcitriol, and retinoic acid are enhanced by the presence of RXR. Gene activation involves binding of the hormone-receptor complex to promoter elements in target genes, followed by dimerization with an RXR-ligand complex. The endogenous RXR ligand is 9-cis-retinoic acid (Heyman et al., 1992; Levin et al., 1992). No comparable receptor for retinol has been identified; retinol may need to be oxidized to retinoic acid to produce its effects within target cells.

Retinoids can influence the expression of receptors for certain hormones and growth factors and thus can influence the growth, differentiation, and function of target cells by both direct and indirect actions (Love and Gudas, 1994).

**Therapeutic Uses.** Nutritional vitamin A deficiency causes xerophthalmia, a progressive disease characterized by nyctalopia (night blindness), xerosis (dryness), and keratomalacia (corneal thinning), which may lead to corneal perforation; xerophthalmia may be reversed with vitamin A therapy (WHO/UNICEF/IVAGG Task Force, 1988). However, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have some role in corneal epithelial wound healing. Currently, there is no evidence to support using topical vitamin A for keratoconjunctivitis sicca in the absence of a nutritional deficiency. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E.

The Age-Related Eye Disease Study (AREDS) found a reduction in the risk of progression of some types of ARMD for those randomized to receive high doses of vitamins C (500 mg), E (400 IU), β-carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg) (Age-Related Eye Disease Study Research Group, 2001). Interestingly, zinc has been found to be neuroprotective in a rat model of glaucoma. The mechanism appears to be mediated by heat shock proteins and may represent a novel treatment strategy for glaucoma (Park et al., 2001).

**Wetting Agents and Tear Substitutes**

**General Considerations.** The current management of dry eyes usually includes instilling artificial tears and ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film. Common viscosity agents include cellulose polymers (e.g., carboxymethylcellulose, hydroxyethyl cellulose, hydroxypropyl cellulose, hydroxypropyl methylcellulose [hypromellose], and methylcellulose), polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycercin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. Tyloxapol (ENCULENE) is marketed as an over-the-counter ophthalmic preparation used to facilitate the wearing comfort of artificial eyes.

The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision, and consequently, they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions. A hydroxypropyl cellulose ophthalmic insert (LACRISERT) that is placed in the inferior cul-de-sac and dissolves during the day is available to treat dry eyes.

Such aqueous, ointment, and insert formulations are only fair substitutes for the precorneal tear film, which truly is a poorly understood lipid, aqueous, and mucin trilaminar barrier (see “Absorption”).

**Therapeutic Uses.** Many local eye conditions and systemic diseases may affect the precorneal tear film. Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes, punctal plugs (see “Absorption”), or ophthalmic cyclosporine (see “Immunomodulatory Agent”). There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren’s syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes, ophthalmic cyclosporine, insertion of punctal plugs, placement of dissolvable collagen implants, or surgical occlusion of the lacrimal drainage system may be indicated. Ophthalmic cyclosporine (RESTASIS) can be used to increase tear production in patients with ocular inflammation associated with keratoconjunctivitis sicca.

**Osmotic Agents**

**General Considerations.** The main osmotic drugs for ocular use include glycerin, mannitol, and hypertonic saline. With the availability of these agents, the use of urea for management of acutely elevated IOP is nearly obsolete.

**Therapeutic Uses.** Ophthalmologists occasionally use glycerin and mannitol for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol and/or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. Identifying the cause of corneal edema will guide therapy, and topical osmotic agents, such as hypertonic saline, may temporize...
the need for surgical intervention in the form of a corneal transplant. Sodium chloride is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain on contact with the cornea and conjunctiva, its use is limited to urgent pressure of filtration-structure closures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred over topical glycerin, which simply clears the cornea temporarily. Reducing the IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

**BIBLIOGRAPHY**

Drugs can be applied to skin for two purposes: to directly treat disorders of the skin and to deliver drugs to other tissues (Figure 65–1). The optimization of cutaneous therapies requires detailed physiological knowledge of the skin as reviewed extensively elsewhere (Wolff et al., 2008). This chapter emphasizes the basis of common skin therapies. Therapies that are used primarily for skin diseases are discussed in detail; other therapies that are applicable for skin disease are summarized and the reader referred to the appropriate portion of this book for their detailed pharmacology and toxicology.

Many skin diseases can be treated with active pharmacological agents topically; understanding the principles for percutaneous drug absorption and metabolism are essential for their effective and safe use.

Non-pharmacological therapy for skin diseases includes the entire electromagnetic spectrum applied by many sources, such as lasers, X-rays, visible light, and infrared light. These approaches may be used alone or to enhance the penetration or alter the nature of drugs and produgs. Freezing and ultrasound are other physical therapies that alter epidermal structure for direct treatment or to enhance percutaneous absorption of drugs. Chemicals are used to decrease the effect of various wavelengths of ultraviolet (UV) light and ionizing radiation.

Effective and safe use of topical agents requires appreciation of the physical and physiological variables that influence the interactions of drugs and the skin, impacting absorption and transport. The skin is a multifunctional and multicompartment organ affected in numerous ways by diseases and their treatments. Figure 65–1 outlines general features of skin structure and percutaneous absorption pathways. The bulk of percutaneous absorption for most agents is through the stratum corneum, which covers almost the entire skin surface. Epidermal structure and the role of hair follicles and sweat glands as pathways for absorption are reviewed below.

**Stratum Corneum.** The stratum corneum (outer 5-600 μm) is the major barrier to percutaneous absorption of drugs and to the loss of water from the body. It is made of “dead” epidermal cells that cannot reproduce and have lost their nuclei and mitochondria. It possesses multiple proteins and lipids that may reversibly or irreversibly bind drugs. Many chemicals and physical treatments to enhance percutaneous absorption work within the stratum corneum. Many drugs may partition into the stratum corneum and can function as a reservoir for drugs that will diffuse into the rest of skin even after topical application of the drug has ceased.

The stratum corneum differs in thickness, with the palm and sole being the thickest (400-600 μm) followed by the general body stratum corneum (10-16 μm), and the scrotum (5 μm). Facial and post-auricular regions have the thinnest stratum corneum. Thickness is only one variable in determining regional differences in drug penetration. Cellular arrangement has a significant role as well.

**Living Epidermis.** The living layers of the epidermis with metabolically active cells comprise a layer ~100 μm thick (Figure 65–2). The lowest layer (basal layer, or stratum basale) is responsible for the bulk of cell division. Several cell layers in the spinous layer (stratum spinosum) contain cells that actively synthesize most epidermal proteins, especially keratins, a large family of intracellular fibrous molecules that form the bulk of the epidermal mass. The uppermost living layer, the granular layer (stratum granulosum), is where extracellular lipids are extruded from the epidermis, forming extracellular lipids that are an important transport pathway; where the cell envelope, resistant to most proteolysis and alkali, is formed; and where extracellular lipids are covalently bound. The granular layer is also the site of synthesis of filaggrin, an intracellular molecule that enhances keratin packing. Filaggrin is proteolyzed at the granular/stratum corneum junction, and its amino acids contribute to a
high free amino acid composition of the stratum corneum, which allows water retention, an acid pH, and natural moisturizing function. Intercalated in the living epidermis are pigment-producing cells (melanocytes), dendritic antigen-presenting cells (Langerhans cells), and other immune cells (γ-δ T cells); in diseased epidermis, many immunological cells, including lymphocytes and polymorphonuclear leucocytes, may be present and be directly affected by applied drugs.

**Dermis and Its Blood Vessels.** There is a superficial capillary plexus between the epidermis and dermis that is the site of the majority of the systemic absorption of cutaneous drugs (Figure 65–1). There are large numbers of lymphatics as well. Beneath the 1.2-mm-thick dermis with its collagen and proteoglycans that may bind drugs, there is subcutaneous tissue (hypodermis). Cells in the dermis that are targets for drugs include mast cells (permanent residents and producers of many inflammatory mediators) and infiltrating immune cells producing cytokines.

Hair follicles form a lipid-rich pathway for drug absorption. The absorption of drugs and chemicals into hair also can be used to measure prior drug exposure. Sweat glands are not known as a pathway for the absorption of drugs. Some drugs (e.g., griseofulvin, ketoconazole) are excreted to the skin by this route.

**Mechanisms of Percutaneous Absorption.** Passage through the outermost layer is the rate-limiting step for percutaneous absorption. The major steps involved in percutaneous absorption include the establishment of a concentration gradient, which provides the driving force for drug movement across the skin, partitioning and movement of the drug from a thin layer outside the stratum corneum into the stratum corneum (partition coefficient), and intrinsic molecular characteristics that allow drug diffusion across the layers of the skin (diffusion coefficient). The ideal relationship of these factors to each other is summarized in the following equation:

$$J = C_{\text{veh}} \cdot K_m \cdot D/x$$

where $J$ is the rate of absorption, $C_{\text{veh}}$ is the concentration of drug in the vehicle, $K_m$ is the partition coefficient, $D$ is the diffusion coefficient, and $x$ is the thickness of stratum corneum (Piacquadio and Kligman, 1998). This equation represents the
ideализированной ситуации и может только приближенно указывать, что происходит в нормальной или больной эпидермисе.

Предпочтительные характеристики топикосов включают низкую молекулярную массу (600 Да), достаточную растворимость в воде и жире, а также высокую коэффициент разделения (Barry, 2004) так, чтобы препарат разделился бы между собой и стратум корнеум. Исключением является очень небольшие частицы, которые полезны для увлажнения и улучшения прохождения через целостную эпидермис. Коммерческие топикосы выпускаются в оптимальной концентрации и разделении, и внешние добавки могут влиять на активность препарата и изменять его поглощение.

Лекарства могут целиться на ферменты или клетки любой из областей эпидермиса, включая воспалительные клетки, которые не являются нормальной частью. В клинических ситуациях обычно не измеряют количество препарата, которое входит в или выходит из кожи, а конечная цель (например, снижение воспаления) является целью.

Увлажнение эпидермиса позволяет более проникающим в кожу и часто достигается через выбор препаратов, разработанных в контактных средствах, таких как мази, пластыри, перчатки и носовые капии, а также через использование препаратов, которые впитываются на пatches или тапы. Ограниченная проницаемость часто связана с ростом бактерий, приводящих к инфекции (фолликулиту) или макерации и разрушению эпидермиса. Перенос большинства препаратов происходит путем被动ного термодинамического процесса, и тепло увеличивает проникновение. Ультразвуковые волны или удары могут использоваться для увеличения проникновения. они могут способствовать созданию пустот в эпидермисе.

Эпидермис содержит различные ферментные системы, способные метabolизировать препараты, достигающие этой области. Многие из ферментов имеют генетически определенные варианты, которые могут влиять на активность препарата. Некоторые из ферментов, которые были подробно изучены, включают CYPs, эпоксидуридилазы, трансферазы, такие как N-ацилтрансферазы, глюкуронилтрансферазы, и сульфатазы (Baron et al., 2001). Определенные ферменты CYP, например, CYP26A1, метаболизируют ретиноиды и могут контролировать их уровень в коже (Baron et al., 2001). В дополнение к транспортерам, которые влияют на приток (OATP) или удаление (MDR, P-гликопротеин) некоторых хинонов, генетические варианты ферментов, регулирующих клеточный приток и удаление метотрексата, были связаны с токсичностью и эффективностью у пациентов с псориазом (Warren et al., 2008).

Фармацевтические последствия эпидермального строения. Врач-препаратолог должен ответить на ряд вопросов при предложении применения топических препаратов (Таблица 65-1), включая рассмотрение правильной дозировки и частоты применения, а также условия использования.

</table>

The permeability barrier, patient age and weight, physical form of the preparation to be applied, and whether intralesional or systemic administration should be used.

Dosage. Covering the entire skin of an adult with a topical preparation requires ~30 g of spreadable material. Underapplication of drug because of cost considerations often occurs when large amounts of skin are treated for a long time.

Regional Anatomical Variation. Permeability generally is inversely proportional to the thickness of the stratum corneum. Drug penetration is higher on the face, intertriginous areas, and perineum due to stratum corneum thickness. Skin sites that are naturally occluded by apposing surfaces, such as the axillae, groin, and inframammary areas, are vulnerable to drug-related atrophy from potent topical glucocorticoids.

Altered Barrier Function in Disease. In many dermatological diseases, the stratum corneum is abnormal and barrier function is compromised. In these settings, increased percutaneous absorption of potential topical steroids can cause systemic toxicity, such as hypothalamic–pituitary–adrenal (HPA) axis suppression.

Vehicle. Drug vehicles are summarized in Table 65–2. Newer vehicles include liposomes and microgel formulations. Liposomes are concentric spherical shells of phospholipids in an aqueous medium intended to enhance percutaneous absorption in normal and abnormal stratum corneum. Variations in size, charge, and lipid content can influence liposome function substantially. Transfersomes are a drug-delivery technology based on highly deformable, ultraflexible lipid vesicles that penetrate the skin when applied nonocclusively (Barry, 2004). Microgels are polymers intended to enhance solubilization of certain drugs, thereby enhancing topical penetration and diminishing irritancy.

Age. Children have a greater ratio of surface area to mass than adults do, so the same amount of topical drug can result in a greater systemic exposure. Based on transepidermal water loss and percutaneous absorption studies, term infants seem to possess a stratum corneum with barrier properties comparable to adults. Preterm infants have markedly impaired barrier function until the epidermis keratinizes completely.

Application Frequency. Topical agents often are applied twice daily. For certain drugs, once-daily application of a larger dose may be equally effective as more frequent applications of smaller doses. For some drugs, the stratum corneum may act as a drug reservoir that allows gradual penetration into the viable skin layers over a prolonged period. Intermittent pulse therapy—treatment for several days or weeks alternating with treatment-free periods—may prevent development of tachyphylaxis (loss of clinical effectiveness associated with drugs such as topical glucocorticoids). The mechanism of loss of effectiveness may be related to the corticosteroid binding and response of nuclear receptors rather than absorption.

Intralesional Administration. Intralesional drug administration is used mainly for inflammatory lesions but also can be used for treatment of warts and selected neoplasms. Medications injected intralesionally have the advantages of direct contact with the underlying pathological process, no first-pass metabolism, and the opportunity for a slowly absorbed depot of drug. In considering the use of intralesional glucocorticoids, it is important to be cognizant of the possibility of complete systemic absorption and suppression of the HPA.

Systemic Administration. Systemic administration of medication in dermatology involves several routes of administration: oral, intramuscular (e.g., methotrexate, glucocorticoids), intravenous (e.g., immunoglobulin, alefacept), or subcutaneous (e.g., efalizumab, etanercept).

GLUCOCORTICOIDS

Glucocorticoids are prescribed frequently for their immunosuppressive and anti-inflammatory properties. They are administered locally, through topical and intralesional routes, and systemically, through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are numerous, as discussed in Chapter 42. These include apoptosis of lymphocytes, inhibitory effects on the arachidonic acid cascade, depression of production of many cytokines, and myriad effects on inflammatory cells.

Topical Glucocorticoids

Topical glucocorticoids have been grouped into seven classes in order of decreasing potency (Table 65–3); many of the more potent drugs have a fluorinated hydrocortisone backbone. Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion, and the area of skin blanching is assessed. Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

Therapeutic Uses. Many inflammatory skin diseases respond to topical or intralesional administration of
glucocorticoids. Absorption varies among body areas; the steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a more potent steroid is used initially, followed by a less potent agent. Most practitioners become familiar with at least one glucocorticoid in each class to facilitate selection of the appropriate strength of therapy. Twice-daily application of topical glucocorticoids is sufficient, and more frequent application does not improve response (Green et al., 2005). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin.

Intralesional preparations of glucocorticoids include insoluble preparations of triamcinolone acetonide (KENALOG-10) and triamcinolone hexacetonide.
(ARISTOSPAN), which solubilize gradually and therefore have a prolonged duration of action.

Toxicity. Chronic use of class 1 topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used on this site. Occlusion increases the risk of HPA suppression.

**Systemic Glucocorticoids**

Therapeutic Uses. Systemic glucocorticoid therapy is used for severe dermatological illnesses. In general, it is best
to reserve this method for allergic contact dermatitis to plants (e.g., poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see Chapter 42).

Daily morning dosing with prednisone generally is preferred, although divided doses occasionally are used to enhance efficacy. Fewer side effects are seen with alternate-day dosing, and if chronic therapy is required, prednisone usually is tapered to every other day as soon as it is practical. Pulse therapy using large intravenous doses of methylprednisolone sodium succinate (solumedrol, others) is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multi-system disease, and dermatomyositis. The dose usually is 0.5-1 g given over 2-3 hours. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

**Toxicity and Monitoring.** Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 42. Most side effects are dose dependent. Long-term use is associated with a number of complications, including psychiatric problems, cataracts, myopathy, osteoporosis, avascular bone necrosis, glucose intolerance or overt diabetes mellitus, and hypertension. In addition, psoriatic patients treated with parenteral or topical glucocorticoids may have a pustular flare, particularly if the steroid is tapered rapidly.

**RETINOIDs**

Retinoids are defined as natural and synthetic compounds that exhibit vitamin A–like biological activity or bind to nuclear receptors for retinoids. Retinoids have many important functions throughout the body, including roles in vision, regulation of cell proliferation and differentiation and bone growth, immune defense, and tumor suppression (Vahlquist et al., 2008). Early use of systemic retinoids to treat acne and disorders of keratinization was limited by the toxic side effects of first-generation retinoids. This was largely solved through molecular modifications that yielded new generations of compounds with vastly improved margins of safety. First-generation retinoids include retinol (vitamin A), tretinoin (all-trans-retinoic acid; vitamin A acid), isotretinoin (13-cis-retinoic acid), and alitretinoin (9-cis-retinoic acid). Second-generation retinoids, also known as aromatic retinoids, were created by aromatization of the cyclic end group and include acitretin and methoxsalen (also known as etretinate; not marketed in the U.S.). Third-generation retinoids were created after the discovery of specific retinoid receptors and have diverse structures designed to optimize receptor-selective binding. Members of this generation include tazarotene, bexarotene, and adapalene. Characteristics of topical and systemic retinoids are summarized in Tables 65–4 and 65–5.

Retinoids exert their effects on gene expression by activating two families of receptors—retinoic acid receptors (RARs) and retinoid X receptors (RXRs)—that are members of the steroid receptor superfamily (Winterfield et al., 2003). Both retinoid receptor families have three isoforms (α, β, and γ), which are expressed in unique combinations in individual tissues and cells. The human epidermis, for example, expresses RAR-α, RAR-γ, RXR-α, and RXR-β (Kang and Voorhees, 2008). Upon binding to a retinoid, RARs and RXRs form heterodimers (RAR-RXR), which subsequently bind specific DNA sequences called retinoic acid–responsive elements (RAREs) that activate transcription of genes whose products produce the desirable pharmacological effects of these drugs and their unwanted side effects (Bastien and Rochette-Egly, 2004).

Unique therapeutic effects can be produced by targeting specific retinoid receptors. For example, retinoids that target RARs predominantly affect cellular differentiation and proliferation, whereas retinoids that target RXRs predominantly induce apoptosis (Germain et al., 2006a; Germain et al., 2006b). Hence, tretinoin, adapalene, and tazarotene, which target RARs, are used in acne, psoriasis, and photoaging (disorders of differentiation and proliferation), whereas bexarotene and alitretinoin, which target RXRs, are used in mycosis fungoides and Kaposi sarcoma (to induce apoptosis of malignant cells). Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of systemic retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, reduced night vision, hair loss, alterations in serum lipids and transaminases, hypothyroidism, inflammatory bowel disease flare, musculoskeletal pain, pseudotumor cerebri, and mood alterations. RAR-selective retinoids are more associated with mucocutaneous and musculoskeletal symptoms, whereas RXR-selective retinoids induce more physiochemical changes (Germain et al., 2006a; Germain et al., 2006b). Because all oral retinoids are potent teratogens, they should be used carefully in females of childbearing potential and not in pregnant patients or patients who are trying to conceive. Suicide or suicide attempts have been associated with the use of isotretinoin. Thus, all patients treated with isotretinoin should be observed closely for symptoms of depression or suicidal thoughts.

**Topical Retinoids**

Acne is believed to result from a combination of sebaceous gland hyperplasia, follicular hyperkeratosis, Propionibacterium acnes colonization, and inflammation. Through incompletely understood mechanisms, topical retinoids correct abnormal follicular keratinization, reduce P. acnes counts, and reduce inflammation, thereby making them the cornerstone of acne therapy. Topical retinoids are first-line agents for non-inflammatory (comedonal) acne and often are combined with other agents in the management of inflammatory acne.

Fine wrinkles and dyspigmentation, two important features of photoaging, also are improved with
topical retinoids. Within the dermis, this is believed to result from inhibition of activator protein-1 (AP-1), a transcription factor composed of c-Jun and c-Fos that normally activates synthesis of matrix metalloproteinases in response to UV irradiation (Kang and Voorhees, 2008). In the epidermis, retinoids induce epidermal hyperplasia in atrophic skin and reduce keratinocyte atypia (Sami and Harper, 2007).

**Toxicity and Monitoring.** Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging (Table 65–4). These effects often decrease with time and are lessened by concomitant use of emollients. Patients also may experience photosensitivity reactions because of enhanced reactivity to UV radiation and have a significant risk for severe sunburn. Although there is little systemic absorption of topical retinoids and no alteration in plasma vitamin A levels with their use, it is recommended that exposure to topical retinoids be avoided during pregnancy.

**Tretinoin**
Topical tretinoin (all-trans-retinoic acid) is photolabile and thus should be applied once nightly for acne and photoaging. Benzoyl peroxide also inactivates tretinoin and should not be applied simultaneously. Formulations with copolymer microspheres (RETIN-A MICRO) or prepolyolprepolymer-2 (AVITA) that gradually release tretinoin to decrease irritancy are available.

**Adapalene**
Adapalene (differin) has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight, stable in the presence of benzoyl peroxide, and tends to be less irritating at the 0.1% concentration.

**Tazarotene**
Tazarotene (TAZORAC, AVAGE) is a third-generation retinoid approved for the treatment of psoriasis, photoaging, and acne vulgaris (Sami and Harper, 2007). Tazarotene gel, applied once daily, may be used...
as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. Topical corticosteroids improve the efficacy of therapy and reduce the side effects of burning, itching, and skin irritation that are commonly associated with tazarotene.

**Alitretinoin**

Alitretinoin (PANRETIN) is a retinoid that binds all types of retinoid receptors and is applied two to four times daily to cutaneous lesions of Kaposi sarcoma. Alitretinoin should not be applied concurrently with insect repellants containing diethyltoluamide (DEET, N,N-diethyl-m-toluamide) because it may increase DEET absorption.

**Bexarotene**

Topical bexarotene (TARGRETIN) is approved for early-stage (IA and IB) cutaneous T-cell lymphoma. Its application is titrated up from every other day to two to four times daily over several weeks to improve patient tolerance. Its mechanism of action may involve downregulation of survivin and upregulation of caspase-3, leading to apoptosis of malignant cells (Sami and Harper, 2007). Patients using bexarotene should avoid products containing DEET due to an increased risk for DEET toxicity.

---

**Systemic Retinoids**

Systemic retinoids are approved for the treatment of acne, psoriasis, and cutaneous T-cell lymphoma (Table 65–5). Off-label uses include ichthyosis, Darier’s disease, pityriasis rubra pilaris, rosacea, hidradenitis suppurativa, chemoprevention of malignancy, lichen sclerosus, subacute lupus erythematosus, and discoid lupus erythematosus. All systemic retinoids are contraindicated in women who are pregnant, contemplating pregnancy, or breast-feeding. Relative contraindications include leukopenia, alcoholism, hyperlipidemia, hypercholesterolemia, hypothyroidism, and significant hepatic or renal disease.

*Toxicity and Monitoring.* Acute retinoid toxicities may include mucocutaneous or laboratory abnormalities; bony changes may occur after chronic use at high doses. Mucocutaneous side effects may include cheilitis, xerosis, blepharoconjunctivitis, cutaneous photosensitivity,
photophobia, myalgia, arthralgia, headaches, alopecia, nail fragility, and increased susceptibility to staphylococcal infections. Some patients develop a “retinoid dermatitis” characterized by erythema, pruritus, and scaling.

Very rarely, patients may develop pseudotumor cerebri, especially when systemic retinoids are combined with tetracyclines (tetracycline or minocycline; the mechanism for this adverse drug event is unknown). There are reports that chronic administration at higher doses can cause diffuse idiopathic skeletal hyperostosis (DISH) syndrome, premature epiphyseal closure, and other skeletal abnormalities (Vahlquist et al., 2008).

Systemic retinoids are highly teratogenic. There is no safe dose during pregnancy. Common malformations include craniofacial, cardiovascular, thymic, and central nervous system (CNS) abnormalities. Although there appears to be minimal, if any, risk of retinoid embryopathy in fetuses conceived by males taking systemic retinoids, it is commonly recommended that men avoid retinoid therapy when actively trying to father children. Prescribing of isotretinoin in the U.S. is restricted via the risk-mitigation iPLEDGE system (Goldsmith et al., 2004).

Serum lipid elevation is the most common laboratory abnormality. This may be due to increased expression of apolipoprotein C-III by systemic retinoids, which prevents the uptake of lipids from very-low-density lipoproteins into cells (Vahlquist et al., 2008). Other, less common, laboratory abnormalities include elevated transaminases, decreased thyroid hormone, and leukopenia. A baseline evaluation of serum lipids, serum transaminases, and complete blood count (CBC) and a pregnancy test should be obtained prior to starting any systemic retinoids. Laboratory values should be checked monthly for the first 3-6 months and once every 3 months thereafter.

Isotretinoin

Isotretinoin (ACCUTANE, others) is approved for the treatment of recalcitrant and nodular acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. It normalizes keratinization in the sebaceous follicle, reduces sebocyte number with decreased sebum synthesis, and reduces P. acnes (Vahlquist et al., 2008). Clinical effects generally are noted within 1-3 months of starting therapy.

Approximately one-third of patients will relapse, usually within 3 years of stopping therapy (Vahlquist et al., 2008). Preteens, males, and patients with acne conglobata or androgen excess are at increased risk of relapse. Although most relapses are mild and respond to conventional management with topical and systemic anti-acne agents, some may require a second course of isotretinoin.

There are several reports of patients developing signs of depression while on isotretinoin. However, large studies have failed to prove an association between isotretinoin use and depression.

Since it is possible that an idiosyncratic reaction occurs in a small group of otherwise healthy individuals, current guidelines recommend monthly monitoring of all patients on isotretinoin for signs of depression.

Acitretin

Acitretin (SORIATANE, SORIATANE CK) is approved for use in the cutaneous manifestations of psoriasis. It is especially useful in pustular psoriasis, although all forms of cutaneous psoriasis are responsive to acitretin. Clinical effect typically begins within 4-6 weeks, with the full clinical benefit occurring at 3-4 months.

Although acitretin has a t1/2 of ~50 hours, when combined with alcohol, acitretin is esterified in vivo to produce etretinate, which has a t1/2 of >3 months (Vahlquist et al., 2008). It is not known how much alcohol (i.e., cough syrup or other alcohol-based medications) is required to induce this conversion. Therefore, female patients of childbearing age should avoid pregnancy for 3 years after receiving acitretin to avoid retinoid-induced embryopathy.

Bexarotene

Bexarotene (TARGETIN) is a retinoid that selectively binds RXRs. Oral and topical formulations of bexarotene are approved for use in patients with cutaneous T-cell lymphoma. Although the exact mechanism of action is unknown, studies suggest that bexarotene induces apoptosis of malignant cells (Budgin et al., 2005). Because it is metabolized by CYP3A4, inhibitors of CYP3A4 (e.g., imidazole antifungals, macrolide antibiotics) will increase and inducers of CYP3A4 (e.g., rifamycins, carbamazepine, dexamethasone, efavirenz, phenobarbital) will decrease plasma levels of bexarotene. Laboratory side effects are more common than with other retinoids, with an increased incidence of significant lipid abnormalities and hypothyroidism secondary to a reversible RXR-mediated suppression of TSH gene expression (Sherman, 2003), pancreatitis, leukopenia, and gastrointestinal (GI) symptoms. Unlike other retinoids, thyroid function should be measured before initiating therapy and periodically thereafter. Mucocutaneous side effects are less than with other systemic retinoids.

**VITAMIN ANALOGS**

**β-Carotene.** β-Carotene is a precursor of vitamin A that is present in green and yellow vegetables. Solatene has been discontinued, and no β-carotene products are currently approved by the U.S. Food and Drug Administration (FDA).

Dietary supplementation with β-carotene is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is not established but may involve an anti-oxidant effect that decreases the production of free radicals or singlet oxygen (Alemzedeh, 2004). However, a recent meta-analysis concluded that β-carotene, vitamin A, and vitamin E given singly or combined with other anti-oxidant supplements actually increase mortality (Bjelakovic et al., 2007). FDA’s Maximum Recommended Therapeutic Dose (MRTD) database (http://www.fda.gov/AboutFDA/CentersOffices/CDER/ucm092199.htm) lists 0.05 mg/kg/day as the MRTD for β-carotene.
Calcipotriene. Calcipotriene (DOVONEX, others) is a topical vitamin D analog that is used in the treatment of psoriasis. Although calcipotriene is not a retinoid, it exerts its effects through modulation of similar proteins and pathways as the retinoids, leading to similar effects. Calcipotriene exerts its effects through the vitamin D receptor (VDR), a member of the thyroid hormone, corticosteroid, and retinoic acid nuclear receptor gene family (see Chapter 44). Upon binding the VDR, the drug-receptor complex associates with the RXR-α and binds to vitamin D response elements on DNA. Genes that modulate epidermal differentiation and inflammation are subsequently expressed, leading to improvement in psoriatic plaques (Bikle et al., 2001).

Calcipotriene is applied twice daily to plaque psoriasis on the body, often in combination with topical corticosteroids. Hypercalcemia and hypercalciuria may develop when the cumulative weekly dose exceeds the recommended 100g/wk limit and resolves within days of discontinuation of calcipotriene (Bleiker et al., 1998). Calcipotriene also causes perilesional irritation and mild photosensitivity. Irritancy is reduced by concomitant administration of topical corticosteroids.

**PHOTOCHEMOTHERAPY**

Electromagnetic radiation is defined by its wavelength and frequency. Based on its biological activity, dermatologists subdivide the UV region into UVB (290-320 nm), UVA2 (320-340 nm), UVA1 (340-400 nm), and UVC (100-290 nm) radiation. UVC radiation is almost completely absorbed by stratospheric ozone, does not reach Earth’s surface, and is not used therapeutically. UVB is the most erythrogenic and melanogenic type of radiation. It is the major action spectrum for sunburn, tanning, skin cancer, and photoaging. UVA radiation is a thousand times less erythrogenic than UVB but penetrates more deeply into the skin and contributes substantially to photoaging and photosensitivity diseases. Visible radiation (400-800 nm) reaches the retina and produces the sensation of vision.

Phototherapy and photochemotherapy are treatment methods in which UV or visible radiation is used to induce a therapeutic response either alone or in the presence of a photosensitizing drug. To be effective, the incident radiation must be absorbed by a target or chromophore in the skin—which in phototherapy is endogenous and in photochemotherapy must be administered exogenously (Table 65–6). Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications before initiation of therapy. Such drugs include phenothiazines, thiazides, sulfonamides, nonsteroidal anti-inflammatory agents, sulfonylureas, tetracyclines, and benzodiazepines.

**PUVA: Psoralens and UVA.** Photochemotherapy with psoralen-containing plant extracts was employed for the treatment of vitiligo in Egypt and India as early as 1500 B.C. Orally administered 8-methoxypsoralen followed by UVA (PUVA) is FDA approved for the treatment of vitiligo and psoriasis.

**Chemistry.** Psoralens are lipophilic molecules belonging to the furocoumarin class of compounds, which are derived from the fusion of a furan with a coumarin. One psoralen, methoxsalen (8-methoxypsoralen, oxsoralen ultra, 8-mop, others) is available in the U.S. The structures of two common psoralens are:

- Methoxsalen
- Trioxsalen

**Dermatological Pharmacology**

**Pharmacokinetics.** Dissolved psoralens (e.g., oxsoralen ultra) are absorbed rapidly after oral administration, whereas crystallized forms (e.g., 8-mop) are absorbed slowly and incompletely. Fatty foods also reduce absorption. Furthermore, there is a significant, but saturable, first-pass elimination in the liver. For these reasons, peak photosensitivity varies significantly between individuals but typically is maximal 1-2 hours after ingestion. Methoxsalen has a serum t½ of ~1 hour, but the skin remains sensitive to light for 8-12 hours.

**Mechanism of Action.** The action spectrum for oral PUVA is between 320 and 340 nm. Two distinct photoreactions take place. Type I reactions involve the oxygen-independent photoaddition of psoralens to pyrimidine bases in DNA. Type II reactions are oxygen dependent and involve the transfer of energy to molecular oxygen, creating reactive oxygen species. Through incompletely understood mechanisms, these phototoxic reactions stimulate melanocytes and induce anti-proliferative, immunosuppressive, and anti-inflammatory effects (Stern, 2007).

**Therapeutic Uses.** Methoxsalen is supplied in soft gelatin capsules (oxsoralen-ultra) and hard gelatin capsules (8-mop) for oral use. The dose is 10-70 mg, depending on weight (0.4-0.6 mg/kg), taken 1.5-2 hours or 2 hours before UVA exposure for oxsoralen-ultra and 8-mop, respectively. A lotion containing 1% methoxsalen (oxsoralen) is available for topical application for vitiligo and can be
diluted for use in bath water to minimize systemic absorption. An extracorporeal solution (UV ADEX) is available for cutaneous T-cell lymphoma (see “Photopheresis”).

Approximately 90% of psoriatic patients have clearing or virtual clearing of skin disease within 30 treatments with methoxsalen (Morison, 2007). Remission typically lasts 3-6 months; thus, patients often require maintenance therapy with intermittent PUVA or other agents (Stern, 2007). Vitiligo typically requires between 150 and 300 treatments to produce satisfactory repigmentation. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed off label in the treatment of atopic dermatitis, alopecia areata, lichen planus, and urticaria pigmentosa and as a preventive modality in some forms of photosensitivity.

**Toxicity and Monitoring.** The major side effects of PUVA are listed in Table 65–6. Phototoxicity is characterized by erythema, edema, blistering, and pruritus. Ocular toxicity can be prevented by wearing UVA-blocking glasses the day of treatment. The risk of nonmelanoma skin cancer is dose dependent, with the greatest risk in those receiving >250 treatments. A possible association of melanoma and extensive exposure to PUVA has been reported; however, several other studies have failed to confirm this association (Morison, 2007). As skin cancer may not develop for decades after exposure, annual skin exams should be continued for years after completion of PUVA.

**Photopheresis.** Extracorporeal photopheresis (ECP) is a process in which extracorporeal peripheral blood mononuclear cells are exposed to UVA radiation in the presence of methoxsalen. Although previously given orally (Edelson et al., 1987), methoxsalen (UV ADEX) now is injected directly into the extracorporeal plasma before radiation and reinfusion. The treated lymphocytes are returned to the patient undergoing apoptosis over 48-72 hours (McKenna et al., 2006).

ECP is used for cutaneous T-cell lymphoma and off label for various other T-cell mediated diseases, including graft-versus-host disease, transplantation rejection, scleroderma, and type 1 diabetes mellitus (McKenna et al., 2006). The mechanism of action of ECP include apoptosis of T cells, generation of clone-specific suppressor T cells, shifting of the T-cell phenotype, production of an immune response against the pathogenic T cells, and release of cytokines (McKenna et al., 2006).

Initially, patients receive therapy every 1–4 weeks, and intervals are increased as the patient improves. In patients who do not respond to monotherapy or those with significant tumor burden, ECP can be combined with adjunctive therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

Photodynamic Therapy (PDT). This modality combines the use of photosensitizing drugs and visible light for the treatment of various dermatological disorders. In dermatology, two drugs are approved for topical PDT: aminolevulinic acid (ALA; LEVULAN KERASTICK) and methylaminolevulinate (MAL; METVIXIA). Both are prodrugs that are converted into protoporphyrin IX within living cells (Figure 65–3). In the presence of specific wavelengths of light (Table 65–6) and oxygen, protoporphyrin produces singlet oxygen (type 2 photochemical reaction), which oxidizes cell membranes, proteins, and mitochondrial structures, leading to apoptosis. Sebaceous glands, the epidermis, and neoplastic cells accumulate more porphyrin than other cutaneous cells and structures; thus, PDT is approved for use on precancerous actinic keratoses and also is commonly used on thin, nonmelanoma skin cancers; acne; and photorejuvenation (improving the appearance of photodamaged skin) (Kalka et al., 2000; Lopez et al., 2004).

Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin (Table 65–6) and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Because the $t_{1/2}$ of the accumulated porphyrins is ~30 hours, patients should protect their skin from sunlight and intense light for at least 48 hours after treatment to prevent phototoxic reactions.

### ANTIHISTAMINES

Histamine (see Chapter 32) is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch receptors (Repka-Ramirez and Baraniuk, 2002). In addition to histamine, multiple chemical itch mediators can act as pruritogens on C fibers, including neuropeptides, prostaglandins, serotonin, acetylcholine, and bradykinin (Stander et al., 2003). Furthermore, receptor systems, such as vanilloid, opioid, and cannabinoid receptors, on cutaneous sensory nerve fibers that may modulate itch and offer novel future targets for anti-pruritic therapy have been identified.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express H$_1$, H$_2$, and H$_4$ receptors but not H$_3$ receptors (Lippert et al., 2004). H$_1$ and H$_2$ receptors are involved in wheal formation and erythema, whereas only H$_1$ receptor agonists cause pruritus (see Chapter 32). Complete blockade of H$_1$ receptors does not totally relieve itching, and combination therapy with H$_1$ and H$_2$ blockers may be superior to the use of H$_1$ blockers alone (Table 65–7).

Oral antihistamines, particularly H$_1$ receptor antagonists, have anticholinergic activity and are sedating (see Chapter 32),...
making them useful for the control of pruritus. First-generation sedating H<sub>1</sub> receptor antagonists include hydroxyzine, diphenhydramine (BENADRYL, others), promethazine, and cyproheptadine. Doxepin, which has tricyclic antidepressant and sedative and antihistaminic effects (see Chapter 15), is a good alternative to traditional oral antihistamines for severe pruritus. A 5% topical cream formulation of doxepin (PRUDOXIN, ZONALON), which can be used in conjunction with low- to moderate-potency topical glucocorticoids, also is available. Allergic contact dermatitis to doxepin has been reported. The anti-pruritic effect from topical doxepin is comparable to that of low-dose oral doxepin therapy.

Second-generation H<sub>1</sub> receptor antagonists lack anticholinergic side effects and are described as non-sedating largely because they do not cross the blood-brain barrier. They include cetirizine (ZYRTEC, others), levocetirizine dichloride (XYZAL), loratadine (CLARITIN, others), desloratadine (CLARINEX), and fexofenadine hydrochloride (ALLEGRA, others). While second-generation “nonsedating” H<sub>1</sub> receptor blockers are as effective as the first-generation H<sub>1</sub> blockers, they are metabolized by CYP3A4 and, to a lesser extent, by CYP2D6 and should not be co-administered with medications that inhibit these enzymes (e.g., imidazole antifungals, macrolide antibiotics).

**ANTIMICROBIAL AGENTS**

**Antibiotics**

These drugs commonly are used to treat superficial cutaneous infections (Table 65–8) (pyoderma) and noninfectious diseases, including acne rosacea, perioral dermatitis, hidradenitis suppurativa, auto-immune blistering diseases, sarcoidosis, and pyoderma gangrenosum (Carter, 2003). Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris. Systemic antibiotics also are prescribed commonly for acne and deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VI, Chemotherapy of Infectious Diseases. Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne vulgaris is the most common dermatological disorder treated with either topical or systemic antibiotics. The anaerobe *P. acnes* is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where O<sub>2</sub> tension is low. *P. acnes* generates free fatty acids that

are irritants and may lead to microcomedo formation and resulting inflammatory lesions. Suppression of cutaneous *P. acnes* with antibiotic therapy is correlated with clinical improvement (Tan, 2003).

Commonly used topical antimicrobials in acne include clindamycin (CLEOCIN-L, others), erythromycin (ERYDERM, others), benzoyl peroxide, and antibiotic–benzoyl peroxide combinations (BENZACLIN, DUAC, others). Other antimicrobials used in treating acne include sulfacetamide (KLARON, others), sulfacetamide/sulfur combinations (SULFACET-R, others), metronidazole (METROCREAM, METROGEL, NORITATE), and azelaic acid (AZELEX, others). *Systemic therapy* is prescribed for patients with more extensive disease and acne that is resistant to topical therapy. In healthy individuals taking oral antibiotics for acne, laboratory monitoring is not necessary. Effective agents include tetracycline (SUMYCIN, others), doxycycline (MONODOX, others), minocycline (MINOCIN, others), and trimethoprim–sulfamethoxazole (BACTRIM, others). Antibiotics usually are administered twice daily, and doses are tapered after control is achieved.

The tetracyclines are the most commonly employed antibiotics because they are inexpensive, safe, and effective. The initial daily dose usually is 1 g in divided doses. Although tetracyclines are antimicrobial agents, efficacy in acne may be more dependent on anti-inflammatory activity. Minocycline has better GI absorption than tetracycline and may be less photosensitizing than either tetracycline or doxycycline. Side effects of minocycline include dizziness and hyperpigmentation of the skin and mucosa, serum sickness–like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with local administration of antifungal drugs.

**Cutaneous Infections.** Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of pyoderma. Skin infections with Gram-negative bacilli are rare, although they can occur in diabetics and patients who are immunosuppressed; appropriate parenteral antibiotic therapy is required for their treatment.

**Topical therapy** frequently is adequate for impetigo, the most superficial bacterial infection of the skin caused by *S. aureus* and *S. pyogenes*. Mupirocin (pseudomonic acid, BACTROBAN, others), produced by *Pseudomonas fluorescens*, is effective for such localized infections. It inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is highly active against *Staphylococcus* and all *Streptococcus* except those of group D. It is less active against gram-negative organisms, but it has *in vitro* activity against *Haemophilus influenzae*, *Neisseria gonorrhoeae*, *Pasteurella multocida*, *Moraxella catarrhalis*, and *Bordetella pertussis*. Mupirocin is inactive against normal skin flora. Its antibacterial activity is enhanced by the acid pH of the skin surface. Mupirocin is available as a 2% ointment or cream and is applied three times daily. A nasal formulation is indicated to eradicate methicillin-resistant *S. aureus* (MRSA) nasal colonization.

Retapamulin ointment 1% (ALTABAX) also is FDA approved for the topical treatment of impetigo caused by susceptible strains of *S. aureus* or *S. pyogenes* in patients ≥9 months of age. Retapamulin selectively inhibits bacterial protein synthesis by interacting at a site on the 50S subunit of bacterial ribosomes.

**Topical therapy** often is employed for prophylaxis of superficial infections caused by wounds and injuries. Neomycin is active against staphylococci and most gram-negative bacilli. It may cause allergic contact dermatitis, especially on disrupted skin. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Polymyxin B is active against aerobic gram-negative bacilli. Neomycin, bacitracin, polymyxin B (NEOSPORIN ORIGINAL OINTMENT, DOUBLE ANTIBIOTIC OINTMENT, others) are sold alone or in various combinations with other ingredients (e.g., hydrocortisone, lidocaine, or pramoxine) in a number of over-the-counter (OTC) formulations for the first aid of minor scrapes, burns, and cuts.

Deeper bacterial infections of the skin include folliculitis, erysipelas, cellulitis, and necrotizing fasciitis. Because streptococcal and *Staphylococcus* species also are the most common causes of deep cutaneous infections, penicillins (especially β-lactamase–resistant β-lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment (Carter, 2003) (see Chapter 44). A growing concern is the increased incidence of skin and soft-tissue infections with hospital- and community-acquired MRSA and drug-resistant pneumonia. Infection with community-acquired MRSA often is susceptible to trimethoprim–sulfamethoxazole (Cohen and Grossman, 2004).

In addition to various traditional systemic antibiotics (such as erythromycin), novel antibacterial agents such as linezolid, quinupristin–dalfopristin, and daptoximycin also have been approved for the treatment of complicated skin and skin-structure infections (see Chapter 53).

**Antifungal Agents**

Fungal infections are among the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. Griseofulvin, topical and oral imidazoles, triazoles, and allylamines are the most effective agents available. Examples include butenafine, clotrimazole, gentian violet, sertaconazole, ketoconazole, nystatin, oxiconazole, sulconazole, tolnaftate, undecylenic acid, and the antifungal combinations BENSAL HP, WHIT-FIELD’S OINTMENT (benzoic acid + salicylic acid), VERSICLEAR LOTION (25% sodium thiosulfate + 1% salicylic acid), CASTELLANI PAINT MODIFIED (basic fuchsin + phenol + resorcinol + acetone), and FUNGI-NAIL (1% resorcinol + 2% salicylic acid + 2% chloroxylenol + 0.5% benzocaine + 50% isopropyl alcohol). The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 57. This section will address the management of common cutaneous fungal
achieved with both drugs (Gupta et al., 1994a; Gupta et al., 1994b). Daily for 1 wk/mo for two pulses. Cure rates of 75% have been obtained with naftifine (NAFTIN) and terbinafine (LAMISIL, others) are effective topical agents for the treatment of localized tinea corporis and uncomplicated tinea pedis. Topical therapy with the azoles is preferred for localized cutaneous candidiasis and tinea versicolor.

Systemic therapy is necessary for the treatment of tinea capitis or follicular-based fungal infections. Oral griseofulvin has been the traditional medication for treatment of tinea capitis. Oral terbinafine is a safe and effective alternative to griseofulvin in treating tinea capitis in children (Moosavi et al., 2001).

**Tinea Pedis.** Topical therapy with the azoles and allylamines is effective for tinea pedis. Macerated toe web disease may require the addition of antibacterial therapy. Econazole nitrate, which has a limited antibacterial spectrum, can be useful in this situation. Systemic therapy with griseofulvin, terbinafine, or itraconazole (SPORANOX, others) is used for more extensive tinea pedis. It should be recognized that long-term topical therapy may be necessary in some patients after courses of systemic antifungal therapy.

**Onychomycosis.** Fungal infection of the nails most frequently is caused by dermatophytes and Candida. Mixed infections are common. Because up to one-third of dystrophic nails that appear clinically to be onychomycosis are actually due to psoriasis or other conditions, the nail must be cultured or clipped for histological examination before initiating therapy.

Systemic therapy is necessary for effective management of onychomycosis. Treatment of onychomycosis of toenails with griseofulvin for 12-18 months produces a cure rate of 50% and a relapse rate of 50% after 1 year. Terbinafine and itraconazole offer significant potential advantages. They quickly produce high drug levels in the nail, which persist after therapy is discontinued. Additional advantages include a broader spectrum of coverage with itraconazole and few drug interactions with terbinafine. Treatment of toenail onychomycosis requires 3 months with terbinafine (250 mg/day) or itraconazole (200 mg/day). Pulsed dosing with itraconazole for fingernail onychomycosis consists of 200 mg twice daily for 1 wk/mo for two pulses. Cure rates of ≥75% have been achieved with both drugs (Gupta et al., 1994a; Gupta et al., 1994b).

Ciclopirox topical (PENLAC, others) solution is a nail lacquer that is FDA-approved for the treatment of onychomycosis but demonstrates low complete cure rates (5.5-8.5%) after 1 year of daily application. Topical ciclopirox treatment of onychomycosis must include active removal of the unattached, infected nails as frequently as monthly.

**Agents Used to Treat Infestations**

Infestations with ectoparasites such as lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations.

Permethrin is a synthetic pyrethroid that interferes with insect sodium transport proteins, causing neurotoxicity and paralysis. Resistance due to mutations in the transport protein has been reported in Chrysoptera cinereariifolium. A 5% cream is available for the treatment of scabies, and a 1% cream, a cream rinse, and topical solutions are available OTC for the treatment of lice. Permethrin is approved for use in infants ≥2 months of age. Other agents used in the treatment of lice are pyrethrins + piperonyl butoxide (lotion, gel, shampoo, and mousse) and KLOUT shampoo (acetic acid + isopropanol).

Lindane (γ-hexachlorocyclo-hexane) is an organochloride compound that induces neuronal hyperstimulation and eventual paralysis of parasites.
Lindane has been used as a commercial insecticide as well as a topical medication. Due to several cases of neurotoxicity in humans, the FDA has labeled lindane as a second-line drug in treating pediculosis and scabies and has highlighted the potential for neurotoxicity in children and adults weighing <110 pounds and in patients with underlying skin disorders such as atopic dermatitis and psoriasis (U.S. Food and Drug Administration, 2003). Lindane is contraindicated in premature infants and patients with seizure disorders. The FDA advises that lindane prescriptions should be limited to amounts for a single application.

Malathion (OVIDE) is an organophosphate that binds acetylcholinesterase in lice, causing paralysis and death. Its structure is:

It is approved for treatment of head lice in children ≥6 years of age. The currently available formulation contains alcohol and is flammable.

Benzyl alcohol (ULESFIA) 5% lotion has recently received FDA approval for the treatment of lice. Benzyl alcohol inhibits lice from closing their respiratory spiracles, which allows the vehicle to obstruct the spiracles and causes the lice to asphyxiate. This mechanism may be less likely to cause resistance than traditional pesticides.

Ivermectin (STROMECTOL) is an oral anthelmintic drug (see Chapter 51) approved to treat onchocerciasis and strongyloidiasis, but it also is effective in the off-label treatment of scabies and lice.

Because ivermectin does not cross the blood-brain barrier of humans, there is no major CNS toxicity. Nevertheless, minor CNS side effects include dizziness, somnolence, vertigo, and tremor. For both scabies and lice, ivermectin typically is given at a dose of 200 μg/kg, which may be repeated in 1 week. It should not be used in children weighing <15 kg.

Other, less effective topical treatments for scabies and lice include 10% crotamiton cream and lotion (EURAX) and extemporaneously compounded 5% precipitated sulfur in petrolatum. The later preparation is sometimes used during pregnancy or during nursing (on infected mothers). Crotamiton and sulfur may be considered for use in patients in whom lindane or permethrin may be contraindicated.

**ANTIMALARIAL AGENTS**

Antimalarials used in dermatology include chloroquine (ARALEN, others), hydroxychloroquine (PLAQUENIL, others), and quinacrine (ATABRINE) (see Chapter 49). Common dermatoses treated with antimalarials include cutaneous lupus erythematosus, cutaneous dermatomyositis, polymorphous light eruption, porphyria cutanea tarda, and sarcoidosis. Other than lupus erythematosus, all dermatological uses of antimalarials are off label. The detailed use of these drugs in those conditions is discussed elsewhere (LaDuca and Gaspari, 2008).

The mechanism by which antimalarial agents exert their anti-inflammatory therapeutic effects is unknown. Proposed mechanisms of action include stabilization of lysosomes, inhibition of antigen presentation, inhibition of prostaglandin synthesis, inhibition of pro-inflammatory cytokine synthesis, photoprotection, inhibition of immune complex formation, and antithrombotic effects. In patients with porphyria cutanea tarda, chloroquine and hydroxychloroquine bind to porphyrins and/or iron to facilitate their hepatic clearance.

The usual dosages of antimalarials are 200 mg twice a day (maximum of 6.5 mg/kg/day) of hydroxychloroquine, 250-500 mg/day (maximum of 3 mg/kg/day) of chloroquine, and 100-200 mg/day of quinacrine. Clinical improvement may be delayed for several months. Hydroxychloroquine is the most common antimalarial used in dermatology. There is strong evidence that smoking may decrease the effectiveness of antimalarials used for lupus erythematosus. If no improvement in the dermatosis is noted in 3 months, quinacrine is added. Alternatively, chloroquine is used as a single agent. Patients with porphyria cutanea tarda require lower doses of antimalarials (100 mg of hydroxychloroquine or 125 mg of chloroquine two to three times weekly) to avoid severe hepatotoxicity.

The toxic effects of antimalarial agents are described in Chapter 49.
**Cytotoxic and immunosuppressive drugs**

Cytotoxic and immunosuppressive drugs are used in dermatology for immunologically mediated diseases such as psoriasis, auto-immune blistering diseases, and leukocytoclastic vasculitis. These agents are discussed in detail in Sections IV and VII. An overview of their mechanisms of action is included in Table 65–9.

**Antimetabolites**

**Methotrexate.** The antimetabolite methotrexate is a folic acid analog that competitively inhibits dihydrofolate reductase. Methotrexate has been used for moderate to severe psoriasis since 1951. It suppresses immunocompetent cells in the skin, and it also decreases the expression of cutaneous lymphocyte-associated antigen (CLA)–positive T cells and endothelial cell E-selectin, which may account for its efficacy (Sigmundsdottir et al., 2004). It is useful in treating a number of other dermatological conditions, including pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and cutaneous T-cell lymphoma.

Despite its widespread acceptance for decades as a first-line systemic monotherapy for the treatment of psoriasis, methotrexate (RHEUMATREX, others) was subjected only recently to a randomized, controlled clinical trial comparing its efficacy with that of orally administered cyclosporine for the treatment of moderate to severe chronic plaque psoriasis (Heydendael et al., 2003). Both medications were equally effective in achieving partial or complete clearing of psoriasis. Methotrexate often is used in combination with phototherapy and photochemotherapy or other systemic agents, and it also may be useful in combination with the biologicals (Saporito and Menter, 2004) (see “Biological Agents”).

A usual starting dosage for methotrexate therapy is 5-7.5 mg/wk (maximum of 15 mg/wk). This dosage may be increased gradually to 10-25 mg/wk if needed. Widely used regimens include three 2.5-mg oral doses given at 12-hour intervals once weekly, or weekly intramuscular injections of 10-25 mg (maximum of 30 mg/wk). Doses must be decreased for patients with impaired renal clearance. Methotrexate often is used in combination with phototherapy and photochemotherapy or other systemic agents, and it also may be useful in combination with the biologicals (Saporito and Menter, 2004) (see “Biological Agents”).

Methotrexate should never be co-administered with trimethoprim–sulfamethoxazole, probenecid, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that may result in bone marrow suppression. Fatalities have occurred because of concurrent treatment with methotrexate and nonsteroidal anti-inflammatory agents. Methotrexate exerts significant anti-proliferative effects on the bone marrow; therefore, CBCs should be monitored serially. Physicians administering methotrexate should be familiar with the use of folinic acid (leucovorin) to rescue patients with hematological crises caused by methotrexate-induced bone marrow suppression. Careful monitoring of liver function tests is necessary but may not be adequate to identify early hepatic fibrosis in patients receiving chronic methotrexate therapy. Methotrexate-induced hepatic fibrosis may occur more commonly in patients with psoriasis than in those with rheumatoid arthritis. Consequently, liver biopsy is recommended when the cumulative dose reaches 1-1.5 g. A baseline liver biopsy is also recommended for patients with increased potential risk for hepatic fibrosis, such as a history of alcohol abuse or infection with hepatitis B or C. Patients with significantly abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. Many clinicians routinely administer folic acid along with methotrexate to ameliorate side effects; this does not reduce efficacy of the methotrexate. Pregnancy and lactation are absolute contraindications to methotrexate use.

**Azathioprine.** Azathioprine (IMURAN, others) is discussed in detail in Chapter 35. In dermatological practice, the drug is used off label as a steroid-sparing agent for auto-immune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma...
Cancer (Silvis, 2001). The usual starting dosage is 1-2 mg/kg/day. Because it generally takes 6-8 weeks to achieve therapeutic effect, azathioprine often is started early in the course of disease management. Careful laboratory monitoring is important (Silvis, 2001). The enzyme thiopurine S-methyltransferase (TPMT) is critical for the metabolism of azathioprine to nontoxic metabolites. Homozygous deficiency of this enzyme may raise plasma levels of the drug and cause myelosuppression. TPMT enzyme activity should be measured before initiating azathioprine therapy (see Chapter 35).

**Fluorouracil.** Fluorouracil (5-FU) interferes with DNA synthesis by blocking the methylation of deoxyuridylic acid to thymidylic acid (Dinehart, 2000). Topical formulations (CARAC, others) are used in multiple actinic keratoses, actinic cheilitis, Bowen’s disease, and superficial basal cell carcinomas not amenable to other treatments.

Fluorouracil is applied once or twice daily for 2-8 weeks, depending on the indication. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralesional injection of 5-FU has been used for keratoacanthomas, warts, and porokeratoses.

**Alkylating Agents**

**Cyclophosphamide.** This is an effective cytotoxic and immunosuppressive agent. Both oral and intravenous preparations of cyclophosphamide are used in dermatology (Fox and Pandya, 2000). Cyclophosphamide is FDA approved for treatment of advanced cutaneous T-cell lymphoma. Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener’s granulomatosis, polyarteritis nodosa, Churg-Strauss angitis, Behçet’s disease, scleromyxedema, and cytophagic histiocytic panniculitis (Silvis, 2001). The usual oral dosage is 2-3 mg/kg/day in divided doses, and there often is a 4- to 6-week delay in onset of action. Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer (Silvis, 2001).

Cyclophosphamide has many adverse effects, including the risk of secondary malignancy and myelosuppression, and thus is used only in the most severe, recalcitrant dermatological diseases. The secondary malignancies have included bladder, myeloproliferative, and lymphoproliferative malignancies and have been seen with the use of cyclophosphamide alone or in combination with other antineoplastic drugs.

Mechlorethamine hydrochloride (MUSTARGEN) and carmustine (BICNU) are used topically to treat cutaneous T-cell lymphoma. Both can be applied topically as a solution or in an extemporaneously compounded ointment form. It is important to monitor CBCs and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and post-treatment telangiectases (Zackheim et al., 1990).

**Calcineurin Inhibitors**

**Cyclosporine.** Cyclosporine (NEORAL, GENGRAF, others) is a potent immunosuppressant isolated from the fungus *Tolypocladium inflatum*. It inhibits calcineurin, a phosphatase that normally dephosphorylates the cytoplasmic subunit of nuclear factor of activated T cells (NFAT), thus permitting NFAT to translocate to the nucleus and augment transcription of numerous cytokines. In T lymphocytes, calcineurin inhibition blocks interleukin-2 (IL-2) gene transcription and release and ultimately results in inhibition of T-cell activation (Cather et al., 2001). The presence of calcineurin in Langerhans cells, mast cells, and keratinocytes may further explain the therapeutic efficacy of cyclosporine and the other calcineurin inhibitors (e.g., tacrolimus, pimecrolimus; see later in this section) (Reynolds and Al-Daraji, 2002). Cyclosporine has FDA approval for the treatment of psoriasis. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual initial oral dosage is 2.5 mg/kg/day given in two divided doses.

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise >30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of <5 mg/kg, and regularly monitoring blood pressure (Cather et al., 2001). Alternation with other therapeutic modalities may diminish cyclosporine toxicity. *Laboratory monitoring during therapy is essential*. As with other immunosuppressive agents, patients with psoriasis who are treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies (Flores and Kerdel, 2000). The risk of cutaneous malignancies is compounded if patients have received phototherapy with PUVA.
Tacrolimus. Tacrolimus (FK506, PROTOPIC), a metabolite of *Streptomyces tsukubaensis*, was discovered in 1984.

It is a potent macrolide immunosuppressant traditionally used to prevent kidney, liver, and heart allograft rejection. Like cyclosporine, tacrolimus works mainly by inhibiting early activation of T lymphocytes, thereby inhibiting the release of IL-2, suppressing humoral and cell-mediated immune responses, and suppressing mediator release from mast cells and basophils (Assmann and Ruzicka, 2002). In contrast to cyclosporine, this effect is mediated by binding to the intracellular protein FK506-binding protein 12, generating a complex that inhibits the phosphatase activity of calcineurin.

Tacrolimus is available in a topical form for the treatment of skin disease and also is marketed in oral and injectable formulations (PROGRAF). Systemic tacrolimus has shown some efficacy in the treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet’s disease (Assmann and Ruzicka, 2002). When administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia. Topical formulations of tacrolimus penetrate into the epidermis.

In commercially available topical formulations (0.03% and 0.1%), tacrolimus ointment is effective in and approved for the treatment of atopic dermatitis in adults (0.03% and 0.1%) and children (0.03%) >2 years of age. Other uses in dermatology include intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea (Ngheim et al., 2002). It is applied to the affected area twice a day and generally is well tolerated.

A major benefit of topical tacrolimus compared with topical glucocorticoids is that tacrolimus does not cause skin atrophy and therefore can be used safely in locations such as the face and intertriginous areas. Common side effects at the site of application are transient erythema, burning, and pruritus, which tend to improve with continued treatment. Other reported adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia (Ngheim et al., 2002). Systemic absorption generally is very low and decreases with resolution of the dermatitis. However, topical tacrolimus should be used with extreme caution in patients with Netherton’s syndrome because these patients have been shown to develop elevated blood levels of the drug after topical application (Assmann and Ruzicka, 2002). Mice treated with 0.1% topical tacrolimus had a higher incidence of lymphoma and, after exposure to UV radiation, showed decreased time to skin tumor formation. Therefore, it is recommended that patients using tacrolimus use sunscreen and avoid excessive UV exposure. The risk of lymphoma development in humans is uncertain.

Pimecrolimus. Pimecrolimus 1% cream (ELIDEL), a macrolide derived from ascomycin, is FDA approved for the treatment of atopic dermatitis in patients >2 years of age.

Its mechanism of action and side-effect profile are similar to those of tacrolimus. Burning, although occurring in some patients, appears to be less common with pimecrolimus than with tacrolimus (Ngheim et al., 2002). In addition, pimecrolimus has less systemic absorption. Similar precautions with regard to UV exposure should be taken during treatment with pimecrolimus.

Due to the potential for malignancy production, topical calcineurin inhibitors are not considered first-line therapy in childhood atopic dermatitis. Tacrolimus and pimecrolimus should only be used as second-line agents for short-term and intermittent treatment of atopic dermatitis (eczema) in patients unresponsive to, or intolerant of, other treatments. The effect of these drugs on the developing immune system in infants and children is not known; therefore, these drugs should be avoided in children <2 years of age. In clinical studies, infants and children <2 years of age treated with tacrolimus had a higher rate of upper respiratory infections than did those treated with placebo cream. Higher doses cause malignancies in animal studies.

**OTHER IMMUNOSUPPRESSIVE AND ANTI-INFLAMMATORY AGENTS**

Mycophenolate mofetil. Mycophenolate mofetil (CELLCEPT), a prodrug, and mycophenolate sodium (MYFORTIC) are immunosuppressants approved for prophylaxis of organ rejection in patients with renal, cardiac, and hepatic transplants (see Chapter 35). Mycophenolic acid, the
active derivative, inhibits the enzyme inosine monophosphate dehydrogenase (IMPDH), thereby depleting guanosine nucleotides essential for DNA and RNA synthesis (Carter et al., 2004). Moreover, mycophenolic acid is a 5-fold more potent inhibitor of the type II isoform of IMPDH found in activated B and T lymphocytes and thus functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation. The drug also may enhance apoptosis.

Mycophenolate mofetil is used increasingly to treat inflammatory and auto-immune diseases in dermatology in dosages ranging from 1-2 g/day orally (Carter et al., 2004). Mycophenolate mofetil is particularly useful as a corticosteroid-sparing agent in the treatment of auto-immune blistering disorders, including pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, and pemphigus foliaceus. It also has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum.

Isolated cases of progressive multifocal leukoencephalopathy (PML) and pure red cell aplasia have been reported in solid organ transplant patients receiving mycophenolate mofetil. PML is a progressive, demyelinating disease of the CNS that usually leads to death or severe disability. PML is caused by the reactivation of the JC virus, a polyomavirus that resides in latent form in 70-90% of the adult population worldwide.

Imiquimod. Imiquimod (ALDARA) is a synthetic imidazoquinoline amine believed to exert immunomodulatory effects by acting as a ligand at toll-like receptors in the innate immune system and inducing the cytokines interferon-α (IFN-α), tumor necrosis factor-α (TNF-α), and IL-1, IL-6, IL-8, IL-10, and IL-12.

![Imiquimod](image)

Approved for the treatment of genital warts, imiquimod is applied to genital or perianal lesions two times a week usually for a 16-week period that may be repeated as necessary. Imiquimod also has been approved for the treatment of actinic keratoses. In this capacity, imiquimod is applied three times a week for 16 weeks to the face, scalp, and arms. No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. Phase II trials evaluating imiquimod for the treatment of nodular and superficial basal cell carcinomas suggest that imiquimod may prove useful (Salasche and Shumack, 2003). The drug is FDA approved for this indication at a dosage of five applications per week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extramammary Paget’s disease, and Bowen’s disease. Irritant reactions occur in virtually all patients, and some develop edema, vesicles, erosions, or ulcers. It appears that the degree of inflammation parallels therapeutic efficacy. Other than minor flu-like symptoms, no severe systemic effects have been reported.

Vinblastine. Systemic vinblastine (VELBAN, others) is approved for use in Kaposi sarcoma and advanced cutaneous T-cell lymphoma. Intralesional vinblastine also is used to treat Kaposi sarcoma (Hengge et al., 2002). Intralesional bleomycin (BLENOXANE, others) is used for recalcitrant warts and has cytotoxic and pro-inflammatory effects. Intralesional injection of bleomycin into the digits has been associated with a vasospastic response that mimics Raynaud’s phenomenon, local skin necrosis, and flagellate hyperpigmentation (Abess et al., 2003). Intralesional bleomycin has been used for palliative treatment of squamous cell carcinoma. Systemic bleomycin has been used for Kaposi sarcoma (see Chapter 61 for a more complete discussion of these agents). Liposomal anthracyclines (specifically doxorubicin [DOXIL, CAELYX]) may provide first-line monotherapy for advanced Kaposi sarcoma (Hengge et al., 2002).

Dapsone. Dapsone (4,4’-diaminodiphenylsulfone) has been in clinical use for ~50 years.

\[
\text{Dapsone} = \text{H}_2\text{N} + \text{SO} + \text{NH}_2
\]

Dapsone is used in dermatology for its anti-inflammatory properties, particularly in sterile (non-infectious) pustular diseases of the skin. Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects; all of these actions are likely to be important in auto-immune skin diseases (Zhu and Stiller, 2001).

Dapsone is approved for use in dermatitis herpetiformis and leprosy. It is particularly useful in the treatment of linear immunoglobulin A (IgA) dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey–Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet’s syndrome, granuloma faciale, relapsing polychondritis, Behçet’s disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare (Paniker and Levine, 2001).
An initial dosage of 50 mg/day is prescribed, followed by increases of 25 mg/day at weekly intervals, titrated to the minimal dosage necessary for effect, always with appropriate laboratory testing. Potential side effects of dapsone include methemoglobinemia and hemolysis. The glucose-6-phosphate dehydrogenase (G6PD) level should be checked in all patients before initiating dapsone therapy because dapsone hydroxylamine, the toxic metabolite of dapsone formed by hydroxylation, depletes glutathione within G6PD-deficient cells. The nitroso derivative then causes peroxidation reactions, leading to rapid hemolysis. A maximum dosage of 150-300 mg/day should be given in divided doses to minimize the risks of methemoglobinemia. The H₂ blocker cimetidine, at a dose of 400 mg three times daily, alters the degree of methemoglobinemia by competing with dapsone for CYPs. Toxicities include agranulocytosis, peripheral neuropathy, and psychosis.

**Thalidomide.** Thalidomide (THALOMID) is an anti-inflammatory, immunomodulating, anti-angiogenic agent experiencing resurgence in the treatment of dermatological diseases (see Chapter 35). Its structure is:

![Thalidomide Structure]

The mechanisms that underlie the pharmacological properties of thalidomide are not clear, although modulation of inflammatory cytokines such as TNF-α, IFN-α, IL-10, IL-12, cyclooxygenase-2, and possibly nuclear factor κB (NF-κB) may be involved (Franks et al., 2004). It also can modulate T cells by altering their patterns of cytokine release and can increase keratinocyte migration and proliferation (Wines et al., 2002).

Thalidomide is FDA approved for the treatment of erythema nodosum leprosum. There are reports suggesting its efficacy in actinic prurigo, aphtous stomatitis, Behçet’s disease, Kaposi sarcoma, and the cutaneous manifestations of lupus erythematosus, as well as prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. In utero exposure can cause limb abnormalities (phocomelia), as well as other congenital anomalies. It also may cause an irreversible neuropathy. Because of its teratogenic effects, thalidomide use is restricted to specially licensed physicians who fully understand the risks. Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.

**BIOLOGICAL AGENTS**

Biological agents (see Chapters 35 and 62) are compounds derived from living organisms that target specific mediators of immunological reactions. Classes of biologicals include recombinant cytokines, interleukins, growth factors, antibodies, and fusion proteins. Currently, five biological agents are approved for the treatment of psoriasis (Table 65–10).

Psoriasis is a disorder of Th1 cell-mediated immunity (Figure 65–4), with the epidermal changes being secondary to the effect of released cytokines. Biological therapies modify the immune response in psoriasis through 1) reduction of pathogenic T cells, 2) inhibition of T-cell activation, 3) immune deviation (from a Th1 to a Th2 immune response), and 4) blockade of the activity of inflammatory cytokines (Weinberg, 2003). The appeal of biological agents in the treatment of psoriasis is that they specifically target the activities of T lymphocytes and cytokines that mediate inflammation versus traditional systemic therapies that are broadly immunosuppressive or cytotoxic. Thus, the use of these agents theoretically should result in fewer toxicities and side effects.

When evaluating the efficacy of biological agents, it is important to understand the standard measurement of efficacy in psoriasis treatment, the Psoriasis Area and Severity Index (PASI). The PASI quantifies the extent and severity of skin involvement in different body regions as a score from 0 (no lesions) to 72 (severe disease). To gain FDA approval for the treatment of psoriasis, a biological agent must decrease the PASI by 75%. Although such quantification is an essential element in controlled clinical trials, many patients in practice may gain clinically significant benefit from biological treatment without achieving this degree of PASI improvement.

**T-cell Activation Inhibitors**

**Alefacept.** Alefacept (AMEVIVE) was the first immunobiological agent approved for the treatment of moderate to severe psoriasis. Alefacept consists of a recombinant fully human fusion protein composed of the binding site of the leukocyte function–associated antigen 3 (LFA-3) protein and a human IgG₁ Fc domain. The LFA-3 portion of the alefacept molecule binds to CD2 on the surface of T cells, thus blocking a necessary co-stimulation step in T-cell activation (Figure 65–5). Importantly, because CD2 is expressed preferentially on memory-effector T cells, naive T cells are largely unaffected by alefacept. A second important action of alefacept is its ability to induce apoptosis of memory-effector T cells through simultaneous binding of its IgG₁ portion to immunoglobulin receptors on cytotoxic cells and its LFA-3 portion to CD2 on T cells, thus inducing granzyme-mediated apoptosis of memory-effector T cells. This may lead to a reduction in CD4⁺ lymphocyte counts, requiring a baseline CD4⁺ lymphocyte count before initiating alefacept and then biweekly during therapy.
Efalizumab. Efalizumab (RAPTIVA) is a humanized monoclonal antibody against the CD11a molecule of LFA-1. By binding to CD11a on T cells, efalizumab prevents binding of LFA-1 to intercellular adhesion molecule (ICAM)-1 on the surface of antigen-presenting cells, vascular endothelial cells, and cells in the dermis and epidermis (Figure 65–5), thereby interfering with T-cell activation and migration and cytotoxic T-cell function (Weinberg, 2003). A transient peripheral leukocytosis occurs in some patients taking efalizumab, which may be due to the inhibition of T-cell trafficking. Other side effects include thrombocytopenia, exacerbation of psoriasis, and rebound psoriasis upon discontinuation. Therefore, CBCs should be obtained at baseline and periodically thereafter. Recent reports have implicated efalizumab in the development of PML, and extra caution should be exercised in patients who develop neurological signs while on efalizumab (Castelo-Soccio and Van Voorhees, 2009).

Tumor Necrosis Factor Inhibitors

TNF-α, produced by macrophages, T cells, dendritic cells, and keratinocytes, is elevated in both the lesions...
and serum of patients with active psoriasis. This cytokine is central to the T<sub>H1</sub> response in active psoriasis, inducing further inflammatory cytokines, upregulating intracellular adhesion molecules, inhibiting apoptosis of keratinocytes, and inducing keratinocyte proliferation. Therefore, blockade of TNF-α with biologicals reduces inflammation, decreases keratinocyte proliferation, and decreases vascular adhesion, resulting in improvement in psoriatic lesions (Richardson and Gelfand, 2008).

Because TNF-α inhibitors alter immune responses, patients on all anti-TNF-α agents are at increased risk for serious infection. They also are theoretically at increased risk for malignancies, because TNF is involved in normal innate immunity and natural killer cell–mediated destruction of tumor cells (Tzu and Kerdel, 2008). Other adverse events related to TNF-α inhibitors include exacerbation of congestive heart failure and demyelinating disease in predisposed patients (Menter and Griffiths, 2007). Therefore, all patients should be screened for tuberculosis, personal or family history of demyelinating disorder, cardiac failure, active infection, or malignancy prior to starting anti-TNF-α therapy.

**Etanercept.** Etanercept (ENBREL) is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor (p75) fused to the Fc portion of IgG1. Etanercept binds soluble and membrane-bound TNF, thereby inhibiting the action of TNF (Krueger and Callis, 2004). There are several case series and a large randomized controlled study supporting the safety and efficacy of etanercept at 0.4 mg/kg twice weekly in pediatric psoriasis (Sukhatme and Gottlieb, 2009). Etanercept use is associated with an increased risk of infections (bacterial...

---

**Figure 65–4. Immunopathogenesis of psoriasis.** Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as-yet undefined antigen(s) presented by antigen-presenting cells. The T cells release pro-inflammatory cytokines, such as tumor necrosis factor-α (TNF-α) and interferon-γ (IFN-γ), that induce keratinocyte and endothelial cell proliferation. APC, antigen-presenting cell; CLA, cutaneous lymphocyte-associated antigen.  

---

**Figure 65–5. Mechanisms of action of selected biological agents in psoriasis.** Newer biological agents can interfere with one or more steps in the pathogenesis of psoriasis, resulting in clinical improvement. See text for details. ICAM-1, intercellular adhesion molecule 1; LFA, lymphocyte function–associated antigen; MHC, major histocompatibility complex; TCR, T-cell receptor.
sepsis, tuberculosis), including leading to hospitalization or death. Patients should be screened for latent tuberculosis infection before beginning treatment and closely monitored during and after drug therapy.

**Infliximab.** Infliximab (REMACADE) is a mouse-human chimeric IgG₁ monoclonal antibody that binds to soluble and membrane-bound TNF-α (Krueger and Callis, 2004). Infliximab is a complement-fixing antibody that induces complement-dependent and cell-mediated lysis when bound to cell-surface-bound TNF-α. Neutralizing antibodies to infliximab may develop against its chimeric structure. Concomitant administration of methotrexate or glucocorticoids may suppress this antibody formation.

**Adalimumab.** Adalimumab (HUMIRA) is a human IgG₁ monoclonal antibody that binds soluble and membrane-bound TNF-α. Like infliximab, it can mediate complement-induced cytolysis on cells expressing TNF. Unlike infliximab, however, it is fully human, which reduces the risk for development of neutralizing antibodies.

**Cutaneous T-cell Lymphoma**

**Denileukin diftitox.** Denileukin diftitox or DAB₃₈₉–IL-2 (ONTAK) is a fusion protein composed of diphtheria toxin fragments A and B and the receptor-binding portion of IL-2. DAB₃₈₉–IL-2 is indicated for advanced cutaneous T-cell lymphoma in patients with >20% of T cells expressing the surface marker CD25. Specificity is derived from the presence of IL-2 receptor (IL-2R) on malignant and activated T cells but not resting B and T cells. Following binding to the IL-2R, DAB₃₈₉–IL-2 is internalized by endocytosis. The active fragment of diphtheria toxin then is released into the cytosol, where it inhibits protein synthesis through ADP ribosylation, leading to cell death. Clinical trials have shown an overall response rate of 30% and a complete response rate of 10% in cutaneous T-cell lymphoma. Adverse effects include pain, fevers, chills, nausea, vomiting, and diarrhea; immediate hypersensitivity reaction (hypotension, back pain, dyspnea, and chest pain) in 60% of patients; and capillary leak syndrome (edema, hypoalbuminemia, and/or hypotension) in 20-30% of patients (Duvic and Talpur, 2008).

**SUNSCREENS**

Photoprotection from the acute and chronic effects of sun exposure is readily available with sunscreens. The major active ingredients of available sunscreens include chemical agents that absorb incident solar radiation in the UVB and/or UVA ranges and physical agents that contain particulate materials that can block or reflect incident energy and reduce its transmission to the skin. Many of the sunscreens available are mixtures of organic chemical absorbers and particulate physical substances. Ideal sunscreens provide a broad spectrum of protection and are formulations that are photostable and remain intact for sustained periods on the skin. They also should be non-irritating, invisible, and nonstaining to clothing. No single sunscreen ingredient possesses all these desirable properties, but many are quite effective nonetheless.

**UVA Sunscreen Agents.** Currently available UVA filters in the U.S. include 1) avobenzone, also known as Parsol 1789; 2) oxybenzone; 3) titanium dioxide; 4) zinc oxide; and 5) ecamsule (MEXORYL SX). Additional UVA sunscreens, including hemotrizinol (TINOSORB S) and bisoctrizole (TINSORB M), are available in Europe and elsewhere, but not in the U.S.

**UVB Sunscreen Agents.** There are numerous UVB filters, including 1) p-aminobenzoic acid (PABA) esters (e.g., padimate O), 2) cinnamates (e.g., octinoxate), 3) octocrylene, and 4) salicylates (e.g., octisalate). The major measurement of sunscreen photoprotection is the sun protection factor (SPF), which defines a ratio of the minimal dose of incident sunlight that will produce erythema or redness (sunburn) on skin with the sunscreen in place (protected) and the dose that
evokes the same reaction on skin without the sunscreen (unprotected). The SPF provides valuable information regarding UVB protection but is useless in documenting UVA efficacy. In 2007, the FDA proposed a consumer-friendly rating system for UVA products consisting of one to four stars representing low, medium, high, and highest UVA protection available in an OTC sunscreen product as an indicator of the product’s ability to prevent tanning. The test proposed to determine UVA rating is analogous to the SPF test used to determine the effectiveness of UVB sunscreen products. At the time of this writing, the FDA had not published a final rule. However, such protocols are needed because >85% of solar UV radiation reaching earth’s surface is UVA, which penetrates more deeply into human skin than does UVB and appears to play an important role in photoaging and photocarcinogenesis. Despite the universal availability of sunscreens, a major problem with them is the fact that people do not use them appropriately or on a regular basis. In a population study evaluating the use of sunscreens in northern England, it was reported that only 35% of females and 8% of males regularly used sunscreens (Ling et al., 2003). Furthermore, 22% of those surveyed used no sunscreen at all, and 34% recalled at least one sunburn reaction in the previous 2 years.

There is evidence that the regular use of sunscreens can reduce the risk of actinic keratoses and squamous cell carcinomas of the skin. One study noted a 46% decrease in the incidence of squamous cell carcinomas in people who used sunscreen regularly for 4.5 years (Green et al., 1999).

**THE TREATMENT OF PRURITUS**

The term *pruritus* is derived from the Latin *prurire*, which means “to itch.” Pruritus is a symptom unique to skin that occurs in a multitude of dermatological disorders, including dry skin or xerosis, atopic eczema, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. In addition to treating the underlying disorder, a general approach to the treatment of pruritus can be made by classifying pruritus into one of four clinical categories (Table 65–11). Long experience shows that gold works well for treatment of the itching palm.

</table>
Keratolytic agents are substances that reduce hyperkeratosis through a variety of mechanisms (e.g., breaking of intercellular junctions, increasing stratum corneum water content, increasing desquamation). Common disorders treated with keratolytics include psoriasis, seborrheic dermatitis, xerosis, ichthyoses, and verrucae.

α-Hydroxy acids are organic acids in which a hydroxyl group is attached to the first carbon (α carbon) following its carboxyl acid group. Various α-hydroxy acids include glycolic, lactic, malic, citric, hydroxycaprylic, hydroxycapric, and mandelic. They reduce the thickness of the stratum corneum by solubilizing components of the desmosome, activating endogenous hydrolytic enzymes, and drawing water into the stratum corneum, allowing cell separation to occur. They also appear to increase glycosaminoglycans, collagen, and elastic fibers in the dermis and are used in various formulations to reverse photaging. The FDA requires that cosmetics containing α-hydroxy acids be labeled with a sunburn alert warning that the product may increase sensitivity to the sun and reminding users to wear protective clothing, use sunscreen, and limit sun exposure.

Salicylic acid functions through solubilization of intercellular cement, reducing corneocyte adhesion, and softening the stratum corneum. Salicylism may occur with widespread and prolonged use, especially in children and patients with renal or hepatic impairment, and use should be limited to <2 g to the skin surface in a 24-hour period. Salicylic acid, while chemically not a true α-hydroxy acid, often is listed as such on cosmetic labels. Other β-hydroxy acids ingredients in cosmetics include β-hydroxybutanoic acid, δ tropic acid, and trethocanic acid. As with α-hydroxy acids, sun protection should accompany the application of skin products containing β-hydroxy acids.

At low concentrations, urea increases skin absorption and retention of water, leading to increased flexibility and softness of the skin (Hessel et al., 2007). At high concentrations (>40%), urea denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

Sulfur is anti-septic, anti-parasitic, anti-seborrheic, and keratolytic, accounting for its myriad uses in dermatology. It is believed to exert its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide. Hydrogen sulfide breaks down keratin, causing dissolution of the stratum corneum (Hessel et al., 2007).

Often used in conjunction with plastic occlusion, propylene glycol (as 60-100% solutions in water) increases the water content of the stratum corneum and enhances desquamation. It is most effective in disorders with retention hyperkeratosis, in which the thickened stratum corneum is slowly reformed.

Minoxidil. Minoxidil (PROGAINE, others) was first developed as an antihypertensive agent (see Chapter 27) and was noted to be associated with hypertrichosis in some patients. A topical formulation of minoxidil then was developed to exploit this side effect. The structure of minoxidil is:

![Minoxidil](image)

Topical minoxidil is available as a 2% or 5% solution. Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hairs. Treatment must be continued, or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil.

Finasteride. Finasteride (PROPECIA, other) inhibits the type II isozyme of 5α-reductase, the enzyme that converts testosterone to dihydrotestosterone (see Chapter 41). The structure of finasteride is:

![Finasteride](image)

The type II 5α-reductase is found in hair follicles. Balding areas of the scalp are associated with increased dihydrotestosterone levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/day) has been shown to variably increase hair growth in men over a 2-year period, increasing hair counts in the vertex and the frontal scalp (Leyden et al., 1999).
Finasteride is approved for use only in men. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. Each of these occurs in <2% of patients (Leyden et al., 1999). Like minoxidil, treatment with finasteride must be continued, or any new hair growth will be lost.

**TREATMENT OF HYPERPIGMENTATION**

The agents mentioned in this section are most effective on hormonally or light-induced pigmentation within the epidermis. They have limited efficacy on post-inflammatory pigmentation within the dermis.

**Hydroquinone.** Hydroquinone (1,4-dihydrobenzene; TRI-LUMA) is the first-line agent in medical therapy of hyperpigmentation. It decreases melanocyte pigment production by inhibiting the conversion of dopa to melanin through inhibition of the enzyme tyrosinase. Other mechanisms include inhibition of DNA and RNA synthesis, degradation of melanosomes, and destruction of melanocytes. There are multiple formulations, to which penetration enhancers, microsponges, and sunscreen ingredients are added. Adverse effects may include dermatitis and ochronosis; patients should be followed regularly while on hydroquinone (Draelos, 2007).

**Monobenzone.** Monobenzone (BENOQUIN), the monobenzyl ether of hydroquinone, causes permanent hypopigmentation and should not be used for routine hormonally induced or post-inflammatory hyperpigmentation.

**Azelaic.** Azelaic acid (AZELEX, FINACEA) is a dicarboxylic acid isolated from cultures of *Pityrosporum ovale*. It was developed through study of the hypopigmentation produced by infection with *P. ovale* (tinea versicolor). It also inhibits tyrosinase activity but is less effective than hydroquinone. Because it has mild comedolytic, antimicrobial, and anti-inflammatory properties, it also is often used in acne and papulopustular rosacea (Draelos, 2007).

Mequinol, also known as 4-hydroxynisole, methoxyphenol, hydroquinone monomethyl ether, or p-hydroxyanisole, is a competitive inhibitor of tyrosinase. It is available as a 2% prescription product (SOLAGE) in combination with 0.01% tretinoin and vitamin C to enhance skin lightening (Draelos, 2007).

**Capsaicin.** Capsaicin (trans-8-methyl-N-vanillyl-6-nonenamide) is an alkaloid derived from plants of the *Solanaceae* family (i.e., hot chili peppers).

Capsaicin interacts with the transient receptor potential vanilloid (TRPV1) receptor on C-fiber sensory neurons. TRPV1 is a ligand-gated nonselective cation channel of the TRP family, modulated by a variety of noxious stimuli (Wang, 2008). Chronic exposure to capsaicin first stimulates and then desensitizes this channel to capsaicin and diverse other noxious stimuli. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin is available as a 0.025%, 0.035%, 0.075%, 0.1%, and 0.25% cream (ZOSTRIX, others); 0.025% and 0.075% lotion (CAPSIN); 0.025% and 0.05% gel; 0.075% roll-on; and 0.025% transdermal patch. Capsaicin is FDA approved for the temporary relief of minor aches and pains associated with backache, strains, and arthritis and is used for off-label treatment of postherpetic neuralgia and painful diabetic neuropathy. It is being investigated for psoriasis, vitiligo, intractable pruritus, and other disorders.

Podophyllin (podophyllum resin) is a mixture of chemicals from the plant *Podophyllum peltatum* (mandrake or May apple). The major constituent of the resin is podophyllotoxin (podoflox). It binds to microtubules and causes mitotic arrest in metaphase. Podophyllin resin (10-40%) is applied by a physician and left in place for no longer than 2-6 hours weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. Podoflox is available as a 0.5% solution for home application twice daily for 3 consecutive days. Weekly cycles are repeated until clearance or for a maximum of four cycles.

**MISCELLANEOUS AGENTS**

**BIBLIOGRAPHY**

U.S. Food and Drug Administration (FDA). *FDA Public Health Advisory: Safety of Topical Lindane Products for the Treatment of Scabies and Lice*. Center for Drug Evaluation and Research, U.S. Food and Drug Administration, Rockville, MD, **2003**.

Drugs used to control fertility and treat disorders of the female reproductive organs collectively are among the most frequently prescribed agents in clinical practice. This chapter discusses a number of common clinical issues and their drug therapies that are central to women’s health. The focus is on reproductive disorders and aspects of therapy rather than comprehensive coverage of the drugs themselves, which are described in more detail elsewhere (e.g., Chapter 33 for prostaglandins; Chapter 38 for the gonadotropins, gonadotropin-releasing hormone [GnRH] agonists and antagonists, and oxytocin; Chapter 40 for estrogens and progestins; Section VII for antibiotics).

**CONTRACEPTION**

Contraception can either be administered as planned prophylaxis (e.g., oral contraceptive pills, patches, implants, vaginal or intrauterine devices, barrier foams, spermicides, tubal ligation, vasectomy) or postcoitally for emergency contraception (i.e., high-dose estrogen-containing oral contraceptive pills, high-dose progestin pills, a progesterone antagonist, intrauterine devices). The progesterone antagonist also can be used to terminate an established pregnancy.

**Planned Contraception**

**Combination Oral Contraceptives.** Of the various contraceptive methods, pills containing an estrogen and progestin in combination are the most widely used and are among the most effective of the nonsurgical modalities (Table 66–1); they act primarily by suppressing the luteinizing hormone (LH) surge and thereby preventing ovulation. A wide variety of preparations are available for oral, transdermal, and vaginal administration (Erkkola, 2007). (See Table 66–2 for a list of branded formulations. Many of the same formulations also are available as generics.) Almost all contain ethinyl estradiol as the estrogen and a 17α-alkyl-19-nortestosterone derivative as the progestin and are administered for the first 21-24 days of a 28-day cycle. The major functions of the estrogen are to sensitize the hypothalamus and pituitary gonadotropes to the feedback inhibitory effects of the progestin and to minimize breakthrough bleeding. The progestin exerts negative feedback, which suppresses the LH surge and thereby prevents ovulation, and protects against uterine cancer by opposing the proliferative effects of the estrogen on the uterine endometrium. Newer formulations offer effective contraception with improved activity profiles. They contain lower amounts of hormones to minimize adverse effects; some incorporate progestins with less androgenic activity (e.g., gestodene, desogestrel) or that antagonize the mineralocorticoid receptor and thereby reduce the tendency toward edema (e.g., drospirenone). Due to diminished endometrial proliferation, patients taking these newer formulations may not experience a menstrual bleed at the end of each cycle; if this occurs, a pregnancy test generally is performed after the first missed cycle to rule out contraceptive failure.

Traditionally, combination oral contraceptives were packaged with 21 pills containing active hormone and 7 placebo tablets; each active pill contained a constant amount of the estrogen and progestin (i.e., a monophasic formulation). In an effort to maximize the anti-ovulatory effects and prevent breakthrough bleeding while minimizing total exposure to the hormones, some formulations provide active pills with two (biphasic) or three (triphasic) different amounts of one or both hormones to be used sequentially during each cycle.

Formulations called “extended-cycle” contraceptives extend the number of active pills per cycle and thus decrease the duration of menstrual bleeding. Two products contain 24 active pills with only 4 placebo tablets (e.g., YAZ [which contains drospirenone as the progestin] and
Two products are packaged as 91-day packets, with 84 estrogen/progestin tablets and 7 placebo tablets (SEASONALE) or 7 tablets containing a lower dose of ethinyl estradiol alone (SEASONIQUE). Finally, LYBREL is provided in 28-day packets that contain only hormone pills and no placebo. All of these extended-cycle formulations appear to be comparable to the traditional products as contraceptives, and, aside from an increased frequency of breakthrough bleeding initially, no unexpected adverse effects have been observed (Kiley and Hammond, 2007).

A weekly transdermal contraceptive patch (ORTHO EVRA) releases ethinyl estradiol (20 μg/day) and norelgestromin (which is metabolized to norgestimate; 150 μg/day). In response to pharmacokinetic data suggesting that this patch provides higher estrogen exposure (AUC) than the low-dose oral contraceptive pills, the FDA added a black box advisory that notes this pharmacokinetic difference and warns of a potential increased risk of venous thromboembolism. Local reactions to the patch occur in ~5-15% of users and may be decreased by pre-application of a topical glucocorticoid. A vaginal ring (NUVARING) also is available that releases ethinyl estradiol (15 μg daily) and etonogestrel (an active metabolite of desogestrel; 120 μg daily). Each ring is used for 3 weeks, followed by a 1-week interval without the ring.

Besides providing highly effective (~99%) contraception when used properly, the combination estrogen/progestin formulations have a number of noncontraceptive benefits, including protection against certain cancers (e.g., ovarian, endometrial, colorectal), decreased iron-deficiency anemia secondary to menstrual blood loss, and decreased risk of fractures due to osteoporosis. Combination oral contraceptives also are widely used for conditions such as endometriosis, dysmenorrhea, menorrhagia, irregular menstrual cycles, premenstrual dysphoric disorder, acne, and hirsutism (see “Endometriosis” and “Drug Therapy in Gynecology”).

Serious adverse effects of the combination estrogen/progestin contraceptive agents are relatively rare. Thromboembolic disease, largely due to the estrogenic component, is the most common serious side effect associated with oral contraceptive use. Estrogen concentration, the patient’s age, smoking, and inherited thrombophilias all influence the risk of developing thromboembolic disease in oral contraceptive users. The impact of combination oral contraceptives on breast cancer has been highly debated; although a meta-analysis that combined the results of published epidemiological studies concluded that the combination oral contraceptives did increase the risk of breast cancer (relative risk of 1.24; Collaborative Group on Hormonal Factors in Breast Cancer, 1996), studies conducted with the lower doses of hormones included in current formulations suggest that the risk of breast cancer is not increased (Marchbanks et al., 2002).

Other adverse effects include hypertension, edema, gallbladder disease, and elevations in serum triglycerides. These are discussed further in Chapter 40. With pills containing drospirenone, which antagonizes the mineralocorticoid receptor, serum K+ should be monitored in women at risk for hyperkalemia (e.g., those on K+-sparing diuretics or drugs that inhibit the renin–angiotensin system). The combination oral contraceptives are contraindicated in women with a history of underlying conditions such as thromboembolic disease, cerebrovascular disease, migraine headaches with aura, estrogen-dependent cancer, impaired hepatic function or active liver disease, undiagnosed uterine bleeding, and suspected pregnancy. In addition, patients with a history of gestational diabetes should be monitored closely, and drug cessation should be strongly considered in anticipation of events associated with an increased risk of venous thromboembolism (e.g., elective surgery).

(Continued)
Progestin-Only Contraceptives. Progestin-only minipills contain derivatives of 17α-alkyl-19-nortestosterone but do not contain an estrogen. Although they do inhibit ovulation to some degree, their efficacy also reflects changes in the cervical mucus that inhibit fertilization and endometrial changes that inhibit implantation. They are slightly less effective than the combination estrogen/progestin formulations, particularly when doses are missed or the pill is taken at different times of the day, but provide an alternative in settings where estrogen-containing formulations are contraindicated. Their major adverse effect is breakthrough bleeding.

Progestins also are used for long-acting contraception. A depot formulation of medroxyprogesterone (DEPO-PROVERA) injected subcutaneously or intramuscularly provides effective contraception for 3 months. Its use has been associated with decreased bone mineral density, as noted by a black box warning in the product label. Teenagers and younger women who have not achieved maximal bone density may be particularly at risk, although the data suggest that bone density returns to pretreatment levels fairly quickly after drug cessation. Subdermal implants of progestin-impregnated rods provide effective contraception over several years. The only implant system currently approved in the U.S. is IMPLANON, which incorporates 3-ketodesogestrel, an active metabolite of desogestrel, into an inert matrix. The progestin is released slowly from the matrix to maintain a serum concentration considerably higher than that needed to suppress ovulation for 3 years. In most women, progestin concentrations are undetectable 1 week after surgical removal of the implant, and ovulation occurs within 6 weeks. Intermittent breakthrough bleeding is the major undesirable effect; acne or weight gain also may occur.

An intrauterine device that releases levonorgestrel (MIRENA) provides highly effective contraception for up to 5 years. It achieves local progestin concentrations that are ~1000-fold higher than systemic levels and is thought to act predominantly to inhibit gamete function and survival via local changes in the cervical mucus. This medical device also is undergoing evaluation for other indications such as menorrhagia, endometriosis, and endometrial protection in menopausal women receiving estrogens (Mansour, 2007; see “Endometriosis”).

Unless otherwise indicated, the products are packaged with 21 active (hormone-containing) pills and 7 placebo tablets. For formulations that differ from this standard (e.g., multiphasic pills, extended-cycle formulations), the numbers of tablets of each pill strength are indicated. Some formulations also contain iron to diminish the risk of Fe-deficiency anemia; these are not listed separately here. Combination formulations contain both an estrogen and a progestin. Denotes continuous administration of active pills.
Postcoital Contraception

Postcoital (or emergency) contraception is indicated for use in cases of mechanical failure of barrier devices or in circumstances of unprotected intercourse (Cheng et al., 2008). Because it is less effective than standard oral contraceptive regimens, it is not intended as a regular method of contraception. The mechanisms of action of the postcoital contraceptives are not fully understood, but their efficacy clearly cannot be accounted for solely by the inhibition of ovulation. Other potential mechanisms of action include effects on gamete function and survival and on implantation. These agents do not affect established pregnancies.

PLAN-B, which contains two tablets of the progestin levonorgestrel (0.75 mg each), is marketed specifically for postcoital contraception and may be obtained in the U.S. without a prescription by women ≥18 years of age. Treatment is most effective if the first dose is taken within 72 hours of intercourse, followed by a second dose 12 hours later; a single dose of 1.5 mg within 72 hours of intercourse appears to be equally effective. The levonorgestrel regimen has largely replaced the Yuzpe regimen (previously marketed in the U.S. as PREVEN), which combined an estrogen and a progestin and was associated with a lower efficacy and a higher incidence of nausea and vomiting.

Other options for postcoital contraception include mifepristone (MIFEPREX), which is not FDA-approved for this indication but is highly effective in oral doses ranging from 10-50 mg when taken within 5 days after unprotected intercourse (Cheng et al., 2008) and copper intrauterine devices when inserted within 4 days of unprotected intercourse. Mifepristone also has abortifacient activity when used in a different treatment regimen (see “Pregnancy Termination”). The selective progesterone receptor modulator ulipristal (ella, ellaOne), was recently approved as an emergency contraceptive, effective up to 120 hours after unprotected intercourse; see Chapter 40 for details.

Pregnancy Termination

If contraception is not used or fails, either mifepristone (RU-486, MIFEPREX) or methotrexate (50 mg/m2 intramuscularly or orally) can be used to terminate an unwanted pregnancy in settings outside surgical centers. A prostaglandin then is administered to stimulate uterine contractions and expel the detached conceptus; in the U.S., prostaglandins used include dinoprostone (PGE2; PROSTIN E2) administered vaginally or the PGE1 analog misoprostol (CYTOTEC) given orally or vaginally, both of which are used off label for this purpose. Prostaglandins used in other countries include the PGE2 analog sulprostone (NALADOR) and the PGE1 analog gemeprost (CERVAGEM).

As approved by the FDA, mifepristone (600 mg) is taken for pregnancy termination within 49 days after the start of a woman’s last menstrual period. The synthetic PGE1 analog misoprostol (400 μg) is administered orally 48 hours later; vaginal administration is at least as effective but is not FDA approved. Complete abortion using this procedure exceeds 90%; when termination of pregnancy fails or is incomplete, surgical intervention is required. Other published regimens include lower doses of mifepristone (200 or 400 mg) and different time intervals between the mifepristone and misoprostol. Finally, repeated doses of misoprostol alone (e.g., 800 μg vaginally or sublingually every 3 hours or every 12 hours for three doses) also have been effective in settings where mifepristone is unavailable. Vaginal bleeding follows pregnancy termination and typically lasts from 1-2 weeks but rarely (in 0.1% of patients) is severe enough to require blood transfusion. A high percentage of women also experience abdominal pain and uterine cramps, nausea and vomiting, and diarrhea secondary to the prostaglandin. Myocardial ischemia and infarction have been reported in association with sulprostone and gemeprost.

Mifepristone is a 17α-alkyl-19-nortestosterone derivative that acts as a competitive antagonist at the progesterone receptor. The biological mechanisms involved in the abortifacient actions of mifepristone are unclear. Its actions are associated with focal hemorrhage and breakdown of the stromal extracellular matrix that ultimately leads to the breakdown of the uterine endometrium. Inhibition of expression of stromal cell “tissue factor,” the primary initiator of hemostasis, and activation of extracellular matrix proteases are thought to contribute to these effects. In addition, mifepristone increases the sensitivity of the uterus to the uterotonic effects of prostaglandins. Mifepristone is metabolized through a series of reactions initiated by hepatic CYP3A4, and interactions can occur with other drugs that are substrates for this enzyme (see Chapters 6 and 40). Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its anti-glucocorticoid activity, and the drug should be used very cautiously in women who are anemic or receiving anticoagulants.

Methotrexate is a potent abortifacient, probably as a result of the ability of the placenta to concentrate FH2Glu4 (dihydrofolate polyglutamate) and its analogs (see Chapter 61).

Because mifepristone carries a risk of serious, and sometimes fatal, infections and bleeding following its use for medical abortion, a black box warning has been added to the product labeling. Women receiving mifepristone should be informed of these risks and cautioned to seek immediate medical attention if symptoms or signs of these conditions occur. Fulminant septic shock associated with Clostridium sordellii infections may result and is attributable to the combined effects of uterine infection and inhibition of glucocorticoid action by mifepristone (Cohen et al., 2007). Patients who develop symptoms and signs of infection, especially a marked leukocytosis even without fever, should be treated aggressively with antibiotics effective against anaerobic organisms such as C. sordellii (e.g., penicillin, ampicillin, a macrolide, clindamycin, a tetracycline, or metronidazole).

DRUG THERAPY IN GYNECOLOGY

Drugs used in the treatment of nonmalignant gynecological disorders include those that induce sexual differentiation in females with impaired biosynthesis of the
sex steroid hormones; are used in assisted reproduction technology in infertile women; treat the various symptoms and signs that accompany menopause (e.g., hot flashes, dyspareunia, mood disorders, osteoporosis); treat estrogen-dependent disorders such as endometriosis and uterine fibroids; and treat androgen-dependent conditions such as acne and hirsutism. Treatment of gynecological malignancies is discussed in Section VII.

**Induction of Sexual Maturation**

A number of clinical disorders, including Turner’s syndrome and other forms of gonadal dysgenesis, are associated with impaired production of ovarian steroids in phenotypic females. Such patients typically fail to develop secondary sexual characteristics at the normal time of puberty (sexual infantilism) or fail to have menses (primary amenorrhea). In these cases, steroid hormones are administered to induce development of the secondary sex characteristics; however, treatment is initiated only after the diagnosis is ascertained and underlying disorders that might respond to more specific therapy (e.g., prolactinomas) are excluded (see Chapter 38).

Types of estrogens used and the treatment regimens may vary by country or individual preference. Examples include conjugated estrogens, 0.3-1.25 mg; micronized 17β-estradiol, 0.5-2.0 mg; ethinyl estradiol, 5-20 μg; and transdermal 17β-estradiol, 25-50 μg. To achieve optimal breast development, treatment typically is initiated with a low dose of estrogen (e.g., conjugated estrogens at a starting dosage of 0.3 mg/day or ethinyl estradiol at 5 μg/day) starting in patients between ages 10 and 12 years or immediately if the diagnosis is made after this age. After 3-6 months, the dosage is increased (e.g., 0.9-1.25 mg/day of conjugated estrogens or 20 μg/day of ethinyl estradiol). Once this is achieved, a progestin (e.g., medroxyprogesterone, 10 mg/day, or micronized progesterone, 200-400 μg/day) for 12 days each cycle is added to the regimen to optimize breast development and permit cyclical menses, thereby avoiding endometrial hyperplasia and its consequent risk of uterine cancer. Once menses are established, many clinicians will switch to a standard low-dose oral contraceptive pill or even may use an extended-cycle formulation.

Short stature, a universal feature of non-mosaic Turner’s syndrome, usually is treated with human growth hormone, often together with an androgen such as oxandrolone (see Chapter 41). Initiating treatment with human growth hormone and androgen and delaying the onset of estrogen therapy generally produces a better growth response. Doses for growth hormone treatment in this context are higher than those in growth hormone–deficient children (e.g., 67 μg/kg/day; see Chapter 38 for further discussion of growth hormone replacement therapy).

**Menopause**

Menopause refers to the permanent cessation of menstrual periods (i.e., for >12 months) resulting from the loss of ovarian follicular activity; it usually occurs when women are between 45 and 60 years of age (mean age of 50). The decline in estradiol levels produces a variety of symptoms and signs, including vasomotor disturbances (hot flashes or flushes), sweating, irritability, sleep disturbances, and atrophy of estrogen-dependent tissue. In addition, postmenopausal women are at increased risk for osteoporosis, bone fractures, and coronary heart disease and experience increased memory loss and other cognitive difficulties.

**Estrogen Therapy.** The observed estrogen deficiency associated with menopause, as well as a number of observational studies showing positive effects of estrogen replacement therapy on these parameters, led to widespread use of hormone replacement therapy in peri- and postmenopausal women. In 2001, 90 million prescriptions were filled for hormone replacement therapy.

The initial publication of data from the Women’s Health Initiative (WHI), a large, randomized, placebo-controlled trial, dramatically altered therapeutic approaches to menopause. As expected, treatment of postmenopausal women with 0.625 mg of conjugated estrogen plus 2.5 mg of medroxyprogesterone (in women with a uterus) or with 0.625 mg of conjugated estrogen alone (in women lacking a uterus) improved bone mineral density and decreased the risk of fractures; a decreased risk of colorectal cancer also was seen. In addition, as might be expected, estrogen therapy in both the estrogen plus progestin and the estrogen-alone groups was associated with an increased incidence of deep venous thrombosis and stroke; unexpectedly, however, the incidence of breast cancer and coronary heart disease also increased in women receiving both estrogen and progestin (Rossouw et al., 2002; Rossouw et al., 2007). In a smaller subset of women >65 years of age, hormone therapy did not improve cognitive function or protect against dementia and, in fact, may have worsened the latter (Rapp et al., 2003; Shumaker et al., 2003). Based on these findings, it was recommended that hormone replacement therapy not be used to decrease the risk of coronary heart disease, cognitive impairment, or dementia.

Since these data were published, some have questioned the general validity of the WHI findings. Concerns include the dose, mode of administration, and specific hormones used, as well as the preponderance of older women in the WHI population. In fact, subgroup analyses of the WHI data suggest that cardiovascular risk was not increased when hormone therapy was initiated within 10 years of menopause. Although post hoc analyses of clinical trials always are accorded less weight than primary outcomes, these findings provide some reassurance that the risks of estrogen therapy may be minimal in women who are perimenopausal or recently menopausal, the majority of those for whom such therapy is contemplated.
Available routes of estrogen administration for hormone replacement therapy (Table 66–3) include oral, transdermal (patch, gel, and spray), and vaginal (cream, ring, and tablets). In women who have undergone hysterectomy, estrogen alone is used. For women with an intact uterus, a progestin also is administered to oppose the proliferative effect of the estrogen on the uterine endometrium.

Typically, the estrogen and progestin are administered together daily without a break; rarely, a cyclic-sequential administration is used, with the estrogen administered daily for 21-28 days of a 28-day cycle and the progestin added during the last 10-12 days.

</tbody>
</table>
Finally, some clinicians use a long-cycle regimen, in which the estrogen is administered continuously over a 3-month cycle and the progestin is only added every third month. Other therapies for vasomotor symptoms include phytoestrogens (e.g., soy products), herbal extracts (e.g., black cohosh), selective serotonin reuptake inhibitors (e.g., fluoxetine, controlled-release paroxetine, sertraline), clonidine, and gabapentin (Nelson, 2008). However, hormone replacement remains the most effective therapy for vasomotor symptoms in menopausal women, and it is reasonable, after a discussion of the relative risks and benefits, to consider hormone replacement therapy in this setting. Current recommendations advise using estrogen replacement at the lowest possible effective dose and for the shortest duration to treat moderate to severe vasomotor symptoms and vaginal dryness. For vaginal dryness alone, topical preparations are preferred.

**Androgen Therapy.** Based on the roles of androgens in normal female physiology and the observed decrease in circulating androgen levels after menopause, some have proposed that therapy with androgens will improve parameters such as libido and sexual satisfaction. Given the lack of a clearly defined disorder related to androgen deficiency in women, the absence of long-term safety data, and the lack of an approved formulation in a dose appropriate for women, one panel of experts recently concluded that the routine treatment of postmenopausal women with androgens was inappropriate (Wierman et al., 2006).

**Endometriosis**

Endometriosis is an estrogen-dependent disorder that results from endometrial tissue ectopically located outside of the uterine cavity (Farquhar, 2007). It predominantly affects women during their reproductive years, with a prevalence of 0.5-5% in fertile women and 25-40% in infertile women. Diagnosis typically is made at laparoscopy, either prompted by unexplained pelvic pain (dysmenorrhea or dyspareunia) or infertility. Although poorly understood, the infertility is thought to reflect involvement of the fallopian tubes with the underlying process and, possibly, impaired oocyte maturation.

Inasmuch as the proliferation of ectopic endometrial tissue is responsive to ovarian steroid hormones, many symptomatic approaches to therapy aim to produce a relatively hypoestrogenic state. Combination oral contraceptives have been standard first-line treatment for symptoms of endometriosis, and ample evidence from observational trials supports their benefit. The predominant mechanism of action is believed to be suppression of gonadotropin secretion, with subsequent inhibition of estrogen biosynthesis. Progestins (e.g., medroxyprogesterone, dienogest) also have been used to promote decidualization of the ectopic endometrial tissue. The levonorgestrel intrauterine system, which is approved for contraception, also has been used off label for this indication, as well as for menorrhagia.

As an alternative to steroid hormones, stable GnRH agonists can suppress gonadotropin secretion and thus effect medical castration. Drugs that carry an indication for endometriosis include leuprolide (LUPRON), goserelin (ZOLADEX), and nafarelin (SYNAREL); other GnRH agonists also may be used off label for this purpose (see Chapter 38). Due to significant decreases in bone density and symptoms of estrogen withdrawal, “add-back” therapy with either a low-dose synthetic estrogen (e.g., conjugated equine estrogens, 0.625-1.25 mg) or a high-dose progestin (e.g., norethindrone, 5 mg) has been used when the duration of therapy has exceeded 6 months (Olive, 2008). A number of clinical trials have shown that such combination regimens can provide symptomatic relief in patients with endometriosis. Danazol (DANOCRINE), a synthetic androgen that inhibits gonadotropin production via feedback inhibition of the pituitary-ovarian axis, also is FDA-approved for endometriosis therapy; it rarely is used now because of its significant adverse effects, including hirsutism and elevation of hepatic transaminases. In Europe and elsewhere, the antiprogestin gestrinone has been employed. By virtue of their ability to block the terminal step in estrogen biosynthesis, inhibitors of aromatase are under investigation for endometriosis (reviewed by Barbieri, 2008), often in conjunction with GnRH agonists, combination oral contraceptives, or a progestin.

When fertility is the goal, no medical therapy has proven efficacy, and surgical approaches (e.g., laparoscopic excision of endometriotic implants, lysis of adhesions) or assisted reproduction technology (e.g., *in vitro* fertilization) should be considered.

**Hirsutism**

Hirsutism, or increased hair growth in the male distribution, affects ~10% of women of reproductive age. It can be a relatively benign, idiopathic process or part of a more severe disorder of androgen excess that includes overt virilization (voice deepening, increased muscle mass, male pattern balding, clitoromegaly) and often results from ovarian or adrenal tumors. Specific etiologies associated with hirsutism include congenital adrenal hyperplasia, polycystic ovary syndrome (PCOS), and Cushing’s syndrome. After excluding serious pathology such as a steroid-producing malignancy, the treatment largely becomes empirical (Martin et al., 2008). Nonpharmacological approaches include bleaching, depilatory treatments (e.g., shaving, treatment with hair-removing chemicals), or methods that remove the entire hair follicle (e.g., plucking, electrolysis, laser ablation).

Pharmacotherapy is directed at decreasing androgen production and action. Initial therapy often involves treatment with combination oral contraceptive pills, which suppress gonadotropin secretion and thus the production of ovarian androgens. The estrogen also increases the concentration of sex hormone–binding globulin, thereby diminishing the free concentration of testosterone. The full effect of this suppression may take up to 6-9 months. Some experts prefer combination oral
contraceptives containing progestins with lower androgenic potential, such as norgestimate or drospirenone; the latter may actually have an anti-androgen effect. Despite this preference, all combination oral contraceptives will decrease plasma testosterone levels and can be used effectively. GnRH agonists downregulate gonadotropin secretion and also may be used to suppress ovarian steroid production.

In patients who fail to respond to ovarian suppression, efforts to block androgen action may be effective. Spironolactone (ALDACONE), a mineralocorticoid-receptor antagonist, and flutamide (EULEXIN; see Chapter 41) inhibit the androgen receptor. In Europe and elsewhere, cyproterone (50–100 mg/day) is used as an androgen-receptor blocker, often in conjunction with a combination oral contraceptive. Efficacy in clinical trials also has been seen with finasteride (PROSCAR), an inhibitor of the type 2 isozyme of 5α-reductase that blocks the conversion of testosterone to dihydrotestosterone. Male offspring of women who become pregnant while taking any of these androgen inhibitors are at risk of impaired virilization secondary to impaired synthesis or action of dihydrotestosterone (FDA category X). The antifungal ketoconazole (NIZORAL), which inhibits CYP steroid hydroxylases (see Chapters 42 and 57), also can block androgen biosynthesis but may cause liver toxicity. Finally, topical eflorenithine (VANIQA), an ornithine decarboxylase inhibitor, has been used with some success to decrease the rate of facial hair growth, thus reducing the frequency with which procedures such as laser ablation are needed for hair removal.

Infections of the Female Reproductive Tract

A variety of pathogens can cause infections of the female reproductive tract that range from vaginitis to pelvic inflammatory disease; Table 66–4 contains current recommendations for pharmacotherapy of selected sexually transmitted gynecological infections as issued by the Centers for Disease Control and Prevention (Workowski and Berman, 2006; www.cdc.gov/mmwr/preview/mmwrhtml/rr5511a1l.htm). Of note, the recommended therapy for gonococcal infections has been updated due to increasing resistance of Neisseria gonorrhoeae to fluoroquinolones. The individual drugs used for systemic or topical therapy are described in more detail in Section VI.

Infections have been implicated as important factors in preterm labor, as discussed further in “Prevention or Arrest of Preterm Labor.”

Fertility Induction

Infertility (i.e., the failure to conceive after 1 year of unprotected sex) affects ~10-15% of couples in developed nations and is increasing in incidence as more women choose to delay childbearing until later in life. The major impediment to pregnancy in an infertile couple can be attributed primarily to the woman in approximately one-third, to the man in approximately one-third, and to both in approximately one-third. The likelihood of a successful pharmacological induction of fertility in these couples depends greatly on the reason for the infertility. For example, a woman with tubal obstruction secondary to previous pelvic inflammatory disease is highly unlikely to become pregnant following drug therapy, whereas a woman with impaired ovulation secondary to a prolactin-secreting pituitary adenoma usually will become pregnant following suppression of prolactin secretion with a dopamine agonist (see Chapter 38).

The evaluation of an infertile couple is guided by the history and physical examination, which are augmented by focused laboratory evaluation. Defined abnormalities in the male partner that lead to impaired fertility (e.g., hypogonadism, Y chromosome microdeletions, Klinefelter’s syndrome) typically are detected by analysis of a semen sample; most often, male infertility is idiopathic. The medical therapy for some of these conditions is discussed in Chapters 38 and 41, while assisted reproduction technology interventions such as intracytoplasmic sperm injection can be used for disorders that severely impair sperm count.

Anovulation accounts for ~50% of female infertility and is a major focus of pharmacological interventions used to achieve conception. Thus, whether a woman is ovulating is a key question. Although a history of regular cyclic bleeding is strong presumptive evidence for ovulation, assessment of urine LH levels with an over-the-counter kit (see Chapter 38) or measurement of the serum progesterone levels during the luteal phase provides more definitive information. In those infertile women who ovulate, analysis of the patency of the fallopian tubes and the structure of the uterus is an important part of the diagnostic evaluation.

A number of approaches have been used to stimulate ovulation in anovulatory women. Often, a stepwise approach is taken, initially using simpler and less expensive treatments, followed by more complex and expensive regimens if initial therapy is unsuccessful. In obese patients with PCOS, the inclusion of lifestyle modifications directed at weight loss is warranted based on the association of obesity with anovulation, pregnancy loss, and complicated pregnancies (e.g., gestational diabetes, pre-eclampsia). Definitive evidence that weight loss improves fertility is not currently available (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008). Clomiphene. Clomiphene citrate (CLOMID, SEROPENHE) is a potent anti-estrogen that primarily is used for treatment of anovulation in the setting of an intact hypothalamic—pituitary axis and adequate estrogen production (e.g., PCOS). By inhibiting the negative feedback effects of estrogen at hypothalamic and pituitary levels, clomiphene increases follicle-stimulating hormone (FSH) levels—typically by ~50%—and thereby enhances follicular maturation (see Chapter 40). The drug is relatively inexpensive, orally active, and requires less extensive monitoring than do other fertility protocols.

A typical regimen is 50 mg/day orally for 5 consecutive days starting between days 2 and 5 of the cycle in women who have spontaneous uterine bleeding or following a bleed induced by progesterone

withdrawal in women who do not. If this regimen fails to induce ovulation, the dose of clomiphene is increased, first to the FDA-approved maximum of 100 mg/day and possibly to higher levels of 150 or 200 mg/day. Although clomiphene is effective in inducing ovulation in perhaps 75% of women, successful pregnancy ensues in only 40-50% of those who ovulate. This has been attributed to clomiphene’s inhibition of estrogen action on the endometrium, resulting in an environment that is not optimal for fertilization and/or implantation.

Untoward effects of clomiphene include the ovarian hyperstimulation syndrome (OHSS; < 1%; see “Gonadotropins”) and increased incidences of multifetal gestations (twins in ~5-10% and more than two babies in ~0.3% of pregnancies), ovarian cysts, hot flashes, headaches, and blurred vision. A few studies have suggested that prolonged use (e.g., ≥12 cycles) may increase the risk of ovarian and endometrial cancer; thus, the recommended maximum number of cycles is six. Clomiphene should not be administered to pregnant women (FDA category X) due to reports of teratogenicity in animals, although there is no definitive evidence of this in humans (Elizur and Tulandi, 2008).

Tamoxifen appears to be as effective as clomiphene for ovulation induction but is not FDA-approved for this indication. It has been used off label as an alternative in women who suffer intolerable side effects (e.g., hot flashes) with clomiphene.

**Gonadotropins.** The preparations of gonadotropins available for clinical use are detailed in Chapter 38 and include gonadotropins purified from human menopausal or pregnant urine and those prepared by recombinant DNA technology. They should be administered by physicians experienced in the treatment of infertility or reproductive endocrine disorders. Although most clearly indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction, gonadotropins also are used to induce ovulation in women with PCOS who do not respond to clomiphene (see “Clomiphene”) and also are used, generally after a trial of clomiphene, in women who are infertile despite normal ovulation.

Given the marked increases in maternal and fetal complications associated with multifetal gestation, the goal of ovulation induction in anovulatory women is to induce the formation and ovulation of a single dominant follicle; generally, the increased risks of twin gestation will be accepted if two follicles are present.

As shown in Figure 66–1, a typical regimen for ovulation induction is to administer 75 IU of FSH daily in a “low-dose, step-up protocol.” After several days of stimulation, the serum estradiol is measured; the target levels of estradiol range from 500-1500 pg/mL, with lower levels indicating inadequate gonadotropin stimulation and higher values portending an increased risk of OHSS. If the estradiol level is too low, then the daily dose of FSH can be increased (the “step-up”) in increments of 37.5 or 75 IU. Ovaries are examined by ultrasonography every 2-3 days to evaluate follicle maturation. The finding of a follicle ≥17 mm in diameter indicates that adequate follicular development has occurred. If three or more follicles of this size are present, gonadotropin therapy generally is stopped to decrease the likelihood of developing OHSS, and barrier contraception is used to prevent pregnancy, thereby avoiding multifetal pregnancy. In the “high-dose, step-down” protocol, higher initial doses of FSH are used, and the dose is decreased thereafter. Anecdotal evidence suggests that this regimen is associated with an increased risk of OHSS.

Gonadotropin induction also is used for ovarian stimulation in conjunction with in vitro fertilization (IVF; Figure 66–1; Macklon et al., 2006). In this setting, larger doses of FSH (typically 225-300 IU/day) are administered to induce the maturation of multiple (ideally at least 5 and up to 20) oocytes that can be retrieved for IVF and intrauterine transfer. To prevent the LH surge and subsequent premature luteinization of the ovarian follicles, gonadotropins typically are administered in conjunction with a GnRH agonist. The length of the IVF protocol is predicated by the initial flare of gonadotropin secretion that occurs in response to the GnRH agonists. In the long protocol, the agonist is started in the luteal phase of the previous cycle (generally on cycle day 21) and then maintained until the time of hCG injection to induce ovulation. Alternatively, in the “flare” protocol, the GnRH agonist is started on cycle day 2 (immediately after the start of menses), and gonadotropin injections are added 1 day later. Adequate follicle maturation with the latter regimen typically takes 10-12 days after gonadotropin therapy is initiated.

Gonadotropin induction also is used to inhibit endogenous LH secretion. Because they do not transiently increase gonadotropin secretion, they can be initiated later in the cycle in a “short protocol.” Current regimens include daily injection in a dose of 0.25 mg (ganirelix [ANTAGON] or cetrorelix [CETROTIDE]) starting on the fifth or sixth day of gonadotropin stimulation or a single dose of 3 mg of cetrorelix administered on day 8 or 9 of the late follicular phase.

Using either the long or short protocols, hCG (at typical doses of 5000-10,000 IU of urine-derived product or 250 μg of recombinant hCG) is given to induce final oocyte development, and the mature eggs are retrieved from the pre-ovulatory follicles at 32-36 hours thereafter. The ova are retrieved transvaginally guided by ultrasonography and fertilized in vitro with sperm (IVF) or by intracytoplasmic sperm injection; one or two embryos then are transferred to the uterus 3-5 days after fertilization. With these approaches, the increased risk of multifetal gestations is related to the number of embryos that are transferred to the woman. To diminish this risk, there is a trend, particularly in Europe, toward transferring only one embryo per cycle.

Because of the inhibitory effects of GnRH agonists or antagonists on pituitary gonadotropes, the secretion of LH that normally sustains the corpus luteum after ovulation does not occur. Repeated injections of hCG, while sustaining the corpus luteum, may increase the risk of OHSS. Thus, standard IVF regimens typically provide exogenous progesterone replacement to support the fetus until the
placenta acquires the biosynthetic capacity to take over this function; regimens include progesterone in oil (50-100 mg/day intramuscularly) or micronized progesterone (180-300 mg twice daily vaginally). Vaginal preparations containing 100 mg (ENDOMETRIN) or 90 mg (PROCHIEVE, CRINONE) of micronized progesterone are approved for administration two or three times daily as part of IVF and other fertility technologies.

Aside from the attendant complications of multifetal gestation, the major side effect of gonadotropin treatment is OHSS. This potentially life-threatening event is believed to result from increased ovarian secretion of substances that increase vascular permeability and is characterized by rapid accumulation of fluid in the peritoneal

---

Figure 66–1. Schematic diagram of idealized regimens using exogenous gonadotropins for fertility induction. A. Step-up regimen for ovulation induction. After menses, daily injections of gonadotropin (75 IU) are started. Follicle maturation is assessed by serial measurement of plasma estradiol and follicle size, as discussed in the text. If an inadequate response is seen, the dose of gonadotropin is increased to 112 or 150 IU/day. When one or two follicles have achieved a size of ≥17 mm in diameter, final follicle maturation and ovulation are induced by injection of human chorionic gonadotropin (hCG). Fertilization then is achieved at 36 hours after hCG injection by intercourse or intrauterine insemination (IUI). If more than two mature follicles are seen, the cycle is terminated and barrier contraception is used to avoid triplets or higher degrees of multifetal gestation. B. Long protocol for ovarian hyperstimulation using gonadotropin-releasing hormone (GnRH) agonist to inhibit premature ovulation, followed by in vitro fertilization (IVF). After the GnRH agonist has inhibited endogenous secretion of gonadotropins, therapy with exogenous gonadotropins is initiated. Follicle maturation is assessed by serial measurements of plasma estradiol and follicle size by ultrasonography. When three or more follicles are ≥17 mm in diameter, then ovulation is induced by injection of hCG. At 32-36 hours after the hCG injection, the eggs are retrieved and used for IVF. Exogenous progesterone is provided to promote a receptive endometrium, followed by embryo transfer at 3-5 days after fertilization. C. Protocol for ovarian hyperstimulation in an IVF protocol using a GnRH antagonist. The cycle duration is shorter because the GnRH antagonist does not induce a transient flare of gonadotropin secretion that might disrupt the timing of the cycle, but many other elements of the cycle are analogous to those in B. IU, intrauterine.
cavity, thorax, and even the pericardium. Symptoms and signs include abdominal pain and/or distention, nausea and vomiting, diarrhea, dyspnea, oliguria, and marked ovarian enlargement on ultrasonography. OHSS can lead to hypovolemia, electrolyte abnormalities, acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction.

In ovulation induction, incipient OHSS should be suspected if routine laboratory investigation reveals the presence of more than four to six follicles >17 mm or a serum estradiol level of >1500 pg/mL; in this setting, hCG should be withheld and barrier contraception used. For controlled ovarian hyperstimulation in anticipation of IVF, a higher risk of OHSS is present if the number of follicles >15 mm exceeds 15-20 or if the plasma level of estradiol is >5000 pg/mL. In an effort to avoid overt hyperstimulation, the FSH can be withheld for a day or two (“coasting”) if the plasma level of estradiol is near the top of this range. The rationale for this approach is that larger follicles become relatively gonadotropin independent and thus will continue to mature, while the smaller follicles undergo atresia in response to gonadotropin deprivation. In either case, ovulation induction with recombinant LH, which has a considerably shorter t½ than hCG, or with a GnRH agonist may diminish the incidence of OHSS without requiring cancellation of the cycle.

The potential deleterious effects of gonadotropins are debated. Some studies have suggested that gonadotropins are associated with an increased risk of ovarian cancer, but this conclusion is controversial (Brinton et al., 2005). Similarly, although IVF and the subsequent embryo manipulation may be associated with abnormal imprinting that increases the risk of developmental syndromes (e.g., Angelman’s and Beckwith-Wiedemann syndromes; Lawrence and Moley, 2008; Niemitz and Feinberg, 2004), the risk is small, and there is no evidence that the gonadotropins themselves or components of the IVF process increase the rate of congenital abnormalities in babies born from stimulated oocytes.

**Insulin Sensitizers.** PCOS affects 4-7% of women of reproductive age and is the most frequent cause of anovulatory infertility. Inasmuch as PCOS patients often exhibit hyperinsulinemia and insulin resistance, insulin sensitizers such as metformin have been evaluated for their effects on ovulation and fertility (see Chapter 43 for a general discussion of drugs used to increase insulin sensitivity). Although several small trials suggested that metformin increased ovulation in PCOS patients relative to placebo, a recent, well-designed trial failed to demonstrate a significant effect of metformin on fertility (Legro et al., 2007); metformin was less effective than clomiphene in inducing ovulation, promoting conception, or improving live birth rates, and there was no benefit of combining metformin with clomiphene on live births, except possibly in women resistant to clomiphene. Thus, except in women who exhibit glucose intolerance, the consensus is that metformin generally should not be used for fertility induction in women with PCOS (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008).

Thiazolidinediones also have been evaluated for their ability to induce ovulation in PCOS patients. One trial demonstrated that troglitazone significantly increased ovulation in PCOS patients compared to placebo controls; this drug was withdrawn from the market due to safety issues, and attention therefore has turned to the use of rosiglitazone (AVANDIA) and pioglitazone (ACTOS), other members of the thiazolidinedione family. Preliminary results suggest that these latter drugs may increase ovulation in PCOS patients, but definitive data are not available. Given the recent association of thiazolidinediones with an increased risk of congestive heart failure and myocardial ischemia, there is considerable reluctance to use these drugs in this setting.

**Aromatase Inhibitors.** Aromatase inhibitors (e.g., letrozole [FEMARA], 5 mg/day for 5 days) are under evaluation as potential drugs for infertility. By inhibiting estrogen biosynthesis, these drugs decrease estrogen negative feedback and thus increase FSH levels and stimulate follicle development. In 2005, the manufacturer of letrozole issued a statement that letrozole is not indicated for ovulation induction or other uses in premenopausal women. Another aromatase inhibitor, anastrozole (ARIMIDEX), also has been used off label for ovulation induction. Some data suggest that anastrozole is less effective than clomiphene in inducing follicle maturation but more likely to lead to pregnancy.

**DRUG THERAPY IN OBSTETRICS**

**General Principles of Drug Therapy of Pregnant Women**

The processes of evaluating potential adverse effects of various drugs in preclinical and clinical trials are described in Chapter 1. Unfortunately, these trials often do not provide sufficient information regarding safety in pregnant women or children. Individuals at the extremes of the age spectrum are particularly vulnerable to the toxic effects of drugs (see Chapter 4). The very young are susceptible due either to incomplete development of certain organs (e.g., the kidney) or the lack of expression of certain drug-metabolizing or transport proteins that play key pharmacokinetic roles (Kearns et al., 2003); the elderly are at increased risk due to age-related changes in body composition, organ function, and drug-metabolizing systems, all of which delay drug clearance (Mangoni and Jackson, 2003).
In pregnant women, the placenta provides a barrier for the transfer of certain drugs from the mother to the fetus (e.g., drug transporters expel toxic natural products and related drugs from the placenta; aromatase converts maternal androgen to estrogens); however, many compounds can freely cross the placental barrier and access the fetal circulation. The teratogenic effects of thalidomide on limb formation, alcohol on development of the CNS and cognition, and diethylstilbestrol (DES) on genital development in males and females and on the subsequent development of vaginal and cervical carcinomas in female offspring are stark reminders of the dangers of fetal exposure to drugs. In the clinical setting, there is no direct method for determining fetal exposure to a drug. Drug concentration over time in the mother’s systemic circulation is the major determinant of this exposure, but other contributing factors include the size, solubility, ionization, and protein binding of the drug; its active transport into and out of the placental circulation; and the rate of fetal clearance, which includes first-pass metabolism by the placenta.

Based on the relative paucity of human data on the teratogenic effects of drugs and the limited reliability of animal models, a fundamental tenet in treating pregnant women is to minimize, whenever possible, the exposure of mother and fetus to drugs; when necessary, one should preferentially use those drugs that have the best record of safety in pregnant women without adverse developmental effects on the fetus. Of equal importance, substances of abuse (e.g., cigarettes, alcohol, illegal drugs) should be avoided and, whenever possible, eliminated before conception. In addition, all pregnant women should take a multivitamin containing 400 μg of folic acid daily to diminish the incidence of neural tube defects. The greatest concern is during the period of organogenesis in the first trimester, when a number of the most vulnerable tissues are formed. Cancer chemotherapy drugs cannot be given with reasonable safety during the first trimester, but most cytotoxics may be administered without teratogenic effects and with maintenance of pregnancy in the third trimester (see Chapters 61-63).

Drugs that are used to promote fertility are a special case, since they, by nature of their use, will be present in the mother at the time of conception. Fortunately, available evidence largely supports the safety of fertility agents for fetal development, although there have been data suggesting increased risk with certain agents (e.g., neural tube defects and hypospadias associated with clomiphene; Elizur and Tulandi, 2008).

The FDA assigns different levels of risk to drugs for use in pregnant women, as listed in Table 66–5.

<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Category A</td>
<td>Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy.</td>
</tr>
<tr>
<td>Category B</td>
<td>No evidence of risk in humans. Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities despite adverse findings in animals, or, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote, but remains a possibility.</td>
</tr>
<tr>
<td>Category C</td>
<td>Risk cannot be ruled out. Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy, but the potential benefits may outweigh the potential risk.</td>
</tr>
<tr>
<td>Category D</td>
<td>Positive evidence of risk. Studies in humans, or investigational or post-marketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.</td>
</tr>
<tr>
<td>Category X</td>
<td>Contraindicated in pregnancy. Studies in animals or humans, or investigational or post-marketing reports, have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient.</td>
</tr>
</tbody>
</table>

Certain drugs are so toxic to the developing fetus that they must never be administered to a pregnant woman (category X); in some cases (e.g., thalidomide, retinoids), the potential for fetal harm is so great that multiple forms of effective contraception must be in place before the drug is initiated. For other drugs, the risk of adverse effects on the fetus may range from category A (drugs that have not been proven to have adverse effects on the fetus despite adequate investigation) to category C (drugs with risks that sometimes may be justified based on the severity of the underlying condition (e.g., hydralazine for pregnancy-induced hypertension, β adrenergic receptor agonists for premature labor; see “Pregnancy-Induced Hypertension/Pre-eclampsia” and “Tocolytic Therapy for Established Preterm Labor”). Unfortunately, the FDA listings may be overly simplistic or outdated for a given drug; for example, oral contraceptives are listed as category X, even though considerable data now indicate that birth defects are not increased in women taking oral contraceptives at the time of conception.
Nursing mothers constitute a second special situation with respect to potential adverse effects of drugs. Some drugs may interfere with milk production and/or secretion (e.g., estrogen-containing oral contraceptives) and thus should be avoided if possible in mothers who wish to breastfeed. Other drugs may be secreted into breast milk and expose the baby to potentially toxic levels during the vulnerable perinatal period (Ito and Lee, 2003). The amount of drug that is secreted in breast milk, like the amount that crosses the placenta, depends on drug characteristics such as size, ionization, protein binding, and pharmacokinetics of clearance. The American Academy of Pediatrics Committee on Drugs periodically reviews agents transferred into human milk and their effects on the infant or on lactation (Hale, 2005). Product information sheets that provide available information regarding the potential for adverse effects of specific drugs on breastfed infants should be consulted before prescribing medications to nursing mothers.

**Pregnancy-Induced Hypertension/Pre-eclampsia**

Hypertension affects up to 10% of pregnant women in the U.S., with the increasing prevalence of hypertension in the general population and the tendency to delay childbearing, drug therapy for maternal hypertension likely will be given greater consideration in the future. A consensus panel has issued guidelines for the management of hypertension in pregnancy (National High Blood Pressure Education Program Working Group, 2000).

Hypertension that precedes pregnancy or manifests before 20 weeks of gestation is believed to overlap considerably in pathogenesis with essential hypertension. These patients appear to be at increased risk for gestational diabetes and need careful monitoring. In contrast, pregnancy-induced hypertension, or pre-eclampsia, generally presents after 20 weeks of gestation as a new-onset hypertension with proteinuria (>300 mg of urinary protein/24 hours); pre-eclampsia is thought to involve placenta-derived factors that affect vascular integrity and endothelial function in the mother, thus causing peripheral edema, renal and hepatic dysfunction, and in severe cases, seizures (Maynard et al., 2008). Chronic hypertension is an established risk factor for pre-eclampsia, but there is no conclusive evidence that antihypertensive therapy during pregnancy affects the incidence or outcome of pre-eclampsia in women with mild to moderate hypertension (Abalos et al., 2007). Nonetheless, the consensus panel recommended initiation of drug therapy in women with a diastolic blood pressure >105 mm Hg or a systolic blood pressure >160 mm Hg (National High Blood Pressure Education Program Working Group, 2000). If severe pre-eclampsia ensues, with marked hypertension and evidence of end-organ damage, then termination of the pregnancy by delivery of the baby is the treatment of choice, provided that the fetus is sufficiently mature to survive outside the uterus. If the baby is very preterm, then hospitalization and pharmacotherapy (expectant management) may be employed in an effort to permit further fetal maturation in utero.

Many pregnant women already carry the diagnosis of hypertension and are on drug therapy, which may be continued with careful monitoring, provided that blood pressure control is effective. In this setting, however, some drugs that commonly are used for hypertension in non-pregnant patients (e.g., angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists) should not be used due to unequivocal evidence of adverse fetal effects in animal models and humans (Podymow and August, 2008). Many experts will convert the patient to the centrally acting α-adrenergic agonist α-methyldopa (ALDOMET) at an initial dose of 250 mg orally twice daily (FDA category B), which rarely is used for hypertension in non-pregnant patients. Other drugs with reasonable evidence of safety (category C) also may be used, including the combination α1-selective, β-nonselective adrenergic antagonist labetalol (TRANDATE; 100 mg twice daily) and the Ca2+ channel blocker nifedipine (PROCARDIA XL, ADALAT CC; 30 mg once daily).

Similar considerations apply in previously normotensive women who develop pre-eclampsia; α-methyldopa again is a reasonable choice for outpatient management if the blood pressure exceeds the threshold for therapy. If severe pre-eclampsia or impending labor requires hospitalization, blood pressure can be controlled acutely with hydralazine (5 or 10 mg intravenously or intramuscularly, with repeated dosing at 20-minute intervals depending on blood pressure response) or labetalol (20 mg intravenously, with dose escalation to 40 mg at 10 minutes if blood pressure control is inadequate).

In addition to drugs for blood pressure control, women with severe pre-eclampsia or those who have central nervous system manifestations, such as headache, visual disturbance, or altered mental status, are treated as inpatients with magnesium sulfate, based on its documented efficacy in seizure prevention and lack of adverse effects on the mother or baby (Altman et al., 2002). Such treatment also should be considered for postpartum women with central nervous system manifestations, because ~20% of episodes of eclampsia occur in women who are more than 48 hours after delivery.

**Prevention or Arrest of Preterm Labor**

**Scope of the Problem and Etiology.** Preterm birth, defined as delivery before 37 weeks of gestation, occurs in >10% of pregnancies in the U.S. and is increasing in frequency; it is associated with significant complications, such as neonatal respiratory distress syndrome, pulmonary hypertension, and intracranial hemorrhage.
Although incompletely understood, risk factors for preterm labor include multifetal gestation, premature rupture of the membranes, intrauterine infection, and placental insufficiency. The more premature the baby, the greater the risk of complications, prompting efforts to prevent or interrupt preterm labor.

The therapeutic objective in preterm labor is to delay delivery so that the mother can be transported to a regional facility specializing in the care of premature babies and supportive agents can be administered; such supportive treatments include glucocorticoids to stimulate fetal lung maturation (see Chapter 42) and antibiotics (e.g., erythromycin, ampicillin) to diminish the frequency of neonatal infection with group B β-hemolytic Streptococcus. Based on concerns over deleterious effects of antibiotic therapy, it is essential that antibiotics not be administered indiscriminately to all women thought to have preterm labor, but rather be reserved for those with premature rupture of the membranes and evidence of infection.

Prevention of Preterm Labor: Progesterone Therapy. Progesterone levels in some species diminish considerably in association with labor, whereas administration of progesterone inhibits the secretion of pro-inflammatory cytokines and delays cervical ripening. Thus, progesterone and its derivatives have long been advocated to diminish the onset of preterm labor in women at increased risk due to previous preterm delivery. Despite considerable controversy, recent randomized trials have revived interest in this approach. One drug used in this setting is 17α-hydroxyprogesterone at a dose of 250 mg administered weekly by intramuscular injection (Meis et al., 2003). Vaginal administration of progesterone (200 mg each night) also was used in one clinical trial with apparent efficacy (Fonseca et al., 2007). One clinical trial suggested that progesterone administration in this setting was associated with an increased incidence of gestational diabetes (Rebarber et al., 2007), and the role of progesterone prophylaxis during pregnancy remains to be established.

Tocolytic Therapy for Established Preterm Labor. Because preterm birth typically is heralded by the uterine contractions of labor, the inhibition of these contractions, or tocolysis, has been a focus of therapy (Simhan and Caritis, 2007). Although tocolytic agents delay delivery in ~80% of women, they neither prevent premature births nor improve adverse fetal outcomes such as respiratory distress syndrome. Thus, while widely employed, they should be viewed as temporizing agents, as described in “Prevention of Preterm Labor: Progesterone Therapy.”

Specific tocolytic agents include β adrenergic receptor agonists, MgSO₄, Ca²⁺ channel blockers, COX inhibitors, oxytocin-receptor antagonists, and nitric oxide donors. The mechanisms of action of these agents are illustrated in Figure 66–2.

The β adrenergic receptor agonists relax the myometrium by activating the cyclic AMP-PKA signaling cascade that phosphorylates and inactivates myosin light-chain kinase, a key enzyme in uterine contraction. Ritodrine, a selective β₂ agonist, was specifically developed as a uterine relaxant and remains the only tocolytic drug to have gained FDA approval; it was voluntarily withdrawn from the U.S. market. Terbutaline (BRETHINE), which is FDA-approved for asthma, has been used off label for this purpose and can be administered orally, subcutaneously, or intravenously. Terbutaline may delay births, but only during the first 48 hours of treatment, and is associated with a number of adverse maternal effects, including tachycardia, hypotension, and pulmonary edema.

Similarly, Ca²⁺ channel blockers inhibit the influx of Ca²⁺ through depolarization-activated, voltage-sensitive Ca²⁺ channels in the plasma membrane, thereby preventing the activation of myosin light-chain kinase and the stimulation of uterine contraction. Nifedipine (PROCARDIA, ADALAT), the Ca²⁺ channel blocker used most commonly for this purpose, can be administered parenterally or orally. Relative to β₂ adrenergic agonists, nifedipine is more likely to improve fetal outcomes and less likely to cause maternal side effects.

Based on the role of prostaglandins in uterine contraction, cyclooxygenase inhibitors (e.g., indomethacin) have been used to inhibit preterm labor, and some data suggest that they may reduce the number of preterm births. Because they also can inhibit platelet function and induce closure in utero of the ductus arteriosus, these inhibitors should not be employed in term pregnancies (or in pregnancies beyond 32 weeks of gestation, when the risk of severe complications of prematurity is relatively lower). Short courses of treatment (<72 hours) pose less risk for impaired circulation in the fetus.

Atosiban (TRACTOCILE), a nonapeptide analog of oxytocin, competitively inhibits the interaction of oxytocin with its membrane receptor on uterine cells and thereby decreases the frequency of uterine contractions. Although atosiban increased the number of women who remained undelivered for 48 hours and is widely used in Europe, it is not FDA-approved in the U.S.

Nitric oxide is a potent vasodilator and smooth muscle relaxant, and drugs such as nitroglycerin and other nitrates that increase its levels are used to treat myocardial ischemia (see Chapter 28). Both intravenous nitroglycerin and transdermal nitrate preparations have been evaluated in clinical trials to inhibit preterm labor. The major adverse effect is maternal hypotension.

Despite numerous clinical trials, the superiority of any one therapy has not been established, and none of the drugs has been shown definitively to improve fetal outcome. Thus, despite widespread and enthusiastic use by some centers, many experts do not endorse the routine use of tocolytic agents. Recent meta-analyses of published reports concluded that Ca²⁺ channel blockers and atosiban (not available in the U.S.) provided the best balance of successfully delayed delivery with lesser risks to the mother and baby (reviewed by Iams et al., 2008).
Initiation of Labor

Labor induction is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of delivery or pharmacological induction. Such circumstances include premature rupture of the membranes, isoimmunization, fetal growth restriction, uteroplacental insufficiency (as in diabetes, pre-eclampsia, or eclampsia), and gestation beyond 42 weeks. Before inducing labor, it is essential to verify that the fetal lungs are sufficiently mature and to exclude potential contraindications (e.g., abnormal fetal position, evidence of fetal distress, placental abnormalities, or previous uterine surgery predisposing to uterine rupture).

Labor induction also is used increasingly in the absence of specific criteria listed above; such elective inductions may be predicated in part on matters of convenience for the mother or medical team. Collectively, induced or augmented labor now accounts for ~20% of all deliveries in the U.S., two-thirds of which are for nonmedical reasons.

Prostaglandins and Cervical Ripening. Prostaglandins play key roles in parturition (see Chapter 33). Thus, PGE, PGE, and PGF are used to facilitate labor by promoting ripening and dilation of the cervix. They can be administered either orally or via local administration (either vaginally or intracervically). The ability of certain prostaglandins to stimulate uterine contractions also makes them valuable agents in the therapy of postpartum hemorrhage (see “Prevention/Treatment of Postpartum Hemorrhage”). Although prostaglandins are widely employed for cervical ripening, their effectiveness versus that of oxytocin alone in diminishing the need for convenience for the mother or medical team. Collectively, induced or augmented labor now accounts for ~20% of all deliveries in the U.S., two-thirds of which are for nonmedical reasons.
cesarean section in labor induction has not been definitively established.

Available preparations include dinoprostone (PGE₂), which is FDA approved to facilitate cervical ripening. Dinoprostone is formulated as a gel for intracervical administration via syringe in a dose of 0.5 mg (Cervidil) or as a vaginal insert (pessary) in a dose of 10 mg (Cervidil); the latter is designed to release active PGE₂ at a rate of 0.3 mg/hr for up to 12 hours and should be removed at the onset of labor or 12 hours after insertion. No more than three doses should be used in a 24-hour period. Dinoprostone should not be used in women with a history of asthma, glaucoma, or myocardial infarction. The major adverse effect is uterine hyperstimulation, which may be reversed more rapidly using the vaginal insert by removing it with the attached tape.

Misoprostol (Cytotec), a synthetic derivative of PGE₁, is FDA-approved for the prevention and treatment of acid peptic disease in patients who are receiving nonsteroidal anti-inflammatory agents (see Chapter 34). Its use in medical abortion is discussed earlier in “Pregnancy Termination.” It also is used off label either orally or vaginally to induce cervical ripening; typical doses are 100 μg (orally) or 25 μg (vaginally); an advantage of misoprostol in this setting is its considerably lower cost. The vaginal dose typically is repeated every 4-6 hours depending on labor progression. Adverse effects include uterine hyperstimulation and, rarely, uterine rupture. Most experts therefore do not use misoprostol for cervical ripening in women who have had previous cesarean section or other uterine surgery. Misoprostol should be discontinued for at least 3 hours before initiating oxytocin therapy.

Oxytocin. The structure and physiology of oxytocin are discussed in Chapter 38. This section presents therapeutic uses of oxytocin in obstetrics, which include the induction of labor, the augmentation of labor that is not progressing, and the prophylaxis and/or treatment of postpartum hemorrhage. Although widely used, oxytocin recently was added to a list of drugs “bearing a heightened risk of harm” (Clark et al., 2009), and its role and specific application to most deliveries in the U.S. remain open to debate. Thus, careful review of the appropriate indications for oxytocin administration and attention to the dose and progress of labor during induction are essential.

Labor Induction. Oxytocin (Pitocin, Synthocinon) is the drug of choice for labor induction; for this purpose, it is administered by intravenous infusion of a diluted solution (typically 10 mIU/mL), preferably via an infusion pump. Current protocols start with an oxytocin dose of 6 mIU/minute, followed by advancement of dose as needed (in one protocol, increases of 6 mIU/minute can be made every 40 minutes if labor is not progressing in a satisfactory manner). Although there are little definitive data, 40 mIU/minute is a reasonable maximum dose, although doses of up to 72 mIU/minute have been used with apparent safety in some studies. Uterine hyperstimulation should be avoided; however, if it occurs, as evidenced by too-frequent contractions (more than five contractions in a 10-minute interval) or the development of uterine tetany, the oxytocin infusion should be discontinued immediately. Because the t½ of intravenous oxytocin is relatively short (12-15 minutes), the hyperstimulatory effects of oxytocin will dissipate fairly rapidly after the infusion is discontinued. Thereafter, the infusion can be reinitiated at a dose of half that at which hyperstimulation occurred and increased cautiously as tolerated.

Because of its structural similarity to vasopressin, oxytocin at higher doses activates the vasopressin V₂ receptor and has antidiuretic effects. Particularly if hypotonic fluids (e.g., dextrose in water) are infused too liberally, water intoxication may result in convulsions, coma, and even death. Vasodilating actions of oxytocin also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

Augmentation of Dysfunctional Labor. Oxytocin also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions in dysfunctional labor, an infusion rate of 10 mIU/minute typically is sufficient; doses in excess of 40 mIU/minute rarely are effective when lower concentrations fail. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion. Oxytocin usually is effective when there is a prolonged latent phase of cervical dilation or when, in the absence of cephalo-pelvic disproportion, there is an arrest of dilation or descent.

Prevention/Treatment of Postpartum Hemorrhage

Postpartum hemorrhage is a significant problem in developed nations and is of even greater importance in developing countries. After delivery of the fetus or after therapeutic abortion, a firm, contracted uterus greatly reduces the incidence and extent of hemorrhage. Oxytocin (10 IU intramuscularly) often is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, oxytocin (20 IU) is diluted in 1 L of intravenous solution and infused at a rate of 10 mL/minute until the uterus is contracted. The infusion
rate then is reduced to 1-2 mL/minute until the mother is ready for transfer to the postpartum unit. Carbetocin, a longer-acting derivative of oxytocin, is under evaluation in clinical trials to prevent or treat postpartum hemorrhage; a dose of 100 μg is given intravenously (Leung et al., 2006).

Ergot alkaloids markedly increase the motor activity of the uterus. Although their capacity to induce sustained uterine tetany precludes their use in the induction or facilitation of labor, they are used to prevent or treat postpartum hemorrhage in normotensive women. In this setting, the preferred ergot alkaloids are ergonovine (ERGOTRATE) or its methyl analog methylergometrine (METHOREX). They are administered intramuscularly or intravenously, exhibit rapid onsets of action (2-3 minutes intramuscularly, <1 minute intravenously), and their effects persist for 45 minutes to 3 hours depending on the route of administration. Adverse effects include nausea and vomiting, elevated blood pressure, and decreased pain threshold requiring analgesia.

Alternatively, the PGE₁ analog misoprostol (600 μg administered orally or sublingually) may be used off label to stimulate uterine contractions and prevent or treat postpartum hemorrhage. Although meta-analyses suggest that it may be slightly less effective than oxytocin, the low cost and lack of need for refrigeration or sterile needles may make misoprostol the preferred agent for use in developing nations. Other approaches under investigation include recombinant factor VIIa and balloon tamponade.

BIBLIOGRAPHY

Humans are exposed to chemicals from their environment daily. Fortunately, mammals have evolved mechanisms to protect themselves from toxic effects of many exogenous chemicals, including the xenobiotic transport and metabolic mechanisms described in Chapters 4-7. While the human body is relatively well adapted to deal with xenobiotics, there are situations in which such environmental agents may cause significant toxicity. The industrial revolution and the development of chemical industries have increased human exposures to chemicals that were previously infrequent or absent. Occupational exposures to xenobiotics are of particular concern because workers often will be exposed to specific chemicals at concentrations that are orders of magnitude higher than those to which the general population is exposed. Increasing concern about environmental toxicants has stimulated interest and research in environmental toxicology, the study of how chemicals in our environment adversely affect human health, and in occupational toxicology, the study of how chemicals in the workplace affect human health. Myriad authoritative textbooks are available in these areas. This chapter does not attempt a thorough coverage; rather, it sets forth a few basic principles, briefly discusses carcinogens and chemoprevention, and then focuses on the pharmacotherapy of heavy metal intoxication.

**ENVIRONMENTAL RISK ASSESSMENT AND RISK MANAGEMENT**

When assessing the risks of environmental exposures to xenobiotics, many of the same principles discussed in Chapter 4 for drug toxicity apply; there are, however, significant differences. With environmental exposures, one has to consider population exposures to low-dose toxicants over long periods of time. Thus, one must give more attention to the low end of the dose-response curve, using experiments based on chronic exposures. Particular attention is given to the potential for individuals with higher susceptibility. Unlike drugs, which are given to treat a specific disease and will have benefits that outweigh the risks, environmental toxicants usually are only harmful. In addition, exposures to environmental toxicants usually are involuntary, there is uncertainty about the severity of their effects, and people are much less willing to accept their associated risks.

Two complimentary approaches are used to predict the toxic effects of environmental exposures: epidemiology and toxicology. Epidemiologists monitor health effects in humans and use statistics to associate those effects with exposure to an environmental stress, such as a toxicant. Toxicologists perform laboratory studies to try to understand the potential toxic mechanisms of a chemical to predict whether it is likely to be toxic to humans. Each of these approaches has strengths and weaknesses, and information from both is integrated into environmental risk assessment. Risk assessment is used to develop management approaches, such as laws and regulations, to limit exposures to environmental toxicants to a level that is considered safe.

**Epidemiological Approaches to Risk Assessment**

Epidemiologists use multiple approaches to assess the risks of human environmental exposures (Gordis, 2008). The disadvantage of these approaches is the variability between people in their exposures and genetics, which results in confounding effects. Epidemiologists cannot control the environment or the genetics of the populations being studied. For example, generally individuals are simultaneously exposed to more than one environmental toxicant. Because of the difficulties in assessing human exposures and the long times required to clinically observe effects on health, epidemiologists rely on biomarkers in risk assessment. There are three different types of biomarkers: biomarkers of exposure, biomarkers of toxicity, and biomarkers of susceptibility. Biomarkers of exposure usually are measurements of toxicants or their metabolites in blood, urine, or hair. Blood and urine concentrations measure recent exposures, while hair levels measure exposure over a period of months.
An example of an unusual exposure biomarker is X-ray fluorescent measurement of bone lead levels, which estimates lifetime exposure to lead. Biomarkers of toxicity are used to measure toxic effects at a subclinical level and include measurement of liver enzymes in the serum, changes in the quantity or contents of urine, and performance on specialized exams for neurological or cognitive function. Biomarkers of susceptibility are used to predict which individuals are likely to develop toxicity in response to a given chemical. Examples include single nucleotide polymorphisms in genes for metabolizing enzymes involved in the activation or detoxification of a toxicant. Some biomarkers simultaneously provide information on exposure, toxicity, and susceptibility. For example, the measurement in the urine of N7-guanine adducts from aflatoxin B1 provides evidence of both exposure and a toxic effect (in this case, DNA damage). These types of biomarkers are particularly valuable because they can support a proposed mechanism of toxicity.

Several types of epidemiological studies are used to assess risks, each with its own set of strengths and weaknesses. Ecological studies correlate frequencies of exposures and health outcomes between different geographical regions. These studies are inexpensive and can detect rare outcomes but are prone to confounding variables, including population migration. Cross-sectional studies examine the prevalence of exposures and outcomes at a single point in time. Such studies are an inexpensive way to determine an association but do not provide a temporal relationship and are not effective for establishing causality. They also can be subject to bias, as a perceived health outcome might cause someone to eliminate his exposure. Case-control studies start with a group of individuals affected by a disease, which then is matched to another group of unaffected individuals for known confounding variables. Questionnaires often are used to evaluate past exposures. This method also is relatively inexpensive and is good for examining rare outcomes because the endpoint is known. However, case-control studies rely on assessments of past exposures that often are unreliable and can be subject to bias. Prospective cohort studies measure exposures in a large group of people and follow that group for a long time to measure health outcomes. These studies are not as susceptible to confounding variables and bias and are good at establishing causality. However, they are extremely expensive, particularly when measuring very rare outcomes, because a large study population is required to observe sufficient disease to obtain statistical significance. One of the key types of human studies used in drug development is the randomized clinical trial (discussed in Chapter 1). These studies cannot be used to directly measure the effects of environmental toxicants (for obvious ethical reasons) but can be used to examine the effectiveness of an interventional strategy for reducing both exposure and disease.

**Toxicological Approaches to Risk Assessment**

Toxicologists use model systems, including experimental animals, to examine the toxicity of chemicals and predict their effect on humans (Faustman and Omenn, 2008). The significance of these model systems to human health is not always well-established. Toxicologists also test chemicals at the high end of the dose-response curve in order to see enough occurrences of an outcome to obtain statistical significance. As a result, there often is uncertainty about the effects of very low doses of chemicals. To determine the applicability of model studies, toxicologists study the mechanisms involved in the toxic effects of chemicals, with the goal of predicting whether that mechanism would occur in humans.

To predict the toxic effects of environmental chemicals, toxicologists perform subchronic (3 months of treatment for rodents) and chronic studies (2 years for rodents) in at least two different animal models. Subchronic experiments provide a model for occupational exposures, while chronic experiments are used to predict effects from lifetime exposures to chemicals in food or the environment. Doses for these studies are based on shorter preliminary studies, with the goal of having one concentration that does not have a significant effect, one concentration that results in statistically significant toxicity at the low end of the dose-response curve, and one or more concentrations that will have moderate-to-high levels of toxicity. A theoretical dose-response curve for an animal study is shown in Figure 67–1. An animal study provides two numbers that estimate the risk from a chemical. The *no observed adverse effect level* (NOAEL) is the highest dose used that does not result in a statistically significant increase in negative health outcomes. The *lowest observed adverse effect level* (LOAEL) is the lowest dose that results in a significant increase in toxicity. The NOAEL is divided by 10 for each source of uncertainty to determine a reference dose (RfD), which is commonly used as a starting point for determining regulations on human exposures to chemicals. The modifiers used to determine the RfD are based on the uncertainties between the experimental and

![Figure 67–1. LOAEL and NOAEL.](image-url)
human exposure. The most common modifiers used are for inter-
species variability (human to animal) and interindividual variability
(human to human), in which case RfD = NOAEL/100. Other modi-
fiers can be used to account for specific experimental uncertainties.
When a NOAEL is unavailable, a LOAEL may be used, in which case
another 10-fold uncertainty factor is used. The use of factors of 10
in the denominator for determination of RfD is an application of
the “precautionary principle,” which attempts to limit human expo-
sure by assuming a worst-case scenario for each unknown variable
(Faustman and Omenn, 2008).

A major concern with animal studies is that they do not detect
effects at low concentrations. Typically, they are designed to obtain
statistical significance with a 10% increase in an outcome. As a
result, there is considerable uncertainty about what occurs below that
level, as demonstrated in Figure 67–1. Toxicologists often assume
that there is a threshold dose (T), below which there is no toxicity.
This condition is true when there are cellular defenses that prevent
toxicity at concentrations below a given level but that can be over-
whelmed. Thresholds usually are observed when the toxic effects of
a chemical are the result of direct cell death. Many carcinogens
and other toxicants with specific molecular targets (e.g., lead) do
not exhibit a threshold. Ideally, mechanistic studies should be done
to predict which dose-response curve is most likely to fit a given
chemical.

Toxicologists perform a variety of mechanistic studies to
understand how a chemical might cause toxicity. Computer model-
ing using a compound’s three-dimensional structure to determine
quantitative structure-activity relationships (QSARs) is commonly
performed on both drugs and environmental chemicals. QSAR
approaches can determine which chemicals are likely to exhibit
toxicities or bind to specific molecular targets. Cell-based
approaches in prokaryotes and eukaryotes are used to determine
whether a compound damages DNA or causes cytotoxicity. DNA
damage and the resulting mutagenesis often are determined with the
Ames test. The Ames test uses Salmonella typhimurium strains with
specific mutations in the gene needed to synthesize histidine. These
strains are treated with chemicals in the presence or absence of a
metabolic activating system, usually the supernatant fraction from
homogenized rat liver. If a compound is a mutagen in the Ames test,
the Ames test uses Salmonella typhimurium strains with
specific mutations in the gene needed to synthesize histidine. These
strains are treated with chemicals in the presence or absence of a
metabolic activating system, usually the supernatant fraction from
homogenized rat liver. If a compound is a mutagen in the Ames test,
it reverts the mutation in the histidine operon and allows the bacte-ia to form colonies on plates with limited histidine. Gene chip
microarrays assess gene expression in cells or tissues from animals
revert the mutation in the histidine operon and allows the bacte-
treated with a toxicant and provide a very useful tool to identify the
molecular targets and pathways altered by toxicant exposures. The
susceptibility of knockout mice to a toxicant can help to determine
whether the knocked-out genes are involved in the metabolic activa-
tion and detoxification of a given toxicant.

Integrated Risk Assessment and Risk Management
Regulatory bodies at local, state, national, and international levels
are involved in limiting the adverse effects of chemicals. In the
U.S., several federal agencies are involved, depending on the
source of the exposure. The U.S. Food and Drug Administration
(FDA) regulates the safety of drugs, the food supply, cosmetics,
and now tobacco products. The Occupational Safety and Health
Administration (OSHA) regulates workplace exposures. The U.S.
Environmental Protection Agency (EPA) regulates exposures
from other environmental sources, particularly the air and water.

Regulators use epidemiological and toxicological data to estimate
the risks from an exposure and come up with a level they consider
to be reasonably safe. Regulators can nominate toxicants for a com-
prehensive study by the National Toxicology Program if there are
insufficient toxicological data. The final stages of risk assessment
and risk management are not based entirely on science; politics and
economics also help determine which regulations are enacted.
Ultimately, the social, economic, and political benefits predicted to
result from limiting human exposure to a given toxicant are weighed
against the corresponding costs.

Interventions for Environmental Exposure: Pharmacology and Prevention
There is considerable interest in pharmacological approaches to prevent disease from environmental exposures. However, pharmacological interventions for chronic environmental exposures remain more of a goal than a reality. There are numerous hurdles for treatment of exposure to environmental toxicants. Because exposures occur over long periods of time, treatments must reverse existing preclinical toxicities or provide protection for a long time. If a pharmaceutical is to be given chronically or in the absence of disease, the extent of side effects and toxicity should be much less than for a drug being given acutely to treat disease. Currently, the most effective approaches for preventing diseases associated with chronic exposures to chemicals are primary prevention and nutrition. Pharmaceuticals can be useful for preventive strategies against chronic exposures (e.g., nicotine replacement therapy in smoking cessation). Ongoing research also is examining pharmacological approaches to prevent cancer in humans exposed to chemical carcinogens. One class of environmental toxicant for which there are drugs available to prevent disease is metals. However, in general, these drugs, known as metal chelators, are only effective against acute, high-dose metal exposure and either have no effect, or actually worsen, toxicity under the low-dose chronic exposures most commonly encountered from the environment.

CARCINOGENS AND CHEMOPREVENTION
Carcinogenesis
Many environmental compounds increase the risk of
developing cancer; these chemicals are called carcino-
gens (Wogan et al., 2004; Klaunig and Kamendulis,
2008). The International Agency for Research on Cancer
(IARC) classifies compounds into groups based on risk
assessments using human, animal, and mechanism data.
Chemicals in group 1 are known human carcinogens;
group 2A includes chemicals that probably are carcinogenic in humans; group 2B chemicals possibly are carcinogenic in humans; group 3 chemicals lack data to suggest a role in carcinogenesis; and group 4 are those with data indicating they are unlikely to be carcinogens. Some important group 1 carcinogens and their sources are given in Table 67–1.

The transformation of a normal cell to a malignancy is a multi-stage process, and exogenous chemicals can act at one or more of these stages (Figure 67–2). A classic model of chemical carcinogenesis is tumor initiation followed by tumor promotion. In this model, a tumor initiator causes gene mutations that increase the ability of cells to proliferate and avoid apoptosis. A tumor promoter does not directly modify genes but changes signaling pathways and/or the extracellular environment to cause initiated cells to proliferate, invade surrounding tissue, and increase access to blood vessels. Although this model is an oversimplification of the many processes of carcinogenesis, it demonstrates the types of changes that must occur to transit a normal cell into tumorigenesis.

Chemical carcinogens cause cancer through genotoxic and non-genotoxic mechanisms (Figure 67–2). Genotoxic carcinogens induce tumor formation through damage to DNA. Typically, genotoxic carcinogens undergo metabolism in a target tissue to a reactive intermediate. This reactive intermediate can directly damage DNA via covalent reaction to form a DNA adduct. Alternatively, it can indirectly damage DNA through the formation of reactive oxygen species (ROS), which can oxidize DNA or form lipid peroxidation products that react with DNA (Mena et al., 2009).

Benzo[a]pyrene, a key carcinogen in tobacco smoke, is an example of a genotoxic carcinogen that forms both direct DNA adducts and ROS. Benzo[a]pyrene is oxidized by CYPs to a 7,8-dihydrodiol, which represents a proximate carcinogen (a more carcinogenic metabolite). This metabolite can either undergo a second oxidation step by a CYP to form a diol epoxide, which readily reacts with DNA, or it can undergo oxidation by aldo-keto reductases to form a catechol, which will redox cycle to form ROS (Conney, 1982; Penning, 2009).

If DNA damage from a genotoxic carcinogen is not repaired prior to DNA replication, a mutation can result. If this mutation is in a key tumor suppressor gene or proto-oncogene, it provides advantages in proliferation or survival. Alternatively, if the mutation is in a DNA repair gene, the mutation increases the probability that other mutations will occur. Given mutations in enough key genes and the

right environment, a cell will proliferate faster than surrounding normal cells and possibly develop into malignant cancer. Genotoxic carcinogens are tumor initiators.

Non-genotoxic carcinogens increase the incidence of cancer without damaging DNA. There are a number of possible non-genotoxic mechanisms, most of which are classified as tumor promotion. Many non-genotoxic carcinogens bind to receptors that stimulate proliferation or other tumor-promoting effects, such as tissue invasion or angiogenesis. For example, phorbol esters mimic diacylglycerol and activate PKC isoforms. This in turn stimulates MAP kinase pathways, leading to proliferation, invasiveness, and angiogenesis (see Chapter 3). In most normal cells, prolonged activation of this pathway stimulates apoptosis, but cells with defective apoptotic mechanisms due to preceding mutation(s) are resistant to this effect. Estrogenic carcinogens activate estrogen receptor-α (ERα) and stimulate proliferation and invasiveness of estrogen responsive cells. Chronic inflammation is another mechanism of non-genotoxic carcinogenesis. Like phorbol esters, inflammatory cytokines stimulate PKC signaling, leading to proliferation, invasiveness, and angiogenesis. Irritants such as asbestos are examples of carcinogens that work through inflammation. Chronic exposure to hepatotoxic chemicals (or chronic liver diseases) also causes non-genotoxic carcinogenesis by stimulating compensatory proliferation to repair the liver damage. This damage and repair process increases the likelihood of DNA damage becoming a mutation, causes chronic inflammation, and selects for cells that proliferate faster or are less sensitive to apoptosis.

Tumor initiation also may occur through non-genotoxic mechanisms. For example, some heavy metals do not directly react with DNA but interfere with proteins involved in DNA synthesis and repair, increasing the likelihood that an error will be made during replication. Non-genotoxic carcinogens also can cause heritable changes to gene expression by altering the methylation state of cytosines in 5’-CpG-3 islands of gene promoters, thus acting as tumor initiators. Methylation can silence tumor suppressor genes, while demethylation of protooncogenes can increase their expression.

Chemoprevention

Drugs that interfere with the carcinogenic process to prevent cancer before it is diagnosed are termed chemopreventive agents (Szabo, 2006; William et al., 2009). The chemoprevention concept was pioneered during the 1960s by Wattenberg and others, who observed that dietary constituents, such as t-butyl hydroquinone, could prevent cancer in rodents (Wattenberg, 1966). Chemoprevention strategies often are based on epidemiological studies on nutrition, where there are many examples of clear protective effects of plant-based foods and drinks on the incidence of various types of cancer (Fahey and Kensler, 2007). By isolating the active compounds from protective plants, researchers hope to understand their protective mechanisms and develop drugs to prevent cancer. Chemoprevention is an emerging field; a number of compounds for the prevention of cancer are in clinical trials (Table 67–2). There currently are no drugs approved for chemoprevention of environmental carcinogenesis, but there
are approved drugs to prevent carcinogenesis due to endogenous estrogen (tamoxifen and raloxifene) and viruses (hepatitis B and human papillomavirus vaccines).

Chemopreventive agents interfere with the processes of initiation and promotion (Figure 67–2). One mechanism of anti-initiation is prevention of carcinogen activation. Isothiocyanates and similar compounds inhibit CYPs involved in activating many carcinogens and also upregulate genes controlled by the antioxidant response element (ARE); the ARE-responsive group includes γ-glutamylcysteine synthase light chain (the gene responsible for the rate-determining step in GSH synthesis) and quinone reductase (NQO1). Increased expression of ARE-regulated genes is predicted to increase the detoxification of proximate carcinogens. Isothiocyanates also stimulate apoptosis of p53-deficient cells via the formation of cytotoxic DNA adducts. Compounds that act as antioxidants may provide protection because many carcinogens work through the generation of ROS. Some compounds simultaneously prevent carcinogen activation and act as antioxidants. For example, flavonoids and other polyphenols found in a wide variety of plants are potent antioxidants that inhibit CYPs and induce expression of ARE-regulated genes. Chlorophyll and other compounds can protect against carcinogens by binding to or reacting with carcinogens or their metabolites and prevent them from reaching their molecular target.

Inflammation is a potential target for chemoprevention through interference with promotion. The COX-2 inhibitor celecoxib (described in Chapter 34) has been tested in phase 3 studies that demonstrated efficacy at reducing the risk of colorectal cancer. However, this benefit was offset by an increased risk of death due to cardiovascular events, forcing the early

termination of the trial (William et al., 2009). Studies examining long-term treatment with aspirin for cardiovascular benefits found that aspirin also reduces the incidence of colorectal adenomas. A phase 3 clinical trial is under way to examine this effect. Natural compounds, such as α-tocopherol, also can exert chemoprevention by reducing inflammation.

One successful approach to chemoprevention is modification of nuclear receptor signaling. Promising preliminary data suggested that retinoids might be beneficial for preventing lung and other cancers. Retinoids reduce the incidence of head and neck cancers, which represented one of the first successful uses of chemoprevention in humans (William et al., 2009; Evans and Kaye, 1999). Retinoids also are effective for the treatment of acute promyelocytic leukemia (see Section VII). However, in large clinical trials, retinoids actually increased the incidence of lung cancer, particularly among women, and had other unacceptable toxicities (Omenn et al., 1996).

The selective ER modulators tamoxifen and raloxifene reduced the incidence of breast cancer in high-risk women in large phase 3 clinical trials and are approved for chemoprevention in these patients (Vogel et al., 2006). The success of selective estrogen-receptor modulators for chemoprevention provides a proof-of-principle that the development of compounds based on mechanistic predictions can lead to effective drugs for the prevention of cancer.

**Aflatoxin B₁.** Promising agents are being developed as chemopreventants of hepatocarcinogenesis mediated by aflatoxin B₁. Aflatoxins are produced by *Aspergillus flavus*, a fungus that is a common contaminant of foods, especially corn, peanuts, cottonseed, and tree nuts.

*A. flavus* is abundant in regions with hot and wet climates, and as a result, hepatocellular carcinoma is a serious problem in subtropical and tropical regions of Latin America, Africa, and Southeast Asia. Human exposure to aflatoxin in the U.S. is very rare and not thought to have a significant impact on health (IARC, 2002).

**Absorption, Distribution, Biotransformation, and Excretion.** Aflatoxin B₁ is readily absorbed from the GI tract and initially distributed to the liver, where it undergoes extensive first-pass metabolism (Guengerich et al., 1996). Aflatoxin B₁ is metabolized by CYPs, including 1A2 and 3A4, to yield either an 8,9-epoxide or products hydroxylated at the 9 position (aflatoxin M₁) or 3 position (aflatoxin Q₁; Figure 67–3). The hydroxylation products are less susceptible to epoxidation and are therefore detoxification products. The 8,9-epoxide is highly reactive toward DNA and is the reactive intermediate responsible for aflatoxin carcinogenesis. The 8,9-epoxide is short lived and undergoes detoxification via non-enzymatic hydrolysis or conjugation with GSH. Aflatoxin M₁ enters the circulation and is excreted in urine and milk. Hydroxylated aflatoxin metabolites also can undergo several additional phase 1 and phase 2 metabolic pathways prior to excretion in urine or bile.

**Toxicity.** Aflatoxin B₁ primarily targets the liver, although it also is toxic to the GI tract and hematological system. High-dose exposures result in acute necrosis of the liver, leading to jaundice and, in many cases, death. Acute toxicity from aflatoxin is relatively rare in humans and requires consumption of milligram quantities of aflatoxin per day for multiple weeks. An outbreak in Kenya in 2004 led to 317 cases and 125 deaths (Groopman et al., 2008). Humans seem to be relatively resistant to acute aflatoxicosis; human outbreaks usually are preceded by the deaths of dogs and other domestic animals. Chronic exposure to aflatoxins results in cirrhosis of the liver and immunosuppression.

![Figure 67–3. Metabolism and actions of aflatoxin B₁.](image-url)

Following absorption, aflatoxin B₁ undergoes activation by CYPs to its 8,9-epoxide, which can be detoxified by glutathione S-transferases (GSTs) or by spontaneous hydration. Alternatively, it can react with cellular macromolecules such as DNA and protein, leading to toxicity and cancer. Oltipraz, green tea polyphenols (GTPs), and isothiocyanates (ITCs) decrease aflatoxin carcinogenesis by inhibiting the CYPs involved in activating aflatoxin and increasing the synthesis of the cofactor GSH for GSTs involved in detoxification.
Carcinogenicity. The primary concern with human exposure to aflatoxins is the development of liver cancer. Based on increased incidence of hepatocellular carcinoma in humans exposed to aflatoxin and supporting animal data, IARC has classified aflatoxin B₁ and several other natural aflatoxins as known human carcinogens (group 1) (IARC, 2002). Aflatoxin exposure and hepatitis B virus work synergistically to cause hepatocellular carcinoma. Many of the regions with elevated aflatoxin exposure also have a high level of endemic hepatitis B infection. Separately, aflatoxin or hepatitis B exposure increases the risk of hepatocellular carcinoma 3.4- or 7.3-fold, respectively; those exposed to both have a 59-fold increased risk of cancer compared to unexposed individuals (Groopman et al., 2005).

The mechanism of aflatoxin carcinogenesis has been extensively studied (IARC, 2002). The 8,9-epoxide of aflatoxin B₁ readily reacts with amines in biological macromolecules. Aflatoxin B₁ 8,9-epoxide forms adducts with deoxyguanosine and albumin that can be detected in the blood or urine of humans and laboratory animals exposed to aflatoxin, providing evidence for the activity of this pathway in vivo. Aflatoxin primarily forms DNA adducts at deoxyguanosine residues, reacting at either the N1 or N7 position. The N7-guanine adduct mispairs with adenine, leading to G → T transversions. Human aflatoxin exposure is associated with hepatocellular carcinomas bearing an AGG to AGT mutation in codon 249 of the p53 tumor suppressor gene, resulting in the replacement of an arginine with cysteine. This mutation is almost never observed in geographical regions with limited aflatoxin exposure (Hussain et al., 2007).

The interaction between aflatoxin and hepatitis B that is responsible for the increased incidence of hepatocellular carcinoma is not well understood (Sylla et al., 1999). Hepatitis B influences the metabolism of aflatoxin B₁ by upregulating CYPs, including 3A4, and decreasing glutathione S-transferase activity. In addition, hepatocellular proliferation to repair damage done by hepatitis B infection increases the likelihood that aflatoxin-induced DNA adducts will cause mutations. The hepatotoxic and tumor-promoting effects of hepatitis B also could provide a more favorable environment for the proliferation and invasion of initiated cells.

Chemoprevention of Aflatoxin-Induced Hepatocellular Carcinoma. The clear relationship between aflatoxin metabolism and its carcinogenicity makes it an appealing target for chemopreventive strategies that modify its metabolism (Groopman et al., 2008; Kensler et al., 2004). Inhibiting CYP activity or increasing glutathione conjugation will reduce the intracellular concentration of the 8,9-epoxide and thus prevent DNA adduct formation. One drug that has been tested as a modifier of aflatoxin metabolism is oltipraz. Oltipraz is an anti-schistosomal drug that potently inhibits CYPs and induces genes regulated by the ARE. In a phase 2 clinical trial, a 125-mg/day dose of oltipraz increased the excretion of aflatoxin N-acetylcycteine, indicating enhanced glutathione conjugation of the epoxide. At 500 mg/wk, oltipraz reduced the levels of aflatoxin M₁, consistent with inhibition of CYP activity.

Green tea polyphenols also have been used to modify aflatoxin metabolism in exposed human populations. Individuals receiving a daily dose of 500 or 1000 mg (equivalent to 1 or 2 L of green tea) demonstrated a small decline in the formation of aflatoxin–albumin adducts and a large increase in the excretion of aflatoxin N-acetylcycteine, consistent with a protective effect. A third approach to modifying aflatoxin metabolism has been to use a broccoli sprout tea containing high levels of the isothiocyanate R-sulforaphane. Because of interindividual variation in the absorption of R-sulforaphane, the protocol did not significantly alter aflatoxin biomarkers. However, there was a significant inverse correlation between excretion of sulforaphane metabolites in the urine and the levels of aflatoxin–N7-guanine adducts.

Yet another approach used for the chemoprevention of aflatoxin hepatocarcinogenesis is the use of “interceptor molecules.” Chlorophyllin, an over-the-counter mixture of water-soluble chlorophyll salts, binds tightly to aflatoxin in the GI tract, forming a complex that is not absorbed. In vitro, chlorophyllin inhibits CYP activity and acts as an antioxidant. Oral doses are poorly absorbed in vivo, so the agent remains largely in the GI tract. In a phase 2 trial, administration of 100 mg of chlorophyllin with each meal reduced aflatoxin–N7-guanine adduct levels in the urine by >50% (Egner et al., 2001).

Chemoprevention of hepatocellular carcinoma in people exposed to aflatoxin also can be achieved by limiting infections with hepatitis B. Because of the strong interaction between hepatitis B and aflatoxin in carcinogenesis, the hepatitis B vaccine will reduce the sensitivity of people to the induction of cancer by aflatoxin. Primary prevention of aflatoxin exposure through hand or fluorescent sorting of crops to remove those with fungal contamination can also reduce human exposure. A more cost-effective primary prevention approach is to improve food storage to limit the spread of A. flavus, which requires a warm and humid environment.

METALS

Metals are an important class of environmental toxicants; they are ubiquitous environmental contaminants that come from both natural and anthropogenic sources. Various toxic metals play important roles in many industrial processes and are occupational health hazards and common pollutants. The top three substances of concern due to their toxicity and likelihood of human exposure as listed under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as Superfund) are arsenic, lead, and mercury. The toxic effects of these three metals have played a central role in the development of the field of toxicology. However, the toxic effects of low-dose chronic exposure to metals have only recently been appreciated.
Many of the toxic metals in the environment also are carcinogens (Table 67–3). In addition to toxic environmental metals, several essential metals also are toxic under conditions of overdose. Copper and especially iron are associated with toxicities, primarily targeting the liver through generation of reactive oxygen species. Toxicities from copper and iron usually result from genetic diseases that interfere with the regulation of metal absorption or excretion (e.g., Wilson’s disease for copper, hemochromatosis for iron) or result from acute overdose, particularly with iron-containing medications or multivitamins. For a more comprehensive review of toxic metals, including essential metals, see Liu et al. (2008).

Not listed in Table 67–3 is the metal gold, which has its own uses and toxicities. Among heavy metals, perhaps only gold is addictive: gold has been used for centuries for relief of the itching palm, and many cannot get enough of its influence.

**Lead**

Exposure to lead has wide-ranging consequences for human health. Chronic exposure of populations to even very low levels of lead has major deleterious effects, which are only now beginning to be understood. It has been proposed that lead exposure contributed to the fall of the Roman Empire and that it plays a role in modern inner-city violence (Woolley, 1984; Needleman et al., 1996).

**Exposure.** In the U.S., paint containing lead for use in and around households was banned in 1978, while the use of tetraethyl lead in gasoline was phased out and eventually eliminated between 1976 and 1996. The economic benefit of the reduction in lead exposure due to these two measures is estimated at hundreds of billions of dollars per year (Grosse et al., 2002). Despite these bans, past use of lead carbonate and lead oxide in paint and tetraethyl lead in gasoline remain the primary sources of lead exposure. Lead is not degradable and remains throughout the environment in dust, soil, and the paint of older homes. Young children often are exposed to lead by nibbling sweet-tasting paint chips or eating dust and soil in and around older homes. Renovation or demolition of older buildings may cause substantial lead exposure. Tetraethyl lead was used as an anti-knock agent in gasoline, which resulted in high levels of lead in air pollution. Removal of lead from gasoline caused lead levels in air pollution to drop by >90% between 1982 and 2002. Lead was commonly used in plumbing and can leach into drinking water. Acidic foods and beverages dissolve lead when stored in containers with lead in their glaze or lead-soldered cans, which was a significant problem through the middle of the 20th century and remains a problem in developing countries. Lead exposure also has been traced to other sources such as lead toys, non-Western folk medicines, cosmetics, retained bullets, artists’ paint pigments, ashes and fumes from painted wood, jewelers’ wastes, home battery manufacture, and lead Table 67–3

type (ATSDR, 2007b; Levin et al., 2008). Blood lead levels in the general population have steadily decreased since the 1970s. Between 1976 and 2002, mean blood levels in children 1-5 years of age dropped from 15-1.9 μg/dL. The Centers for Disease Control and Prevention (CDC) recommends screening of children at 6 months of age and the use of aggressive lead abatement for children with blood lead levels >10 μg/dL.

Occupational exposure to lead also has decreased markedly because of protective regulations. Occupational exposure generally is through inhalation of lead containing dust and lead fumes. Workers in lead smelters and in storage battery factories are at the greatest risk for lead exposure because fumes are generated and dust containing lead oxide is deposited in their environment. Other workers at risk for lead exposure are those associated with steel welding or cutting, construction, rubber and plastic industries, printing, firing ranges, radiator repair shops, and any industry where lead is flame soldered (ATSDR, 2007b).

Chemistry and Mode of Action. Lead exists in its metallic form and as divalent or tetravalent cations. Divalent lead is the primary environmental form; inorganic tetravalent lead compounds are not naturally found. Organo-lead complexes primarily occur with tetravalent lead and include the gasoline additive tetraethyl lead.

Lead toxicity results from molecular mimicry of other divalent metals (Garza et al., 2006). Lead takes the place of zinc or calcium in a number of important proteins. Because of its size and electron affinity, lead alters protein structure and can inappropriately activate or inhibit protein function. Specific molecular targets for lead are discussed below.

Absorption, Distribution, and Excretion. Lead exposure occurs through ingestion or inhalation. GI absorption of lead varies considerably with age and diet. Children absorb a much higher percentage of ingested lead (~40% on average) than adults (<20%). Absorption of ingested lead is drastically increased by fasting. Dietary calcium or iron deficiencies increase lead absorption, suggesting that lead is absorbed through divalent metal transporters. The absorption of inhaled lead generally is much more efficient (~90%), particularly with smaller particles. Tetraethyl lead is readily absorbed through the skin, but this is not a route of exposure for inorganic lead.

About 99% of lead in the bloodstream binds to hemoglobin. Lead initially distributes in the soft tissues, particularly in the tubular epithelium of the kidney and the liver. Over time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the adult body burden of lead is found in bone. Growing bones will accumulate higher levels of lead and can form lead lines visible by radiography. Bone lead is very slowly reabsorbed into the bloodstream, except when calcium levels are depleted, such as during pregnancy. Small quantities of lead accumulate in the brain, mostly in gray matter and the basal ganglia. Lead readily crosses the placenta.

Lead is excreted by humans primarily in the urine, although there also is some biliary excretion. The concentration of lead in urine is directly proportional to its concentration in plasma, but because most lead is in erythrocytes, only a small quantity of total lead is removed by filtration. Lead is excreted in milk and sweat and deposited in hair and nails. The serum t1/2 of lead is 1-2 months, with a steady state achieved in ~6 months. Lead accumulates in bone, where its t1/2 is estimated at 20-30 years.

Health Effects. Although the effects of high-dose lead poisoning have been known for >2000 years, the insidious toxicities of chronic low-dose lead poisoning (blood lead <20 μg/dL) have only recently been discovered. Although lead is a nonspecific toxicant, the most sensitive systems are the nervous, hematological, cardiovascular, and renal systems (Figure 67–4). Uncovering the effects of low-level lead exposure on complex health outcomes, such as neurobehavioral function and blood pressure, has been the subject of extensive research.

Neurotoxic Effects. The biggest concerns with low-level lead exposure are cognitive delays and behavior changes in children (ATSDR, 2007b; Bellinger and Bellinger, 2006). The developing nervous system is very sensitive to the toxic effects of lead.

Lead interferes with the pruning of synapses, neuronal migration, and the interactions between neurons and glial cells. Together, these alterations in brain development result in decreased IQ, poor performance on exams, and behavioral problems such as distractibility.

**Figure 67–4. Heme biosynthesis and actions of lead.** Lead interferes with the biosynthesis of heme at several enzymatic steps. Steps that definitely are inhibited by lead are indicated by red blocks. Steps at which lead is thought to act but where evidence is inconclusive are indicated by pink blocks.
impulsivity, short attention span, and inability to follow even simple sequences of instructions. Recent studies have shown neurobehavioral deficits even with lead exposures below the CDC action level of 10 μg/dL. There is no evidence for a threshold; associations with neurobehavioral effects are evident at the lowest measurable blood lead levels (Lanphear et al., 2005). Because different areas of the brain mature at different times, the neurobehavioral changes vary between children, depending on the timing of the lead exposure. Children with very high lead levels (>70 μg/dL) are at risk for encephalopathy. Symptoms of lead-induced encephalopathy include lethargy, vomiting, irritability, anorexia, and vertigo, which can progress to ataxia, delirium, and eventually coma and death. Mortality rates for lead-induced encephalopathy are ~25%, and most survivors develop long-term sequelae such as seizures and severe cognitive deficits.

Adults also develop encephalopathy from lead exposure, although they are less sensitive than children. Encephalopathy in adults requires blood lead levels >100 μg/dL. The symptoms are similar to those observed with children. Workers chronically exposed to lead can develop neuromuscular deficits, termed lead palsy. Symptoms of lead palsy, including wrist drop and foot drop, were commonly associated with painters and other lead-exposed workers during previous eras but are very rare today. Lead induces degeneration of motor neurons, usually without affecting sensory neurons. Studies in older adults have shown associations between lead exposure and decreased performance on cognitive function tests, suggesting that lead accelerates neurodegeneration due to aging (ATSDR, 2007b).

The neurodevelopmental effects of lead primarily result from inhibition of calcium transporters and channels and altered activities of calcium responsive proteins, including PKC and calmodulin (Garza et al., 2006; Bellinger and Bellinger, 2006). These actions limit the normal activation of neurons caused by calcium release and cause inappropriate production and/or release of neurotransmitters. Lead affects almost all the neurotransmitter pathways, with the dopaminergic, cholinergic, and glutamatergic systems receiving the most attention. Neurotransmitter release and PKC signaling determine which synapses are maintained and which are lost during development. At high concentrations, lead causes disruption of membranes, including the blood-brain barrier, increasing their permeability to ions. This effect is likely responsible for encephalopathy.

**Cardiovascular and Renal Effects.** Low-level lead exposure increases blood pressure. Correlations between lead exposure and blood pressure extend to concentrations of lead <20 μg/dL. Although the change in blood pressure is small, ~1 mm Hg for each doubling of the blood lead concentration, a significant effect persists across a wide number of studies, and there is evidence of causality (Navas-Acien et al., 2007). Elevated blood pressure is a lasting effect of lead exposure. Adults who were exposed to lead during infancy and childhood have elevated blood pressure even in the absence of a recent exposure; thus, blood pressure correlates better to lead levels in bone than in blood (ATSDR, 2007b). Lead exposure also is associated with an increased risk of death due to cardiovascular and cerebrovascular disease (Schober et al., 2006).

The kidney is a very sensitive target of lead. Low-level lead exposure (blood levels <10 μg/dL) depresses glomerular filtration. Higher levels (>30 μg/dL) cause proteinuria and impaired transport, while very high levels (>50 μg/dL) cause permanent physical damage, including proximal tubular nephropathy and glomerulosclerosis. Impaired glomerular filtration and elevated blood pressure are closely interrelated and likely have causative effects on one another (ATSDR, 2007b).

The exact mechanisms for the cardiovascular and renal effects of lead are not known. The cardiovascular effects of lead are thought to involve the production of reactive oxygen species by lead, through an unknown mechanism. Reactive oxygen species react with nitric oxide, which may contribute to the elevated blood pressure by reducing NO-induced vasodilation and contribute to cardiovascular toxicity through the formation of highly reactive peroxynitrite (Vaziri and Khan, 2007). Lead also forms inclusion bodies with various proteins, including metallothionein, in the kidney. The formation of these bodies greatly increases intracellular lead concentrations in the kidney but appears to be protective. It is not known how lead reduces glomerular filtration rate, although there is evidence that lead targets kidney mitochondria and may interfere with the electron transport chain (ATSDR, 2007b).

**Hematological Effects.** Chronic lead intoxication is associated with hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to iron-deficient anemia. The anemia is thought to result from both decreased erythrocyte life span and inhibition of several enzymes involved in heme synthesis, which is observed at very low lead levels (Figure 67–5).

Inhibition of γ-aminolevulinate (γ-ALA) dehydratase and ferrochelatase is well documented. Ferrochelatase is responsible for incorporating the ferrous ion into protoporphyrin IX to form heme. When ferrochelatase is inhibited by lead, zinc is incorporated in place of iron, resulting in zinc-protoporphyrin, which is highly fluorescent and diagnostic of lead poisoning. γ-ALA dehydratase is the most sensitive of these enzymes to inhibition by lead; very low levels of lead increase urinary excretion of γ-ALA. Lead also causes both immunosuppression and increased inflammation, primarily through changes in helper T-cell and macrophage signaling (Dietert and Pieperbrink, 2006).

**Gastrointestinal Effects.** Lead affects the smooth muscle of the gut, producing intestinal symptoms that are an early...
sign of high-level exposure to the metal. The abdominal syndrome often begins with a persistent metallic taste, mild anorexia, muscle discomfort, malaise, headache, and usually constipation. Occasionally, diarrhea replaces constipation. As intoxication advances, symptoms worsen and include intestinal spasms that cause severe intestinal pain (lead cholic). Intravenous calcium gluconate can relieve this pain.

Carcinogenesis. IARC recently upgraded lead to “probably carcinogenic to humans” (group 2A; IARC, 2006). Epidemiological studies have shown associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to lead develop kidney tumors, and some rats develop gliomas. Lead is not mutagenic but increases clastogenic events. The mechanism of lead carcinogenesis is unknown but may result from inhibition of DNA binding zinc-finger proteins, including those involved in DNA repair and synthesis (Silbergeld, 2003). Lead is a good example of a non-genotoxic carcinogen.

Treatment. The most important response to lead poisoning is removal of the source of lead exposure. Supportive measures should be undertaken to relieve symptoms.

Chelation therapy is warranted for children and adults with high blood lead levels (>45 μg/dL and >70 μg/dL, respectively) and/or acute symptoms of lead poisoning (Ibrahim et al., 2006). Although chelation therapy is effective at lowering blood lead levels and relieving immediate symptoms, it does not reduce the chronic effects of lead beyond the benefit of lead abatement alone (Rogan et al., 2001). In rats, chelators enhance mobilization of lead from the soft tissues to the brain and may increase the adverse neurodevelopmental effects of lead (Andersen and Aaseth, 2002).

Mercury
Mercury is a unique metal in that it is a liquid at room temperature. Because of its capacity to amalgamate with other metals, mercury has been used industrially since ancient Greece, and mercury’s toxicity was noted by Hippocrates. Mercury also was used as a therapeutic drug for several centuries. Indeed, its use for the treatment of syphilis inspired Paracelsus’ observation that “the dose makes the poison,” one of the central concepts of toxicology, and also gave rise to the cautionary expression, “A night with Venus, a year with Mercury.” Toxicities from occupational exposure to mercury have been known for a long time. For instance, the phrase “mad as a hatter” originated from the exposure of hatters to metallic mercury vapor during production of felt for hats using mercury nitrate (Goldwater, 1972). While the phrase likely inspired the character of the Mad Hatter in Alice in Wonderland, his symptoms are not consistent with mercury exposure.
Exposure. Inorganic mercury cations and metallic mercury are found in the Earth’s crust, and mercury vapor is released naturally into the environment through volcanic activity and off-gassing from soils. Mercury also enters the atmosphere through human activities such as combustion of fossil fuels. Once in the air, metallic mercury is photo-oxidized to inorganic mercury, which can then be deposited in aquatic environments in rain. Microorganisms can then conjugate inorganic mercury to form methyl mercury. Methyl mercury concentrates in lipids and will bioaccumulate up the food chain so that concentrations in aquatic organisms at the top of the food chain, such as swordfish or sharks, are quite high (Figure 67–6; ATSDR, 1999).

The primary source of exposure to metallic mercury in the general population is vaporization of mercury in dental amalgam, which often contains >50% Hg⁰ mixed with silver and other metals. This release is enhanced by chewing. There also is limited exposure through broken thermometers and other mercury-containing devices. Human exposure to organic mercury primarily is through the consumption of fish. Other foods contain inorganic mercury at low levels (ATSDR, 1999).

Workers are exposed to metallic and inorganic mercury, most commonly though exposure to vapors. The highest risk for exposure is in the chloralkali industry (i.e., bleach) and in other chemical processes in which mercury is used as a catalyst. Mercury is a component of many devices, including alkaline batteries, fluorescent bulbs, thermometers, and scientific equipment, and exposure occurs during the production of these devices. Dentists also are exposed to mercury from amalgam. Mercury can be used to extract gold during mining, which results in substantial occupational exposure, because the last step involves vaporization of the mercury. This process is still commonly used in developing countries. Mercuric salts are used as pigments in paints (ATSDR, 1999).

Mercury salts were once found in a number of medications, including antiseptics, antidiuretics, skin-lightening creams, and laxatives. Most of these uses have been replaced by safer and more effective drugs. Thimerosal is an antimicrobial agent used as a preservative in vaccines. Its use is controversial because it releases ethyl mercury, which is chemically similar to methyl mercury. Due to the concerns of some parents that thimerosal might be a cause of autism, the American Academy of Pediatrics and the U.S. Public Health Service issued a call for its replacement in vaccines to improve the prevalence of vaccination (Ball et al., 2001). However, studies have not found an association between thimerosal use in vaccines and negative outcomes, and it is still used in influenza vaccines (Heron and Golding, 2004).

Chemistry and Mode of Action. There are three general forms of mercury of concern to human health. Metallic, or elemental, mercury (Hg⁰) is the liquid metal found in thermometers and dental amalgam; it is quite volatile, and exposure is often to the vapor form. Inorganic mercury can be either monovalent (mercurous, Hg¹⁺) or divalent (mercuric, Hg²⁺) or...
divalent (mercuric, Hg\(^{2+}\)) and forms a variety of salts. Organic mercury compounds consist of divalent mercury complexed with one or occasionally two alkyl groups. The organic mercury compound of most concern is methyl mercury (MeHg\(^{+}\)), which is formed environmentally from inorganic mercury by aquatic microorganisms.

Both Hg\(^{2+}\) and MeHg\(^{+}\) readily form covalent bonds with sulfur, which causes most of the biological effects of mercury. At very low concentrations, mercury reacts with sulfhydryl residues on proteins and disrupts their functions. Given the large numbers of proteins with important cysteines, determination of the specific mechanism for cellular dysfunction has been difficult, and there are probably multiple pathways affected. One of these pathways involves the generation of oxidative stress in cells. Also, microtubules are particularly sensitive to the toxic effects of mercury, which disrupts their formation and can catalyze their disassembly (Clarkson, 2002). There also may be an autoimmune component to mercury toxicity.

Absorption, Distribution, Biotransformation, and Excretion. Hg\(^{0}\) vapor is readily absorbed through the lungs (~70-80%), but GI absorption of metallic mercury is negligible. Once absorbed, Hg\(^{0}\) distributes throughout the body and crosses membranes such as the blood-brain barrier and the placenta via diffusion. Hg\(^{0}\) is oxidized by catalase in the erythrocytes and other cells to form Hg\(^{2+}\). Shortly after exposure, some Hg\(^{0}\) is eliminated in exhaled air. After a few hours, distribution and elimination of Hg\(^{0}\) resemble the properties of Hg\(^{2+}\). After exposure to Hg\(^{0}\) vapor, it is oxidized to Hg\(^{2+}\) and retained in the brain (ATSDR, 1999).

GI absorption of mercury salts varies depending on the individual and on the particular salt and averages ~10-15%. Hg\(^{1+}\) will form Hg\(^{0}\) or Hg\(^{2+}\) in the presence of sulfhydryl groups. Hg\(^{2+}\) primarily is excreted in the urine and feces; a small amount also can be reduced to Hg\(^{0}\) and exhaled. With acute exposure, the fecal pathway predominates, but following chronic exposure, urinary excretion becomes more important. All forms of mercury also are excreted in sweat and breast milk and deposited in hair and nails. The t\(_{1/2}\) for inorganic mercury is approximately 1-2 months (ATSDR, 1999).

Orally ingested MeHg\(^{+}\) is almost completely absorbed from the GI tract. MeHg\(^{+}\) readily crosses the blood-brain barrier and the placenta and distributes fairly evenly to the tissues, although concentrations are highest in the kidneys (ATSDR, 1999). MeHg\(^{+}\) can be demethylated to form inorganic Hg\(^{2+}\). The liver and kidney exhibit the highest rates of demethylation, but this also occurs in the brain. MeHg\(^{+}\) is excreted in the urine and feces, with the fecal pathway dominating. The t\(_{1/2}\) for MeHg\(^{+}\) is ~2 months. The pharmacokinetic properties of MeHg\(^{+}\) are thought to result from molecular mimicry. Complexes between MeHg\(^{+}\) and cysteine resemble methionine and can be recognized by transporters for that amino acid and taken across membranes (Ballatori, 2002).

Health Effects

Metallic Mercury. Inhalation of high levels of mercury vapor over a short duration is acutely toxic to the lung. Respiratory symptoms of mercury exposure start with cough and tightness in the chest and can progress to interstitial pneumonitis and severely compromised respiratory function. Other initial symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, and dyspnea. Acute exposure to high doses of mercury also is toxic to the CNS, with symptoms similar to those of chronic exposure (Figure 67–7).

![Figure 67–7. The concentration of mercury vapor in the air and related concentrations of mercury in urine are associated with a variety of toxic effects.](image-url)
Toxicity to the nervous system is the primary concern with chronic exposure to mercury vapor. Mercury vapor induces characteristic CNS symptoms that are consistent across patients exposed to mercury over short or long periods. These symptoms include tremors (particularly of the hands), emotional lability (irritability, shyness, loss of confidence, and nervousness), insomnia, memory loss, muscular atrophy, weakness, paresis, and cognitive deficits. These symptoms intensify and become irreversible, with increases in duration and concentration of exposure. Other common symptoms of chronic mercury exposure include tachycardia, labile pulse, severe salivation, and gingivitis. Prolonged exposure to mercury also causes kidney damage.

**Inorganic Salts of Mercury.** Ingestion of Hg\(^{2+}\) salts is intensely irritating to the GI tract, leading to vomiting, diarrhea, and abdominal pain. The kidney is the primary target of both valence states of inorganic mercury. Acute exposure to mercury salts (typically in suicide attempts) leads to tubular necrosis, resulting in decreased urine output and often acute renal failure. Chronic exposures also target the kidney, with glomerular injury predominating.

**Organic Mercury.** The CNS is the primary target of methyl mercury toxicity. Two incidents of high-dose exposure to methyl mercury provide much of our knowledge regarding methyl mercury poisoning. One was in fishing villages surrounding the heavily polluted Minamata Bay in Japan, and the other was in Iraq, where grains treated with methyl mercury were accidentally consumed. Symptoms of methyl mercury exposure include visual disturbances, ataxia, paresthesia, fatigue, hearing loss, slurring of speech, cognitive deficits, muscle tremor, movement disorders, and, following severe exposure, paralysis and death. The developing nervous system exhibits increased sensitivity to methyl mercury. Children exposed in utero can develop severe symptoms, including mental retardation and neuromuscular deficits, even in the absence of symptoms in the mother. In adults, methyl mercury causes focused lesions in specific areas of the brain, while the brains of children exposed in utero sustain widespread damage (Clarkson, 2002).

The effects of low-dose methyl mercury exposure from routine consumption of fish are difficult to assess due to the opposing beneficial effects of \(\omega-3\) fatty acids found in fish oils, and studies have produced discrepant results (Grandjean et al., 1999; Myers et al., 2003; Myers et al., 2007).

**Treatment.** With exposure to metallic mercury, termination of exposure is critical and respiratory support may be required. Emesis may be used within 30-60 minutes of exposure to inorganic mercury, provided the patient is awake and alert and there is no corrosive injury. Maintenance of electrolyte balance and fluids is important for patients exposed to inorganic mercury. Chelation therapy is beneficial in patients with acute inorganic or metallic mercury exposure. There are limited treatment options for methyl mercury. Chelation therapy does not provide clinical benefits, and several chelators potentiate the toxic effects of methyl mercury (Rush, 2008). Nonabsorbed thiol resins may be beneficial by preventing reabsorption of methyl mercury from the GI tract.

Because of the conflicting effects of mercury and \(\omega-3\) fatty acids, there is considerable controversy regarding the restriction of fish intake in women of reproductive age and children. The EPA recommends limiting fish intake to 12 oz (two meals) per week. Many experts feel this recommendation is too conservative, and the FDA is considering revising their recommendation to state that the benefits of fish consumption outweigh the risks. The recommendation that women consume fish that is lower in mercury content (i.e., canned light tuna, salmon, pollock, catfish) and avoid top predators, such as swordfish, shark, and tilefish, is not controversial.

**Arsenic**

Arsenic is a metalloid that is common in rocks and soil. Arsenic compounds have been used for >2400 years as both therapeutic agents and poisons. In the late 19th century, Robert Ehrlich coined the terms “magic bullet” and “chemotherapy” to describe his work using the organic arsenic compound arsphenamine for the treatment of syphilis. The use of arsenic in drugs has been mostly phased out, but arsenic trioxide (ATO) is still used as an effective chemotherapy agent for acute promyelocytic leukemia (see Chapter 63).

**Exposure.** The primary source of exposure to arsenic is through drinking water. Arsenic naturally leaches out of soil and rocks into well and spring water (Mead, 2005). Levels of arsenic in drinking water average 2 \(\mu\)g/L (ppb) in the U.S. but can be >50 \(\mu\)g/L (five times the EPA standard) in private well water, particularly in California, Nevada, and Arizona. Drinking water from other parts of the world where well water has been promoted to prevent waterborne illness, particularly Taiwan, China, Argentina, Chile, Bangladesh, and eastern India, sometimes is contaminated with much higher levels of arsenic (sometimes several hundred micrograms per liter), and widespread poisonings have resulted (Figure 67–8). Studies in Bangladesh found that ~40% of water samples from across the country were contaminated with >50 \(\mu\)g/L of arsenic, and some samples had far higher levels (Mead, 2005; Chowdhury et al., 1999; BGS and DPHE, 2001). Arsenic also can enter the environment through human activities such as the use of arsenic-containing pesticides, mining, and burning of coal. Food, particularly seafood, often is contaminated with arsenic. Arsenic in seafood exists primarily as organic compounds (i.e., arsenobetaine) that are much less toxic than inorganic arsenic. The average daily human intake of arsenic is 10 \(\mu\)g/day, almost exclusively from food and water.

Before 2003, >90% of arsenic used in the U.S. was as a preservative in pressure-treated wood, but the lumber industry has...
Figure 67–8. Arsenic in drinking water. (A) World map demonstrating regions where there is increased arsenic exposure in drinking water. (B) Map of Bangladesh demonstrating arsenic concentrations in drinking water in samples from wells across the country. (Adapted from BGS and DPHE, 2001. This report was produced by the British Geological Survey and the Department of Public Health Engineering (Bangladesh) undertaking a project funded by the UK Department for International Development.)
voluntarily replaced arsenic with other preservatives. Arsenic-treated wood is thought to be safe unless burned (Hall, 2002). The major source of occupational exposure to arsenic is in the production and use of organic arsenicals as herbicides and insecticides. Exposure to metallic arsenic, arsine, arsenic trioxide, and gallium arsenide also occurs in high-tech industries, such as the manufacture of computer chips and semiconductors.

**Chemistry and Mode of Action.** Arsenic exists in its elemental form and trivalent (arsenites/arsenious acid) and pentavalent (arsenates/arsenic acid) states. Arsine is a gaseous hydride of trivalent arsenic that exhibits toxicities that are distinct from other forms. Organic compounds containing either valence state of arsenic are formed in animals. The toxicity of a given arsenical is related to the rate of its clearance from the body and its ability to concentrate in tissues. In general, toxicity increases in the sequence: organic arsenicals $< \text{As}^{3+} < \text{arsine gas (AsH}_3\text{)}.$

Like mercury, trivalent arsenic compounds form covalent bonds with sulphydryl groups. The pyruvate dehydrogenase system is particularly sensitive to inhibition by trivalent arsenicals because the two sulphydryl groups of lipoic acid react with arsenic to form a six-membered ring. Inorganic arsenate (pentavalent) inhibits the electron transport chain. It is thought that arsenate competitively substitutes for phosphate during the formation of adenosine triphosphate, forming an unstable arsenate ester that is rapidly hydrolyzed.

**Absorption, Distribution, Biotransformation, and Excretion.** The absorption of arsenic compounds is directly related to their solubility. Poorly water-soluble forms such as arsenic sulfide, lead arsenate, and arsenic trioxide are not well absorbed. Water-soluble arsenic compounds are readily absorbed from both inhalation and ingestion. GI absorption of arsenic dissolved in drinking water is $>90\%$ (ATSDR, 2007a).

At low doses, arsenic is fairly evenly distributed throughout the tissues of the body. Nails and hair, due to their high sulphydryl content, exhibit high concentrations of arsenic. After an acute high dose of arsenic (i.e., fatal poisoning), arsenic is preferentially deposited in the liver and, to a lesser extent, kidney, with elevated levels also observed in the muscle, heart, spleen, pancreas, lungs, and cerebellum. Arsenic readily crosses the placenta and blood-brain barrier.

Arsenic undergoes biotransformation in humans and animals (Figure 67–9). Trivalent compounds can be oxidized back to pentavalent compounds, but there is no evidence for demethylation of methylated arsenicals. Biotransformation of arsenic varies greatly across species, with humans excreting much higher levels of monomethylarsenic (MMA) compounds than most other animals (ATSDR, 2007a).

Because the pentavalent methylated arsenic compounds have greatly reduced toxicity, the methylation pathway was long thought to be a detoxification pathway. However, the trivalent methylated arsenicals actually are more toxic than inorganic arsenite, due to an increased affinity for sulphydryl groups, and formation of MMA$^{\text{III}}$ now is considered a bioactivation pathway (Aposhian and Aposhian, 2006).

Elimination of arsenicals by humans primarily is in the urine, although some is also excreted in feces, sweat, hair, nails, skin, and exhaled air. Compared to most other toxic metals, arsenic is excreted quickly, with a $t_{\frac{1}{2}}$ of 1-3 days. In humans, ingested inorganic arsenic in urine is a mixture of 10-30% inorganic arsenicals, 10-20% monomethylated forms, and 60-80% dimethylated forms.

**Health Effects.** With the exception of arsine gas (which is discussed later in “Arsine Gas”), the various forms of inorganic arsenic exhibit similar toxic effects. Inorganic arsenic exhibits a broad range of toxicities and has been associated with effects on every organ system tested, although some systems are much more sensitive than others (ATSDR, 2007a). Humans also are exposed to large organic arsenic compounds in fish, which are relatively nontoxic. Humans are the most sensitive species to the toxic effects of inorganic arsenic. Acute exposure to large doses of arsenic (>70-180 mg) often is fatal. Death immediately following arsenic poisoning typically is the result of its effects on the heart and GI tract. Death sometimes occurs later as a result of arsenic’s combined effect on multiple organs.

**Cardiovascular System.** Acute and chronic arsenic exposure cause myocardial depolarization, cardiac arrhythmias, and ischemic heart disease; these are known side effects of arsenic trioxide for the treatment of leukemia. Chronic exposure to arsenic causes peripheral vascular disease, the most dramatic example of which is “blackfoot disease,” a condition characterized by cyanosis of the extremities, particularly the feet, progressing to gangrene. Blackfoot disease is endemic in regions of Taiwan, with arsenic levels of between 170 and 800 μg/L. Arsenic dilates capillaries and increases their permeability. This causes edema after acute exposures and is likely responsible for peripheral vascular disease following chronic exposure.

---

**Figure 67–9. Metabolism of arsenic.** GSH, reduced glutathione; GSSG, oxidized glutathione; SAM, S-adenosyl-L-methionine; SAH, S-adenosyl-L-homocysteine. AS3MT, arsenite methyltransferase; MMA$^V$, monomethylarsonic acid; MMA$^{\text{III}}$, monomethylarsonous acid; DMA$^V$, dimethyl arsinic acid.
Skin. The skin is very sensitive to chronic arsenic exposure. Dermal symptoms often are diagnostic of arsenic exposure. Arsenic induces hyperkeratinization of the skin (including formation of multiple corns or warts), particularly of the palms of the hands and the soles of the feet. It also causes areas of hyperpigmentation interspersed with spots of hypopigmentation. These symptoms can be observed in individuals exposed to drinking water with arsenic concentrations of at least 100 μg/L and are typical in those chronically exposed to much higher levels. Hyperpigmentation can be observed after 6 months of exposure, while hyperkeratinization takes years. Children are more likely to develop these effects than adults. The mechanism of arsenic-induced changes to the skin is unknown, partly because these effects are not seen in other animals (Mead, 2005; ATSDR, 2007a).

GI Tract. Acute or subacute exposure to high-dose arsenic by ingestion is associated with GI symptoms ranging from mild cramping, diarrhea, and vomiting to GI hemorrhaging and death. GI symptoms are caused by increased capillary permeability, leading to fluid loss. At higher doses, fluid forms vesicles that can burst, leading to inflammation and necrosis of the submucosa and then rupture of the intestinal wall. GI symptoms are not observed with chronic exposure to lower levels of arsenic.

Nervous System. Acute high-dose arsenic exposure causes encephalopathy in rare cases, with symptoms that can include headache, lethargy, mental confusion, hallucination, seizures, and coma. However, the most common neurological effect of acute or subacute arsenic exposure is peripheral neuropathy involving both sensory and motor neurons. This effect is characterized by the loss of sensation in the hands and feet (a stocking and glove distribution). This often is followed by muscle weakness. Neuropathy occurs several days after exposure to arsenic and can be reversible following cessation of exposure, although recovery usually is not complete. Arsenic exposure may cause intellectual deficits in children. Wasserman et al. (2007) observed a negative association between arsenic levels in drinking water and performance on intelligence tests.

Other Non-Cancer Toxicities. Acute and chronic arsenic exposures induce anemia and leukopenia. Arsenic likely causes both direct cytotoxic effects on blood cells and suppression of erythropoiesis through bone marrow toxicity. Arsenic also may inhibit heme synthesis. In the liver, arsenic causes fatty infiltrations, central necrosis, and cirrhosis of varying severity. The action of arsenic on renal capillaries, tubules, and glomeruli can cause severe kidney damage. Inhaled arsenic is irritating to the lungs, and ingested arsenic may induce bronchitis progressing to bronchopneumonia in some individuals. Chronic exposure to arsenic is associated with an increased risk of diabetes.

Carcinogenesis. Arsenic compounds were among the first recognized human carcinogens. At the end of the 19th century, Hutchinson observed that patients receiving arsenic-containing drugs had an increased occurrence of skin tumors. Epidemiological studies performed in regions with very high arsenic levels in drinking water consistently observe substantially increased rates of skin cancer (squamous cell and basal cell carcinomas), bladder cancer, and lung cancer. There also are associations between arsenic exposure and other cancers, including liver, kidney, and prostate tumors. Inhalation exposure to arsenic in occupational settings causes lung cancer. IARC classifies arsenic as “carcinogenic to humans (group 1).”

The developing fetus and young children may be at increased risk of arsenic carcinogenesis, because humans exposed to arsenic in utero and in early childhood have a greatly elevated risk of lung cancer (Smith et al., 2006). Studies in rodents also have observed increased cancer risks from in utero exposure and suggest that the second trimester of pregnancy represents a critical susceptibility window (Waalkes et al., 2007).

The mechanism of arsenic carcinogenesis is poorly understood. Arsenic is an unusual carcinogen in that evidence for human carcinogenesis is much stronger than for carcinogenesis in laboratory animals. Arsenic does not directly damage DNA; rather, arsenic is thought to work through changes in gene expression, DNA methylation, inhibition of DNA repair, generation of oxidative stress, and/or altered gene expression pathways (Salnikow and Zhitkovich, 2008; Hartwig et al., 2002). Arsenic compounds can act as tumor promoters or co-carcinogens in rodents, particularly when combined with ultraviolet light (Burns et al., 2004). In humans, exposure to arsenic potentiates lung tumorigenesis from tobacco smoke. Smokers in regions with high concentrations of arsenic in the drinking water have a 5-fold increased risk of cancer over smokers living in low arsenic regions (Ferreccio et al., 2000). Arsenic co-carcinogenesis may involve inhibition of proteins involved in nucleotide excision repair (Salnikow and Zhitkovich, 2008; Hartwig et al., 2002). Arsenic also has endocrine-disrupting activities on several nuclear steroid hormone receptors, enhancing hormone-dependent transactivation at very low concentrations and inhibiting it at slightly higher levels (Bodwell et al., 2006).

Arsine Gas. Arsine gas, formed by electrolytic or metallic reduction of arsenic, is a rare cause of industrial poisonings. Arsine induces rapid and often fatal hemolysis, which probably results from arsine combining with hemoglobin and reacting with oxygen. A few hours after exposure, patients can develop headache, anorexia, vomiting, paresthesia, abdominal pain, chill, hemoglobinuria, bilirubinemia, and anuria. Jaundice appears after 24 hours. Arsine induces renal toxicities that can progress to kidney failure. Approximately 25% of cases of arsine exposure result in death.

Treatment. Following acute exposure to arsenic, stabilize the patient and prevent further absorption of the poison. Close monitoring of fluid levels is important because arsenic can cause fatal hypervolemic shock. Chelation therapy is effective following short-term exposure to arsenic.
but has very little or no benefit in chronically exposed individuals. Exchange transfusion to restore blood cells and remove arsenic often is warranted following arsine gas exposure (Ibrahim et al., 2006).

**Cadmium**

Cadmium was discovered in 1817 and first used industrially in the mid-20th century. Cadmium is resistant to corrosion and exhibits useful electrochemical properties, which has led to its use in electroplating, galvanization, plastics, paint pigments, and nickel-cadmium batteries.

**Exposure.** In the general population, the primary source of exposure to cadmium is through food, with an estimated average daily intake of 50 μg/day. Cadmium also is found in tobacco; a cigarette contains 1-2 μg of cadmium (Jarup and Akesson, 2009). Workers in smelters and other metal-processing industries can be exposed to high levels of cadmium, particularly by inhalation.

**Chemistry and Mode of Action.** Cadmium exists as a divalent cation and does not undergo oxidation-reduction reactions. There are no covalent organometallic complexes of cadmium of toxicological significance. The mechanism of cadmium toxicity is not fully understood. Like lead and other divalent metals, cadmium can replace zinc in zinc-finger domains of proteins and disrupt them. Through an unknown mechanism, cadmium induces formation of reactive oxygen species, resulting in lipid peroxidation and glutathione depletion. Cadmium also upregulates inflammatory cytokines and may disrupt the beneficial effects of nitric oxide.

**Absorption, Distribution, and Excretion.** Cadmium is not well absorbed from the GI tract (1.5-5%) but is better absorbed via inhalation (~10%). Cadmium primarily distributes first to the liver and later absorbed from the GI tract (1.5-5%) but is better absorbed via inhalation. Inhaled cadmium causes respiratory tract irritation with severe, early pneumonitis accompanied by chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema. Ingested cadmium induces nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody.

Symptoms of chronic cadmium toxicity vary by exposure route. The lung is an important target of inhaled cadmium, while the kidney is a major target of cadmium from both inhalation and ingestion.

Cadmium bound to metallothionein is transported to the kidney, where it can be released. The initial toxic effect of cadmium on the kidney is increased excretion of small-molecular-weight proteins, especially β2-microglobulin and retinol-binding protein. Cadmium also causes glomerular injury, with a resulting decrease in filtration. Chronic occupational exposure to cadmium is associated with an increased risk of renal failure and death. There is no evidence for a threshold level for cadmium’s effects on the kidney; cadmium levels consistent with normal dietary exposure can cause renal toxicity, including a reduction in glomerular filtration rate and creatinine clearance (Jarup and Akesson, 2009).

Workers with long-term inhalation exposure to cadmium exhibit decreased lung function. Symptoms initially include bronchitis and fibrosis of the lung, leading to emphysema. The exact cause of cadmium-induced lung toxicity is not known but may result from inhibition of the synthesis of α1-antitrypsin. Chronic obstructive pulmonary disease causes increased mortality in cadmium-exposed workers.

When accompanied by vitamin D deficiency, cadmium exposure increases the risks for fractures and osteoporosis. This may be an effect of cadmium interfering with calcium and phosphate regulation due to its renal toxicity.

**Carcinogenicity.** Chronic occupational exposure to inhaled cadmium increases the risk of developing lung cancer (IARC, 1993; NTP, 2004). The mechanism of cadmium carcinogenesis is not fully understood. Cadmium causes chromosomal aberrations in exposed workers and treated animals and human cells. It also increases mutations and impairs DNA repair in human cells (NTP, 2004). Cadmium substitutes for zinc in DNA repair proteins and polymers and may inhibit nucleotide excision repair, base excision repair, and the DNA polymerase responsible for repairing single-strand breaks (Hartwig et al., 2002). There is evidence that cadmium also alters cell signaling pathways and disrupts cellular controls of proliferation (Waisberg et al., 2003). Thus, cadmium acts as a non-genotoxic carcinogen.

**Treatment.** Treatment of cadmium poisoning is symptomatic. Patients suffering from inhaled cadmium may require respiratory support. Patients suffering from kidney failure due to cadmium poisoning may require a transplant. There is no evidence for clinical benefit from chelation therapy following cadmium poisoning, and chelation therapy may result in adverse effects (ATSDR, 2008a).

**Chromium**

Chromium is an industrially important metal used in a number of alloys, particularly stainless steel, which contains at least 11% chromium. Chromium can be oxidized to multiple valence states, with trivalent (CrIII) and hexavalent chromium (CrVI) being the two forms of biological importance. Chromium exists almost exclusively as the trivalent form in nature, and CrIII is an essential metal involved in the regulation of glucose metabolism. CrVI is thought to be responsible for the toxic effects of chromium exposure (ATSDR, 2008b).

**Exposure.** Exposure to chromium in the general population primarily is through the ingestion of food, although there also is exposure from drinking water and air. Workers are exposed to chromium during chromeate production, stainless steel production and welding, chromium plating, ferrochrome alloy and chrome pigment production, and in tanning industries (Ashley et al., 2003). Exposure usually is a mixture of CrIII and CrVI, except in chromium plating, which usually uses CrVI and tanning, where CrIII is used.

**Chemistry and Mode of Action.** Chromium occurs in its metallic state or in any valence state between divalent and hexavalent. CrIII is the most stable and common form. CrVI is corrosive and is readily reduced to lower valence states. The primary reason for the different toxicological properties of CrIII and CrVI is thought to be differences in their absorption and distribution. Hexavalent chromate resembles...
sulfate and phosphate and can be taken across membranes by anion transporters. Once inside the cell, CrVI undergoes a series of reduction steps, ultimately forming CrIII, which is thought to cause most of the toxic effects. Trivalent chromium readily forms covalent interactions with DNA. Hexavalent chromium also induces oxidative stress and hypersensitivity reactions.

Absorption, Distribution, Biotransformation, and Excretion. Absorption of inhaled chromium depends on its solubility, valence state, and particle size. Smaller particles are better deposited in the lungs. Absorption into the bloodstream of hexavalent and soluble forms is higher than the trivalent or insoluble forms, with the remainder often retained in the lungs. Approximately 50-85% of inhaled CrVI particles (<5 μm) are absorbed. Absorption of ingested chromium is <10%. Soluble CrVI compounds are better absorbed from the GI tract than other forms. CrVI crosses membranes by facilitated transport, while CrIII crosses by diffusion. CrVI is distributed to all of the tissues and crosses the placenta. The highest levels are attained in the liver, kidney, and bone; CrVI also is retained in erythrocytes, bound tightly to hemoglobin and other ligands. Excretion primarily is through urine, with small amounts also excreted in bile and breast milk and deposited in hair and nails. The t1/2 of ingested CrVI is ~40 hours, while the t1/2 of CrIII is ~10 hours, reflecting the enhanced tissue retention of CrVI (ATSDR, 2008b).

Toxicity. Acute exposure to very high doses of chromium causes death via damage to multiple organs, particularly the kidney, where it causes tubular and glomerular damage. Chronic low-dose chromium exposure primarily causes toxicity at the site of contact. Workers exposed to inhaled chromium develop symptoms of lung and upper respiratory tract irritation, including epistaxis, chronic rhinorrhea, nasal itching and soreness, nasal mucosal atrophy, perforations and ulceration of the nasal septum, bronchitis, pneumoconiosis, decreased pulmonary function, and pneumonia. Chronic exposure to chromium via ingestion, including after mucociliary clearance of inhaled particles, causes symptoms of GI irritation such as oral ulcer, diarrhea, abdominal pain, indigestion, and vomiting. CrVI is a dermal irritant and can cause ulceration or burns. Following low-dose exposure by any route, some individuals become sensitized to chromium and develop allergic dermatitis following dermal exposure to chromium, including products containing metallic chromium. Chromium-sensitized workers often also develop asthma following inhalation exposure (ATSDR, 2008b).

Carcinogenicity. CrVI compounds are known human carcinogens (group 1; IARC, 1990). There is insufficient evidence for carcinogenesis from metallic and trivalent chromium (group 3). Workers exposed to CrVI via inhalation have elevated incidence of and mortality from lung and nasal cancer. Environmental exposure to CrVI in drinking water increases the risk of developing stomach cancer. Based on animal studies, the most potent carcinogenic compounds are slightly soluble CrVI compounds.

There are multiple potential mechanisms for chromium carcinogenicity (Salnikow and Zhitkovich, 2008). After uptake into cells, reduction of CrVI to CrIII occurs with concomitant oxidation of cellular molecules. Ascorbate is the primary reductant, but other molecules, including glutathione, lipids, proteins, and DNA, also can be oxidized. CrIII forms a large number of covalent DNA adducts, primarily at the phosphate backbone. The most common DNA adducts are either binary (DNA-CrIII) adducts or cross-links to small molecules such as ascorbate and glutathione. The DNA adducts are not very mutagenic and are repaired by nucleotide excision repair. It is thought that the high level of nucleotide excision repair activity following chromium exposure contributes to carcinogenesis, either by preventing repair of mutagenic lesions formed by other carcinogens or through the formation of single-strand breaks due to incomplete repair. Chromium also forms toxic cross-links between DNA and protein. Chronic inflammation due to chromium-induced irritation also may promote tumor formation.

Treatment. There are no standard protocols for treatment of acute chromium poisoning. One approach that has shown promise in rodents is the use of reductants such as ascorbate, glutathione, or N-acetylcysteine to reduce CrVI to CrIII after exposure but before absorption to limit bioavailability (ATSDR, 2008b). These compounds and EDTA also increase urinary excretion of chromium after high-dose exposure, particularly if given soon enough to prevent uptake into cells. Exchange transfusion to remove chromium from plasma and erythrocytes may be beneficial.

**TREATMENT OF METAL EXPOSURE**

The most important response to environmental or occupational exposures to metals is to eliminate the source of the exposure. For instance, with children exposed to lead, the CDC recommends aggressive lead-abatement practices to ensure that the home is free of lead-based paints and other sources of lead exposure. In occupational settings, often removing exposed workers from the toxic work environment will reverse many of the symptoms of metal poisoning. It also is important to stabilize the patient and provide symptomatic treatment.

Treatment for acute metal intoxications often involves the use of chelators. A chelator is a compound that forms stable complexes with metals, typically as five- or six-membered rings. Formation of complexes between chelators and metals should prevent or reverse metal binding to biological ligands. The ideal chelator would have the following properties: high solubility in water, resistance to biotransformation, ability to reach sites of metal storage, ability to form stable and non-toxic complexes with toxic metals, and ready excretion of the metal-chelator complex. A low affinity for the essential metals calcium and zinc also is desirable, because toxic metals often act through competition with these metals for protein binding.

In cases of acute exposure to high doses of most metals, chelation therapy reduces toxicity. However, following chronic exposure, chelation therapy does not show clinical benefits beyond those of cessation of
exposure alone and, in some cases, does more harm than good. Chelation therapy may increase the neurotoxic effects of heavy metals and is only recommended for acute poisonings. The structures of the most commonly used chelators are shown in Figure 67–10.

**Ethylenediaminotetraacetic Acid (EDTA)**

EDTA and its various salts are effective chelators of divalent and trivalent metals. Calcium disodium EDTA (CaNa$_2$EDTA) is the preferred EDTA salt for metal poisoning, provided that the metal has a higher affinity for EDTA than calcium. CaNa$_2$EDTA is effective for the treatment of acute lead poisoning, particularly in combination with dimercaprol, but is not an effective chelator of mercury or arsenic *in vivo*.

**Chemistry and Mechanism of Action.** The pharmacological effects of CaNa$_2$EDTA result from chelation of divalent and trivalent metals in the body. Accessible metal ions (both exogenous and endogenous) with a higher affinity for CaNa$_2$EDTA than Ca$^{2+}$ will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells. CaNa$_2$EDTA mobilizes several endogenous metallic cations, including those of zinc, manganese, and iron. Additional supplementation with zinc following chelation therapy may be beneficial. The most common therapeutic use of CaNa$_2$EDTA is for acute lead intoxication. CaNa$_2$EDTA does not provide clinical benefits for the treatment of chronic lead poisoning. There is evidence in rats that CaNa$_2$EDTA mobilizes lead from various tissues to the brain and liver, which may account for this observation (Sánchez-Fructuoso et al., 2002; Andersen and Aaseth, 2002).

CaNa$_2$EDTA is available as edetate calcium disodium (calcium disodium versenate). Intramuscular administration of CaNa$_2$EDTA results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, CaNa$_2$EDTA is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis. To minimize nephrotoxicity, adequate urine production should be established prior to and during treatment with CaNa$_2$EDTA. However, in patients with lead encephalopathy and increased intracranial pressure, excess fluids must be avoided. In such cases, intramuscular administration of CaNa$_2$EDTA is recommended.

EDTA and its glycol congener, EGTA, are used in biological research to chelate and control the concentration of Ca$^{2+}$ in biological buffer solutions. The 2008 Nobel laureate, Roger Tsien, and his colleagues used the EDTA/EGTA structure as a starting point in the development of fluorescent sensors of cellular [Ca$^{2+}$] (Tsien et al., 1984).

**Absorption, Distribution, and Excretion.** Less than 5% of CaNa$_2$EDTA is absorbed from the GI tract. After intravenous administration, CaNa$_2$EDTA has a $t_{1/2}$ of 20-60 minutes. In blood, CaNa$_2$EDTA is found only in the plasma. CaNa$_2$EDTA is excreted in the urine by glomerular filtration, so adequate renal function is necessary for successful therapy. Altering either the pH or the rate of urine flow has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids; very little gains access to the spinal fluid (5% of the plasma concentration).

**Toxicity.** Rapid intravenous administration of Na$_2$EDTA causes hypocalcemic tetany. However, a slow infusion (<15 mg/minute) administered to a normal individual elicits no symptoms of hypocalcemia because of the availability of extracirculatory stores of Ca$^{2+}$. In contrast, CaNa$_2$EDTA can be administered intravenously with no untoward effects because the change in the concentration of Ca$^{2+}$ in the plasma and total body is negligible.

The principal toxic effect of CaNa$_2$EDTA is on the kidney. Repeated large doses of the drug cause hydropic vacuolization of the proximal tubule, loss of the brush border, and eventually, degeneration of proximal tubular cells. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly with cessation of treatment. The most likely mechanism of toxicity is chelation of essential metals, particularly zinc, in proximal tubular cells.

Other side effects associated with CaNa$_2$EDTA include malaise, fatigue, and excessive thirst, followed by the sudden
appearance of chills and fever and subsequent myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. CaNa₂EDTA is teratogenic in laboratory animals, probably as a result of zinc depletion; it should be used in pregnant women only under conditions in which the benefits clearly outweigh the risks (Kalia and Flora, 2005). Other possible undesirable effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B₆ deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

**Dimercaprol**

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas; hence its alternative name, British anti-lewisite (BAL). Arsenicals form a stable and relatively nontoxic chelate ring with dimercaprol. Pharmacological investigations revealed that dimercaprol protects against other heavy metals as well.

**Chemistry and Mechanism of Action.** The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. Dissociation of dimercaprol–metal complexes and oxidation of dimercaprol occurs in vivo. Furthermore, the sulfur–metal bond may be labile in the acidic tubular urine, which may increase the delivery of metal to renal tissue and increase toxicity. The dosage regimen should maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL–metal) complex. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated dosage until the metal is excreted.

Dimercaprol is most beneficial when given very soon after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol limits toxicity from arsenic, gold, and mercury, which form mercaptides with essential cellular sulfhydryl groups. It also is used in combination with CaNa₂EDTA to treat lead poisoning.

Dimercaprol is contraindicated for use following chronic exposures to heavy metals because it does not prevent neurotoxic effects. There is evidence in laboratory animals that dimercaprol mobilizes lead and mercury from various tissues to the brain (Andersen and Aaseth, 2002). This effect may be due to the lipophilic nature of dimercaprol and is not observed with its more hydrophilic analogs described later (see “Succimer” and “Sodium 2,3-Dimercaptopyrrole Sulfonate [DMPSJ”).

**Absorption, Distribution, and Excretion.** Dimercaprol cannot be administered orally; it is given by deep intramuscular injection as a 100 mg/mL solution in peanut oil and should not be used in patients who are allergic to peanuts or peanut products. Peak concentrations in blood are attained in 30-60 minutes. The $t_{1/2}$ is short, and metabolic degradation and excretion essentially are complete within 4 hours. Dimercaprol and its chelates are excreted in both urine and bile.

**Toxicity.** The administration of dimercaprol produces a number of side effects, which occur in ~50% of subjects receiving 5 mg/kg intramuscularly. One of the most consistent responses to dimercaprol is a rise in systolic and diastolic arterial pressures, accompanied by tachycardia. The rise in pressure may be as great as 50 mm Hg in response to the second of two doses (5 mg/kg) given 2 hours apart. The pressure rises immediately but returns to normal within 2 hours.

Dimercaprol also can cause anxiety and unrest, nausea and vomiting, headache, a burning sensation in the mouth and throat, a feeling of constriction or pain in the throat and chest, conjunctivitis, blepharospasm, lacrimation, rhinorrhea, salivation, tingling of the hands, a burning sensation in the penis, sweating, abdominal pain, and the occasional appearance of painful sterile abscesses at the injection site. The dimercaprol–metal complex breaks down easily in an acidic medium; production of an alkaline urine protects the kidney during therapy. Children react similarly to adults, although ~30% also may experience a fever that disappears on drug withdrawal. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this condition is a result of arsenic poisoning.

**Succimer**

Succimer (2,3-dimercaptosuccinic acid [DMSA], CHEMET) is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify the spectrum of absorption, distribution, and chelation of the drug. It has an improved toxicity profile over dimercaprol.

**Absorption, Distribution, and Excretion.** After its absorption in humans, succimer is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 2006). Succimer lowers blood lead levels and attenuates lead toxicity. The succimer–lead chelate is eliminated in both urine and bile. The fraction eliminated in bile can undergo enterohepatic circulation.

**Succimer has several desirable features over other chelators.** It is orally bioavailable, and because of its hydrophilic nature, it does not mobilize metals to the brain or enter cells. It also does not significantly chelate essential metals such as zinc, copper, or iron. As a result of these properties, succimer exhibits a much better toxicity profile relative to other chelators. Animal studies suggest that succimer also is effective as a chelator of arsenic, cadmium, mercury, and other toxic metals (Andersen and Aaseth, 2002; Kalia and Flora, 2005).

**Toxicity.** Succimer is much less toxic than dimercaprol. Transient elevations in hepatic transaminases have been observed with succimer treatment. The most commonly reported adverse effects are nausea, vomiting, diarrhea, and loss of appetite. In a few patients, rashes necessitate discontinuation of therapy.

Succimer has been approved in the U.S. for treatment of children with blood lead levels >45 μg/dL. Because of its oral availability, improved toxicity profile, and selective chelation of heavy metals, succimer also is used off label for the treatment of adults with lead poisoning and for the treatment of arsenic and mercury intoxication, although no large clinical trials have been undertaken for these indications.

**Sodium 2,3-Dimercaptopyrrole Sulfonate (DMPS)**

DMPS is another dimercapto compound used for the chelation of heavy metals. DMPS is not approved by
the FDA but is approved for use in Germany. DMPS is available from compounding pharmacies and is used by some doctors in the U.S.

Chemistry and Mode of Action. DMPS is a clinically effective chelator of lead, arsenic, and especially mercury. It is orally available and is rapidly excreted, primarily through the kidneys. It is negatively charged and exhibits distribution properties similar to those of succimer. DMPS is less toxic than dimercaprol but mobilizes zinc and copper and thus is more toxic than succimer. In a small clinical trial, DMPS exhibited some clinical benefit for the treatment of chronic arsenic poisoning. Similar benefits were not observed with either dimercaprol or succimer, suggesting that DMPS might be effective for treatment of chronic heavy metal poisonings (Kalila and Flora, 2005). However, more thorough clinical studies are needed.

Penicillamine; Trientine

Penicillamine was first isolated in 1953 from the urine of patients with liver disease who were receiving penicillin. Discovery of its chelating properties led to its use in patients with Wilson’s disease (excess body burden of copper due to diminished excretion) and heavy-metal intoxications. Penicillamine is more toxic and is less potent and selective for chelation of heavy metals relative to other available chelation drugs. It is therefore not a first-line treatment for acute intoxication with lead, mercury, or arsenic. However, because it is inexpensive and orally bioavailable, it is often given at fairly low doses following treatment with CaNa\textsubscript{2}EDTA and/or dimercaprol to ensure that the concentration of metal in the blood stays low following the patient’s release from the hospital.

Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine.

Absorption, Distribution, Biotransformation, and Excretion.

Penicillamine (CUPRIMINE, DEPEN) is available for oral administration. For chelation therapy, the usual adult dose is 1-1.5 g/day in four divided doses. The drug should be given on an empty stomach to avoid interference by metals in food. In addition to its use as a chelating agent for the treatment of copper, mercury, and lead poisoning, penicillamine is used in Wilson’s disease (hepatolenticular degeneration owing to an excess of copper), cystinuria, and rheumatoid arthritis (rarely). For the treatment of Wilson’s disease, 1-2 g/day usually is administered in four doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate.

Penicillamine is well absorbed (40-70%) from the GI tract. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained between 1 and 3 hours after administration. Penicillamine is relatively stable in vivo compared to its unmethylated parent compound cysteine. Hepatic biotransformation primarily is responsible for degradation of penicillamine, and very little drug is excreted unchanged. Metabolites are found in both urine and feces. N-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury, presumably because it is more resistant to metabolism.

Toxicity. With long-term use, penicillamine induces several cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, dermatomyositis, adverse effects on collagen, and other less serious reactions, such as dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur as many as one-third of patients taking penicillamine. The hematological system also may be affected severely; reactions include leukopenia, aplastic anemia, and agranulocytosis. These may occur at any time during therapy and may be fatal, so patients should be monitored carefully.

Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to nephrotic syndrome with membranous glomerulopathy. More rarely, fatalities have been reported from Goodpasture’s syndrome. Toxicity to the pulmonary system is uncommon, but severe dyspnea has been reported from penicillamine-induced bronchoalveolitis. Myasthenia gravis also has been induced by long-term therapy with penicillamine. Penicillamine is a teratogen in laboratory animals, but for pregnant women with Wilson’s disease, the benefits appear to outweigh the risks. Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy, renal insufficiency, or a previous history of penicillamine-induced agranulocytosis or aplastic anemia.

Trientine. Penicillamine is the drug of choice for treatment of Wilson’s disease. However, the drug produces undesirable effects, as discussed in “Toxicity,” and some patients become intolerant. For these individuals, trientine (triethylenetetramine dihydrochloride, SYPRINE) is an acceptable alternative. Trientine is an effective cupriuretic agent in patients with Wilson’s disease, although it may be less potent than penicillamine. The drug is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in two to four divided portions on an empty stomach. Trientine may cause iron deficiency; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 hours of each other.

Deferoxamine; Deferasirox

Deferoxamine is isolated as the iron chelate from Streptomyces pilosus and is treated chemically to obtain the metal-free ligand. Deferoxamine has the desirable properties of a remarkably high affinity for ferric iron ($K_a = 1031$) coupled with a very low affinity for calcium ($K_a = 102$). In vitro, it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine.
Absorption, Distribution, and Excretion. Deferoxamine (deferoxamine mesylate, DESFERAL) is poorly absorbed after oral administration, and parenteral administration is required. For severe iron toxicity (serum iron levels >500 μg/dL), the intravenous route is preferred. The drug is administered at 10-15 mg/kg/hour by constant infusion. Faster rates of infusion (45 mg/kg/hour) have been used in a few cases; rapid boluses usually are associated with hypotension. Deferoxamine may be given intramuscularly in moderately toxic cases (serum iron 350-500 μg/dL) at a dose of 50 mg/kg with a maximum dose of 1 g. Hypotension also can occur with the intramuscular route.

For chronic iron intoxication (e.g., thalassemia), an intramuscular dose of 0.5-1.0 g/day is recommended, although continuous subcutaneous administration (1-2 g/day) is almost as effective as intravenous administration. During blood transfusion, patients with thalassemia should be given 2 g deferoxamine (per unit of blood) by slow intravenous infusion (rate not to exceed 15 mg/kg/hour) by a separate line. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Deferoxamine also has been used for the chelation of aluminum in dialysis patients.

Deferoxamine is metabolized by plasma enzymes, but the pathways have not yet been defined. The drug is excreted readily in the urine.

Toxicity. Deferoxamine causes a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cardiac arrest have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major, both visual and auditory changes have been described. A “pulmonary syndrome” has been associated with high-dose (10-25 mg/kg/hr) deferoxamine therapy; tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

Deferasirox. Deferasirox (EXJADE) is an orally administered chelator of iron. It is FDA-approved for treatment of chronic iron overload in patients receiving therapeutic blood transfusions.

From the wrong drug prescribed to the wrong dosage or administration schedule advised, dispensed, or administered, the impact of medication misadventures is a costly problem. Errors of these sorts occur because human beings are involved, and such errors can be prevented only by systems that make it difficult to do the wrong thing. This appendix provides a primer on the proper approach to the medication prescription and order process and a resource for practitioners in effectively providing pharmaceutical care for their patients.

THE MECHANICS OF PRESCRIPTION ORDER WRITING

History

Early medicines were made up of multiple ingredients requiring complex preparation, and Latin was adopted as the standard language of the prescription to ensure understanding between physician and pharmacist and consistency in pharmaceutical composition. Latin no longer is the international language of medicine, but a number of commonly used abbreviations derive from old Latin usage. The symbol “Rx” is said to be an abbreviation for the Latin word *recipere*, meaning “take” or “take thus,” as a direction to a pharmacist, preceding the physician’s “recipe” for preparing a medication. The abbreviation “Sig” for the Latin *Signatura*, is used on the prescription to mark the directions for administration of the medication.

Current Practice

The prescription consists of the *superscription*, the *inscription*, the *subscription*, the *signa*, and the *name and signature of the prescriber*, all contained on a single form (Figure AI–1).

The *superscription* includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx (*Take*). The body of the prescription, or *inscription*, contains the name and amount or strength of the drug to be dispensed, or the name and strength of each ingredient to be compounded. The *subscription* is the instruction to the pharmacist, usually consisting of a short sentence such as: “make a solution,” “mix and place into 30 capsules,” or “dispense 30 tablets.” The *signa* or “Sig” is the instruction for the patient as to how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the U.S., prescriptions should always be written in English. Many physicians continue to use Latin abbreviations; for example, “1 cap tid pc,” will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations for these directions only mystifies the prescription and is discouraged. This can be a hindrance to proper patient-physician communication and is an otherwise unnecessary source of potential dispensing errors. Because the pharmacist always writes the label in English (or, as appropriate, in the language of the patient), the use of such abbreviations or symbols is unnecessary. Many serious dispensing errors can be traced to the use of abbreviations (Cohen, 2007).

The instruction “take as directed” is not satisfactory and should be avoided by the physician. Such directions assume an understanding on the part of the patient that may not be realized and inappropriately exclude the pharmacist from the pharmaceutical care process. Such directions are inadequate for the pharmacist, who must determine the intent of the physician before dispensing the medication, and who shares the responsibility for the patient’s safe and proper use of the medication. The best directions to the patient will include a reminder of the
intended purpose of the medication by including such phrases as “for relief of pain” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions should begin with “take” or “give”; for externally applied products, the word “apply”; for suppositories, “insert”; and for eye, ear, or nose drops, “place” is preferable to “instill.”

Prescriptive Authority
In many states in the U.S., healthcare practitioners other than M.D. and D.O. physicians can write prescriptions. Licensed physician’s assistants (P.A.), nurse practitioners, pharmacists, and clinical psychologists can prescribe medications under various circumstances.

Avoiding Confusion
Doses always should be listed by metric weight of the active ingredient; doses for liquid medications should include the volume. Older systems of measure such as minims for volume (15 minims = 1 mL) and grains for weight (1 grain = 60 mg) are obscure and should not be used. Writing “μg” for micrograms can very easily be misinterpreted as “mg” (milligrams). Even the abbreviation “mcg” for micrograms can be misinterpreted (Koczmara et al., 2005). Writing out the word micrograms or milligrams is preferable. When specifying the dose to be dispensed, a zero should be used before a decimal (0.# milligrams, rather than .# milligrams) but not after (use # milligrams rather than #.0 milligrams). The metric system should be used in place of common household measurements such as “dropperful” and “teaspoon” in the directions for the patient except when the dropper is provided with the prescription, as in the case of pediatric antibiotic suspensions. Both the doctor and the pharmacist should be sure that the patient understands the measurement prescribed. For medical purposes, a “teaspoon” or “teaspoonful” dose is considered
to be equivalent to 5 mL and a “tablespoon” equivalent to 15 mL, but the actual volumes held by ordinary household teaspoons and tablespoons are far too variable to be used reliably for measurement of medications. Prescribing oral medications in “drops” likewise can cause problems when accuracy of dose is important, unless the patient understands that only the calibrated dropper (for drops or teaspoon measures) provided by the manufacturer or pharmacist should be used to dispense the medication. Thus, one possible dosage for a pediatric iron product would be more accurately written “15 milligrams (0.6 mL) three times daily” instead of “one dropperful three times daily,” because a true dropperful could result in iron overdose.

Abbreviations lead to dispensing errors (Teichman and Caffee, 2002). A prescription intending every-other-day dosing (qod) may be miswritten as “od” by the physician for “other-day dosing”; the pharmacist may interpret “od” as the abbreviation of the Latin for “right eye.” Once-daily dosing at bedtime (qhs) may be misinterpreted as “qhr” for “every hour.” The use of a slash mark (/) to separate names and doses can result in the incorrect drug or dose being dispensed; the slash mark may be interpreted as a letter or number. When medications are measured in units, or international units, the abbreviation “U” or “I” must NOT be used, as it leads to errors such as misinterpretation of “U” as 0 or 4, or “IU” as 10 or 14. The word “unit” should be written as such. Drug products available in the U.S. that are dosed in units (e.g., corticotropin) or international unit measures are “harmonized” by those responsible for drug standardization to avoid errors in dosing (see “Drug Standards and Classification”). Examples of confusion in the interpretation of a physician order abound (Kohn, 2001) and are considered further in “Errors in Drug Orders.” To avoid errors, practitioners in the U.S. must write out the Rx fully in English, and pharmacists must clarify their concerns with prescribers, not patients.

Proper Patient Information

The patient’s name and address are needed on the prescription order to ensure that the correct medication goes to the proper patient and also for identification and recordkeeping purposes. For medications whose dosage involves a calculation, a patient’s pertinent factors, such as weight, age, or body surface area, also should be listed on the prescription. Prescribers should view this effort as one that serves their goal of protecting their patient from errors rather than a burden (safety first).

Prescribers often commit errors in dosage calculations (Lesar et al., 1997) that can be prevented (Kuperman et al., 2001; Conroy et al., 2007). When prescribing a drug whose dosage involves a calculation based on body weight or surface area, both the calculated dose and the dosage formula used, such as “240 mg every 8 hours (40 mg/kg/day),” should be included to allow another healthcare professional to double-check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling such prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or anti-seizure medications that are sometimes difficult to adequately dose (e.g., phenytoin), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist.

Proper Use of Prescription Pad

All prescriptions should be written in ink; this practice is compulsory for schedule II prescriptions under the U.S. Controlled Substances Act (CSA) of 1970, because erasures on a prescription easily can lead to dispensing errors or diversion of controlled substances.

Prescription pad blanks normally are imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure AI–1). When using institutional blanks that do not bear the physician’s information, the physician always should print his or her name and phone number on the face of the prescription to clearly identify the prescriber and facilitate communication with other healthcare professionals if questions arise. U.S. law requires that prescriptions for controlled substances include the name, address, and Drug Enforcement Administration (DEA) registration number of the physician.

The date of the prescription is an important part of the patient’s medical record, and it can assist the pharmacist in recognizing potential problems. For example, when an opioid is prescribed for pain due to an injury, and the prescription is presented to a pharmacist 2 weeks after issuance, the drug may no longer be indicated. Compliance behavior also can be estimated using the dates when a prescription is filled and refilled. The CSA requires that all orders for controlled substances (Table AI–1) be dated as of, and signed on, the day issued and prohibits filling or refilling orders for substances in schedules III and IV >6 months after their date of issuance. When writing the original prescription, the physician should designate the number of refills allowed. For maintenance medications without abuse potential, it is reasonable to write for a 1-month supply and to mark the prescription form for refills to be dispensed over a period sufficient to supply the patient until the next scheduled visit to the physician.
A statement such as “refill prn” (refill as needed) is not appropriate, as it could allow the patient to misuse the medicine or neglect medical appointments. If no refills are desired, “zero” (not “0”) should be written in the refill space to prevent alteration of the prescriber’s intent. Refills for controlled substances are discussed later, in “Refills” under “Controlled Substances.” Concern about the rising cost of healthcare has favored the dispensing of so-called “generic” drugs. A drug is called by its generic name (in the U.S., this is the U.S. Adopted Name or USAN) or the manufacturer’s proprietary name, called the trademark, trade name, or brand name. In most states in the U.S., pharmacists have the authority to dispense generic drugs rather than brand-name medications. The physician can request that the pharmacist not substitute a generic for a branded medication by indicating this on the prescription (“do not substitute”), although this generally is unnecessary because the U.S. Food and Drug Administration (FDA) requires that generic medications meet the same bioequivalence standards as their brand-name counterparts. In some jurisdictions, prescriptions may not be filled with a generic substitution unless specifically permitted on the prescription. Occasions when substituting generic medications is discouraged are limited to products with specialized release systems and narrow therapeutic indices, or when substantial patient confusion and potential non-compliance may be associated with substitution.

Choice and Amount of Drug Product Dispensed

Inappropriate choice of drugs by physicians is a problem in prescribing. As learned recently with the cyclooxygenase-2 (COX-2) inhibitors, a drug’s therapeutic promise or popularity is not proof of its overall clinical superiority or safety (Topol, 2004). Physicians must rely on unbiased sources when seeking drug information that will influence their prescribing habits; use of the original medical literature will ensure instruction of the prescriber’s best judgment.

The amount of a drug to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed, because this not only is expensive for the patient but may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient’s family if used inappropriately. It is far better to have several refills of a prescription than to have more than necessary prescribed at one time.

The Prescription as a Commodity

Prescribers must be aware that patients may visit their doctor to “get” a prescription. Indeed, in an era when the time spent between physician and patient is ever
shorter due to limits and pressures of physician reimbursements, patients often feel that a trip to the doctor that does not result in a new prescription somehow is a failed visit or a lost opportunity. Similarly, physicians may feel that they have fulfilled their role if the patient leaves with a prescription. Physicians must educate their patients about the importance of viewing medicines as to be used only when really needed and that remaining on a particular medicine when their condition is stable may be preferable to seeking the newest medications available.

### Prescription Drug Advertising

The Federal Food, Drug, and Cosmetic Act as amended (Food and Drug Administration Modernization Act of 1997) permits the use of print and television advertising of prescription drugs. The law requires that all drug advertisements contain (among other things) summary information relating to side effects, contraindications, and effectiveness. The current advertising regulations specify that this information disclosure needs to include all the risk information in a product’s approved labeling or must direct consumers to healthcare professionals to obtain this information. Typically, print advertisements will include a reprinting of the risk-related sections of the product’s approved labeling (package insert), while television advertising will not. In addition, advertisements cannot be false or misleading or omit material facts. They also must present a fair balance between effectiveness and risk information.

The benefits of these types of direct-to-consumer (DTC) advertising, including Internet advertising, are controversial (Findlay, 2001). Dramatizations employed by television commercials may be a disservice to the physician’s ability to educate and care for the patient if such advertisements only create brand loyalty. Alternatively, patients who learn about drugs on television may interact more effectively with their healthcare providers by asking questions about the medicines they take. Prescription drug advertising has alerted consumers to the existence of new drugs and the conditions they treat, but it has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues) and has contributed to the higher pharmaceutical costs borne by health insurers, government, and consumers. In the face of a growing demand for particular brand-name drugs driven by advertising, physicians and pharmacists must be able to counsel patients effectively and provide them with evidence-based drug information (Khanfar et al., 2007).

### Errors in Drug Orders

The Institute of Medicine (IOM) estimates that the annual number of medical errors in the U.S. that results in death is between 44,000 and 98,000 (Kohn et al., 2000). Although there is some controversy about these estimates (Sax and Woloshin, 2000), it is clear that the large number of medical errors includes medication errors resulting in adverse events, including death (Mangino, 2004; Tzimenatos and Bond, 2009). Databases of anonymously reported errors are maintained jointly by the Institute for Safe Medication Practices (ISMP), the U.S. Pharmacopeia Medication Errors Reporting Program (USP MERP), and the FDA’s MedWatch program. Adverse drug events occur in ~3% of hospitalizations, and this number is larger for special populations such as those in pediatric and neonatal intensive care units (Chedoe et al., 2007).

By examining aspects of prescription writing that can cause errors and by modifying prescribing habits accordingly, the physician can increase the probability that the patient will receive the correct prescription. By being alert to common problems that can occur with medication orders and communicating with the patient’s physician, pharmacists and other healthcare professionals can assist in reducing medication errors (Murray et al., 2009). Good practice in the preparation of medication orders in both the institutional and outpatient settings can be summarized as follows:

1. Write all orders clearly using metric measurements of weight and volume.
2. Include patient age and weight on the prescription, when appropriate, so dosage can be checked.
3. Use Arabic (decimal) numerals rather than Roman numerals (e.g., does “IL-II” mean “IL-11” or “IL-2”?) in some instances, it is preferable for numerals to be spelled out.
4. Use leading zeros (0.125 milligrams, not .125 milligrams); never use trailing zeros (5 milligrams, not 5.0 milligrams).
5. Avoid abbreviating drug names; abbreviations may lead to misinterpretation.
6. Avoid abbreviating directions for drug administration; write out directions clearly in English.
7. Be aware of possibilities for confusion in drug names. Some drug names sound alike when spoken and may look alike when spelled out. The U.S. Pharmacopeial Convention Medication Errors Reporting Program maintains a current list of drug names that can be confused (www.usp.org). The list of alliterative drug names currently contains...
>750 pairs of potentially confusing names that could lead to harmful prescribing or dispensing errors. Alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.

- Provide the patient’s diagnosis on the prescription order. This is the single most important measure to prevent dispensing errors based on sound-alike or look-alike drug names. For instance, an order for administration of magnesium sulfate must not be abbreviated “MS,” as this may result in administration of morphine sulfate. Including the therapeutic purpose and/or the patient’s diagnosis can prevent this error.

- Write clearly. Poor handwriting is a well-known and preventable cause of dispensing errors. Both physician and pharmacist share in the responsibility for preventing adverse drug events by writing prescriptions clearly (When in doubt, write it out!) and questioning intent whenever an order is ambiguous (When in doubt, check it out!).

- Think.

**CONTROLLED SUBSTANCES**

In the U.S., the DEA within the Department of Justice is responsible for the enforcement of the Federal Controlled Substances Act (CSA). The DEA regulates each step of the handling of controlled substances from manufacture to dispensing (21 U.S.C. § 811). The law provides a system that is intended to prevent diversion of controlled substances from legitimate uses. Substances that come under the jurisdiction of the CSA are divided into five schedules (Table AI–1), but practitioners should note that individual states may have additional schedules. Physicians must be authorized to prescribe controlled substances by the jurisdiction in which they are licensed, and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances. Criminal prosecution and penalties for misuse generally depend on the schedule of a substance as well as the amount of drug in question.

State agencies may impose additional regulations, such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. Some U.S. states, such as California, have placed marijuana, classified by the FDA as a schedule I substance, in a special category by decriminalizing its possession and sale for medical use. Under California’s medical marijuana laws, patients and caregivers are exempt from prosecution by the state of California, notwithstanding contrary federal law. This legal difference of opinion between state and federal regulation is the source of considerable controversy. Generally, the most stringent law takes precedence, whether it is federal, state, or local.

**Prescription Orders for Controlled Substances**

To be valid, a prescription for a controlled substance must be issued for a legitimate medical purpose by an individual practitioner acting in the usual course of his or her professional practice. An order that does not meet these criteria, such as a prescription issued as a means to obtain controlled substances for the doctor’s office use or to maintain addicted individuals, is not considered a legitimate prescription within the meaning of the law, and thus does not protect either the physician who issued it or the pharmacist who dispensed it. Most states prohibit physicians from prescribing controlled substances for themselves; it is prudent to comply with this guideline even if it is not mandated by law.

**Execution of the Order**

Prescriptions for controlled substances should be dated and signed on the day of their issuance and must bear the full name and address of the patient and the printed name, address, and DEA number of the practitioner and should be signed the way one would sign a legal document. Preprinted orders are not allowed in most states, and pre-signed blanks are prohibited by Federal law. When oral orders are not permitted (schedule II), the prescription must be written with ink or typewritten. The order may be prepared by a member of the physician’s staff, but the prescriber is responsible for the signature and any errors that the order may contain.

**Oral Orders**

Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician or by trusted staff in the same manner as a prescription for a noncontrolled substance, although it is in the physician’s best interest to keep his or her DEA number as private as reasonably possible (see “Preventing Diversion”). Schedule II prescriptions
may be telephoned to a pharmacy only in emergency situations. To be an emergency:

- Immediate administration is necessary
- No appropriate alternative treatment is available
- It is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 hours. If mailed, the prescription must be postmarked within 72 hours. The pharmacist must notify the DEA if this prescription is not received.

### Refills

No prescription order for a schedule II drug may be refilled under any circumstance. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, there are no restrictions on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

### Preventing Diversion

Prescription blanks often are stolen and used to sustain abuse of controlled substances and to divert legitimate drug products to the illicit market. To prevent this type of diversion, prescription pads should be protected in the same manner as one would protect a personal checkbook. A prescription blank should never be pre-signed for a staff member to fill in at a later time. Also, a minimum number of pads should be stock, and they should be kept in a locked, secure location except when in use. If a pad or prescription is missing, it should be reported immediately to local authorities and pharmacies; some areas have systems in place to allow the rapid dissemination of such information. Ideally, the physician’s full DEA number should not be pre-printed on the prescription pad, because most prescriptions will not be for controlled substances and will not require the registration number, and anyone in possession of a valid DEA number may find it easier to commit prescription fraud. Some physicians may intentionally omit part or all of their DEA number on a prescription and instead write “pharmacist call to verify” or “call for registration number.” This practice works only when the pharmacist may independently verify the authenticity of the prescription, and patients must be advised to fill the prescription during the prescriber’s office hours. Pharmacists can ascertain the likely authenticity of a physician’s DEA number using an algorithm.

Another method employed by the drug seeker is to alter the face of a valid prescription to increase the number of units or refills. By spelling out the number of units and refills authorized instead of giving numerals, the prescriber essentially removes this option for diversion. Controlled substances should not be prescribed excessively or for prolonged periods, as the continuation of a patient’s addiction is not a legitimate medical purpose.

### DRUG STANDARDS AND CLASSIFICATION

The U.S. Pharmacopeial Convention, Inc. is a non-governmental organization that promotes the public health and benefits practitioners and patients by disseminating authoritative standards and information on medicines and other healthcare technologies. This organization is home to the U.S. Pharmacopeia (USP), which, together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. These standards are enforceable by the FDA and the governments of other countries and are recognized worldwide. Drug monographs are published in the USP/National Formulary (USP-NF), the official drug standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP-NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such standards are essential for agents possessing biological activity, such as insulin.

The USP also is home to the *USP Dictionary of U.S. Adopted Names (USAN) and International Drug Names*. This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. Entries include one or more of the following: U.S. Adopted Names, official drug names for the *National Formulary* (NF), previously used official names, International Nonproprietary Names, British Approved Names, Japanese Accepted Names, trade names, and other synonyms. In addition to names, the records in this file contain other substance information such as Chemical Abstract Service (CAS), registry number (RN), molecular formula, molecular weight, pharmacological and/or therapeutic category, drug sponsor, reference information, and structure diagram.
if available. The USP maintains an electronic web site that can be accessed for useful drug naming, classification, and standards information (www.usp.org).

In the U.S., drug products also are coded under the National Drug Code (NDC). The NDC originally was established as an essential part of out-of-hospital drug reimbursement under Medicare. In the U.S., the NDC serves as a universal product identifier for drugs used in humans. The current edition of the National Drug Code Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, known as the NDC number, identifies the labeler/vendor, product, and package size. The labeler/vendor code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer.

In addition to classification of drugs by therapeutic category, drugs also are grouped by control schedule. Drug schedules in the U.S. are listed in Table AI–1 from schedule I to schedule V and are discussed above under “Controlled Substances.”

The FDA also categorizes drugs that may be used in pregnant women. These categories are similar to those used in other countries and provide guidance based on available science. The risk from a drug may be throughout pregnancy or limited to a particular period of fetal development. The categories range from A to X, in increasing order of concern, as noted here:

**Pregnancy Category A:** Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). Because of the obvious nature of the risk associated with the use of medications during gestation, the FDA requires a body of high-quality data on a drug before it can be considered for Pregnancy Category A.

**Pregnancy Category B:** Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women, OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester.

**Pregnancy Category C:** Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

**Pregnancy Category D:** There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

**Pregnancy Category X:** Studies in animals or humans have demonstrated fetal abnormalities, and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.

Physicians should realize that the pregnancy categories by themselves provide little guidance for the physician treating pregnant women. For example, angiotensin-converting enzyme (ACE) inhibitors such as captopril cause developmental toxicity (Category X) only after the first trimester. Physicians’ primary responsibility remains treating the pregnant patient. However, the risks of withholding treatment to the mother because of possible risks to the fetus have to be considered as well.

Drugs also are grouped by their potential for misuse under British and U.N. legal classifications as class A, B, or C. The classes are linked to maximum legal penalties in a descending order of severity, from A to C.

**COMPLIANCE**

Compliance may be defined as the extent to which the patient follows a regimen prescribed by a healthcare professional. The assumption that the doctor tells the patient what to do and then the patient meticulously follows orders is unrealistic. The patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—compliance, adherence, therapeutic alliance, or concordance—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The doctor is the medical expert; the patient is the expert on himself and his beliefs, values, habits, and lifestyle. The patient’s quality-of-life beliefs may differ from the clinician’s therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.
Even the most carefully prepared prescription for the ideal therapy will be useless if the patient’s level of compliance is not adequate. Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled (Hagstrom et al., 2004); therapeutic failures can result (Hobbs, 2004). Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy. The reported incidence of patient noncompliance varies widely but usually is in the range of 30-60% (Zyczynski and Coyne, 2000); the rate for long-term regimens is ~50% but can be impacted by pharmaceutical care management (Klein et al., 2009).

Hundreds of variables that may influence compliance behavior in a specific patient or condition have been identified. A few of the most frequently cited are discussed here, along with some suggestions for improving compliance, although none provides 100% compliance (Table AI–2).

### Table AI–2

**Suggestions for Improving Patient Compliance**

<table>
<thead>
<tr>
<th>Suggestion</th>
<th>Details</th>
</tr>
</thead>
<tbody>
<tr>
<td>Provide respectful communication; ask how patient takes medicine.</td>
<td></td>
</tr>
<tr>
<td>Develop satisfactory, collaborative relationship between physician and patient; encourage pharmacist involvement.</td>
<td></td>
</tr>
<tr>
<td>Provide and encourage use of medication counseling.</td>
<td></td>
</tr>
<tr>
<td>Give precise, clear instructions, with most important information given first.</td>
<td></td>
</tr>
<tr>
<td>Support oral instructions with easy-to-read written information.</td>
<td></td>
</tr>
<tr>
<td>Simplify whenever possible.</td>
<td></td>
</tr>
<tr>
<td>Use mechanical compliance aids as needed (sectioned pill boxes or trays, compliance packaging, color-coding).</td>
<td></td>
</tr>
<tr>
<td>Use optimal dosage form and schedule for each individual patient.</td>
<td></td>
</tr>
<tr>
<td>Assess patient’s literacy, language, and comprehension, and modify educational counseling as needed. Be culturally aware and sensitive.</td>
<td></td>
</tr>
<tr>
<td>To improve compliance, don’t rely on patient’s own knowledge of disease alone.</td>
<td></td>
</tr>
<tr>
<td>Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).</td>
<td></td>
</tr>
<tr>
<td>Enlist support and assistance from family or caregivers.</td>
<td></td>
</tr>
<tr>
<td>Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.</td>
<td></td>
</tr>
</tbody>
</table>

### The Patient–Provider Relationship

Patient satisfaction with the physician has a significant impact on compliance behavior and is one of few factors that the physician can directly influence. Patients are more likely to follow instructions and recommendations when their expectations for the patient–provider relationship and for their treatment are met. These expectations include not only clinical but also interpersonal competence, so cultivating good interpersonal and communication skills is essential. Cultural sensitivity is of growing importance, as healthcare providers see more patients from countries and cultures different from their own.

When deciding on a course of therapy, it can be useful to discuss a patient’s habits and daily routine as well as the therapeutic options with the patient. This information may suggest cues for remembrance, such as storing a once-daily medicine atop the books on the bedside table for a patient who reads nightly, or in the cabinet with the coffee cups if it is to be taken in the morning (noting that the humid environment of a bathroom can be the worst place to store a medication in terms of its physical and chemical preservation). The information also can help tailor the regimen to the patient’s lifestyle. A lack of information about a patient’s lifestyle can lead to situations such as prescribing a medication to be taken with meals three times daily for a patient who only eats twice a day or a medication to be taken each morning for a patient who works a night shift and sleeps during the day. Rarely is there only one treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Involving patients in the control of any appropriate aspects of their therapy may improve compliance, not only by aiding memory and making the dosage form or schedule more agreeable or convenient, but also by giving patients a feeling of empowerment and emphasizing their responsibility for the treatment outcome.

It is not unreasonable for the physician to ask the patient whether he or she intends to adhere to the prescribed therapy and to negotiate to get a commitment to do so. Attempts should be made to resolve collaboratively any conflicts that may hinder compliance.

### Patients and Their Beliefs

Behavioral models suggest that patients are more likely to be compliant when they perceive that they are susceptible to the disease, that the disease may have serious
negative impact, that the therapy will be effective, and that the benefits outweigh the costs, and when they believe in their own efficacy to execute the therapy. From the standpoint of compliance, the actual severity of and susceptibility to an illness is not necessarily an issue; rather, the patient’s perception of severity affects compliance (Dijkstra et al., 2008).

Patients’ beliefs can lead them to deliberately alter their therapy, whether for convenience, for personal experiments, because of a desire to remove themselves from the sick role, as a means to exercise a feeling of control over their situation, or for other reasons. This reinforces the need for excellent communication and a good patient–provider relationship to facilitate the provision of additional or corrective education when the beliefs would suggest poor compliance as an outcome.

It is difficult to predict whether a particular patient will be compliant, because there is no consistent relationship with isolated demographic variables such as age, sex, education level, intelligence, personality traits, and income. Certain of these variables have been implicated in specific situations, but they cannot be applied to the population as a whole. Social isolation generally has been found to be associated with poor compliance, although family members or other people close to the patient can undermine compliance as easily as they can support it. As noted above, the actual severity of the patient’s disease is not predictive of compliance behavior, but characteristics of the disease can make adherence less likely, as with certain neurodegenerative or psychiatric illnesses.

Pharmacists have a legal and professional responsibility to offer medication counseling in many situations—even though practice environments are not always conducive to its provision—and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient’s therapy can help identify compliance and other problems, educate the patient, and notify the physician as appropriate. Indeed, data from the Asheville Project indicate that a pharmacist-based medication management program provides significant advantages with respect to compliance, health outcomes, and cost (Bunting et al., 2008).

Elderly patients often face a number of barriers to compliance related to their age. Such barriers include increased forgetfulness and confusion; altered drug disposition and higher sensitivity to some drug effects; decreased social and financial support; decreased dexterity, mobility, or sensory abilities; and the use of a greater number of concurrent medicines (both prescription and over-the-counter) whose attendant toxicities and interactions may cause decreased mental alertness or intolerable side effects. There are drugs known to be inappropriate to prescribe to elderly patients (Curtis et al., 2004; Fick et al., 2003) and some that may adversely affect compliance. Despite these obstacles, evidence does not show that elderly patients in general are significantly less compliant than any other age group. Still, as the U.S. population ages, elderly patients will consume a disproportionate fraction of medicines and healthcare resources, so there is great opportunity and motivation to improve their drug-taking habits. Physicians must be careful in choosing medications for the elderly (O’Mahony and Gallagher, 2008; Lopez and Goldoftas, 2009). Pharmacists must pay particular attention to thorough and compassionate counseling for elderly patients and should assist patients in finding practical solutions when problems, such as polypharmacy, are noted.

The Therapy
Increased complexity and duration of therapy are perhaps the best-documented barriers to compliance. The patient for whom multiple drugs are prescribed for a given disease or who has multiple illnesses that require drug therapy will be at higher risk for noncompliance, as will the patient whose disease is chronic. The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable.

The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients but are not necessarily predictive, especially if patient beliefs or other positive factors tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another. The cost of medicine can be a heavy burden for patients with limited economic resources, and healthcare providers should be sensitive to this fact (Restrepo et al., 2008). Mobile devices (e.g., iPhone) running drug formulary/therapeutic software now can provide the costs of medications, as can physicians who are familiar with the patient’s insurance plan. Mobile phone systems that provide reminders and collect patient response information are being introduced and may become more popular as patients become increasingly tech savvy.
ELECTRONIC PRESCRIBING

The era of e-prescribing has begun. Its implementation is still expensive, but the subsequent benefits to patients and savings in personnel costs, along with its integration with electronic medical records, drug inventory control, and billing, point to the wide use of e-prescribing in the future. Computerized prescription ordering eliminates some of the subjective features of prescribing. Thus, if the proper information is entered correctly in the electronic system, medication errors due to illegible handwriting, incorrect dose, incorrect medication for medical condition, and drug interactions can be reduced, because each prescription can be linked to high-quality drug databases that check that the information on the prescription is appropriate for the patient (e.g., age, weight, gender, condition, lab values, disease being treated, concurrent medications) and that known warnings and potential problems are brought to the attention of the physician, pharmacist, and patient. Such systems must not be used as a substitute for personal attention to the individual patient by healthcare workers but, rather, as an adjunct measure that ensures safe, high-quality, efficient care.

REFERENCES

This page intentionally left blank
This appendix provides a summary of basic pharmacokinetic information pertaining to drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or non-parenteral administration. Because of space limitations, this list cannot be exhaustive. Drugs designed exclusively for topical administration and not to be significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications; Chapters 64 and 65) are not included. A few other selection criteria have influenced the makeup of the list, but, in general, the authors have tried to include one or more representative drugs in each of the therapeutic areas in this text, based on distinct mechanism(s) of action. In some instances, drugs may be excluded because pharmacokinetics are not relevant to their therapeutic management. An obvious case is when drug efficacy is not apparently correlated with drug concentration in a reversible fashion (e.g., some cytotoxic anticancer drugs). Also, for a number of therapeutic antibodies, the antibody is administered at a fixed dose at prolonged intervals that allows for its near complete clearance (e.g., infliximab).

Often, the issue comes down to deciding which of the many drugs within a class should be selected. This is particularly problematic when the choices are largely therapeutic equivalents. Two criteria that have proven useful are prevalence of use and uniqueness of mechanism of action. For the present edition, we have consulted the “2008 Top 200 Branded Drugs by Total Prescriptions” and “2008 Top 200 Generic Drugs by Total Prescriptions” published in the respective May 22 and 26, 2009, issues of Drug Topics (http://drugtopics.modernmedicine.com) for usage data. Drugs that fall into the top 200 list are selected. As mentioned above, a less used drug may be included if it has a different mechanism of action than the frequently used drugs, some additional actions that offer a unique therapeutic advantage, or a more acceptable side-effects profile.

Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. Table AII–1 contains quantitative information about the absorption, distribution, and elimination of drugs; the effects of disease states on these processes; and the correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in Chapter 2. Their application using the data in Table AII–1 for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some measures of the extent and kinetics of drug absorption and distribution. The text below defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values in both normal subjects and patients with renal or liver disease. It obviously would be more straightforward if there were a consensus on a standard value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In Table AII–1, a single set of values for each parameter and its variability in a relevant population
has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value ± 1 standard deviation (mean ± SD). However, some data are presented as mean and range of values (in parentheses) observed for the study population (i.e., the lowest and highest value reported). There are times when data are reported as a geometric mean with a 95% confidence interval. If sufficient data were available, we presented a range of mean values obtained from different studies of similar design in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about both the prodrug and the active molecule are needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed [e.g., $G(V)$ indicates a parameter for ganciclovir after administration of the prodrug, valganciclovir].

A number of recently approved drugs are actually the active metabolite or stereoisomer of a previously marketed drug. For example, desloratadine is the $O$-desmethyl metabolite of loratadine, and esomeprazole is the active $S$-enantiomer of omeprazole. Unless the parent drug and the active metabolite offer distinct therapeutic advantages, only the more established or more commonly used drug is listed, and relevant information on its alternate active form is presented in the same table. This approach has permitted us to include more drugs in the Appendix, hopefully without undue confusion. The only exception is with prednisone and prednisolone, which undergo interconversion in the body.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states is noted below the average value. One or more references are provided for each of the established drugs, typically an original journal publication, a review on its clinical pharmacokinetics, or web-based drug database; the latter two secondary sources provide a broader range of papers for the interested reader. In some instances, we have relied on unpublished data provided by the drug sponsor in its New Drug Application (NDA) files or package labeling submitted to the U.S. Food and Drug Administration (FDA).

**TABULATED PHARMACOKINETIC PARAMETERS**

Each of the eight parameters presented in Table AII–1 has been discussed in detail in Chapter 2. The following discussion focuses on the format in which the values are presented as well as on factors (physiological or pathological) that influence the parameters.

Bioavailability. The extent of oral bioavailability is expressed as a percentage of the administered dose. This value represents the percentage of the administered dose that is available to the systemic circulation—the fraction of the oral dose that reaches the arterial blood in an active or prodrug form, expressed as a percentage (0-100). Fractional availability ($F$), which appears elsewhere in this appendix, denotes the same parameter; this value varies from 0-1. Measures of both the extent and rate (see $T_{max}$) of availability are presented in the table. The extent of availability is needed for the design of an oral dosage regimen to achieve a specific target blood concentration. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of area under the plasma drug concentration–time curve (AUC) between the oral dose and an intravenous reference dose. For those drugs where intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug, especially when the nonrenal route of elimination is minimal) is presented, or the column is left blank (denoted by a long dash [—]). A dash also will appear when a drug is given by parenteral administration only.

A low bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluid, degradative loss of drug in the gastrointestinal fluid, poor mucosal permeability, first-pass metabolism during transit through the intestinal epithelium, active efflux transport of drug back into the lumen, or first-pass hepatic metabolism or biliary excretion (see Chapter 2). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases and/or because vascular shunts develop around the liver.

Urinary Excretion of Unchanged Drug. The second parameter in Table AII–1 is the amount of drug eventually excreted unchanged in the urine, expressed as a
percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance \(\geq 100 \text{ mL/min}\)). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater utility because it reflects the relative contribution of renal clearance to total body clearance irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways of elimination are available; thus, as renal function decreases, a greater fraction of the dose is available for elimination by other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with \(pK_a\) values within the normal range for urine pH, changes in urine pH will affect their rate or extent of urinary excretion (see Chapter 2).

**Binding to Plasma Proteins.** The tabulated value is the percentage of drug in the plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed *in vitro* (rather than from *ex vivo* measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percent bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma-protein binding; in those cases, the range of reported values is given.

Plasma-protein binding is affected primarily by disease states, notably hepatic disease, renal failure, and inflammatory diseases, that alter the concentration of albumin, \(\alpha_1\)-acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the binding affinity of albumin for some drugs. Disease-induced changes in plasma–protein binding can dramatically affect the volume of distribution, clearance, and elimination \(t_{1/2}\) of a drug. In regard to clinical relevance, it is important to assess the change in unbound drug concentration or AUC, particularly when only unbound drug can cross biological barriers and gain access to the site of action.

**Plasma Clearance.** Systemic clearance of total drug from plasma or blood (see Equations 2–5 and 2–6) is given in Table AII–1. Clearance varies as a function of body size and, therefore, most frequently is presented in the table in units of mL/min/kg of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimate, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is conventionally used. When unit conversion was necessary, we used individual or mean body weight or body surface area (when appropriate) from the cited study, or if this was not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m\(^2\) for healthy adults.

In some cases, separate values for renal and non-rerenal clearance are also provided. For some drugs, particularly those that are excreted predominantly unchanged in the urine, equations are given that relate total or renal clearance to creatinine clearance (also expressed as mL/min/kg). For drugs that exhibit saturation kinetics, \(K_m\) and \(V_{\text{max}}\) are given and represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached (in units of mass/volume) and the maximal rate of elimination (in units of mass/time/kg of body weight). \(K_m\) must be in the same units as the concentration of drug in plasma (\(C_p\)).

Intrinsic clearance from blood is the maximal possible clearance by the organ responsible for elimination when blood flow (delivery) of drug is not limiting. When expressed in terms of unbound drug, intrinsic clearance reflects clearance from intracellular water. Intrinsic clearance is tabulated for a few drugs. It also is mathematically related to the biochemical intrinsic clearance \([V_{\text{max}}/(K_m + C)]\) determined *in vitro*. In almost all cases, clearances based on plasma concentration data are presented in Table AII–1, because drug analysis most often is performed on plasma samples. The few exceptions where clearance from blood is presented are indicated by footnote. Clearance estimates based on blood concentration may be useful when a drug concentrates in the blood cells.
To be accurate, clearances must be determined after intravenous drug administration. When only non-parenteral data are available, the ratio of CL/F is given; values offset by the fractional availability (F) are indicated in a footnote. When a drug, or its active isomer for racemic compounds, is a substrate for a cytochrome P450 (CYP) or drug transporter, this information is provided in a footnote. This information is important for understanding pharmacokinetic variability due to genetic polymorphisms and for predicting metabolically based drug-drug interactions.

Volume of Distribution. The total body volume of distribution at steady state (Vss) is given in Table AII–1 and is expressed in units of L/kg or in units of L/m² for some anticancer drugs. Again, when unit conversion was necessary, we used individual or mean body weights or body surface area (when appropriate) from the cited study, or if such data were not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

When estimates of Vss were not available, values for Varea were provided; Varea represents the volume at equilibrated distribution during the terminal elimination phase (see Equation 2–12). Unlike Vss, Varea varies when drug elimination changes, even though there is no change in the distribution space. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define volume in terms of Vss, a parameter that is less likely to depend on changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript.

As with clearance, Vss usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the apparent volume estimate, Vss/F, is offset by the fractional availability.

Half-Life. Half-life (t1/2) is the time required for the plasma concentration to decline by one-half when elimination is first order. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one t1/2, 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, etc. Determination of t1/2 is straightforward when drug elimination follows a monoexponential pattern (i.e., one-compartment model). However, for a number of drugs, plasma concentration follows a multiexponential pattern of decline over time. The mean value listed in Table AII–1 corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases, this t1/2 refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the t1/2 of an earlier phase is presented, even though a prolonged t1/2 may be observed at very low plasma concentrations when extremely sensitive analytical techniques are used. If the latter component accounts for ≤10% of the AUC, predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer t1/2 is ignored. The clinician should know the t1/2 that will best predict drug accumulation in the patient, which will be the appropriate t1/2 to use for estimating the rate constant in Equations 1–19 through 1–21 (see Chapter 1) to predict time to steady state. It is this t1/2 of accumulation during multiple dosing that is given in Table AII–1.

Half-life usually is independent of body size because it is a function of the ratio of two parameters, clearance and volume of distribution, each of which is proportional to body size. It also should be noted that the t1/2 is preferably obtained from intravenous studies, if feasible, because the t1/2 of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow release formulations are given. If the t1/2 is derived from an oral dose, this will be indicated in a footnote of Table AII–1.

Time to Peak Concentration. Because clearance concepts are used most often in the design of multiple dosage regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the degree of fluctuation in plasma drug concentration (i.e., peak and trough concentrations), which govern drug efficacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained- or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from three or four times daily to once or twice daily. There also are drugs that are given on an acute basis (e.g., for the relief of breakthrough pain or to induce sleep), for which the rate of drug absorption is a critical determinant of onset of effect. Thus, information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in Table AII–1.
The time required to achieve a maximal concentration \( T_{\text{max}} \) depends on the rate of drug absorption into blood from the site of administration and the rate of elimination. From mass balance principles, \( T_{\text{max}} \) occurs when the rate of absorption equals the rate of elimination from the reference compartment. Prior to this time, absorption rate exceeds elimination rate, and the plasma concentration of drug increases. After the peak is reached, elimination rate exceeds the absorption rate and, at some point, defines the terminal elimination phase of the concentration-time profile.

The rate of drug absorption following oral administration will depend on the formulation and physicochemical properties of the drug, its permeability across the mucosal barrier, and the intestinal villous blood flow. For an oral dose, some absorption may occur very rapidly within the buccal cavity, esophagus, and stomach, or absorption may be delayed until the drug reaches the small intestine or until the local pH in the intestine permits drug release from the dosage formulation. In the most extreme case, the rate of absorption can be sufficiently controlled by the drug formulation to permit sustained or extended delivery as the dosage form traverses the entire length of the gastrointestinal tract. In some instances, the terminal elimination of drug from the body following a peak concentration reflects the slower rate of absorption and not elimination.

When more than one type of drug formulation is available commercially, we have provided absorption information for both the immediate- and sustained-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and extent of drug availability. We have indicated with footnotes when the consumption of food near the time of drug ingestion may have a significant effect on the drug bioavailability.

**Peak Concentration.** There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single-effect parameter or effective concentration is difficult. This is particularly true for antimicrobial agents because the effective concentration depends on the identity of the microorganism causing the infection. It also is important to recognize that concentration-effect relationships are most easily obtained at steady state or during the terminal log-linear phase of the concentration-time curve, when the drug concentration(s) at the site(s) of action are expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the past 5 years, it is rare to find a declaration of an *effective concentration range*, even in the manufacturer’s packaging labeling. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following *effective dosage* regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (i.e., \( \bar{C}_{\text{ss}} \) as estimated by dividing the mean AUC by the duration of the dosing interval) and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also, \( \bar{C}_{\text{ss}} \) does not take into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval. In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for special populations (e.g., elderly) sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most commonly reported parameter, \( C_{\text{max}} \) (peak concentration), rather than effective or toxic concentrations, is presented in Table AII–1. This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. Although the value reported is the highest that would be encountered in a given dose interval, \( C_{\text{max}} \) can be related to the trough concentration \( (C_{\text{min}}) \) through appropriate mathematical predictions (see Equation 1–21). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak level can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations or about concentrations at which toxicity occurs, it has been incorporated in a footnote. For individual drugs, the reader also is referred to the index to locate pages where more detailed information is provided.

It is important to recognize that significant differences in \( C_{\text{max}} \) will occur when comparing similar daily-dose regimens for an immediate-release and
sustained-release product. Indeed, the sustained-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report $C_{\text{max}}$ for both immediate- and extended-release formulations, when available. In addition to parent drug concentrations, we have included information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, we present information on the levels of the individual enantiomers or the active enantiomer that contributes most to the drug’s efficacy.

### ALTERATIONS OF PARAMETERS IN THE INDIVIDUAL PATIENT

Dose adjustments for an individual patient should be made according to the manufacturer’s recommendation in the package labeling when available. This information generally is available when disease, age, or race has a significant impact on drug disposition, particularly for drugs that have been introduced within the past 10 years. In some cases, a significant difference in drug disposition from the “average” adult can be expected but may not require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available. Under these circumstances, an estimate of the appropriate dosing regimen can be obtained based on pharmacokinetic principles described in Chapter 1.

Unless otherwise specified, the values in Table AII–1 represent mean values for populations of normal adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available ($F$) and clearance ($CL$) also must be estimated to compute a maintenance dose necessary to achieve a desired average steady-state concentration.

To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated $t_{1/2}$ is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note that this may be the apparent $t_{1/2}$ following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than ~30 kg (after proper adjustment for size; see “Clearance” and “Volume of Distribution” later), it is best to consult pediatrics textbooks or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative direction of changes is noted, such as “↓ LD,” which indicates a significant decrease in the parameter in a patient with chronic liver disease. The relevant literature and the package label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

#### Plasma-Protein Binding

Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as propranolol, often bind to other plasma proteins (e.g., $\alpha_1$-acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma-protein concentrations. Significant pharmacokinetic effects from a change in plasma-protein binding will be denoted under clearance or volume of distribution.

Although pharmacokinetic parameters based on total drug or metabolite concentrations often are reported, it is important to recognize that in many cases it is the concentration of unbound drug that drives access to the site of action and the degree of pharmacological effect. Remarkable changes in the total plasma concentration may accompany disease-induced alteration in protein binding; however, the clinical outcome is not always affected because an increase in free fraction also will increase the apparent clearance of an orally administered drug and of a low-extraction drug dosed intravenously. Under such a scenario, the mean unbound plasma concentration at steady state will not change with reduced or elevated plasma-protein binding, despite a significant change in mean total drug concentration. If so, no adjustment of daily maintenance dose is needed.

#### Clearance

For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes in accordance with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient’s creatinine clearance ($CL_{\text{cr}}$) to a normal value (100 mL/min/70 kg body weight). If urinary creatinine clearance has not been measured, it may be
estimated from the concentration of creatinine in serum ($C_{cr}$). In men:

$$CL_{cr} (\text{mL/min}) = \frac{[140 - \text{age (yr)}] \cdot [\text{weight (kg)}]}{72 \cdot [C_{cr} (\text{mg/dL})]}$$

(Equation A-1)

For women, the estimate of $CL_{cr}$ by the above equation should be multiplied by 0.85 to reflect their smaller muscle mass. The fraction of normal renal function ($rf_{x_{pt}}$) is estimated from the following:

$$rf_{x_{pt}} = \frac{CL_{cr,pt}}{100 \text{ mL/min}}$$

(Equation A-2)

A more accurate measure of $rf_{x_{pt}}$ seldom is necessary because, given the considerable degree of interindividual variation in nonrenal clearance, the adjustment of clearance is an approximation. The following equation for adjustment of clearance uses the quantities discussed:

$$rf_{pt} = 1 - [fe_{nl} \cdot (1 - rf_{x_{pt}})]$$

(Equation A-3)

where $fe_{nl}$ is the fraction of systemic drug excreted unchanged in normal individuals (see Table AII–1). The renal factor ($rf_{pt}$) is the value that, when multiplied by normal total clearance ($CL_{nl}$) from the table, gives the total clearance of the drug adjusted for the impairment in renal function.

**Example.** The clearance of vancomycin in a patient with reduced renal function (creatinine clearance = 25 mL/min/70 kg) may be estimated as follows:

$$rf_{x_{pt}} = \frac{25 \text{ mL/min}}{100 \text{ mL/min}} = 0.25$$

$$fe_{nl} = 0.79 (\text{see listing for vancomycin})$$

$$rf_{pt} = 1 - [0.79 \cdot (1 - 0.25)] = 0.41$$

$$CL_{pt} = (1.3 \text{ mL/min/kg}) \cdot 0.41$$

$$= 0.53 \text{ mL/min/kg}$$

Importantly, such a clearance adjustment should be regarded only as an initial step in optimizing the dosage regimen; depending on the patient’s response to the drug, further individualization may be necessary.

Conventionally, clearance is adjusted for the size of the patient to reflect a difference in the mass of the eliminating organ. For orally administered drugs, the applicability of such an adjustment may be limited by the available dosage strengths of commercial formulations. In some cases, scored tablets can be split, or commercial tablet splitters are used to increase the range of available dosage strengths. However, this practice should be followed only with the recommendation of the drug manufacturer because splitting a tablet sometimes can compromise the bioavailability of a product.

With the exception of certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in obese or malnourished individuals. Alternative approaches such as normalization by body surface area or other measures of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area (see Chapter 51). In the tabulation, if the literature reported dose per body surface area, we presented the data in the same unit. If the cited clearance data were not normalized, but the preponderance of the literature utilized body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m² for a healthy adult.

**Volume of Distribution.** Volume of distribution should be adjusted for the modifying factors indicated in Table AII–1 as well as for body size. Again, the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual most often is proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether or not to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends critically on whether or not the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

**Half-Life.** Half-life may be estimated from the adjusted values of clearance ($CL_{pt}$) and volume of distribution ($V_{pt}$) for the patient:

$$t_{1/2} = \frac{0.693 \cdot V_{pt}}{CL_{pt}}$$

(Equation A-4)
Because $t_{1/2}$ has been the parameter most often measured and reported in the literature, qualitative changes for this parameter almost always are given in the table.

**INDIVIDUALIZATION OF DOSAGE**

By using the parameters for the individual patient, calculated as described in the previous section, initial dosing regimens may be chosen. The maintenance dosage rate may be calculated with Equation 1–18, using the estimated values for $CL$ and $F$ for the individual patient. As described earlier, the target concentration may have to be adjusted for changes in plasma-protein binding in the patient, as described in “Plasma-Protein Binding.” The loading dose may be calculated using Equation 1–22 and estimates for $V_{ss}$ and $F$. A particular dosing interval may be chosen; the maximal and minimal steady-state concentrations can be calculated by using Equations 1–20 and 1–19 or 1–21, and these calculated concentrations can be compared with the known efficacious and toxic concentrations for the drug. As with the target concentration, these values may need to be adjusted for changes in the extent of plasma-protein binding. Use of Equations 1–19 and 1–20 also requires estimates of values for $F$, $V_{ss}$, and $K (K = 0.693/t_{1/2})$ for the individual patient.

Note that these adjustments of pharmacokinetic parameters for an individual patient are suggested for the rational choice of initial dosing regimen. As indicated in Chapter 1, steady-state measurement of drug concentrations in the patient then can be used as a guide to further adjust the dosage regimen. However, optimization of a dosage regimen for an individual patient ultimately will depend on the clinical response produced by the drug.
### Pharmacokinetic Data

Key: Unless otherwise indicated by a specific footnote, the data are presented for the study population as a mean value ± 1 standard deviation, a mean and range (lowest-highest in parentheses) of values, a range of the lowest-highest values, or a single mean value. ACE, angiotensin-converting enzyme; ADH, alcohol dehydrogenase; Aged, aged; AIDS, acquired immunodeficiency syndrome; Alb, hypoalbuminemia; Alcohol, chronic consumption of ethanol; Atr Fib, atrial fibrillation; AVH, acute viral hepatitis; Burn, burn patients; Cmax, peak concentration; CAD, coronary artery disease; Celiac, celiac disease; CF, cystic fibrosis; CHF, congestive heart failure; Child, children; COPD, chronic obstructive pulmonary disease; CP, cor pulmonale; CPBS, cardiopulmonary bypass surgery; CRI, chronic respiratory insufficiency; Crohn, Crohn’s disease; Cushing’s, Cushing’s syndrome; CYP, cytochrome P450; F or Fem, female; Hep, hepatitis; HIV, human immunodeficiency virus; HL, hyperlipoproteinemia; HT, hyperthyroid; IM, intramuscular; Infl, inflammation; IV, intravenous; LD, chronic liver disease; LTh, hypothyroid; M, male; MAO, monoamine oxidase; MI, myocardial infarction; NAT, N-acetyltransferase; Neo, neonate; NIDDM, non-insulin-dependent diabetes mellitus; NS, nephrotic syndrome; Obes, obese; PDR, Physicians’ Desk Reference; Preg, pregnant; Prem, premature infants; RA, rheumatoid arthritis; Rac, racemic mixture of stereoisomers; RD = renal disease (including uremia); SC, subcutaneous; Smk, smoking; ST, sulfotransferase; Tmax, peak time; Tach, ventricular tachycardia; UGT, UDP-glucuronosyl transferase; Ulcer, ulcer patients. Other abbreviations are defined in the text section of this appendix.

<tr>
<th>Ambrisentana</th>
<th>99</th>
<th>600 ng/mL</th>
</tr>
</thead>
</table>

Ambrisentana appears to be cleared primarily by the liver; however, the relative contribution from metabolism (glucuronidation and oxidation) versus biliary excretion is unclear. It is exported into the canalicular space of sandwich-cultured hepatocytes, possibly by P-glycoprotein. There also is evidence to suggest that it undergoes active hepatic uptake by organic anion transporting polypeptide (OATP) transporters. The absolute bioavailability is unknown. No IV dose data available; CL/F = 0.27 mL/min/kg following an oral dose in patients with pulmonary arterial hypertension (PAH).

### Amikacin

<table>

<th>Amikacin</th>
<th>98</th>
<th>1.3 ± 0.6</th>
</tr>
</thead>
</table>

CL = 0.6CL_cr ± 0.14

| 26 ± 4 μg/mL |

Amikacin is metabolized predominantly by the liver, with a half-life of approximately 14 hours. It is eliminated primarily via the kidneys. The absolute bioavailability is unknown. Following a 1-hour IV infusion of a 6.3 ± 1.4-mg/kg dose given three times a day to steady state in patients without renal impairment.

<sup>a</sup>Data for amphotericin B shown. <sup>b</sup>Data for eight children (ages 8 months to 14 years) yielded a linear regression, with CL decreasing with age: CL = -0.046 · age (years) + 0.86. Newborns show highly variable CL values. <sup>c</sup>Volume of central compartment, V<sub>c</sub>, increases with dose from 3.4 L/kg for a 0.25-mg/kg dose to 8.9 L/kg for a 1.5-mg/kg dose. Also available as liposomal encapsulated formulations (ABELCET and AMBISOME). Amphotericin distribution and CL properties of these products are different from the nonencapsulated form; they have a terminal t<sub>1/2</sub> of 173 ± 78 and 110-153 hours, respectively; however, an effective steady-state concentration can be achieved within 4 days. <sup>d</sup>t<sub>1/2</sub> for multiple dosing. In single-dose studies, a prolonged dose-dependent t<sub>1/2</sub> is seen. Following a 0.5-mg/kg IV dose of amphotericin B given as a 1-hour infusion, once daily for 3 days. Whole blood concentrations (free and liposome encapsulated) of 1.7 ± 0.8 μg/mL and 83 ± 35 μg/mL were reported following a 5-mg/kg/day IV dose (presumed 60- to 120-minute infusion) of ABELCET and AMBISOME, respectively.

<sup>a</sup>Extensively metabolized, primarily by CYP3A4. No significant gender differences. <sup>b</sup>Exhibits a slightly disproportional increase in AUC with increasing oral dose. Following a single 125-mg oral dose.

---

---

---

---

### Aripiprazole

| 87 | <1 | >99 | 0.83 ± 0.17<sup>b</sup> | 4.9<sup>b</sup> | 47 ± 10 | 3.0 ± 0.6<sup>c</sup> | 242 ± 36 ng/mL<sup>c</sup> |

<sup>a</sup>Eliminated primarily by CYP2D6- and CYP3A4-dependent metabolism. The major metabolite, dehydro-aripiprazole, has affinity for D<sub>2</sub> receptors similar to parent drug; found at 40% of parent drug concentration in plasma; <i>t</i><sub>1/2</i> is 94 hours. CYP2D6 poor metabolizers exhibit increased exposure (80%) to parent drug but reduced exposure (30%) to the active metabolite. No significant gender differences. <sup>b</sup>CL/F and V/F at steady state reported. <sup>c</sup>Following a 15-mg oral dose given once daily for 14 days.

### Atazanavir

| Food | 7 | 86 | 3.4 ± 1.0<sup>c</sup> | 1.6-2.7<sup>c</sup> | 7.9 ± 2.9 | 2.5<sup>d</sup> | 5.4 ± 1.4 μg/mL<sup>d</sup> |

<sup>b</sup>Undergoes extensive hepatic metabolism, primarily by CYP3A. Pharmacokinetic data reported for healthy adults. No significant gender or age differences. <sup>c</sup>Absolute bioavailability is not known, but food enhances the extent of absorption. <sup>d</sup>CL/F and V/F reported. Metabolic elimination affected by inhibitors and inducers of CYP3A. Co-administration with low-dose ritonavir increases systemic atazanavir exposure. <sup>e</sup>Following a 400-mg oral dose given with a light meal once daily to steady state.

### Atenolol

| 58 ± 16 | 94 ± 8 | <5 | 2.4 ± 0.3 | 1.3 ± 0.5<sup>b</sup> | 6.1 ± 2.0<sup>c</sup> | 3.3 ± 1.3<sup>d</sup> | 0.28 ± 0.09 μg/mL<sup>d</sup> |

<sup>a</sup>Atenolol is administered as a racemic mixture. No significant differences in the pharmacokinetics of the enantiomers. <sup>b</sup>V<sub>area</sub> reported. <sup>c</sup>1/2 of <i>R</i>- and <i>S</i>-atenolol are similar. <sup>d</sup>Following a single 50-mg oral dose.

### Atomoxetine

| 63<sup>b</sup> | 1-2% | 98.7 ± 0.3 | 6.2<sup>b</sup> | 0.60<sup>b</sup> | 2.3<sup>b</sup> | 11.1<sup>b</sup> | 5.3<sup>b</sup> | 2<sup>c</sup> | 160 ng/mL<sup>f</sup> | 915 ng/mL<sup>f</sup> |

<sup>a</sup>Metabolized by CYP2D6 (polymorphic). Poor metabolizers (PM) exhibit a higher oral bioavailability, higher C<sub>max</sub>, lower CL, and longer <i>t</i><sub>1/2</sub> than extensive metabolizers (EM). No differences between adults and children >6 years of age. <sup>b</sup>CL/F, V/F, and <i>t</i><sub>1/2</sub> measured at steady state. <sup>c</sup>Following a 20-mg oral dose given twice daily for 5 days.

<sup>a</sup>Data from healthy adult male and female subjects. No clinically significant gender differences. Atorvastatin undergoes extensive CYP3A-dependent first-pass metabolism. Metabolites are active and exhibit a longer t<sub>1/2</sub> (20-30 hours) than parent drug. <sup>b</sup>Mean CL/F parameter calculated from reported AUC data at steady state after a once-a-day 20-mg oral dose, assuming a 70-kg body weight. <sup>c</sup>AUC following oral administration increased, mild to moderate hepatic impairment. <sup>d</sup>Following a 20-mg oral dose once daily for 14 days.

<sup>a</sup>Azathioprine is metabolized to mercaptopurine (MP), listed later in this table. <sup>b</sup>Determined as the bioavailability of MP; intact azathioprine is undetectable after oral administration because of extensive first-pass metabolism. Kinetic values are for IV azathioprine. <sup>c</sup>Data from kidney transplant patients. <sup>d</sup>MP concentration following a 135 ± 34-mg oral dose of azathioprine given daily to steady state in kidney transplant patients.

<sup>a</sup>Azathioprine undergoes extensive CYP3A-dependent first-pass metabolism. Metabolites are active and exhibit a longer t<sub>1/2</sub> (20-30 hours) than parent drug. <sup>b</sup>Mean CL/F parameter calculated from reported AUC data at steady state after a once-a-day 20-mg oral dose, assuming a 70-kg body weight. <sup>c</sup>AUC following oral administration increased, mild to moderate hepatic impairment. <sup>d</sup>Following a 20-mg oral dose once daily for 14 days.

<sup>a</sup>Measure of ultrafilterable platinum, which essentially is unchanged carboplatin. <sup>b</sup>Following a single 170 to 500-mg/m² IV dose (30-minute infusion) given to adult patients with ovarian cancer.

<sup>4</sup>Racemic mixture: S(-)-enantiomer responsible for β<sub>1</sub> adrenergic–receptor blockade. R(+)– and S(-)-enantiomers have nearly equivalent α<sub>1</sub>-receptor blocking activity. <sup>R</sup>(+)-enantiomer is more tightly bound than the S(-)-antipode. <sup>c</sup>Longer t<sub>1/2</sub> of ~6 hours has been measured at lower concentrations. <sup>d</sup>Following a 12.5-mg oral dose given twice a day for 2 weeks to healthy young adults.

<sup>a</sup>Area under the curve. <sup>4</sup>Following a single 1-g IV (model-fitted C<sub>max</sub>) or IM dose to healthy adults.

*Ceftriaxone is most commonly administered by IV or IM injection and cleared unchanged by both renal and biliary excretion. *bValue for a 2-g IV dose; similar values reported for 0.5- and 1-g doses. *cExhibits saturable binding. *dStudy in patients with mild to severe hepatic impairment. *eTotal clearance and distribution volume vary with dose and plasma free fraction; however, the unbound concentration at steady state is dose proportional. Mean t1/2 values for 0.5- to 2-g doses not significantly different. Study in anephric patients with normal nonrenal clearance. Much greater increases seen in patients with both renal and hepatic disease. *hImpact of liver disease is limited by apparent offsetting changes in plasma-free fraction and unbound intrinsic clearance. *iFollowing twice-daily dosing to steady state.

<sup>a</sup>Data from healthy male and female subjects receiving cetirizine (Rac) or the active R-enantiomer, levocetirizine (Levo). <sup>b</sup>Based on recovery of unchanged drug in urine. <sup>c</sup>CL/F, V<sub>F</sub>/F reported for oral dose. <sup>d</sup>CL/F reduced, hepatocellular and cholestatic liver diseases. <sup>e</sup>CL/F reduced, moderate to severe renal impairment. <sup)f</sup>CL/F increased, ages 1-5 years. <sup>g</sup>Following a single 10-mg oral dose of Rac or 5 mg of Levo.

### Chloroquine

| S | 66.6 ± 3.3<sup>c</sup> |
| R | 42.7 ± 2.1 |
| 3.7-13<sup>b</sup> |

| 132-261<sup>b</sup> |
| 10-24 days<sup>b,d</sup> |
| IM: 0.25<sup>e</sup> |
| PO: 3.6 ± 2.0<sup>e</sup> |
| IV: 837 ± 248 ng/mL |
| IM: 57-480 ng/mL |
| PO: 76 ± 14 ng/mL |

<sup>a</sup>Active metabolite, desethylchloroquine, accounts for 20 ± 3% of urinary excretion; t<sub>1/2</sub> = 15 ± 6 days. Racemic mixture; kinetic parameters for the two isomers are slightly different [e.g., mean residence time = 16.2 days and 11.3 days for the R-isomer and S-isomer, respectively].<sup>b</sup>Range of mean values from different studies (IV administration).<sup>c</sup>Concentrates in red blood cells. Blood-to-plasma concentration ratio for racemate = 9. A longer t<sub>1/2</sub> (41 ± 14 days) has been reported with extended blood sampling. Following a single 300-mg IV dose (24-minute infusion) of chloroquine HCl or a single 300-mg IM or oral dose of chloroquine phosphate given to healthy adults. Effective concentrations against *Plasmodium vivax* and *Plasmodium falciparum* are 15 ng/mL and 30 ng/mL, respectively. Diplopia and dizziness can occur >250 ng/mL.

### Chlorpheniramine

| 41 ± 16 |
| 0.3-26<sup>b</sup> |
| 70 ± 3 |
| 1.7 ± 0.1 |
| 3.2 ± 0.3 |
| 20 ± 5 |
| IR: 2-3<sup>e</sup> |
| IR: 16-71 ng/mL<sup>c</sup> |

<sup>a</sup>Administered as a racemic mixture; reported parameters are for racemic drug. Activity comes predominantly from S-(+)-enantiomer, which has a 60% longer t<sub>1/2</sub> than the R-(−)-enantiomer. <sup>b</sup>Renal elimination increases with increased urine flow and lower pH. <sup>c</sup>Range of data from different studies following a 4-mg oral immediate-release (IR) dose given every 4-6 hours to steady state or following an 8-mg oral sustained-release (SR) dose given every 12 hours to steady state, both in healthy adults.

<sup>a</sup>Clindamycin hydrochloride given orally. <sup>b</sup>\(V_{area}\) reported. <sup>c</sup>Following a 1200-mg IV dose (30-minute infusion) of clindamycin phosphate (prodrug) given twice daily to steady state in healthy adult women. <sup>d</sup>Following a single 150-mg oral dose of clindamycin hydrochloride to adults.

| Clonazepam | | | | | | | |
| 98 ± 31 | <1 | 86 ± 0.5 | 1.55 ± 0.28<sup>a,b</sup> | 3.2 ± 1.1 | 23 ± 5 | PO: 2.5 ± 1.3<sup>c</sup> | IV: 3-29 ng/mL<sup>c</sup> |
| | | | | | | PO: 17 ± 5.4 ng/mL<sup>c</sup> |

<sup>a</sup>CL/F reported; this value is consistent for a number of studies but is higher than the \(CL\) determined in a single study of IV administration. <sup)b</sup>Metabolized by CYP3A. <sup>c</sup>Range of \(C_{max}\) values following a single 2-mg IV dose (model-fitted for bolus dose) or mean following a 2-mg oral dose (tablet) given to healthy adults. Most patients, including children whose seizures are controlled by clonazepam have steady-state concentrations of 5-70 ng/mL. However, patients who do not respond and those with side effects achieve similar levels.

| Clonidine | | | | | | | |
| PO: 95 | 62 ± 11 | 20 | 3.1 ± 1.2 | 2.1 ± 0.4 | 12 ± 7 | PO: 2<sup>a</sup> | PO: 0.8 ng/mL<sup>a</sup> |
| TD: 60 | | | ↓ RD | | ↑ RD | TD: 72<sup>a</sup> | TD: 0.3-0.4 ng/mL<sup>a</sup> |

<sup>a</sup>Mean data following a 0.1-mg oral dose given twice a day to steady state or steady-state concentration \((C_{ss})\) following a 3.5-cm<sup>2</sup> transdermal (TD) patch administered to normotensive male adults. Concentrations of 0.2-2 ng/mL are associated with a reduction in blood pressure; >1 ng/mL will cause sedation and dry mouth.

### Clopidogrel

|  | Clopidogrel (Clo) is a prodrug that is converted to a minor unstable active metabolite (AM) via two sequential cytochrome P450-dependent reactions. The majority of the dose gets converted rapidly to an inactive hydrolytic product by esterases. Although multiple P450 isoforms contribute to the formation of AM, blood levels of AM have been associated with the CYP2C19 genotype and phenotype status, with poor metabolizers (PM) exhibiting lower levels, on average, than extensive metabolizers (EM). Formation of AM accounts for ≤10% of the administered dose and may be dose dependent due to saturable metabolism. The absolute bioavailability of Clo is unknown. There is one report of food greatly enhancing the systemic exposure of Clo following oral administration. The reported value may represent disappearance of high levels of metabolite formed during first-pass and not the terminal t_{1/2}, which should be formation limited. Following a single 300-mg loading dose of Clo. |

### Clorazepate

|  | Clorazepate is essentially a prodrug for nordiazepam (N). Bioavailability, T_{max}, and C_{max} values for N were derived after oral administration of clorazepate. Significantly different for male subjects only. Clo, V_{ss}, and t_{1/2} values are for IV nordiazepam. Data for N following a 20-mg IM dose of clorazepate given to nonpregnant women. |

<sup>a</sup>Codeine is metabolized by CYP2D6 (polymorphic) to morphine. Analgesic effect is thought to be due largely to derived morphine. <sup>b</sup>Oral/IM bioavailability reported. <sup>c</sup>CL/F and V<sub>area</sub>/F reported. <sup>d</sup>Data for codeine (C) and morphine (M) following a 60-mg oral codeine dose given three times daily for 7 doses to healthy male adults.

| Cyclobenzaprine<sup>a</sup> | | | | | | | | |
|--------------------------|---|---|---|---|---|---|---|
| IR: 55 (51-60) | 93 | 9.8 ± 3.1 | 18 (8-37)<sup>f</sup> | IR: 3.9 ± 1.8<sup>g</sup> | IR: 26 ± 11 ng/mL<sup>g</sup> |
| ER: —<sup>b</sup> | | | | | | | |
| | | ↓ Aged<sup>c</sup> | ↑ LD<sup>d</sup> | | | |

<sup>a</sup>Cleared primarily by cytochrome P450-dependent metabolism; multiple isoforms involved, including CYP3A4 and CYP1A2. Both immediate-release (IR) and extended-release (ER) products available. <sup>b</sup>Similar systemic exposure from a single 30-mg ER dose and three 10-mg IR doses. <sup>c</sup>For both IR and ER products, systemic exposure is increased in the elderly, compared to young adults. <sup>d</sup>Study in patients with mild to moderate hepatic impairment. <sup>e</sup>No published value available; V<sub>β</sub> estimated from reported mean clearance and t<sub>1/2</sub> = 15.3 L/kg. <sup>f</sup>Apparent t<sub>1/2</sub> of ER product: 32 ± 10 hours. <sup>g</sup>Following the 10-mg IR product given three times daily to steady state in young adults. <sup>h</sup>Following a single dose of the 30-mg ER product in young adults.

| Cyclophosphamide<sup>a</sup> | | | | | | | | |
|-----------------------------|---|---|---|---|---|---|---|
| 74 ± 22 | 6.5 ± 4.3 | 13 | 1.3 ± 0.5 | 0.78 ± 0.57 | 7.5 ± 4.0 | — | 121 ± 21 μM<sup>b</sup> |
| | | | | | | | |

<sup>a</sup>Cyclophosphamide is primarily activated by CYP2C9 to hydroxycyclophosphamide. The metabolite is further converted to the active alkylating species, phosphoramid mustard (t<sub>1/2</sub> = 9 hours) and nonnitrogen mustard (apparent t<sub>1/2</sub> = 3.3 hours). Kinetic parameters are for cyclophosphamide. <sup>b</sup>Following a 600-mg/m² IV (bolus) dose given to breast cancer patients.

**Notes:**

- Available for IV administration only. bChanges reported for patients with severe renal impairment. cC_{max} at the end of a 30-minute IV infusion of a 6-mg/kg dose given once daily for 7 days. No significant accumulation with multiple dosing.

**References:**

- Darunavir should be taken in combination with ritonavir, a potent CYP3A and P-glycoprotein inhibitor, which profoundly increases systemic exposure to darunavir. Data reported are for combined administration of darunavir (IV or oral) with 100-mg oral ritonavir, twice daily. bSystemic exposure increased 42% when taken with a meal. cStudy in patients with mild to moderate liver impairment. dStudy in patients with moderate renal impairment. eFollowing 600-mg darunavir once daily and 100-mg ritonavir twice daily, steady state; C_{trough} = 3.5 (1.6-7.4) μg/mL.

**References:**

- Amphetamine is available as a racemate (Rac), dextro-isomer (Dextro), and a mixture of the two, in both immediate- and extended-release formulations. Pharmacokinetic data on both racemic and dextroamphetamine are presented. bAbsolute bioavailability not reported; >55% based on urine recovery of unchanged drug under acidic urinary pH conditions. cMeasured under uncontrolled urinary pH condition. Renal CL of amphetamine is dependent on urine pH. Acidification of urine results in increased urinary excretion, up to 55%. dCL/F and t_{1/2} following oral dose to adults is reported. t_{1/2} in children reported. fFollowing a 20-mg immediate-release oral dose given once daily for >1 week. An extended-release formulation consisting of a mixture of dextroamphetamine and amphetamine salts (ADDERALL XR) exhibits a delayed T_{max} of ~7 hours.

<sup>a</sup>Cleared primarily by cytochrome P450-dependent metabolism; evidence suggests polymorphic CYP2C9 is a major contributor. <sup>b</sup>Somewhat lower values (2.8-3.5 mL/min/kg) also were reported, but a higher systemic clearance is most consistent with the low oral bioavailability. <sup>c</sup>Study in long-term users of THC. <sup>d</sup>Exhibits biphasic kinetics; the longer terminal elimination phase most likely represents redistribution from fatty tissue. <sup>e</sup>No change in terminal (redistribution) *t*<sub>1/2</sub>. Following a 5-mg dose given twice daily to steady state.

### Duloxetine

Cleared primarily by CYP3A-dependent metabolism. *Systemic exposure increased 20-30% with high-fat meal. *Data from patients with HIV infection. No significant gender differences. Metabolized primarily by CYP2B6 and to a lesser extent by CYP2A6 and through N-glucuronidation. *Absolute oral bioavailability is unknown. Oral AUC increased 50% with high-fat meal. *Single dose (SD) data reported for CL/F and both SD and multiple dose (MD) data for t1/2. Efavirenz is a weak inducer of CYP3A4 and its own metabolism. *3-16 years of age, no difference in weight-adjusted CL/F compared to adult. *Following a 600-mg oral dose given daily to steady state.

</thead>
</table>

\(^a\) Hydrolyzed by esterases to the active metabolite, enalaprilic acid (enalaprilat); except when noted, pharmacokinetic values and disease comparisons are for enalaprilat, following oral enalaprilat administration. \(^b\) For IV enalaprilat. \(^c\) \(CL/F\) and \(V_{ss}/F\) after multiple oral doses of enalaprilat. Values after single IV dose of enalaprilat are misleading because binding to ACE leads to a prolonged \(t_{1/2}\), which does not represent a significant fraction of the \(CL\) upon multiple dosing. \(^d\) Estimated from the approach to steady state during multiple dosing. \(^e\) Mean values for enalaprilat following a 10-mg enalapril oral dose given daily for 8 days to healthy young adults. The \(EC_{50}\) for ACE inhibition is 5-20 nM enalaprilat.

### Enoxaparina

<table>
<thead>
<tr>
<th></th>
<th>↓ RD</th>

<td>(\leftrightarrow RD, LD)</td>
</tr>
<tr>
<td>(\uparrow LD)^c</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

\(^a\)Data from healthy male subjects. Eliminated primarily by biliary excretion. \(^b\)The bioavailability of entacapone appears to be dose dependent (increases from 29–46% over a 50- to 800-mg dose range). \(^c\)Increased bioavailability, moderate hepatic impairment with cirrhosis. \(^d\)Value represents the \(t_{1/2}\) for the initial distribution phase, during which 90% of a dose is eliminated. The terminal \(t_{1/2}\) is 2.9 ± 2.0 hours. \(^e\)Following a single 400-mg oral dose. No accumulation with multiple dosing.

### Eplerenone\(^a\)

<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>—</td>
<td>7(^b)</td>
<td>33-60(^c)</td>
<td>2.4(^d)</td>
<td>(\downarrow CHF, LD)</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

\(^a\)Eplerenone is converted (reversibly) to an inactive ring-open hydroxy acid. Both eplerenone (E) and the hydroxy acid (EA) circulate in plasma; concentrations of E are much higher than EA. Irreversible metabolism is catalyzed predominantly by CYP3A4. Data for E in healthy male and female volunteers reported; no significant gender differences. \(^b\)Recovered as E and EA following an oral dose. \(^c\)Protein binding is concentration dependent over the therapeutic range; lower at the highest concentration. \(^d\)\(CL/F\) and \(V_{ss}/F\) reported. \(^e\)Following a 50-mg oral dose given once daily for 7 days.

### Erlotinib\(^a\)

<p>| | | | | |</p>
<table>
<thead>
<tr>
<th></th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>59 (55-66)</td>

\(^a\)Racemic mixture; \(S-(-)-\) enantiomer is an active Ca\(^{2+}\) channel blocker; different enantiomer pharmacokinetics result in \(S-(-)-\) enantiomer concentrations about 2-fold higher than those of \(R-(+)-\) isomer. \(^b\)Undergoes significant CYP3A-dependent first-pass metabolism in the intestine and liver. \(^c\)May be age related rather than CHF related. \(^d\)Following a 10-mg oral immediate-release (IR) or extended-release (ER) tablet given twice daily to steady state in healthy subjects. \(EC_{50}\) for diastolic pressure decrease is 8 ± 5 nM in patients with hypertension. 

### Fenofibrate\(^a\)

</tr>
</tbody>
</table>

\(^a\)Fenofibrate is a prodrug that is hydrolyzed by esterases to fenofibric acid, the pharmacologically active compound. All values reported are for fenofibric acid. \(^b\)Absolute bioavailability is not known. Recovery of radiolabeled dose in urine as fenofibric acid and its glucuronide is 60%. Immediate-release (IR) tablet and micronized (Mic) capsule are bioequivalent. Bioavailability is increased when taken with a standard meal. \(^c\)Recovery following oral dose. \(^d\)CL/F and V/F reported. \(^e\)Following a 300-mg IR fenofibrate tablet given once daily to steady state. \(^f\)Following a 200-mg Mic capsule given once daily to steady state.

### Fentanyl

<th>F: 200-531 ng/mL&lt;sup&gt;f&lt;/sup&gt;</th>
</tr>
</thead>
</table>

<sup>a</sup>Active metabolite, norfluoxetine; t<sub>1/2</sub> of norfluoxetine is 6.4 ± 2.5 days (12 ± 2 days in cirrhosis). Absolute bioavailability is unknown, but ≥80% of the dose is absorbed.<sup>b</sup>Reduced CL with repetitive dosing (~2.6 mL/min/kg) and with increasing dose between 40 and 80 mg.<sup>c</sup>CL/F reported; fluoxetine is a CYP2D6 substrate and inhibitor. V<sub>bio</sub>/F reported. <sup>d</sup>Longer t<sub>1/2</sub> with repetitive dosing and with increasing doses.<sup>e</sup>Range of data for fluoxetine (F) and norfluoxetine (NF) following a 60-mg oral dose given once daily for 1 week. NF continues to accumulate for several weeks.

### Fluphenazine<sup>a</sup>

<table>
<thead>
<tr>
<th></th>
<th></th>
<th>10 ± 7</th>
<th>11 ± 10</th>
<th>IV: 12 ± 4&lt;sup&gt;c&lt;/sup&gt;</th>
<th>IR: 14.4 ± 7.8&lt;sup&gt;e&lt;/sup&gt;</th>
<th>DN: 24-48&lt;sup&gt;d&lt;/sup&gt;</th>
<th>DN: 1.3 ng/mL&lt;sup&gt;d&lt;/sup&gt;</th>
</tr>
</thead>
</table>

<sup>a</sup>Data from healthy male and female volunteers. Fluphenazine is extensively metabolized.<sup>b</sup>Available in immediate-release (IR) oral and IM formulations and depot SC or IM injections as the enanthate (EN) or decanoate (DN) esters. Geometric mean (90% confidence interval).<sup>c</sup>Reported t<sub>1/2</sub> for a single IV dose and apparent t<sub>1/2</sub> following oral administration of IR and slow-release (SR) formulations. Longer apparent t<sub>1/2</sub> with oral dosing reflect an absorption-limited elimination.<sup>d</sup>Following a single 12-mg oral dose (IR) or 5-mg IM injections of DN and EN.

### Flutamide<sup>a</sup>

<table>
<thead>
<tr>
<th></th>
<th>&lt;1</th>
<th>F: 94-96&lt;sup&gt;b&lt;/sup&gt;</th>
<th>280&lt;sup&gt;b&lt;/sup&gt;</th>

<th>F: 1.3 ± 0.7&lt;sup&gt;c&lt;/sup&gt;</th>
<th>F: 0.11 ± 0.21 μg/mL&lt;sup&gt;c&lt;/sup&gt;</th>
</tr>
</thead>
</table>

<sup>a</sup>Data obtained primarily from elderly men. Flutamide (F) is metabolized rapidly to a number of metabolites, which are mainly excreted in urine. One major metabolite, 2-hydroxyflu- tamide (HF), is biologically active (equal potency); formation is catalyzed primarily by CYP1A2. <sup>b</sup>CL/F and t<sub>1/2</sub> (terminal) reported for oral dose.<sup>c</sup>Data for F and HF following a 250-mg oral dose given three times daily to steady state in healthy geriatric male volunteers.

<sup>a</sup>Renal CL reported, which should approximate total plasma CL. <sup>b</sup>Changes may reflect decreased renal function. <sup>c</sup>V<sub>area</sub> calculated from individual values of renal CL, terminal t<sub>1/2</sub>, and fraction of drug excreted unchanged; 70-kg body weight assumed. <sup>d</sup>Longer terminal t<sub>1/2</sub> of 8 ± 2.8 hours has been reported with a corresponding increase in V<sub>area</sub> to 2.8 L/kg. <sup>e</sup>Following a single (SD) or multiple (MD) 12.5-mg oral dose of hydrochlorothiazide; MD given once daily for 5 days to healthy adults.

### Hydrocodone<sup>a</sup>

| PO: 42 ± 23 | 6 | 7.1 | 14.6 ± 7.6 | 2.90 ± 1.31<sup>b</sup> | 2.4 ± 0.6 | IV: —<sup>c</sup> | PO: 1.1 ± 0.2<sup>c</sup> | IV: 242 ng/mL<sup>e</sup> |

<sup>a</sup>Data from healthy male and female subjects. The metabolism of hydrocodone to hydromorphone (more active) is catalyzed by CYP2D6. Subjects were phenotyped as extensive metabolizers (EM) and poor metabolizers (PM). V<sub>area</sub>, CL/F and t<sub>1/2</sub> reported for oral dose. Following a 10-mg oral dose (syrup). Maximal hydromorphone concentrations are higher in EM than in PM (5.2 versus 1.0 ng/mL).

### Hydromorphone<sup>a</sup>

| PO: 42 ± 23 | 6 | 7.1 | 14.6 ± 7.6 | 2.90 ± 1.31<sup>b</sup> | 2.4 ± 0.6 | IV: —<sup>c</sup> | PO: 1.1 ± 0.2<sup>c</sup> | IV: 242 ng/mL<sup>e</sup> |

<sup>a</sup>Data from healthy male subjects. Extensively metabolized. The principal metabolite, 3-glucuronide, accumulates to much higher (27-fold) levels than the parent drug and may contribute to some side effects (not antinociceptive). V<sub>area</sub> reported. Following a single 2-mg IV (bolus, sample at 3 minutes) or 4-mg oral dose.

### Hydroxychloroquinena

Hydroxychloroquine is marketed as a racemic mixture of R- and S-hydroxychloroquine. Data for the racemic mixture is reported. Plasma clearance is reported. Hydroxychloroquine accumulates in red blood cells with an average blood-to-plasma ratio of 7.2. Blood clearance of hydroxychloroquine is 1.3 mL/min/kg. Following oral administration of a single 155-mg tablet.

### Hydroxyurea

Hydroxyzine is metabolized to an active metabolite, cetirizine. Plasma concentrations of cetirizine exceed those of the parent drug; its t<sub>1/2</sub> is similar to that of hydroxyzine when formed from parent drug. Hydroxyurea data for adults (A) and children (C) are reported. CL<sub>F</sub>, V<sub>F</sub>, and t<sub>1/2</sub> after oral dose reported. t<sub>1/2</sub> increases with increasing age (1-15 years of age). Following a single 0.7-mg/kg oral dose given to healthy adults and children.

<sup>a</sup>Racemic mixture. Kinetic parameters for the active <i>S</i>-(+)-enantiomer do not differ from those for the inactive <i>R</i>-(–)-enantiomer when administered separately; 63 ± 6% of the <i>R</i>-(–)-enantiomer undergoes inversion to the active isomer. <sup>b</sup>Unbound percent of <i>S</i>-(+)-ibuprofen (0.77 ± 0.20%) is significantly greater than that of <i>R</i>-(–)-ibuprofen (0.45 ± 0.06%). Binding of each enantiomer is concentration dependent and is influenced by the presence of the optical antipode, leading to nonlinear elimination kinetics. <sup>c</sup>CL/F and <i>V</i>₅₀/F reported. <sup>d</sup>Following a single 800-mg dose of racemate. A level of 10 µg/mL provides antipyresis in febrile children.

| **Idarubicin**<sup>a</sup> |                      |                     |                       |                  |                  |                  |                   |

|                  | ↔ Aged         | ↔ Prem, Neo, Aged |
|                  | 2.4 ± 0.2      | 0.29 ± 0.04  |
|                  | ~1.3           | ~1.3         |
|                  | ~2.4 µg/mL     | ~2.4 µg/mL   |

*Undergoes significant enterohepatic recycling (~50% after an IV dose). Following a single 50-mg oral dose given after a standard breakfast. Effective at concentrations of 0.3-3 µg/mL and toxic at >5 µg/mL.

**Interferon Alfa**

|                  | I-SC: 90       | PI12kD: 0.17 |
|                  | —              | 0.014-0.024  |
|                  | I: 1.7(1.2-2.3) ng/mL | 0.91 ± 0.33 ng/mL |
|                  | PI12kD: 0.17 | 26 ± 8.8 ng/mL |

*Values for recombinant interferon alfa-2a (I) and its 40-kDa pegylated form (PI12kD) and the 12-kDa pegylated form of interferon alfa-2b (PI40kD) are reported. I undergoes renal filtration, tubular reabsorption, and proteolytic degradation within tubular epithelial cells. Renal elimination of I forms is much less significant than that of I, although not negligible. CL values in four patients with leukemia were more than halved (1.1 ± 0.3 mL/min/kg), while $V_s$ increased more than 20-fold (9.5 ± 3.5 L/kg) and terminal $t_{1/2}$ changed only minimally (7.3 ± 2.4 hours). A terminal $t_{1/2}$ of 5.1 ± 1.6 hours accounts for 23% of the CL of I. Following a single 36 x 106 units SC dose of I. Following 4 weeks of multiple SC dosing of 1 µg/kg of PI12kD. Following 48 weekly SC doses of 180 µg of PI40kD.

* Racemic mixture; S(−)-enantiomer is much more active than the R(+)-enantiomer. Following IM injection, the mean AUC ratio for S/R-enantiomers was 0.44 ± 0.04, indicating a higher CL and shorter *t 1/2 for the S(−)-enantiomer. Values reported are for the racemate.  
* Probably due to the accumulation of glucuronide metabolite, which is hydrolyzed back to parent drug.  
* Range of mean *C<sub>max</sub> and *T<sub>max</sub> from different studies following a single 30-mg IM or 10-mg oral dose in healthy adults.

* Leflunomide is a prodrug that is converted almost completely (~95%) to an active metabolite A77–1726 (2-cyano-3-hydroxy-N-(4-trifluoromethylphenyl)-crotonamide). All pharmacokinetic data reported are for the active metabolite.  
* Absolute bioavailability is not known; parent drug/metabolite are well absorbed.  
* Apparent *CL/F and *V/F in healthy volunteers reported. Both parameters are a function of the bioavailability of leflunomide and the extent of its conversion to A77–1726.  
* In patients with RA.  
* Following a 20-mg oral dose given once daily to steady state in patients with RA.

<sup>a</sup>Racemic mixture; no information on relative kinetics of the enantiomers.  
<sup>b</sup>Absolute bioavailability is not known; reported values of >85% represent comparison of oral tablet to solution.  
<sup>c</sup>CL/F and V<sub>ss</sub>/F reported.  
<sup>d</sup>Range of mean values from different studies following a single 1000-mg oral dose (SD) and mean following a 250-mg oral dose given once weekly for 4 weeks (MD).  

Memantine<sup>a</sup>

Cleared primarily by the kidney and to a lesser extent by non-cytochrome P450-dependent metabolism.  
After a 20-mg single oral dose.  
CL/F reported.  
Study in patients with moderate to severe renal impairment.  
V<sub>ss</sub>/F reported.  
Study in patients with severe renal impairment.  
Following a single 20-mg oral dose.

Meperidine<sup>a</sup>

Meperidine undergoes cytochrome P450-dependent N-demethylation to normeperidine. The metabolite is not an analgesic but is a potent central nervous system–excitatory agent and is associated with adverse side effects of meperidine.  
Meperidine is a weak base (pK<sub>a</sub> = 8.6) and is excreted to a greater extent in the urine at low urinary pH and to a lesser extent at high urinary pH.  
Correlates with the concentration of α<sub>1</sub>-acid glycoprotein.  
A longer t<sub>1/2</sub> (7 hours) also is observed.  
Following a continuous 24-mg/hr IV infusion or 100-mg IM injection every 4 hours to steady state. Postoperative analgesia occurs at 0.4-0.7 μg/mL.

<sup>a</sup>Plasma concentrations of the 7-hydroxy metabolite approach those of the parent drug. Metabolite may have both therapeutic and toxic effects. Bioavailability is dose dependent and may be as low as 20% when doses are >80 mg/m². IM bioavailability is only slightly higher. Exhibits triexponential elimination kinetics. A shorter t₁/₂ (2 hours) is seen initially, and a longer (52 hours) terminal t₁/₂ has been observed with increased assay sensitivity. Following a 15-mg SC dose given once weekly to steady state in adult patients with inflammatory bowel disease. Initial steady-state concentrations in young (1-22 years of age) leukemia patients receiving a 500-mg/m² loading dose given over 1 hour followed by an infusion of 196 mg/m²/hr for 5 hours.

*Data for racemic mixture reported. Metabolism of less active R- (+)-enantiomer (CL/F = 28 mL/min/kg; V<sub>area</sub>/F = 7.6 L/kg; t<sub>1/2</sub> = 2.7 hours) is slightly faster than that of more active S-(-)-enantiomer (CL/F = 20 mL/min/kg; V<sub>area</sub>/F = 5.5 L/kg; t<sub>1/2</sub> = 3 hours). Metabolically cleared by CYP2D6 (polymorphic). Compared to extensive metabolizers (EM), individuals who are poor metabolizers (PM) have a lower CL/F, and a longer t<sub>1/2</sub> (7.6 ± 1.5 versus 2.8 ± 1.2 hours) and excrete more unchanged drug in urine (15 ± 7% versus 3.2 ± 3%) due to reduced hepatic metabolism. t<sub>1/2</sub> hours following a single 100-mg oral dose in CYP2D6 EM and PM patients with hypertension. Plasma concentrations of the more active S-enantiomer are ~35% higher than the R-antipode in CYP2D6 EM. No stereochemical difference was observed in PM subjects. EC<sub>50</sub> for decreased heart rate during peak submaximal exercise testing was 16 ± 7 ng/mL; EC<sub>50</sub> for decreased systolic blood pressure during exercise testing was 25 ± 18 ng/mL.*

<sup>a</sup>Active hydroxylated metabolite accumulates in renal failure. <sup>b</sup>Bioavailability is 67-82% for rectal suppositories and 53 ± 16% for intravaginal gel. <sup>c</sup>Following a single 100-mg dose of vaginal (VA) cream, a 100-mg IV infusion over 20 minutes three times daily to steady state, or a 100-mg oral dose three times daily to steady state. 

<sup>a</sup>Undergoes arylsulfatase-dependent metabolism and biliary excretion. <sup>b</sup>Study in patients with moderate liver impairment; no difference in weight-adjusted clearance. <sup>c</sup>Study in patients with CL<sub>cr</sub> <30 mL/min. <sup>d</sup>Following a 100-mg IV infusion administered over 1 hour.

<sup>a</sup>Metabolically cleared exclusively by CYP3A. <sup>b</sup>Undergoes extensive first-pass metabolism by intestinal and hepatic CYP3A. Bioavailability appears to be dose dependent; 35-67% at 15-mg, 28-36% at 7.5-mg, and 12-47% at 2-mg oral dose, possibly due to saturable first-pass intestinal metabolism. <sup>c</sup>Increased CL due to increased plasma free fraction; unbound CL is unchanged. <sup>d</sup>Following a single 5-mg IV bolus or 10-mg oral dose.

\(^a\)Modafinil is available either as a racemic mixture or as the pure (R)-enantiomer armodafinil. Pharmacokinetic data after dosing of racemate (Rac) or armodafinil (Arm) is reported. Modafinil is extensively metabolized in the liver to two major metabolites, modafinil acid and modafinil sulfone. \(\text{CL/F} = 0.72 ± 0.10 \text{mL/min/kg and } V/F = 0.77 ± 0.11 \text{L/kg after an oral dose of racemic modafinil.}\)

\(^b\)The exposure to Arm is 40% higher than that of racemic modafinil after equal oral doses. Arm \(\text{CL/F} = 0.47 \text{mL/min/kg and } V/F = 0.6 \text{L/kg.}\)

\(^c\)Study in patients with moderate to severe liver impairment receiving oral racemic modafinil; \(\text{CL/F reduced by 60\% and steady-state concentrations doubled in patients with liver impairment.}\)

\(^d\)Following a 200-mg single oral dose of modafinil or Arm.

| Montelukast\(^b\) | | | | | | | |
| 62 | <0.2 | >99 | 0.70 ± 0.17 | 0.15 ± 0.02 | 4.9 ± 0.6 | 3.0 ± 1.0 \(^d\) | 542 ± 173 ng/mL \(^d\) |
| \(\downarrow LD\) | \(\leftrightarrow \text{ Child}\) \(^c\) | | | | \(\uparrow LD\) | | |

\(^b\)Data from healthy adult subjects. No significant gender differences. Montelukast is metabolized by CYP3A4 and CYP2C9. \(\text{CL/F is reduced by 41\%, mild to moderate hepatic impairment with cirrhosis.}\)

\(^c\)Similar plasma profile with 5-mg chewable versus 10-mg tablet in adults. \(^d\)Following a single 10-mg oral dose.

| Morphine\(^a\) | | | | | | | |
| PO: 24 ± 12 | 4 ± 5 | 35 ± 2 | 24 ± 10 \(\leftrightarrow \text{ Aged, LD, Child}\) \(^b\) \(\downarrow \text{ Neo, Burn, RD, Prem}\) | 3.3 ± 0.9 \(\leftrightarrow \text{ LD, Neo}\) \(\leftrightarrow \text{ LD, RD, Child}\) | 1.9 ± 0.5 \(\leftrightarrow \text{ PO-IR: 0.5–1.5}\) \(^c\) | IM: 0.2–0.3 \(^c\) | IV: 200–400 ng/mL \(^c\) |
| IM: ~100 | | | \(\downarrow \text{ RD}\) | | | IM: ~70 ng/mL \(^e\) | |

\(^a\)Active metabolite, morphine-6-glucuronide; Urinary excretion = 14 ± 7%; \(t_{1/2} = 4.0 ± 1.5\) hours. Steady-state ratio of active metabolite to parent drug after oral dosing = 4.9 ± 3.8. In renal failure, \(t_{1/2}\) increases to 50 ± 37 hours, resulting in significant accumulation of active glucuronide metabolite. \(^b\)Decreased in children undergoing cardiac surgery requiring inotropic support.

\(^c\)Following a single 10-mg IV dose (bolus with 5-minute blood sample), a 10-mg/70-kg IM, a 10-mg/70-kg immediate-release oral (PO-IR) dose, or a 50-mg sustained-release oral dose (PO-SR). Minimum analgesic concentration is 15 ng/mL.

### Moxifloxacin

| 86 ± 1 | 21.9 ± 3.6 | 39.4 ± 2.4 | 2.27 ± 0.24 | 2.05 ± 1.15 | 15.4 ± 1.2 | 2.0 (0.5-6.0) | 2.5 ± 1.3 μg/mL |

^aData from healthy adult male subjects. Moxifloxacin is metabolized by ST and UGT. ^bFollowing a single oral 400-mg dose.

### Mycophenolate

| MM: ~0 MPA: <1 MPA: 97.5 | MM: 120-163 MPA: 2.5 ± 0.4 | MM: 3.6-4 | MM: <0.033 | MPA: 1.1-2.2 | MPA: 8-19 μg/mL |

^aData from healthy adult male and female subjects and organ transplant patients. No significant gender differences. Mycophenolate mofetil (MM) is rapidly converted to the active mycophenolic acid (MPA) after IV and oral doses. Kinetic parameters refer to MM and MPA after a dose of MM. MPA metabolized by UGT to MPA-glucuronide (MPAG). MPA undergoes enterohepatic recycling; MPAG is excreted into bile and presumably is hydrolyzed by gut flora and reabsorbed as MPA. ^bAccumulation of MPA and MPAG and increased unbound MPA; severe renal impairment. ^cCL/F and V_{ss}/F reported for MPA. ^dRange of mean MPA

C_{max} and T_{max} from different studies following a 1- to 1.75-g oral dose given twice daily to steady state in renal transplant patients.

### Nabumetone

| 35 | ~ 50 | ~ 99 | 0.37 ± 0.25 | 0.79 ± 0.38 | 23 ± 4 | Y: 4-5 | Y: 22-52 μg/mL |

^aData are for the active metabolite, 6-methoxy-2-naphthylacetic acid (6-MNA). The conversion of nabumetone to the active metabolite 6-MNA is mediated predominantly by CYP1A2. ^b99.7-99.8% over concentration range following multiple 1-g doses; 99.2-99.4% following multiple 200-mg doses. ^cCl/F and V_{ss}/F reported; calculated assuming a 70-kg body weight. Following IV dosing of 6-MNA, Cl is 0.04-0.07 mL/min/kg and V_{ss}/F averages 0.11 L/kg. ^dRange of mean values from different studies following a 1-g oral dose given once daily for 7-14 days to young healthy adults (Y) and elderly patients with arthritis (E).

### Naltrexone

| 20 ± 5 | 2 | 21 | 18.3 ± 1.4 | 16.1 ± 5.2 | 10.3 ± 3.3 | 1 | 15-64 ng/mL |

^aNaltrexone has an active metabolite, 6β-naltrexol, that circulates at greater concentrations than naltrexone and has a 10-fold higher AUC than naltrexone after oral administration of naltrexone. ^bThe oral AUC of naltrexone was significantly increased in patients with liver impairment, whereas the AUC of 6β-naltrexol was not changed. ^cA t\(_1/2\) of 2.7 hours after IV administration also reported. ^dFollowing a single 100-mg oral dose.

<sup>a</sup>Metabolically cleared by CYP2C9 (polymorphic) and CYP1A2. <sup>b</sup>Estimated bioavailability. <sup>c</sup>Saturable plasma protein binding yields apparent nonlinear elimination kinetics. <sup>d</sup>No change in total CL, but a significant (50%) decrease in CL of unbound drug; it is thus suggested that dosing rate be decreased. A second study in elderly patients found a decreased CL and increased t<sub>1/2</sub> with no change in percent bound. <sup>e</sup>CL<sub>F</sub> and V<sub>area</sub>/F reported. <sup>f</sup>Following a single 250-mg dose of suspension (S) given orally to pediatric patients or a 250-mg immediate-release tablet (T-IR) or a 500-mg controlled-release tablet (T-CR) given to adults.

| **Niacin**               |                       |                     |                       |                  |                  |                  |                    |
| 12<sup>c</sup>           | —                     | 14.6 ± 5.0<sup>d</sup> | —                     | —                | 0.15-0.25<sup>e</sup> | ER: 4-5<sup>f</sup> | ER (1 g): 0.6 μg/mL<sup>f</sup> |
| ▲ Food                   |                       |                     |                       |                  |                  |                  | ER (2 g): 15.5 μg/mL<sup>f</sup> |

<sup>a</sup>Niacin (nicotinic acid) is metabolized to nicotinamide, which in turn is converted to the coenzyme NAD and other inactive metabolites. It also undergoes direct glycine conjugation to nicotinic acid. <sup>b</sup>The absolute bioavailability is not known. Niacin is well-absorbed but undergoes first-pass metabolism. Absorption is improved when taken with a low-fat meal. <sup>c</sup>Recovery of unchanged drug after multiple oral dose administration. <sup>d</sup>CL calculated from C<sub>ss</sub> (6.6 ± 2.4 μg/mL) during an IV infusion of niacin. Niacin metabolic CL appears to be saturable. <sup>e</sup>Estimated from the terminal log-linear portion of a disappearance curve following the end of a 0.1-mg/kg/min IV infusion in two subjects. <sup>f</sup>Following a single 1-g or 2-g oral dose of extended-release (ER) NIASPAN. Markedly disproportional increases in plasma concentrations with increasing dose.

| **Nifedipine**           |                       |                     |                       |                  |                  |                  |                    |
| 50 ± 13                  | 96 ± 1                | 7.0 ± 1.8           | 0.78 ± 0.22           | 1.8 ± 0.4<sup>b</sup> | IR: 0.5 ± 0.2<sup>c</sup> | IR: 79 ± 44 ng/mL<sup>c</sup> |
| ▲ RD                    | ▲ RD, Smk             | ▲ Smk               | ▲ Smk                 | ▲ Smk             | ▲ Smk             | ▲ Smk             |

<sup>a</sup>Metabolically cleared by CYP3A; undergoes significant first-pass metabolism. <sup>b</sup>Longer apparent t<sub>1/2</sub> after oral administration because of absorption limitation, particularly for extended-release (ER) formulations. <sup>c</sup>Mean following a single 10-mg immediate-release (IR) capsule given to healthy male adults or a range of steady-state concentrations following a 60-mg ER tablet given daily to healthy male adults. Levels of 47 ± 20 ng/mL were reported to decrease diastolic pressure in hypertensive patients.

**Dinitrate metabolites have weak activity compared to nitroglycerin (<10%), but because of a prolonged t1/2 (~40 min), they may accumulate during administration of sustained-release preparations to yield concentrations in plasma 10- to 20-fold greater than parent drug.**

**Follow ing sublingual (SL) dose rinsed out of mouth after 8 minutes. Rinse contained 31 ± 19% of the dose.**

**Following a 40- to 100-minute IV infusion.**

**Steady-state concentration following a 20-54 μg/min IV infusion over 40-100 minutes or a 0.4-mg SL dose. Levels of 1.2-11 ng/mL associated with a 25% drop in capillary wedge pressure in patients with CHF.**

<sup>a</sup>Olmesartan is administered as a prodrug, olmesartan medoxomil. Pharmacokinetic data for olmesartan is reported. <sup>b</sup>Following 40-mg/day olmesartan medoxomil for 10 days. References: Drugs@FDA. Benicar label approved on 07/13/05. Available at: http://www.accessdata.fda.gov/scripts/cder/drugsatfda/index.cfm. Accessed May 17, 2010.

<sup>c</sup>In 26 cancer patients (62 ± 10 years), F = 86 ± 26%.<sup>d</sup>Mild to moderate liver impairment. Mean (95% confidence interval) values following a single dose of 0.15 mg/kg IV or an oral dose of 8 mg given three times daily for 5 days to healthy adults. Reference: Roila F, et al. Ondansetron clinical pharmacokinetics. Clin Pharmacokinet, 1995, 29:95–109.

<sup>e</sup>Oxaliplatin is an organoplatinum complex; Pt is coordinated with diaminocyclohexane (DACH) and an oxalate ligand as a leaving group. Oxaliplatin (Ox) undergoes non-enzymatic biotransformation to reactive derivatives, notably Pt(DACH)Cl<sub>2</sub> (PtDC). Antitumor activity and toxicity are thought to relate to the concentration of oxaliplatin and PtDC in plasma ultrafiltrate (i.e., unbound concentration). For IV administration only. ~54% of the platinum eliminated is recovered in urine. Binding to plasma proteins is irreversible. <sup>f</sup>CL of total platinum is much lower; ~2-4 mL/min/kg. The elimination of platinum species in plasma follows a triexponential pattern. The quoted t<sub>1/2</sub> reflects the t<sub>1/2</sub> of the first phase, which is the clinically relevant phase. The t<sub>1/2</sub> for the slower two phases are 17 and 391 hours. <sup>§</sup>Steady-state plasma ultrafiltrate concentration of Ox and PtDC after an 85-mg/m² IV infusion over 2 hours during cycles 1 and 2.

Oxcarbazepinea

<th>XL: 4.2 ± 1.6 ng/mLd</th>
</tr>
</thead>
</table>

aData from healthy female subjects. No significant gender differences. Racemic mixture; anticholinergic activity resides predominantly with R-enantiomer; no stereoselectivity exhibited for anti-spasmodic activity. bCL/F for O reported. HC eliminated by glucuronidation. cExhibits a longer apparent t1/2 following oral dosing due to absorption rate-limited kinetics: immediate-release (IR) t1/2 = 9 ± 2 hours; extended-release (XL) t1/2 = 14 ± 3 hours. The apparent t1/2 for DEO was 4.0 ± 1.4 hours and 8.3 ± 2.5 hours for the IR and XL formulations, respectively. dFollowing a dose of 5-mg IR given three times daily or 15-mg XL given once daily for 4 days. Peak DEO levels at steady state were 45 and 23 ng/mL for IR and XL, respectively.

Oxycodonea

| CR: 60-87b | —— | 45 | 12.4 (9.2-15.4) | 2.0 (1.1-2.9) | 2.6 (2.1-3.1)d | CR: 3.2 ± 2.2e | CR: 15.1 ± 4.7 ng/mLc | CR: 15.1 ± 4.7 ng/mLc |
| IR: 42 ± 7b |        |   |        |         |           | IR: 1.6 ± 0.8e | IR: 15.5 ± 4.5 ng/mLc |                   |

aOxycodone is metabolized primarily by CYP3A4/5, with a minor contribution from CYP2D6. Oxymorphone is an active metabolite produced by CYP2D6-mediated O-dealkylation. The circulating concentrations of oxymorphone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy male and female subjects reported. bValues reported for OXYCONTIN [oxycodone controlled release (CR)] and immediate-release (IR) tablets. cUp to 19% excreted unchanged after an oral dose. dThe apparent t1/2 for the CR oral formulation is ~5 hours; this most likely reflects absorption-limited terminal elimination kinetics. eFollowing 10 mg of OXYCONTIN (CR) given twice daily to steady state or a 5-mg IR tablet given every 6 hours to steady state.

aMetabolized by CYP2C8 and CYP3A, and substrate for P-glycoprotein. bBinding of drug to dialysis filtration devices may lead to overestimation of protein binding fraction (88% suggested). cAverage accumulation t1/2; longer terminal t1/2 up to 50 hours are reported. dSteady-state concentration during a 250-mg/m² IV infusion given over 24 hours to adult cancer patients.

Paliperidone is a racemate: its enantiomers have similar pharmacological profiles. The (+) and (–)-enantiomers of paliperidone interconvert, reaching an AUC (+) to (–) ratio of ~1.6 at steady state. High-fat/high-caloric meal increased Cmax and AUC by 60% and 54%, respectively. No data on the absolute bioavailability of IM paliperidone palmitate (IM PP). The initiation regimen for INVEGA SUSTENNA (234 mg/156 mg in the deltoid muscle on day 1/day 8) produces paliperidone concentrations matching the range observed with 6- to 12-mg oral ER paliperidone. At steady-state during once-daily doses of 3 mg, assuming an average body weight of 73 kg.

V is estimated from CL/F and t1/2. Patients with moderate hepatic impairment showed a modest increase in clearance and plasma free fraction with no significant change in unbound AUC. The apparent long terminal t1/2 of paliperidone following IM depot injection reflects the slow dissolution of paliperidone palmitate and release of active paliperidone.

Pantoprazole is cleared primarily by CYP2C19 (polymorphic)-dependent metabolism. Poor metabolizers (PM) exhibit profound differences in CL (lower) and t1/2 (higher), compared to extensive metabolizers (EM). Pantoprazole is available as a racemic mixture of (+) and (–) isomers. In CYP2C19 EM, no significant differences in the pharmacokinetics of (+) and (–) pantoprazole were observed, whereas in CYP2C19 PM, the CL of (–) pantoprazole was significantly greater than that of (+) pantoprazole. No unchanged drug recovered in urine. Following a single 40-mg oral dose.

**Notes:**
- Prednisolone and prednisone are interconvertible; an additional 3 ± 2% is excreted as prednisone.
- Extent of binding to plasma proteins is dependent on concentration over range encountered. Total CL increases as protein binding is saturated. CL of unbound drug increases slightly but significantly with increasing dose. Changes are for unbound drug.
- V increases with dose due to saturable protein binding. Following a 30-mg oral dose given twice daily for 3 days to healthy adult male subjects. The ratio of prednisolone/prednisone is dose dependent and can vary from 3-26 over a prednisolone concentration range of 50-800 ng/mL.

**References:**

</tbody>
</table>

<sup>a</sup>Pregabalin undergoes minimal metabolism; an N-methylated metabolite has been identified in urine and accounts for 0.9% of oral dose. ≥90% of dose is excreted in urine as unchanged drug. Pregabalin pharmacokinetics is dose independent and predictable from single to multiple dosing. <sup>b</sup>Bioavailability does not vary with dose up to 600 mg. **T<sub>max</sub>** is delayed from 1 hour to 3 hours and C<sub>max</sub> decreased by 25-30% when pregabalin is given with food. No change in AUC or extent of absorption is noted. <sup>c</sup>Mean renal clearance in healthy young subjects ranges from 67 to 81 mL/min and assuming 70-kg body weight. <sup>d</sup>Pregabalin clearance is proportional **CL<sub>c</sub>;** hence, dosage can be adjusted in accordance to **CL<sub>c</sub>** in renal dysfunction. Plasma pregabalin decreased by ~50% after 4 hours of hemodialysis. <sup>e</sup>Steady-state concentration in healthy subjects receiving 200-mg pregabalin every 8 hours.

### Procainamide

| ↑ Cirr        | ↑ Inflam,  | ↑ Hep, HTh           | ↑ Hep, HTh           | ↑ Hep, HTh        | ↓ Hep, LD, Obes, Fem | HP: 1.0<sup>e</sup> | HP: 37 ± 9 ng/mL<sup>e</sup> |
|               | Crohn, Preg, Obes |                   |                   |                   |                  |                  |                  |

<sup>a</sup>Racemic mixture. For S-(-)-enantiomer (100-fold more active) compared to R-(+)-enantiomer, CL is 19% lower and V<sub>area</sub> is 15% lower because of a higher degree of protein binding (18% lower free fraction); hence, there is no difference in t<sub>1/2</sub>. Active metabolite, 4-hydroxypropranolol (HP). <sup>b</sup>Drug is bound primarily to α₁-acid glycoprotein, which is elevated in a number of inflammatory conditions. <sup>c</sup>Based on blood measurements; blood-to-plasma concentration ratio = 0.89 ± 0.03. <sup>d</sup>CYP2D6 catalyzes the formation of HP; CYP1A2 is responsible for most of the N-desisopropyl metabolite; UGT catalyzes the major conjugation pathway of elimination. <sup>e</sup>Following a single 80-mg oral dose given to healthy adults. Plasma accumulation factor was 3.6-fold after 80 mg was given four times daily to steady state. A concentration of 20 ng/mL gave a 50% decrease in exercise-induced cardiodeceleration. Anti-anginal effects manifest at 15-90 ng/mL. A concentration up to 1000 ng/mL may be required for control of ventricular arrhythmias.

### Pseudoephedrine

<table>

**References:**

**Notes:**
- Active metabolite, 3-hydroxyquinidine (t₁/₂ = 12 ± 3 hours; percent bound in plasma = 60 ± 10%).
- Metabolically cleared primarily by CYP3A.
- Following a 400-mg IV dose (22-minute infusion) of quinidine gluconate or a single 400-mg oral dose of immediate-release (IR) quinidine sulfate or a 300-mg dose of extended-release (ER) quinidine sulfate (QUINIDEX) to healthy adults. Specific assay methods for quinidine show >75% reduction in frequency of premature ventricular contractions at levels of 0.7-5.9 µg/mL, but active metabolite was not measured; therapeutic levels of 2-7 µg/mL were reported for nonspecific assays.

- Data from normal adults (N-A) and range of means from different studies of adults (M-A) or children (M-C) with malaria reported.
- Correlates with serum α₁-acid glycoprotein levels. Binding is increased in severe malaria.
- From patients with malaria.
- Following a single 10-mg/kg dose given as a 0.5- to 4-hour IV infusion or orally (PO) to children or adults with malaria. A level >0.2 µg/mL for unbound drug is targeted for treatment of *falciparum* malaria. Oculotoxicity and hearing loss/tinnitus associated with unbound concentrations >2 µg/mL.

**References:**
### Rabeprazole

| 52<sup>b</sup> | 0<sup>b</sup> | 95-98 | 4.2 ± 1.2<sup>c</sup> | 0.37<sup>c</sup> | 1.0 ± 0.6<sup>c</sup> | 3.8-4.6  | EM: 437 ± 241 ng/mL<sup>d</sup>  
| PM: 600 ± 319 ng/mL<sup>d</sup>  |

Rabeprazole is primarily converted non-enzymatically to rabeprazole-thioether; some of it is oxidized to desmethylrabeprazole and rabeprazole sulfone by CYP2C19 and CYP3A4, respectively. CYP2C19 genetic polymorphism has a modest effect on rabeprazole clearance. Rabeprazole possesses an asymmetric sulfur center; the enantiomers inhibit H<sup>+</sup>/K<sup>+</sup>-ATPase with equal potency <sup>in vitro</sup>. <sup>b</sup>~90% of radiolabeled oral dose is recovered in urine, indicating near-complete gastrointestinal absorption. Incomplete systemic availability is due to instability and first-pass metabolism of rabeprazole. <sup>c</sup>Based on data from a 20-mg IV dose of rabeprazole in subjects with unknown CYP2C19 genotype or phenotype, most likely reflecting characteristics of extensive metabolizers (EM). Elimination <i>t</i><sub>1/2</sub> up to 2-3 hours has been observed in poor metabolizers (PM) of CYP2C19 following oral rabeprazole. <sup>d</sup>At steady state during a 20-mg once-a-day regimen for duodenal ulcer.

### Raloxifene

| 2<sup>b</sup> | <0.2 | >95 | 735 ± 338<sup>c</sup>  | 2348 ± 1220<sup>c</sup> | 28 (11-273) | 6<sup>d</sup> | 0.5 ± 0.3 ng/mL<sup>d</sup>  |

<sup>b</sup>~60% absorption from the gastrointestinal tract; not significantly affected by food. <sup>c</sup>CL<sub>F</sub> and V<sub>F</sub> reported for an oral dose. <sup>d</sup>Following a single 1-mg/kg oral dose.

### Raltegravir

| ≥31.8 ± 9.4<sup>b</sup> | 8.8 ± 4.7 | 83 | 16.1 (11.4, 22.6)<sup>c</sup>  | α: 0.92 ± 0.21<sup>d</sup> | 1.0<sup>e</sup> | 4.5 (2.0, 10.2) μM<sup>e</sup>  |
| ← RD  | ← LD (modest)  |

<sup>b</sup>Data from postmenopausal women. Undergoes extensive first-pass metabolism (UGT catalyzed) and enterohepatic recycling. <sup>c</sup>CL<sub>F</sub> and V<sub>F</sub> reported for an oral dose. <sup>d</sup>Following a single 1-mg/kg oral dose. <sup>e</sup>Plasma concentration time course of raltegravir exhibits multiphasic washout kinetics. Initial (α) and terminal (β) <i>t</i><sub>1/2</sub>s are reported because the early phase accounts for a large portion of the AUC from time 0 to ∞. Median for <i>T</i><sub>max</sub> and geometric mean (95% confidence interval) for <i>C</i><sub>max</sub> following a 400-mg twice-daily monotherapy regimen for 10 days in treatment-naive patients with HIV-1 infection.

<sup>a</sup>Ramelteon undergoes primary oxidative metabolism followed by glucuronidation as secondary metabolism. CYP1A2 is the major enzyme involved in oxidative metabolism; CYP3A and CYP2C9 also are involved as minor enzymes. Remarkable elevation in $C_{\text{max}}$ and AUC were observed with the concurrent administration of the strong CYP1A2 inhibitor fluvoxamine. The M-II metabolite contributes to the hypnotic effects of ramelteon. M-II has 1/5th to 1/10th the affinity of ramelteon as an agonist for the melatonin receptors (MT-1 and MT-2); however, it circulates at 20- to 100-fold higher concentrations relative to ramelteon. <sup>b</sup>Poor systemic availability of ramelteon is due to extensive first-pass metabolism. $C_{\text{max}}$ and AUC are elevated by a high-fat meal; $T_{\text{max}}$ is slightly delayed. <sup>c</sup>Intersubject variability is notably large.

<sup>d</sup>Four- and 10-fold elevation in AUC in mild and moderate hepatic impairment. <sup>e</sup>Parent drug: M = M-II metabolite. $C_{\text{max}}$, following a single 16-mg oral dose of ramelteon in young adult subjects. There is no measurable accumulation of parent drug or active metabolite because of their short elimination $t_{1/2}$.

| **Ramipril** |                |                       |                     |                       |                   |                   |                   |                   |

<sup>a</sup>Eliminated primarily by CYP1A2-dependent metabolism; metabolites are inactive. Involvement of CYP1A2 may contribute to ethnic (lower CL/F in Japanese) and gender (lower CL in women) differences and inductive effects of smoking (higher CL in smokers).<br>
<sup>b</sup>High-fat meal. Following a 50-mg oral dose given twice daily to steady state.<br>
<sup>c</sup>Following a 50-mg oral dose given twice daily to steady state.<br>

<sup>a</sup>The active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a t<sub>1/2</sub> of 20 ± 3 hours. In extensive metabolizers, 35 ± 7% of an IV dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function. 9-Hydroxyrisperidone is catalyzed by CYP2D6. Parameters reported for extensive metabolizers. In poor metabolizers, F is higher; ~20% of an IV dose is excreted unchanged, 10% as the 9-hydroxy metabolite: CL is slightly <1 mL/min/kg, and t<sub>1/2</sub> is similar to that of the active metabolite, ~20 hours. 77% for 9-hydroxyrisperidone. Changes in elderly subjects due to decreased renal function affecting the elimination of the active metabolite. 7 Mean steady-state C<sub>min</sub> for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3-mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers.<br>

<sup>a</sup>Ritonavir is extensively metabolized primarily by CYP3A4. It also appears to induce its own CL with single-dose (SD) to multiple-dose (MD) administration. Absolute bioavailability unknown (>60% absorbed); food elicits a 15% increase in oral AUC for capsule formulation. 9-CL/F, V<sub>area</sub>/F, and t<sub>1/2</sub> reported for oral dose. 3-CL/F reduced slightly and t<sub>1/2</sub> increased slightly, moderate liver impairment. Following a 600-mg oral dose given twice daily to steady state.<br>

### Rivastigmine

</tr>
</tbody>
</table>

<sup>a</sup>Rivastigmine is metabolized by cholinesterase. No apparent gender differences. <sup>b</sup>Following a 6-mg oral dose. Bioavailability increases with dose; following a 3-mg dose, the median bioavailability is 36%. <sup>c</sup>IV dose of 2 mg. <sup>d</sup>The pharmacodynamic t1/2 is ~10 hours due to tight binding to acetylcholinesterase. Following oral administration of a 6-mg capsule. C<sub>max</sub> increases more than proportionally at doses >3 mg.

<sup>a</sup>Solifenacin is extensively metabolized by CYP3A. The 4R-hydroxy-solifenacin metabolite is pharmacologically active but not likely to contribute to the therapeutic efficacy of solifenacin because of low circulating levels.  
<sup>b</sup>Primarily bound to α<sub>1</sub>-acid glycoprotein.  
<sup>c</sup>Dosage reduction is advised in patients with severe renal impairment (CL<sub>cr</sub> < 30 mL/min), in whom a 2-fold reduction in clearance and prolongation in t<sub>1/2</sub> are expected.  
<sup>d</sup>At steady state following 21 days of dosing with 10 mg once daily.

<sup>a</sup>Sorafenib undergoes oxidative metabolism mediated by CYP3A and glucuronidation mediated by UGT1A9.  
<sup>b</sup>Oral bioavailability of NEXAVAR tablet relative to an oral solution. Sorafenib bioavailability reduced by 29% when administered with a high-fat meal.  
<sup>c</sup>Range of geometric means determined at steady state in three phase I studies in patients with advanced refractory solid tumors at the dose level of 400 mg two times a day.  
<sup>d</sup>Sorafenib AUCs were 23-63% lower in patients with mild and moderate hepatic impairment compared to patients with normal hepatic function.

<sup>a</sup>Sotalol is available as a racemate. The enantiomers contribute equally to sotalol’s anti-arrhythmic action; hence, pharmacokinetic parameters for total enantiomeric mixture are reported herein. β-adrenoreceptor blockade resides solely with S(-)-isomer.  
<sup>b</sup>Following 80-mg, twice-a-day dosing to steady state.

<sup>a</sup>Spironolactone (S) is extensively metabolized; it has three known active metabolites: canrenone (C), 7α-thiomethylspironolactone (TS), and 6β-hydroxy-7α-thiomethylspironolactone (HTS). Absolute bioavailability is not known; old values reported in the literature were based on nonspecific assays for C; likely to exhibit first-pass metabolism. AUC of parent drug and metabolites increased when S taken with food. Measured after an oral dose. Binding of S and its active metabolites. CL/F and V<sub>area</sub>/F; calculated from reported AUC and t<sub>1/2</sub> data. Following a single 200-mg oral dose of S. C accumulates 2.5-fold with multiple S dosing.<sup>g</sup><sup>i</sup> of parent drug and metabolites increased in patients with cirrhosis.

- *Data from healthy adult male and female subjects and female patients with breast cancer. Toremifene (T) is metabolized by CYP3A to \( N \)-desmethyltoremifene (DMT), a metabolite that accumulates in blood and has anti-estrogenic activity. Toremifene appears to undergo enterohepatic recycling, prolonging its apparent \( t_{1/2} \). \( CL/F, V_{\text{area}}/F, \) and \( t_{1/2} \) reported for oral dose. \( CL/F \) reduced, hepatic cirrhosis or fibrosis. Following a 60-mg oral dose given once daily to steady state in patients with breast cancer.

<sup>a</sup>Tramadol (T) is available as a racemic mixture. At steady state, the plasma concentration of (+) (1R,2R)-tramadol is ~30% higher than that of (−) (1S,2S)-tramadol. Both isomers contribute to analgesia. Data reported are for total (+ and −) T. T is metabolized by CYP2D6 to an active O-desmethyl metabolite (M1); there are other CYP-catalyzed metabolites. <sup>b</sup>Recovery following an oral dose was reported. <sup>c</sup>Following a 100-mg immediate-release tablet given every 6 hours for 7 days.

<sup>b</sup>LD, RD

Vancomycin

| --- | 79 ± 11 | 30 ± 11 | \( CL = 0.79CL_{cr} + \) 0.22 | 0.39 ± 0.06 | 5.6 ± 1.8 | --- | 18.5 (15-25) μg/mLb |
| --- | ↓ RD, Aged, Neo | " | ↓ Obes | ↑ RD, CPBS | " | ↓ Obes |

\(^a\)Very poorly absorbed after oral administration, but used by this route to treat *Clostridium difficile* and staphylococcal enterocolitis. \(^b\)Following a dose of 1000-mg IV (1-hour infusion) given twice daily or a 7.5-mg/kg IV (1-hour infusion) given four times daily to adult patients with staphylococcal or streptococcal infections. Levels of 37-152 μg/mL have been associated with ototoxicity.

Vardenafil\(^a\)

15 (8-25) 2-6 93-95 (parent and M1) 56 3.0b 4-5 (parent and M1) 0.7 (0.25-3)c 19.3 ± 1.7 ng/mLc

\(^a\)Vardenafil is primarily metabolized by CYP3A with minor involvement of CYP2C9. The major oxidative metabolite (M1), a product of N-desmethylation at the piperazine ring, is a less potent PDE5 inhibitor and circulates at a level 28% that of the parent drug. It contributes only 7% of the in vivo activity of vardenafil. \(^b\)\( V_{ss} \) of 208 L, assuming 70-kg bodyweight. \(^c\)Following a single 20-mg dose. There is no change in pharmacokinetics between single and multiple dosing.

Varenicline\(^a\)

≥87%b 86.2 ± 6.2 ≤20 2.27 ± 0.34c 6.2c 31.5 ± 7.7c 2.0 (1-0-4.0)d 10.2 ± 1.0 ng/mLd

\(^a\)Varenicline is eliminated mostly by renal excretion with minimal metabolism. Organic Cation Transporter 2 (OCT2) is involved in renal tubular secretion, as evidenced by inhibition of varenicline renal clearance by cimetidine, a known OCT2 inhibitor. \(^b\)87.1 ± 5.5% of radioactivity is excreted in urine after an oral dose of [14C]-varenicline. Minimal first-pass metabolism is expected. \(^c\)\( CL/F \) and \( V_z/F \) estimated from steady-state AUC and \( t_{1/2} \) during 1-mg twice-daily dosing of varenicline in healthy adult smokers and assuming an average body weight of 70 kg. \(^d\)After the first dose of a multiple-dosing regimen. An accumulation factor of 2.85 ± 0.73 was reported.

aVenlafaxine (V) is available as a racemic mixture; antidepressant activity resides with the L-(-)-enantiomer and its equipotent O-desmethyl metabolite (formation catalyzed by CYP2D6—polymorphic). Parameters for the derived O-desmethylvenlafaxine (ODV) are included. bO-Desmethyl metabolite is marketed as desvenlafaxine in an extended-release formulation as a successor to V. It has a higher oral bioavailability (80%), with a T_{max} of 7.5 hours. Desvenlafaxine has a much lower CL (3.5 mL/min/kg) and a smaller V_{ss} (3.4 L/kg). Its reported t_{1/2} matches that observed for metabolite derived from V. cValues for ODV after V dosing. dCL/F and V_{ss}/F reported. eMean data for V and ODV, following a 75-mg oral dose (immediate-release tablet) given three times daily for 3 days to healthy adults. T_{max} for an extended-release formulation is 5.5 (V) and 9 (DV) hours.

aRacemic mixture; (-)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (-)-verapamil because of a lower CL (10 ± 2 versus 18 ± 3 mL/min/kg). Relative concentration of the enantiomers changes as a function of route of administration. bActive metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or P-R interval. At steady state (oral dosing), AUC is equivalent to that of parent drug (t_{1/2} = 9 ± 3 hours). cMultiple dosing causes a greater than 2-fold decrease in CL/F and prolongation of t_{1/2} in some studies, but no change of t_{1/2} in others. dVerapamil is a substrate for CYP3A4, CYP2C9, and other CYPs. eMean data following a 120-mg oral conventional tablet (IR) given twice daily or range of data following a 240-mg oral extended-release (XR) dose given once daily, both for 7-10 days to healthy adults. EC_{50} for prolongation of P-R interval after an oral dose of racemate is 120 ± 20 ng/mL; the value for IV administration is 40 ± 25 ng/mL. After oral administration, racemate concentrations >100 ng/mL cause >25% reduction in heart rate in Atr Fib, >10% prolongation of P-R interval, and >50% increase in duration of exercise in angina patients. A level of 120 ± 40 ng/mL (after IV administration) was found to terminate reentrant supraventricular tachycardias.

<sup>a</sup>Approximately one-third of the dose is oxidized by CYP3A4, and the remainder undergoes reduction. <sup>b</sup>Recovery following oral administration. <sup>c</sup>A longer t<sub>1/2</sub> after oral dosing is rate limited by absorption; food decreases apparent t<sub>1/2</sub>. In the elderly, the t<sub>1/2</sub> is slightly longer. <sup>d</sup>Following a 20-mg oral dose given twice daily for 8 days. <sup>e</sup>Following a single 10-mg IM dose.

<sup>a</sup>Primary routes of metabolism involve reductive cleavage of the isoxazole ring (CYP3A4) and N-acetylation. <sup>b</sup>Absolute bioavailability is not known; minimum equal to urine recovery after an oral dose. <sup>c</sup>Recovery in erythrocytes to as much as 8-fold. <sup>d</sup>Steady-state CL/F for a 400-mg once-daily dose reported. AUC increases proportionately when the dose is increased from 400-800 mg. <sup>e</sup>V/F for a single dose is reported; decreases as the dose is increased from 200-800 mg. <sup>f</sup>Following a 400-mg oral dose given once daily to steady state in healthy adults.

with cardiac conduction abnormalities, recommended treatment for, 769t
epidemiology, 751
exertional, calcium channel antagonists for, 766–767
with left ventricular dysfunction, recommended treatment for, 769t
nitrates for, 759–760
buccal administration, 760
cutaneous administration, 760
mechanism of action of, 756–757
oral administration, 759–760
sublingual administration, 759
transmucosal administration, 760
with other medical conditions, recommended treatment for, 769t
treatment, 752
strategies for, comparison of, 768–771
typical, 751
unstable, 751
beta-adrenergic antagonists for, 768
calcium channel antagonists for, 767
nitrates for, 760
Angina pectoris (Cont.):
variant (Prinzmetal’s), 751, 752
calcium channel antagonists for,
766
nitrates for, 761
treatment of, 761
Angioedema
ACE inhibitors and, 736, 932
androgen treatment of, 1204
H₁ receptor antagonists for, 922
kinins and, 931
Angiogenesis
definition of, 1738
inhibitors, 1738–1740
mechanism of efficacy of, 1738
toxicity of, 1739–1740
Angiogenic factors, 1738
Angiotensin, biosynthesis, alternative pathways for, 726
Angiotensin (1-7), 725
Angiotensin (3-8), 725
Angiotensinases, 725
Angiotensin converting enzyme (ACE), 721, 724–725
Angiotensin converting enzyme 2, 725
Angiotensin-converting enzyme (ACE), 722f, 927f, 929
Angiotensin-converting enzyme (ACE) inhibitors, 730, 731–736, 731f, 926, 927f, 931, 932–933
Acute renal failure caused by, 736
adverse effects and side effects of, 798
adverse effects of, 735–736
angioedema caused by, 736
clinical pharmacology of, 731–734
for congestive heart failure, 793
cough caused by, 735–736
drug interactions with, 736
dysgeusia caused by, 736
effects on renin-angiotensin system, 746f
fetopathic potential of, 736
glycosuria caused by, 736
hepatotoxicity, 736
history of, 721, 731
hyperkalemia caused by, 736
hypoglycemia and, 1248f
hypotension caused by, 735
mechanism of action of, 797
neutropenia caused by, 736
pharmacological effects in normal animals and humans, 731
pharmacological effects in normal humans, 731
Angiotensin-converting enzyme (ACE) inhibitors (Cont.):
skin rash caused by, 736
structure of, 732f
therapeutic uses of
for heart failure, 797–798
survival rates with, 798
for hypertension, 734
in left ventricular dysfunction, 734–735
in myocardial infarction, 735
in patients at high risk of cardiovascular events, 735
in progressive renal impairment, 735
in scleroderma renal crisis, 735
Angiotensin converting enzyme (ACE) polymorphisms, 160t
Angiotensin-converting enzyme (ACE) inhibitors (ACEI), 753. See also specific agent
as antihypertensive agents, 774t, 784–785
drug interactions with, 976
hemodynamic effects of, with long-term administration, 774t

ABC transporters and, 105f, 106t

arrhythmias caused by, 832

Antibacterial agents, for neoplastic disease, 1712–1715
(Antibiotic(s) (Cont.):
and benzoyl peroxide, combinations, 240–241
for acne, 1817
for cancer, 1712–1715
histamine and, 914
for inflammatory bowel disease, 1360
and statins, interactions, 896
systemic
for acne, 1816–1817
for cutaneous infections, 1816
therapeutic uses of, for inflammatory bowel disease, 1352f
topical, for acne, 1816–1817

Anticancer drugs, polymorphisms and response to, 159f

Anticholinergic agents, 211–212
anticholinesterase for intoxication with, 252
for bowel disorders, 1340–1341
for nausea and vomiting, 1344

Anticholinergic toxidrome, 83
Anticholinergic toxidrome antidote, 86f

Anticholinesterase agents
absorption of, 247
acetylcholinesterase structure and, 240–241
acute intoxication by, 248
“aging” of, 249
for Alzheimer’s disease, 252–253
for anticholinergic intoxication, 252
chemistry of, 242–245
cholinesterase reactivators and, 249
definition of, 239
disposition of, 249
effector organ action, 242
excretion of, 247
eye and, 246, 250–251
gastrointestinal tract and, 246
for glaucoma, 250–251
heart and, 246–247
history of, 239
mechanism of action of, 241–242
for myasthenia gravis, 251–252
neuromuscular junction and, 246
noncovalent, 242
for paralytic ileus, 250
for polyneuropathy, 250
pharmacological properties of, 245–247
as prophylaxis for cholinesterase poisoning, 252

“reversible” carbamate inhibitors, 242

Anticholinesterase agents
absorption of, 247
acetylcholinesterase structure and, 240–241
acute intoxication by, 248
“aging” of, 249
for Alzheimer’s disease, 252–253
for anticholinergic intoxication, 252
chemistry of, 242–245
cholinesterase reactivators and, 249
definition of, 239
disposition of, 249
effector organ action, 242
excretion of, 247
eye and, 246, 250–251
gastrointestinal tract and, 246
for glaucoma, 250–251
heart and, 246–247
history of, 239
mechanism of action of, 241–242
for myasthenia gravis, 251–252
neuromuscular junction and, 246
noncovalent, 242
for paralytic ileus, 250
pharmacological properties of, 245–247
as prophylaxis for cholinesterase poisoning, 252

“reversible” carbamate inhibitors, 242
Anticholinesterase agents (Cont.):
- structure-activity relationships, 242–245
- therapeutic uses of, 250–253
- toxicology of, 247–250
- treatment of intoxication by, 248–249
Anticholinesterase poisoning, 234
Anticoagulants, 849
- antithrombin (recombinant), 860
- argatroban, 859–860
- desirudin, 859
- drotrecogin alfa, 860
- bivalirudin, 859–860
- antithrombin (recombinant), 860
- oral
- decreased effect of, causes, 863–864
- drug interactions with, 863–864
- mechanism of action of, 860–862
- new, 865–866
- parenteral, 853–860
Anticonvulsants, for mania, 444–445
Antidepressants, 398–413
- for mania, 444–445
Antiepileptic drugs
- barbiturates, 593–594
- benzodiazepines, 598–599
- choice of, 603–606
- duration of therapy with, 604–605
- general principles, 603–606
- history of, 590
- hydantoins, 591–593
- iminostilbenes, 594–596
- pregnancy and, 605–606
- therapeutic aspects of, 590
- valproic acid, 596–598
Antiestrogens, 1668
- for ER+ breast cancer, 1756–1760
- for neoplastic disease, 1668–1670
Antifungal agents
- ABC transporters and, 105
- atypical, disposition of, 409
- clinical considerations with, 399, 405
- disposition of, 409
- dosage of, 400–403
- drug interactions with, 412
- mechanism of action of, 398–399
- norepinephrine-selective, potencies, at human transporters for monamine neurotransmitters, 406
- polymorphisms and response to, 159, 160
- potencies
- at human transporters for monamine neurotransmitters, 406
- at neurotransmitter receptors, 410
- serotonin-selective, potencies, at human transporters for monamine neurotransmitters, 406
- side effects of, 400–403
- ultra-rapid pharmacokinetics of, 157
Antidiuretic hormone (ADH), opioids and, 495
Antidiuretic system, mammalian, anatomy of, 701–702
Antiflatulence agents, 1347
Antihistamines, 911

  - pimecrolimus for, 1822
- Atorvastatin, 893
- absorption, fate, and excretion of, 896
- chemistry of, 894
- ASCORBIC acid (vitamin C), SLC
Atorvastatin (Cont.):
dosage of, required to achieve
cut in LDL-C, 895t
pharmacokinetics of, 1816t
SLC transporters and, 102t
structure of, 893f
therapeutic uses of, 897
in children, 898
Atosiban, for prevention of preterm
labor, 1848
Atovaquone, 1398–1399
treatment regimen for, 1389t
ATP. See Adenosine triphosphate
(ATP)
ATP-binding cassette (ABC),
note 878
ATP-binding cassette (ABC) proteins,
note 89, 94, 94f, 96
in absorption, 105t–106t, 107
at blood-brain barrier, 104
in intestine, 103
in kidneys, 103–104, 105t–106t
linked genetic diseases, 104
in liver, 103–104, 105t–106t, 108
MRP family, 104
physiological roles of, 107–108
properties related to drug action, 103–108
substrate specificity of, 104
superfamily, 99–108
tissue distribution of, 103–107
ATP-mediated transport, 674
Atracurium
characteristics of, 264t
cholinergic receptors and, 206t
dosing of, 265t
structure of, 259f
Atrial depolarization, premature,
treatment of, 824t
Atrial fibrillation, 823, 830
drugs for
dipryramide, 839
flecainide, 840–841
quinidine, 843–844
sotalol, 845
ECG of, 825f
management of, 824t
rapid, angina pectoris with,
treatment of, 769t
Atrial flutter, 822, 830
drugs for
dipryramide, 839
quinidine, 843–844
sotalol, 845
ECG of, 825f
management of, 824t
with variable AV conduction, ECG
of, 825f
Atrial natriuretic peptide, for asthma,
1046
Atrial natriuretic peptide, for asthma,
1046
Atrial flutter, 822, 830
Atrial fibrillation, 823, 830
Atrial fibrillation, 823, 830
Atrial fibrillation, 823, 830
Atrial natriuretic peptide, for asthma,
1046
Azelastine hydrochloride, 922, 922r for ophthalmic use, 1789
AZELEX (azelaiic acid), 1817, 1830
Azithromycin
for chancroid, 1842r
for Chlamydia, 1842t
for non-gonococcal urethritis, 1842t
for ophthalmic use, 1781t
pharmacokinetics of, 1816t
volume distribution, 1816t
Azlocillin, 1484
Azoles
arrhythmias caused by, 832
for cutaneous fungal infection, 1818
indications for, 1816t
and statins, interactions, 896
AZOPT (brinzolamide), 680
Babesiosis, 1423
Bacillus Calmette-Guérin (BCG), 1022
Bacitracin, 1543–1544
prophylaxis, for superficial infections, 1817
Baclofen, pharmacokinetics of, 1816t
Bacteria
susceptibility testing in, 1369–1370
Bacterial endocarditis, gentamicin for, 1515–1516
Bacterial infections, of skin, 1817
Bacterial vaginosis, 1842t
BACTRIM (trimethoprim-sulfamethoxazole), 1817
BACTROBAN (mupirocin), 1817
Balantidiasis, 1423
Baldness
female pattern, 1829–1830
male pattern, 1829–1830
Barbiturates
absorption, fate, and excretion of, 473
abuse and addiction to, 472
addiction, 657
as anesthetics, 539–540
cardiovascular system and, 472
central nervous system and, 469–472
chemistry of, 469
as dose-dependent toxicity, 75
for epilepsy, 593–594
gastrointestinal tract and, 472–473
liver and, 472–473
peripheral nervous structures and, 472
pharmacological properties of, 469–473
Barbiturates (Cont.):
poisoning, 474
respiration and, 472
sleep and, 472
therapeutic uses of, 473–474
tolerance to, 472
Bare lymphocyte syndrome, 104t
Baroreceptors, intrarenal, and renin release, 722, 723f, 724
Barter’s syndrome, 947–948
Barter syndrome, 972
Basal cell carcinoma (BCC)
5-fluorouracil for, 1821
imiquimod for, 1823
Base(s), organic, secretion in proximal tubule, 676f
Basophils, increased proliferation of, histamine and, 915
BAY 58-2667, 808
Bay-H-Dole Act, 12
BBB. See Blood-brain barrier (BBB)
BCR-ABL kinase, inhibitors, 1732–1734. See also Dasatinib; Imatinib mesylate; Nilotinib resistance, mechanisms of, 1732–1733, 1733f
BCRP. See Breast cancer resistance protein (BCRP)
Bed bugs, 1818
Behavior, dopamine and,
356–357
Behçet’s disease
azathioprine for, 1821
cyclophosphamide for, 1821
dapsone for, 1823
tacrolimus for, 1822
thalidomide for, 1824
Belladonna alkaloids, 226. See also Atropine; Scopolamine
Bemotrizinol, 1827
BENADRYL (diphenhydramine), 1816
BENADRYL (diphenhydramine hydrochloride), 921t
Benazepril
as antihypertensive agent, 774t, 784–785
clinical pharmacology of, 733
structure of, 732f
Bendroflumethiazide
pharmacology of, 688t
structure, 688t
BENICAR (olmesartan medoxomil), 745
Benign prostatic hyperplasia (BPH), alpha-adrenergic receptor antagonists for, 308
BENOQUIN (monobenzone), 1830
BENSAL HP (antifungal combination), 1817
BENZACIN (antibiotic-benzoyl peroxide combination), 1817
Benzathine penicillin, for syphilis, 1842r
Benzbromarone, 999–1000
Benzimidazoles
absorption, fate, and excretion of, 1450–1451
anthelmintic action of, 1450 in children, 1453
history of, 1449–1450
precautions and contraindications with, 1452–1453
in pregnancy, 1452–1453
toxicity and side effects of, 1452–1453
Benzimidazole, 1431–1432
Benzocaine, 138t for pruritus, 1828t
Benzodiazepine-receptor agonists, novel, 467–469
Benzodiazepines
absorption, fate, and excretion of, 463–465
diagnosis to, 656–657
adverse psychological effects, 465 as anesthetic adjunct, 552–553
antidote for, 86r
as antiepileptics, 598–599
central nervous system and, 460
chemistry of, 458, 459r
for nausea and vomiting, 1345–1346
pharmacological properties of, 458–465
for pruritus, 1828t
sleep and, 460–461
therapeutic uses of, 465–467, 466r
tolerance to, 460
Benzoic acid, 1589
Benzothiadiazides, 686
Benzothiadiazines (thiazide diuretics), as antihypertensive agents, 775–777
Benztiazepines, 102r
Benztiazipines, 761
Benzoyl peroxide, for acne, 1817
interactions with tretinoin, 1810
Benzphetamine, structure of, 279t
Benztropine, as antidote, 86t
Benztropine mesylate, for parkinsonism, 234
Benzyl alcohol, for lice, 1819
Bepotastine, for ophthalmic use, 1789
BEPREVE (bepotastine), 1789
Bepridil, antiarrhythmic use of, 830
Berberine, 1339
Besifloxacin, for ophthalmic use, 1781
Beta adrenergic agonists, 289–294
Beta adrenergic antagonist antidote, 86
Beta adrenergic receptor antagonists, 310–316
Beta adrenergic antagonist antidote, 86t
BETAPACE (sotalol), 845
BETATREX (betamethasone valerate ointment), 1225
Betaxolol, 312f
Bicalutamide, 1205, 1765–1766
Bicalutamide, 1205
and lipoproteins, 902
mechanism of action of, 902
structure of, 901f
BG9179, therapeutic uses of, 793
Biclonidines, 91–92
Bile acid binding resins, 1266
Bile acids, 1346–1347
Bile acid sequestrant agents, 1336–1337
Bile-acid sequestrants, 898–899
adverse effects of, 899
chemistry of, 898–899
drug interactions with, 899
and lipoprotein levels, 899
mechanism of action of, 899
structures of, 898
therapeutic uses of, 899
Bile acid synthesis, 127
Bile salt export pump (BSEP), 93, 107
Bile salt malabsorption, primary, 102
Bile salts, ABC transporters and, 105
Biliary excretion, 26
Biliary tract
muscarinic antagonists and, 229
opioids and, 498
Bilirubin monoglucoronide, 105
Bimatoprost, 952
for glaucoma, 1787
nor-Binaltorphimine, actions and selectivities of, 485
Bioavailability
absorption vs., 19
of common drugs, 1809r–1890r
definition of, 19
disposition and, 28
extent of, 33–34
factors influencing, 20
first-pass effect and, 19–20
hepatic disease and, 1802
in parenteral administration, 20
as pharmacodynamic parameter, 1802
rate of, 33–34
Bioactive polymers, 23
Bioequivalence, 23
Biological agents
classes, 1824
in dermatology, 1824–1827, 1825r
for inflammatory bowel disease, 1359–1360
for psoriasis, 1824
mechanism of action of, 1826
Biological induction therapy,
1006–1007
Biological License Application (BLA), 79
Biological response modifier(s), in cancer treatment, 1745–1750
Biological response modifiers
for inflammatory bowel disease, 1352r
for neoplastic disease, 1668r–1670r
Biological toxins, 575
Biotransformation, in liver, 27
Biperiden, 234
Bipolar (manic-depressive) disorder
lithium for, 447
prophylactic treatment of, 448
Birth defects, oral anticoagulant-induced, 864
Bishydroxycoumarin, 860
Bismuth compounds, 1337
Bisoprolol, 312–328
as antihypertensive agent, 774–775
Bisphosphonates, 1294–1296
absorption of, 1296
adverse effects of, 1296
excretion of, 1296
for osteoporosis, 1299
Bitolterol, 292–293
for asthma, 293
Bivalirudin, 859–860
therapeutic uses of, in myocardial ischemia, 771
BLA. See Biological License Application (BLA)
“Black box,” 9
Bladder, urinary
ABC transporters in, 106
acetylcholine and, 221–222
atony, anticholinesterase agents for, 250
in autonomic nervous system, 179–180
bathanechol and, 224
choline esters and, 223–224
muscarinic antagonists and, 231
opioids and, 497
Bladder cancer, drugs for, 1668r–1670r
BLENOXANE (bleomycin), 1823
Bleomycin(s), 1668–1670
for cancer, 1716–1718
intralesional adverse effects and side effects of, 1823
for squamous cell carcinoma, 1823
for warts, 1823
mechanism of action of, 1820–1821
systemic, for Kaposi sarcoma, 1823
Blepharitis
fungal, 1784
yeast, 1784
Blepharoconjunctivitis, bacterial, treatment of, 1781
Blinking, 1773
Blistering diseases, autoimmune, 1816
mycophenolate mofetil for, 1823
Blood-cerebrospinal fluid barrier, intrathecal injection and, 22
Blood-brain barrier (BBB), 365–366
ABC transporters and, 104
distribution of drugs and, 25
intrathecal injection and, 22
transporters and, 91–93, 116
vectorial transport in, 96
Blood-cerebrospinal fluid barrier intrathecal injection and, 22
transporters and, 116
Blood circulation, muscarinic antagonists and, 228
Blood dyscrasias, androgens for, 1204
Blood pressure
angiotensin II and, 727–730
epinephrine and, 282–283
kinins and, 931
normal, in adults, 773
pharmacological lowering of, effects on RAS, 746r, 747
regulation, role of kidneys and fluids and electrolytes, 698
Blood vessels
alpha adrenergic receptors in, 203r
in autonomic nervous system, 178
BMS-354825 (dasatinib), 1732
Body temperature
ethanol and, 637
muscarinic antagonists and, 229–230
opioids and, 498
Bolus injection, 22
Bone
disorders of, 1286–1290
distribution in, 24–25
eicosanoids and, 951
infections of, quinolones for, 1473
mass, 1285
parathyroid hormone and, 1279
physiology, 1285–1286
remodeling, 1285–1286
skeletal organization and, 1285
Bone marrow, alkylating agents and, 1681
Bone mineral, mobilization of, vitamin D and, 1283
Bone mineral density (BMD) bone physiology and, 1285
postmenopausal, estrogens and, 1838
Bortezomib, 1742–1743
absorption, 1743
chemistry, 1742
elimination, 1743
Bortezomib (Cont.):
- mechanism of action of, 1743
- pharmacokinetics of, 1743
- structure of, 1743
- therapeutic uses of, 1743
- toxicity of, 1743

Bosentan, 110

Botulinum toxin
- adverse effects and side effects of, 1792
- cholinergic receptors and, 206t

Bowel irrigation, 84–85

Bowen’s disease
- 5-fluorouracil for, 1821
- imiquimod for, 1823

Bowman’s membrane, 1774–1775

Bradycardia
- atropine for, 233
- differential diagnosis of, in toxicity, 83t

Bradykinin, 911, 926–932, 927t
- antagonists, 932
- degradation, 930f
- [des-Arg9]-, structure of, 928t
- history of, 926
- and inflammation, 931, 960
- pain and, 930–931
- as pruritogen, 1815
- structure of, 928t
- therapeutic uses of, potential, 926

Bradykinin receptor(s), 926, 929–930

Brain
- cellular organization of, 364
- drug action in, transporters and, 115–116
- microanatomy of, 364–366

Brain natriuretic peptide (BNP), 695–696

Brainstem, 364
- alpha adrenergic receptors in, 203t
- beta adrenergic receptors in, 204t

Brain tumor, drugs for, 1668t–1670t

Bran, constipation and, 1331

Brater’s algorithm, for diuretic therapy, 699, 700f

Breast
- progestins and, 1182
- cancer
  - drugs for, 1668t–1670t
  - ER+, anti-estrogen therapy for, 1756–1760, 1757f
  - HER2/neu-overexpressing, 1737
  - metastatic, 1755–1756
  - risk, oral contraceptives and, 1834
  - tamoxifen for, 1179

Breast cancer (Cont.):
- treatment
  - androgens in, 1756
  - estrogens in, 1756

Breast cancer resistance protein (BCRP), 107, 116

Breast milk, drugs in, 1847

Bremazocine, actions and selectivities, 485t

BRETHINE (terbutaline), 1848

Bretylium
- adrenergic receptors and, 206t
- antiarrhythmic use of, 837
- contraindications to, 833t
- BRETYLOL (bretylium tosylate), 837

BREVIBLOC (esmolol), 840

BREVICON (ethinyl estradiol/norethindrone), 1835t

BRILINTA (ticagrelor), 871–872

Brimonidine, 297
- for ophthalmic use, 1787

Brinzolamide, 680
- for ophthalmic use, 1787

Broad Institute Software, 153t

Bromfenac, for ophthalmic use, 1789

Bromocriptine, 1114
- as antidote, 86t
- dosage of, 614t
- hypoglycemia and, 1248t
- therapeutic use of, for parkinsonism, 614t

BROMPHEN (brompheniramine maleate), 921t

Brompheniramine maleate, 921t

Bronchial muscle, eicosanoids and, 950

Bronchodilators, 1035
- arrhythmias caused by, 832
- novel classes of, 1046

Bronchomotor tone, acetylcholine and, 221

Bronchospasm
- angina pectoris with, recommended treatment for, 769t
- histamine and, 917–918

Brotizolam, structure of, 459t

BRUFEN (ibuprofen), 988t

Brugia malayi, 1446

Brugia timori, 1446

BSEP. See Bile salt export pump (BSEP)

BuChE. See Butyrylcholinesterase (BuChE)

Bucindolol, 312f, 329

Bulk-flow transfer, limitations of, 17

Bulk-forming agents, 1336

Bullous disease(s), autoimmune, IVIG for, 1827

Bullous pemphigoid
- azathioprine for, 1820–1821
- cyclophosphamide for, 1821
- cyclosporine for, 1821
- dapsone for, 1823
- glucocorticoids for, 1809
- mycophenolate mofetil for, 1823

Bumetanide, 682–684
- as antihypertensive agent, 774t, 777
- for heart failure, 790–791
- pharmacology of, 683t
- structure of, 683t

BUMEX (bumetanide), 682–684, 683t, 790–791

Bunazosin, 310

Bupivacaine, as anesthetic, 573

Buprenorphine
- actions and selectivities of, 485t
- dependence on, 512
- pharmacokinetics of, 1817t
- pharmacological actions of, 512
- side effects of, 512
- therapeutic uses of, 512–513

Bupropion
- adverse effects of, 411
- disposition of, 409t
- dose and dosage forms of, 402t
- drug interactions with, 412
- mechanism of action, 407
- pharmacokinetics of, 1817t
- potencies
  - at human transporters for monamine neurotransmitters, 406t
  - at neurotransmitter receptors, 410t
- side effects of, 402t

Buserelin, 1119t, 1765
- structure of, 1764t

Buspirone, 349
- pharmacokinetics of, 1818t

Busulfan, 1668t–1670t
- 1685–1686
- extramedullary toxicity of, 1668t–1670t
- metabolism of, 128t
- pharmacokinetics of, 1818t

Butabarbital, structure of, 470t

Butalbital, 470t

Butenafine, 1589, 1817

Butoconazole, 1587
- for vaginal candidiasis, 1842t
Butorphanol
actions and selectivities of, 485t
pharmacological actions of, 512
side effects of, 512
therapeutic uses of, 511–512
and vasopressin secretion, 704

Butyrylcholinesterase (BuChE), 219, 240

CAB. See Combined androgen blockade (CAB)
Cabergoline, 1114–1115

side effects of, 138t
CALAN (verapamil), 763, 831
CALCIDRINE SYRUP (calcium iodide), 1153t
Calcineurin inhibitors
in dermatology, 1821–1822
in immunosuppressive therapy, 1008–1012
Calcipotriene
dosage and administration of, 1813
mechanism of action of, 1813
for psoriasis, 1813
structure of, 1813
Calcitonin (CT)
chemistry and immunoreactivity of, 1283–1284
diagnostic uses of, 1294
history and source of, 1283
mechanism of action of, 1284
secretion of, regulation of, 1284
therapeutic uses of, 1294
Calcitonin gene-related peptide (CGRP), 172
Calcitriol, 1277–1292, 1818t
Calcium
abnormal metabolism of, 1286–1288
homeostasis, 1275–1276
hormonal regulation of, 1277–1285
hypercalcemia, 1286–1288
hypocalcemia, 1288
hypoglycemia and, 1248t
intestinal absorption of, 1282–1283
Calcium (Cont.):  
for osteoporosis, 1300
parathyroid hormone and, 1278–1280
as second messenger, 57–58
therapeutic uses of, 1291
vitamin D regulation of, 1280–1283
Calcium channel(s)
acetylcholine and, 221
Calcium channel antagonists
ABC transporters and, 105t
antidote, 86t
hypoglycemia and, 1248t
polymorphisms and response to, 159t
toxidrome, 83t
Calcium channel blockers, for prevention of preterm labor, 1848
Calcium-channel blockers
absorption, fate, and excretion of, 765
as antianginal agents, 752, 766–767
as antiarrhythmic agents, 767
antiarrhythmic use of, 830–831
as antihypertensive agents, 767, 784t
cardiac electrophysiological actions of, 829t
cardiovascular pharmacology of, 762t–763t
chemistry of, 761, 762t–763t
drug interactions with, 766
effects on renin-angiotensin system, 746t
frequency dependence, 764
hemodynamic effects of, with long-term administration, 774t
history of, 761
mechanism of action of, 761–763
pharmacological properties of, 763–766
cardiac, 763–764
vascular, 763
hemodynamic, 764–765
renal, 763
renal effects of, 767
structures, 762t–763t
therapeutic uses of, 766–767
in myocardial ischemia, 761–767
with beta-adrenergic receptor antagonists, 768, 770
with nitrates, 770
toxicity and untoward responses to, 765–766
use dependence, 764
Calcium channels, acetylcholine and, 221
Calcium chloride, as antidote, 86t
Calcium gluconate, 86t, 1291
Calcium iodide, 1153t
CALDOLOR (ibuprofen), 988
Calicheamicin, 23
CAMPATH (alemtuzumab), 1748
Camptothecin analogs, 1670t–1670t
Candida, vaginal, 1842t
Candidate gene association studies, 152–153
Candidiasis
localized, therapy for, 1816t

for pruritus, 1828
structure of, 1830
CAPSIN (capsaicin), 1830
Captopril, 732–733
as antihypertensive agent, 774
for heart failure, 797
history of, 731
in renal failure, 735
structure of, 732
therapeutic uses of, 738–745
CAR. See Constitutive androstane receptor (CAR)
CARAC (5-fluorouracil), 1821
Carbachol
acetylcholine vs., 222
in ocular surgery, 1788
for ophthalmic use, 1788
pharmacological properties of, 223
structure of, 222
therapeutic use of, 224
Carbamate inhibitors, reversible, 242.
See also Anticholinesterase agents; specific agent
Carbamazepine, 594–595
metabolism of, 128f, 130, 131f
pharmacokinetics of, 1819
polymorphisms and response to, 160t
for pruritus, 1828
and vasopressin secretion, 704
Carbapenems, 1499–1501
Carbenicillin
activity of, 1484
chemistry of, 1479t
properties of, 1479t
Carbenicillin indanyl
chemistry of, 1479t
properties of, 1479t
Carbetocin, 1850
Carbidopa, pharmacokinetics of, 1819t
Carbidopa/levodopa
dosage of, 614t
therapeutic uses of, for parkinsonism, dosage of, 614t
Carbinoxamine maleate, 921t
Carbohydrate plasma expanders, histamine and, 914
Carbon dioxide, 561–562
Carbonic anhydrase inhibitors,
677–681
absorption and elimination of, 680
chemistry, 679t
drug interactions with, 680
excretory and renal hemodynamic effects of, 678t
mechanism of action of, 678–679, 679f
pharmacology of, 679t
and renal hemodynamics, 680
site of action of, 678–679
structure of, 679t
toxicity, adverse effects, and contraindications to, 680
and urinary excretion, 679–680
Carbonic anhydrase inhibitors (CAIs),
for glaucoma, 1787
Carbon monoxide, in central nervous system, 390
Carbon monoxide antidote, 86t
Carboplatin, 1668–1670
extramedullary toxicity of, 1682
pharmacokinetics of, 1820–1821
Carboxylestrases, 131
Carboxypeptidase M, 929–930
Carboxypeptidase N, 929
Carcinogen(s), 1855–1860
Carcinogensis, 1855–1857
Carcinoid, malignant, drugs for,
1668–1670
Cardiac action potentials. See Action potential(s), cardiac
Cardiac arrhythmias
ethanol and, 636
sympathomimetic drugs for, 302
Cardiac Arrhythmia Suppression Trial (CAST), 832
Cardiac cell, 815–816, 816f
sodium and calcium exchange in,
802f
Cardiac conduction
decremental, 819
factors affecting, 819
failure, 819
Cardiac electrophysiology, 815–819
action potentials in, 816–817
heterogeneity of, 817–818
conduction failure and, 819, 819f
impulse propagation, 818–819
impulse propagation and ECG, 818f
Cardiac electrophysiology (Cont.):
maintenance of intracellular ion homeostasis in, 818
as “moving target” for therapy, 833
refractoriness, 819, 819f, 826f
sodium and calcium exchange in,
802f
Cardiac glycoside antidote, 86t
Cardiac glycosides, 801–804, 837–839
electrophysiologic actions, 803
for heart failure, 801–804
inhibition of Na,K-ATPase, 801
mechanism of action of, 801–803
pharmacokinetics of, 803
positive inotropic effect, 802–803
regulation of sympathetic nervous system activity, 803
toxicity of, 803–804
Cardiomyopathy
ethanol and, 636
hypertrophic, angina pectoris with, recommended treatment for,
769t
Cardioprotection, NSAIDs for,
971–972
Cardiovascular disease (CVD), risk assessment
for men, 888t
for women, 889t
Cardiovascular system
acetylcholine and, 220–221
adrenocorticosteroids and, 1220–1221
atropine and, 233
beta-adrenergic receptor antagonists and, 313–314, 316
choline esters and, 223t
dobutamine and, 290
dopamine and, 288
drug effects on prostaglandin, 946–947
thromboxane, 946–947
eicosanoids and, 948–949
ethanol and, 635–636
fentanyl and, 507
ganglionic blocking drugs and, 273
halothane and, 546–547
histamine and, 916
isoflurane and, 548
kinins and, 931
meperidine and, 506
nicotine and, 271
norepinephrine and, 287
Cardiovascular system (Cont.):
oxygen inhalation and, 559
platelet-activating factor and, 954
serotonin and, 340–341
thyroid hormones and, 1140–1141
vasopressin and, 708
Cardioversion, 823, 824t
Cardioverter/defibrillator, indications for, 823
CARDIZEM (diltiazem), 762t, 831
Carmoterol, 292t, 294
Carmustine, 1668t–1670t, 1686
adverse effects and siide effects of, 1821
in dermatology, 1821
extramedullary toxicity of, 1682t
mechanism of action of, 1820t
Carnitine
as antidote, 86t
deficiency syndrome, systemic, 102t, 113
β-Carotene, 1813
Maximum Recommended Therapeutic Dose, 1813
Carperitide, 696
Carrier-mediated diffusion, 674
Carrier-mediated membrane transport, 19
Carteolol, as antihypertensive agent, 774t
Carvedilol, 312t, 329
as antihypertensive agent, 774t, 780–781
for heart failure, 801
pharmacokinetics of, 1820t
CARVERJECT (alprostandil), for impotence, 952
CASODEX (bicalutamide), 1765
Caspofungin acetate, 1583–1584
Catecholamines (Cont.):
in central nervous system, 382–384
dopamine and, 355
endogenous, 282–289
monoamine oxidase and, 200
release, 199
angiotensin II and, 729
storage, 196–199
synthesis, 194–196
termination of actions of, 200–201
Catechol-O-methyltransferase (COMT), 138
catecholamine termination and, 200
Catechol-O-methyltransferase (COMT) inhibitors, for parkinsonism, 617–618
Cathartics, 85, 1328–1336
Causative polymorphism, 153
Cavelac, 17
Caveolin, 17
CCR5. See Chemokine receptor 5 (CCR5)
CECLOR (cefaclor), 1494t, 1496t
Cefaclor
antibacterial spectrum of, 1496t
chemistry of, 1494t
dosage and dosage forms of, 1494t
Cefadroxil
chemistry of, 1494t
dosage and dosage forms of, 1494t
Cefamandole
chemistry of, 1494t
dosage and dosage forms of, 1494t
Cefazolin
antibacterial spectrum of, 1496t
chemistry of, 1494t
dosage and dosage forms of, 1494t
pharmacokinetics of, 1820t
Cefdinir, pharmacokinetics of, 1821t
Cefepime
chemistry of, 1494t
dosage and dosage forms of, 1494t
pharmacokinetics of, 1821t
Cefixime, for gonococcal urethritis, 1842t
CEFIXOX (ceftizoxime), 1494t
Cefobid (cefopeprazone), 1494t
Cefonicid
chemistry of, 1494t
dosage and dosage forms of, 1494t
Cefoperazone
chemistry of, 1494t
dosage and dosage forms of, 1494t
Ceforanide
chemistry of, 1494t
dosage and dosage forms of, 1494t
CEFOTAN (cefotetan), 1494t, 1496t
Cefotaxime, antibacterial spectrum of, 1496t
Cefotetan
antibacterial spectrum of, 1496t
chemistry of, 1494t
dosage and dosage forms of, 1494t
for pelvic inflammatory disease, 1842t
Cefoxitin
antibacterial spectrum of, 1496t
chemistry of, 1494t
dosage and dosage forms of, 1494t
for pelvic inflammatory disease, 1842t
Cefpodoxime proxetil
chemistry of, 1494t
dosage and dosage forms of, 1494t
Ceftazidime
antibacterial spectrum of, 1496t
chemistry of, 1494t
dosage and dosage forms of, 1494t
Ceftizoxime
chemistry of, 1494t
dosage and dosage forms of, 1494t
Ceftriaxone
antibacterial spectrum of, 1496t
chemistry of, 1494t
dosage and dosage forms of, 1494t
pharmacokinetics of, 1821t
CEFTIN (cefuroxime axetil), 1494t, 1496t
Ceftizoxime
chemistry of, 1494t
dosage and dosage forms of, 1494t
Cefixime, for gonococcal urethritis, 1842t
for pelvic inflammatory disease, 1842t
pharmacokinetics of, 1822t
Cefuroxime
antibacterial spectrum of, 1496t
chemistry of, 1494t
dosage and dosage forms of, 1494t
Cefuroxime axetil
chemistry of, 1494t
dosage and dosage forms of, 1494t
CELEBREX (celecoxib), 964–965, 991
Celecoxib, 964–965, 991
absorption, 991
adverse effects and side effects of, 991
arrhythmias caused by, 832
in cancer prevention, 972–973
compared to aspirin, 970t
Central nervous system (CNS) (Cont.):
- drug interactions, 392–393
- eicosanoids and, 951
- epinephrine and, 285
- ethanol and, 633–635
- fentanyl and, 507
- GABA in, 376–379
- glutamate in, 379–380
- glycine in, 379
- histamine and, 384–388, 915
- H, receptor antagonists and, 919–920
- integrative chemical communication in, 366–371
- lipid mediators in, 389–390
- meperidine and, 503–505
- methadone and, 508
- muscarinic antagonists and, 230, 233–234
- neuromuscular blocking agents and, 261–262
- neurotransmitter receptor-effector coupling in, 371–372
- nicotine and, 271
- nitric oxide in, 390
- organizational principles of, 363–366
- plasticity of, 366
- repair of, 366
- serotonin and, 341–342
- stimulants, 392
- supportive cells in, 365
- synaptic transmission in, 373–376
- transmitter interactions, 393
- vasopressin in, 378
- Central nervous system depressants, 654–657

Central nervous system depressants, 654–657

Celecoxib (Cont.):
- COX isomeric selectivity, 962f
- distribution of, 991
- dosage and administration of, 970t
- elimination, 991
- pharmacokinetics of, 970t, 991
- 1822t
- pharmacology of, 962f
- plasma binding of, 1822t
- plasma pharmacokinetics of, 962f
- structure of, 991
- therapeutic uses of, 970t, 991

Celiac ganglion, 173f

Celiprolol, 312f, 329–330

Cell-based screening, in drug discovery, 393
dopamine and, 355–356

depressants, 390–392, 654–657

distribution of drugs and, 25

dopamine and, 355–356

drug discovery, 393

Central nervous system (CNS) (Cont.):
- drug interactions, 392–393
- eicosanoids and, 951
- epinephrine and, 285
- ethanol and, 633–635
- fentanyl and, 507
- GABA in, 376–379
- glutamate in, 379–380
- glycine in, 379
- histamine and, 384–388, 915
- H, receptor antagonists and, 919–920
- integrative chemical communication in, 366–371
- lipid mediators in, 389–390
- meperidine and, 503–505
- methadone and, 508
- muscarinic antagonists and, 230, 233–234
- neuromuscular blocking agents and, 261–262
- neurotransmitter receptor-effector coupling in, 371–372
- nicotine and, 271
- nitric oxide in, 390
- organizational principles of, 363–366
- plasticity of, 366
- repair of, 366
- serotonin and, 341–342
- stimulants, 392
- supportive cells in, 365
- synaptic transmission in, 373–376
- transmitter interactions, 393
- vasopressin in, 378
- Central nervous system depressants, 654–657
- Central neurotransmitters, 376–390

Cephalexin
- antibacterial spectrum of, 1496t
- chemistry of, 1494t
- dosage and dosage forms of, 1494t
- pharmacokinetics of, 29, 1823

Cephalosporins
- antibacterial spectrum of, 1496t
- bacterial resistance to, 1817
- chemistry of, 1494t
- for deep cutaneous infections, 1817
- dosage and dosage forms of, 1494t
- drug interactions with, 1529
- first-generation, 1494t, 1496t, 1497
- fourth-generation, 1494t, 1496t, 1498–1499
- general features of, 1496–1497

Cephalosporins (Cont.):
- mechanism of action of, 1478–1481
- second-generation, 1494t, 1496t, 1497
- therapeutic uses of, 1499
- third-generation, 1494t, 1496t, 1497–1498

Cephalothin
- antibacterial spectrum of, 1494t
- chemistry of, 1494t
- dosage and dosage forms of, 1494t

Cocaine
- abuse and addiction, 661–663
- as anesthetic, 572
- cholinergic receptors and, 206
- metabolism of, 128
Codeine
- drug interactions with, 844
- metabolism of, 128
- pharmacokinetics of, 1828
- polymorphisms and response to, 159
Codominant trait, 147
Codons, 148
Coenzyme A (CoA), 185
Cognition
- dopamine and, 357
- estrogen and, 1175
- muscarinic receptors in, 223–224
Colchicine
- absorption, 995
- adverse effects and side effects of, 996
Colchicine (Cont.):
- distribution of, 995
- elimination, 995
- mechanism of action of, 995
- structure of, 995
- therapeutic uses of, 995–996
Colestervelam, 898–899
- adverse effects of, 899
- chemistry of, 898–899
- drug interactions with, 899
- and lipoprotein levels, 899
- and statins, combination therapy with, 898
- structure of, 898
- therapeutic uses of, 899
monitoring, 899
COLESTID (colestipol hydrochloride), 899
Colestipol, 898–899
- adverse effects of, 899
- chemistry of, 898–899
- drug interactions with, 899
- and lipoprotein levels, 899
- and statins, combination therapy with, 898
- structure of, 898
- therapeutic uses of, 899
Colon cancer
- drugs for, 1668–1670
- metastatic, 1737
- prevention of, NSAIDs for, 972–973
Colony-stimulating factor(s), in cancer treatment, 1750
Colterol, structure of, 279
Coma, myxedema, 1144–1145
COMBICAN, 1787
Combination therapy, 50
Combinatorial chemistry, 4
Combined androgen blockade (CAB), 1765

drug interactions with, 778, 839
effects on renin-angiotensin system, 746
for heart failure, 790–793
in clinical practice, 791–792
in decompensated patient, 792
metabolic consequences, 792
resistance, 792, 793
hemodynamic effects of, with long-term administration, 774
high-ceiling, 682–686, 683
excretory and renal hemodynamic effects of, 678
hyperglycemia and, 1248
Diuretics (Cont.):
inhibitors of Na⁺-Cl⁻ symport, 678, 686–690, 688r
inhibitors of Na⁺-K⁺-2Cl⁻ symport, 678, 682–686, 683r
inhibitors of nonspecific cation channel, 695–696
inhibitors of renal epithelial sodium channels, 678, 690–692, 690r
intolerance, 701
loop (See Loop diuretics)
mechanism of action of, 697f
and organic acid and organic base secretion, 676, 676f
osmotic (See Osmotic diuretics)
polymorphisms and response to, 160r
potassium-sparing, 690–692, 690r
as antihypertensive agents, 774r, 778
chemistry of, 690, 690r
drug interactions with, 691–692
excretory and renal hemodynamic effects of, 678, 691
mechanism of action of, 690–691, 691f
pharmacology of, 690r
and renal hemodynamics, 691
site of action of, 690–691
structure of, 690r
therapeutic uses of, 692
toxicity, adverse effects, and contraindications to, 691–692
and urinary excretion, 691
renal epithelial transport and, 674–676
renal handling of specific anions and cations and, 676–677
resistance (edema refractory to), 699
role in clinical medicine, 698–701
site of action of, 697f
therapeutic uses of, Brater’s algorithm for, 699, 700f
thiazide (See Thiazide diuretics)
thiazide, SLC transporters and, 102r
DIURIL (chlorothiazide), 688r, 791
Diversity, ethnic, 150–151
DIVIGEL (estradiol), 1839r
DMPP. See
Dimethylphenylpiperazinium (DMPP)
DNA methylation, 97

Dobutamine
adrenergic receptors and, 206r
adverse effects of, 290, 321t
cardiovascular effects of, 290
pharmacological properties of, 321r
structure of, 279r
therapeutic uses of, 290, 321r
for heart failure, 804–805
Docetaxel, 1668r–1670r
pharmacokinetics of, 1832r
Docosanol, 1596r, 1604
for cutaneous viral infections, 1818
Docusate, 1330r
Dofetilide, 839
adverse effects of, 839
arrhythmias caused by, 821t
contraindications to, 833
Dosage regimens
design and optimization of, 34–37
individualization, 37, 1808
intermittent, interval for, 36
loading, 36–37
maintenance, 35–36
median effective, 73, 74f
median lethal, 73, 74f
Dose
 calculation, in prescription writing, 1881
loading, 36–37
of neuromuscular blocking agents, 265t
Dose-dependent reactions, 75–76

Dopamine (DA) (Cont.):
kidneys and, 355
learning and, 357
memory and, 357
metabolism of, 351–353
Parkinson disease and, 356–357
pharmacology of, 288
physiological functions of, 353–359
pituitary gland and, 355
precautions, adverse reactions, and contraindications to, 288
sources of, 351
structure of, 279t
synthesis of, 194–196, 351–353
therapeutic uses of, 288–289, 290
vasculature and, 355
Dopamine hypothesis, 417
Dopamine receptor(s)
agonists, 357–358, 616–617, 1114–1115
antagonists, 358–359, 1325–1326
for nausea, 1343
antipsychotics and, 427t
D₂, 427r
Dopaminergic agonists, therapeutic uses of, for heart failure, 804–805
Dopamine transporter, antidepressant potencies at, 406t
Dopamine transporter (DAT), 116, 198t
polymermorphisms in, 150f
DOPEG. See 3,4-dihydroxyphenyl glycol (DOPEG)
DOPET. See 3,4-dihydroxyphenylethanol (DOPET)

Gynecology, drug therapy in, 1837–1845

Gyromitra, 225

H

Haemophilus influenzae, ABC transporter in, 100f

Hageman factor, 929

Hailey-Hailey disease, dapsone for, 1823

Hair, drug absorption into, 1804

Halazepam administration and uses of, 466

Halbetasol propionate, 1808

Halcinonide cream, 1225

HALCION (triazolam), 466

Half-life alteration for individual patients, 1807–1808

of common drugs, 1809–1890

definition of, 32–33

as pharmacodynamic parameter, 1804

Halobetasol propionate ointment, 1225

HALOG-E (halcinonide cream), 1225

HALOG (halcinonide), 1225

Haloperidol arrhythmias caused by, 832

dosage of, 424–425

metabolism of, 434

pharmacokinetics of, 1847–1890

polymorphisms and response to, 160

potencies at neurotransmitter receptors, 427f

side effects of, 424f

and vasopressin secretion, 704

Haloprogin, 1588

Halothane, 546–547

Haplotype, 148–149

Haploview, 149, 149f

Hapten, 76

Hardy-Weinberg equilibrium, 152

hCG. See Human chorionic gonadotropin (hCG)

Headache, vascular, angina pectoris with, recommended treatment for, 769f

Head and neck cancer, 1736–1737

drugs for, 1668–1670f

HEALON (hyaluronate), 1790

Healthcare, funding of, 11–12

Heart

alpha adrenergic receptors in, 203

anticholinesterase agents and, 246–247

in autonomic nervous system, 178

beta adrenergic receptors in, 204

with diastolic dysfunction, pressure-volume relationships in, 806f

dopamine and, 355

eicosanoids and, 948

epinephrine and, 284–285

histamine effects on, 917

muscarnic antagonists and, 227–228

normal, pressure-volume relationships in, 806f

Heart disease, ischemic, 751–758

definition of, 790

diastolic, 805–806

clinical use and monitoring of, 865

diuretics for, 699–701, 790–793

dopaminergic agonists for, 804–805

diuretics for, 699–701

diuretics for, 699–701

hemodynamic responses to pharmacological interventions in, 792f

loop diuretics for, 790–791

nitrates for, 760

pharmacology of, 791f

phosphodiesterase inhibitors for, 805

sites of drug action in, 791f

stages of, 808, 809f

sympathomimetic drugs for, 302

thiazide diuretics for, 791

vasodilators for, 793–797

vasopressin receptor antagonists for, 799–800

Heart Outcomes Prevention Evaluation (HOPE) study, 735

Heart rate

acetylcholine and, 220–221

muscarnic antagonists and, 227–228

Heavy metals

bone binding and, 24–25

dose-response curve for, 74f

as environmental toxins, 1860–1872

treatment of exposure to, 1872–1876

Helicobacter pylori infection, 1320

Helium, 564–559

Helminthiasis, 1444–1449

chemotherapy for, 1449–1459

Hematopoietic agents, growth factors, 1067–1076

erthropoiesis stimulating agents, 1068–1073

diabetes, 1247

and antianginal therapy, 752

clinical use and monitoring of, 865

derivatives, 854

features of, 854f

hypoglycemia and, 1248f

mechanism of action of, 856f

pharmacokinetics of, 1847f

pharmacological effects of, 854–855

structure of, 855, 855f

therapeutic uses of, 855–857

in myocardial ischemia, 771

thrombocytopenia caused by, 859, 864–865

USP unit dose, 854

Hepatic clearances, 29–30

Hepatic drug transporters, 90f

Hepatic glucose metabolism, diabetes, 1247

Hepatic lipase (HL), 881, 884

Hepatic transporters, 108–111

Hepatic uptake, transporters in, 110–111
Hepatitis
drugs for, 1609–1617
interferons for, 1609–1614
Hepatitis B virus infection, drugs for,
1614
Hepatitis C virus infection, drugs for,
1609–1614
Hepatocellular carcinoma (HCC),
1740, 1860
Hepatocytes, ABC transporters in, 108,
109
Hepatotoxicity
of acetaminophen, 983
of angiotensin converting enzyme
inhibitors, 736
of niacin, 900
of statins, 896
Hepoxilins, 937, 946
HER1. See Epidermal growth factor
receptor(s) (EGFR)
Herbal extracts, for menopausal
symptoms, 1840
HERCEPTIN (trastuzumab), 1737
Hereditary hemochromatosis, 102
HER2/neu inhibitors, 1737–1738
Herpes simplex virus (HSV)
drugs for, 1598–1599
iridocyclitis, 1783
keratoconjunctivitis, 1783
skin infection, 1818
Herpesviruses, treatment of,
1593–1605
HERPES ZOSTER OPHTHALMICUS, 1783t
HERPLEX (idoxuridine), 1596t
HETERODIMERIZATION, 487
Heterophyes heterophyes, 1449
Heterozygotes, 147
HETEs, 938f, 939–941, 940f
Hexachlorocyclohexane. See Lindane
Hexamethonium (C6), 273f
Hexamethylenelamine, 1668r–1670r
Hexobarbital, polymorphisms and
response to, 159t
HGPRT. See Hypoxanthine guanine
phosphoribosyl transferase (HGPRT)
HGVbase. See Human Genome
Variation Database (HGVbase)
Hidradenitis suppurativa
retinoids for, 1811
treatment of, 1816
HIF. See Hypoxia-inducible factor
(HIF)
HIVID (zalcitabine), 1626

HISTOACRYL (cyanoacrylate tissue adhesive), 1790

L-Histidine decarboxylase, 912

Histamine H1 receptor antagonists (Cont.):
teratogenicity of, 923
therapeutic uses of, 920–924
for allergic diseases, 920–922
for common cold, 923
for motion sickness, 923
for sedation, 923
for vertigo, 923
trade names, 921t
Histamine H1 receptor antagonists, clinical summary, 926
Histamine H1 receptor antagonists, pharmacokinetics of, 1816t
Histamine H2 receptor antagonists, clinical summary, 926
Histamine H2 receptor antagonists, 911, 916, 924–925
clinical summary, 926
Histamine H3 receptor antagonists, 925
clinical summary, 926
Histamine N-methyltransferase (HNMT), 139
Histamine receptor(s), 911
characteristics of, 913t
effector coupling, 915–916
H1, 911, 916
characteristics of, 913t
H2, 911, 916
characteristics of, 913t
H3, 911–912, 916, 924–925
characteristics of, 913t
H4, 912, 916, 925
characteristics of, 913t
Histamine receptor blockers. See Antihistamines; Histamine H1 receptor antagonists; Histamine H2 receptor antagonists; Histamine H3 receptor antagonists; Histamine H4 receptor antagonists
Histamine shock, 917
L-Histidine decarboxylase, 912
HISTOACRYL (cyanoacrylate tissue adhesive), 1790
Histone deacetylase inhibitors, 1723–1724
Histrelin, 1119t, 1122, 1765
structure of, 1764t
HIV. See Human immunodeficiency virus (HIV) infection
HIVID (zalcitabine), 1626t
HMG CoA reductase, reaction catalyzed by, 892–893, 894
HMG-CoA reductase, reaction catalyzed by, 808, 893f
HMG CoA reductase inhibitors, 109, 892–893, 894
absorption, fate, and excretion of, 895–896
HMG-CoA reductase inhibitors, 808
HNMT. See Histamine N-methyltransferase (HNMT)
Hodgkin’s disease (HD), drugs for, 1668t–1670t, 1755
HOE 140, 932
[des-Arg10]-, structure of, 928t
structure of, 928t
HOE-140, 930
Homatropine, 226, 227f
for uveitis, 1788
Homatropine hydrobromide, 233
Homatropine methylbromide, 234
Home poisoning prevention, 81–82
Homocysteinemia, 163
Homovanillic acid (HVA), 196, 352f, 352–353
Hookworm infections, 1445–1447
Horizontal gene transfer, 1378
Horizontal gene transfer, 1388
Horizonal gene transfer, 1378
Hormonal contraceptives,
1185–1189
Hormone replacement therapy (HRT)
postmenopausal, 1838–1840
preparations for brand names, 1839t
formulations, 1839t
Hormones
ABC transporters and, 105t
and antagonists, for neoplastic disease, 1668t–1670t
general concepts, 1103
HPETEs, 938f, 939, 940f
H1 receptor antagonists, 911, 916
adverse effects of, 1314
chemistry of, 1313
drug interactions with, 1314
hypoglycemia and, 1248t
intravenous doses of, 1313t
mechanism of action of, 1313
pharmacokinetics of, 1313–1314
pharmacological properties of, 1313
therapeutic uses of for gastroesophageal reflux disease, 1318t
for ulcers, 1319t
tolerance, 1314
HRT. See Hormone replacement therapy (HRT)
HSV. See Herpes simplex virus (HSV)
HuGE Navigator, 153t
Human chorionic gonadotropin (hCG), 1117–1120
diagnostic uses of, 1123–1124
for ovulation induction, 1843
human ether-a-go-go-related gene (HERG), 817
Human Genome Variation Database (HGVDbase), 153t
Human immunodeficiency virus (HIV) infection
antiretroviral therapy for entry inhibitors, 1656–1658
history of, 1625–1626
integrase inhibitors, 1658–1659
nonnucleoside reverse transcriptase inhibitors, 1640–1644
nucleoside reverse transcriptase inhibitors, 1629–1640
principles of, 1626–1628
protease inhibitors, 1644–1656
drugs for, ABC transporters and, 105t–106t, 106
life cycle of, 1624–1625
pathogenesis of, 1623–1626
structure of virus, 1624
susceptibility testing in, 1370–1371
Human leukocyte antigen (HLA), soluble, 1021
Human leukocyte antigen polymorphism, 160t
Human papillomavirus (HPV), verrucae caused by, 1818
HUMIRA (adalimumab), 1827
Huntington’s disease, 622–624
antipsychotics for, 436
clinical features of, 622–623
genetics of, 623
pathology of, 623
selective vulnerability to, 623–624
treatment of, 624
HVA. See Homovanillic acid (HVA)
Hydantoin, 591–593
Hydralazine
absorption, fate, and excretion of, 787
adverse effects and side effects of, 787
as antihypertensive agent, 774t, 786–788
mechanism of action of, 787
pharmacology of, 787
polymorphisms and response to, 159t
side effects of, 138t
Hyaluronic acid, 559
Hydralazine
Hydrogen sulfide, 559
Hydrolysis reactions, 128
Hydrolytic enzymes, 130–131, 131
Hydromorphone
Hydromorphone
Hydroquinone monomethyl ether. See Mequinol
Hydroscopic agents, 1336

Hydroxyzine, 921

Hyperbaric oxygen, as antidote, 86
Hyperbaric oxygen therapy, 128
Hypercholesterolemia, 877
Hypercalcemia, 1286–1288
bisphosphonates for, 1296
treatment of, 1290–1291
Hypercholesterolemia, 877
and atherogenesis, epidemiological studies of, 885
nicotinic acid for, 901
treatment of, 883
Hyperesinophilia syndrome, 1732, 1734
Hyperglycemia
drugs causing, 1248
nicin-induced, 900
Hyperkalemia, ACE inhibitors and, 769
treatment for, 769
angiotensin II receptor antagonists for, 738–745
beta-adrenergic receptor antagonists for, 314–315
definition of, 772
diagnostic criteria for, 772
in adults, 773
direct renin inhibitors for, 745–747
and dyslipidemia treatment, 890
epidemiology, 772
ethanol and, 636
malignant, 773
nonpharmacological therapy for, 783
pathophysiology of, 772, 773
pulmonary, eicosanoids for, 952
pulmonary arterial, 1059–1061
resistant, 784
and risk for coronary heart disease, 887
sympathomimetic drugs for, 302
systolic versus diastolic, 772–773
Hyperthyroidism, 1141–1142
angina pectoris with, recommended treatment for, 769
Hypertriglyceridemia, 877–878
classification of, 892
drugs for, 902, 903
reduction of, by statins, 894
treatment of, 892, 902
Hypertrophic cardiomyopathy, angina pectoris with, recommended treatment for, 769
Hypervitaminosis D, 1288–1289
Hypnotics, history of, 457–458
Hypoaalbuminemia, 24

Hyperbaric helium applications, 564–559
Hyperbaric oxygen, as antidote, 86
Hyperbaric oxygen therapy, 560–561
Hypercalcemia, 1286–1288
bisphosphonates for, 1296
treatment of, 1290–1291
Hypercholesterolemia, 877
and atherogenesis, epidemiological studies of, 885
nicotinic acid for, 901
treatment of, 883
Hyperesinophilia syndrome, 1732, 1734
Hyperglycemia
drugs causing, 1248
nicin-induced, 900
Hyperkalemia, ACE inhibitors and, 769
treatment for, 769
angiotensin II receptor antagonists for, 738–745
beta-adrenergic receptor antagonists for, 314–315
definition of, 772
diagnostic criteria for, 772
in adults, 773
direct renin inhibitors for, 745–747
and dyslipidemia treatment, 890
epidemiology, 772
ethanol and, 636
malignant, 773
nonpharmacological therapy for, 783
pathophysiology of, 772, 773
pulmonary, eicosanoids for, 952
pulmonary arterial, 1059–1061
resistant, 784
and risk for coronary heart disease, 887
sympathomimetic drugs for, 302
systolic versus diastolic, 772–773
Hyperthyroidism, 1141–1142
angina pectoris with, recommended treatment for, 769
Hypertriglyceridemia, 877–878
classification of, 892
drugs for, 902, 903
reduction of, by statins, 894
treatment of, 892, 902
Hypertrophic cardiomyopathy, angina pectoris with, recommended treatment for, 769
Hypervitaminosis D, 1288–1289
Hypnotics, history of, 457–458
Hypoaalbuminemia, 24

Hyperlipoproteinemias, drugs for bile-acid sequestrants, 898–899
fibrac acid derivatives, 902, 903
nicotinic acid, 900
Hyperopia, 1788
Hyperpigmentation, treatment of, 130
Hyperprolactinemia, ergot alkaloids for, 358
Hyperprostaglandin E syndrome, 948
Hypersensitivity reactions delayed, 76
H receptor antagonists and, 919
Hypertriglyceridemia, 877–878
classification of, 892
drugs for, 902, 903
reduction of, by statins, 894
treatment of, 892, 902
Hypertrophic cardiomyopathy, angina pectoris with, recommended treatment for, 769
Hypervitaminosis D, 1288–1289
Hypnotics, history of, 457–458
Hypoaalbuminemia, 24
Hypobetalipoproteinemia, 891
Hypocalcemia, 1288
treatment of, 1291
Hypocarbia, 562
Hypoglycemia, 1270–1272
drugs causing, 1248
persistent hyperinsulinemic, of infancy, 104
Hypogonadism, female, 1203
Hypoparathyroidism, vitamin D for, 1293
Hypoprothrombinemia, drug- and venom-induced, 874
Hypoprothrombinemia of the newborn, 873–874
Hypotension
ACE inhibitors and, 735
sympathomimetic drugs for, 301–302
Hypothalamic-pituitary-adrenal (HPA) axis, 1104–1105
clinical disorders of, 1120–1123
Hypothermia, with general anesthesia, 532
Hypothyroidism, 1141, 1143
congenital, 1145
and dyslipidemia, 890
in pregnancy, 1144
subclinical, 1144
Hypoxanthine guanine phosphoribosyl transferase (HGPRT), 139, 1702
Hypoxemia, pulmonary mechanisms of, 556
Hypoxia
adaptation to, 558–559
cardiovascular effects of, 558
cellular effects of, 558
correction of, 560
effects of, 556–559
metabolic effects of, 558
neurological effects of, 558
nonpulmonary causes of, 556
respiratory effects of, 558
Hypoxia-inducible factor (HIF), 140
HYTONE (hydrocortisone cream), 1225

I
Ibandronate, pharmacokinetics of, 1849
Ibopamine, for heart failure, 805
IBUDONE, 988
Ibuprofen, 987
absorption, 988
Ibuprofen (Cont.):
adverse effects and side effects of, 988
compared to aspirin, 968
COX isoform selectivity, 962
distribution of, 988
do dosage and administration of, 968
elimination, 988
metabolism of, 128
pharmacokinetics of, 968, 988, 1850
pharmacology of, 962
plasma pharmacokinetics of, 962
structure of, 988
therapeutic uses of, 968, 988
Ibutilide
antiarrhythmic use of, 835
arrhythmias caused by, 821
contraindications to, 833
dosage and administration of, 835
electrophysiological actions of, 829
mechanism of action of, 830
pharmacokinetics of, 835
structure of, 841
Icatibant, 930, 932
ICCS. See Interstitial cells of Cajal (ICCs)
Ichthyosis
keratolytics for, 1829
retinoids for, 1811
Idiosyncratic reactions, 76–77
Idoxifene, 1756
Idoxuridine, 1596
Idoxuridine ophthalmic solution, 1153
Idrarubicin, pharmacokinetics of, 1850
Idraparinux, 858
Idrarubicin, pharmacokinetics of, 1850
Iloprost, 952
Imatinib mesylate (Cont.):
resistance, mechanisms of, 1732–1733, 1733
structure of, 1732
therapeutic uses of, 1732, 1734
toxicity of, 1734
Imatinib (STI-565), 1668–1670
IMDUR (isosorbide-5-mononitrate), 754
Imidazoles, 1576, 1817–1818
for ophthalmic use, 1784
for topical use, 1586–1587
IMiDs. See Immunomodulatory analogs
Iminostilbenes, 594–596
Imipenem, pharmacokinetics of, 1851
Imipramine
adrenergic receptors and, 206
disposition of, 409
dose and dosage forms of, 400
metabolism of, 128
potencies
at human transporters for
monamine neurotransmitters, 406
at neurotransmitter receptors, 410
side effects of, 400
Imiquimod, 1596
adverse effects and side effects of, 1823
for cutaneous viral infections, 1818
in dermatology, 1823
for genital warts, 1823
mechanism of action of, 1820
structure of, 1823
Immune globulins, 1023–1024
Immune response, 1005–1006
eicosanoids and, 948, 949–950
Immunization, 1023–1024
Immunomodulators, topical, for pruritus, 1828
Immunomodulatory agents, for ophthalmic use, 1790
Immunomodulatory analogs. See also Lenalidomide; Thalidomide
in cancer treatment, 1740–1742
Immunomodulatory therapy, 1054–1058
Immunostimulation, 1021–1024
Immunosuppression, 1006–1019
biological, 1015–1016
tolerance and, 1019–1021
Immunosuppressive agents
in dermatology, 1820–1822
for inflammatory bowel disease,
1357–1359
mechanism of action of, 1820
Immunosuppressive agents, ABC
transporters and, 105t
IMPDH. See Inosine monophosphatase
dehydrogenase (IMPDH)
Impentamine, 925
Impetigo, 1817
IMPLANON, 1834
Implanted cardiac defibrillator (ICD),
1836
Impotence, eicosanoids for, 952
Impulsivity, 5-HT and, 343
Inactivation, 78
Inamrinone, for heart failure, 805
IND. See Investigational New Drug
(IND) application; Notice of
Claimed Investigational
Exemption for a New Drug
(IND)
Indacaterol, 292f, 294
Indandione
antidote, 86t
structure of, 860f
Indapamide
as antihypertensive agent, 774t, 775
pharmacology of, 688t
structure of, 688t
Indels, 147, 147f
Indications
labeling and, 9
“off-label,” 9
Indinavir, 1626t, 1654
ABC transporters and, 105t
structure of, 1648f
Individualization of dosage, 37, 1808
Individual pharmacodynamics, 48–50
INDOCIN (indomethacin), 984–985
Indomethacin, 984–985
absorption, 984
adverse effects and side effects of,
985
and antidiuretic response to
vasopressin, 707–708
compared to aspirin, 966t
COX isoform selectivity, 962f
distribution of, 984
dosage and administration of, 966t
drug interactions with, 985
Indomethacin (Cont.):
efficiency, 984
hypoaggregation and, 1248t
mechanism of action of, 984
metabolism of, 128t
pharmacokinetics of, 966t, 984,
1851t
pharmacology of, 962f
plasma pharmacokinetics of, 962f
for prevention of preterm labor,
1848
structure of, 984
therapeutic uses of, 984, 985
Infliximab, 1626
Induction therapy, biological,
1006–1007
Infection(s)
Induction of drug metabolism,
for inflammatory bowel disease,
in dermatology, 1820–1822
tolerance and, 1019–1021
biological, 1015–1016
drug interactions with, 985
dosage and administration of, 966t
mechanism of action of, 1827
method of administration, 1825t
Influenza, drugs for, 1605–1609
Inhalants, abuse and addiction, 666
Inhalational administration, 22–23,
1034–1035
Inhalers
dry-powder, 1035
metered-dose, 1035
Inheritance. See Pharmacogenetics
Inhibition
competitive, 95
noncompetitive, 96
uncompetitive, 96
Inhibitory neurotransmission, 183f
Inhibitory postsynaptic potential
(IPSP), 184
Injection, parenteral, 22

dermal, 1804
  neuromuscular blocking agents and, 262–263
  proliferation of, histamine and, 915
Mastocytosis, systemic, NSAIDs for, 971
MATEs. See Multidrug and toxin extrusion family (MATEs)
MAVIK (trandolapril), 733, 797
MAXIFLOR (diflorasone diacetate), 1225t
Maximum Recommended Therapeutic Dose database, 1813
MAXIPME (cefpime), 1494t, 1496t
MDRI gene, 89
MDS. See Myelodysplastic syndrome (MDS)
Mebendazole, hypoglycemia and, 1248t
Mecamylamine, 272
  structure of, 273f
Mechanism of action, 51–65
Mechlorethamine, 1668t–1670t, 1683
Mechlorethamine hydrochloride
  adverse effects and side effects of, 1821
  in dermatology, 1821
  mechanism of action of, 1820t
Meclizine, 921t, 924
  therapeutic uses of, 923
Mefenamic acid, sodium, 989
  adverse effects and side effects of, 989
  compared to aspirin, 968t
  COX isofom selectivity, 962f
  dosage and administration of, 968t
  pharmacokinetics of, 968t
  pharmacology of, 962f
Median effective dose (ED50), 73, 74f
Median lethal dose (LD50), 73, 74f
animal testing of, 78
Mediator antagonists, 1052–1054
Medical addict, 654
Medical errors, 1883
“Medical imperialism,” 13
Medication errors, reduction of, 80–81
Medication errors, “Swiss cheese” model of, 81t
Medication seeking, 1882–1883
Medroxyprogesterone, in cancer chemotherapy, 1756
Medroxyprogesterone acetate (MPA), 1668t–1670t, 1766
Mefenamic acid, 989
  adverse effects and side effects of, 989
  compared to aspirin, 968t
  dosage and administration of, 968t
  pharmacokinetics of, 968t
  therapeutic uses of, 968t
Mefloquine, 1392t, 1408–1409
  pharmacokinetics of, 1860t
MEFOXIN (cefoxitin), 1494t, 1496t
MEGACE (megestrol acetate), 1668t–1670t, 1756
  Megestrol acetate, 1668
Mefenamic acid, 989
  adverse effects and side effects of, 990
  compared to aspirin, 970t
  COX isoform selectivity, 962f
  dosage and administration of, 970t
  pharmacokinetics of, 970t
  pharmacology of, 962f
  plasma pharmacokinetics of, 962f
  therapeutic uses of, 970t, 990
Mephenytoin, polymorphisms and response to, 159t
Mephenytoin hydroxylase, 157
Meprobamate, 476
  polymorphisms and response to, 159t
Mepivacaine, 573
Mephenytoin, polymorphisms and response to, 159t
Mephenytoin hydroxylase, 157
Mepivacaine, 573
Meprobamate, 476
  metabolism of, 128t
Mercury, 1864–1867
  Mercury antidote, 86r
Mesalamine
  chemistry, 1354–1355
  for inflammatory bowel disease, 1354–1356
  mechanism of action, 1354–1355
  pharmacological properties, 1354–1355
Mesenteric ganglia, 173f
Mesoridazine, potencies at neurotransmitter receptors, 427t
Metabolic effects
  of beta-adrenergic receptor antagonists, 315
  of epinephrine, 285–286
  of estrogens, 1169–1170
  of oral contraceptives, 1187–1188
  progestins and, 1182
  of thyroid hormones, 1141
Metabolic rickets, 1289
Metabolic syndrome, 877–878, 891
  clinical identification of, 891r
Metabolism interaction, 77
Metabolism of drugs, 27
  absorption and, 18f

Metabolites, as drugs, 1802

Metabolism of drugs (Cont.):

Methicillin

Methicillin-resistant Staphylococcus aureus (MRSA)

infection, antibiotics for, 1817

nasal colonization, antibiotic for, 1817

Methohexital

formulations of, 538
pharmacological properties of, 538
structure of, 470

Methotrexate, 994t, 1668t–1670t

ABC transporters and, 105t, 106t
as abortifacient, 1837
adverse effects and side effects of, 1820
contraindications to, 1820
in dermatology, 1820
drug interactions with, 1820
hepatic fibrosis caused by, 1820
for inflammatory bowel disease, 1358
intraocular use, 1790
leucovorin rescue for, 1820
mechanism of action of, 1820, 1820t
pharmacokinetics of, 1862
polymorphisms and action of, 159
polymorphisms and action of, 162–163
polymorphisms and response to, 159, 161t
for psoriasis, 1805, 1820
SLC transporters and, 102
therapeutic uses of, for inflammatory bowel disease, 1352
Methotrexate antidote, 86t

Methoxsalen, 1809, 1813

Methylchlothiazide, as

Methoxamine, structure of, 279

Methoxyphenol.

Methylguanine-methyltransferase (MTHFR), 162

Methylergonovine, for postpartum hemorrhage, 1850

Methylguanine-methyltransferase polymorphism, 161t

4-Methylhistamine, 912, 912f, 916

N-Methylhistamine, 913

Methylhydrazine derivative, for neoplastic disease, 1668t–1670t

Methylhydrazines, 1687

N-Methylimidazole acetic acid, 913

Methylmelamines, 1668–1670t

Methylparathion, 243

Methylphenidate, 299–300
pharmacokinetics of, 1862t

Methylprednisolone, 1216t

Methylprednisolone sodium succinate, dosage and administration of, 1809

Methyl salicylate, structure of, 977f

Methyltransferases (MT), 125, 125

Methylergonovine

Methylenetetrahydrofolate reductase, 162

Methyldopa, 297, 780–781

as antihypertensive agent, 774

as antihypertensive agent, 1325

chemistry of, 904–905
dosing of, 265

dosage of, 904–905
pharmacology of, 904–905
nonbronchodilator effects, 1042
side effects, 1043

Methylxanthines, 1040–1044

clinical use, 1043

Mechanism of action, 1040–1042

metabolism of, 1042

nonbronchodilator effects, 1042

pharmacokinetics, 1042

preparations of, 1042–1043

routes of administration, 1042–1043

side effects, 1043

Methysergide, 349, 351

Metoclopramide

adverse effects of, 1326

chemistry of, 1325
effects on bowel function, 1330t

mechanism of action of, 1325

pharmacokinetics of, 1325, 1863t

pharmacological effects of, 1325

therapeutic uses of, 1325

as antinausea agent, in cancer chemotherapy, 1344t

Metocurine, 264t

dosing of, 265t

Metolazone, 776–777

as antihypertensive agent, 774t

pharmacology of, 688t

structure of, 688t

“Me too” drugs, 13–14
Metoprolol, 777
   absorption, fate, and excretion of, 326
   adrenergic receptors and, 207
   for angina, 767
   antiarrhythmic use of, 774
   as antihypertensive agent, 774
   cardioprotective effects of, 767
   pharmacokinetics of, 1863
   structure of, 311
   therapeutic uses of, 326–327
   for myocardial ischemia, 767
Metrifonate, 1458
Metrizamide, 1153
METROCREAM (metronidazole), 1817
METROGEL (metronidazole), 1817
Metronidazole
   absorption, fate, and excretion of, 1429
   antiparasitic and antimicrobial effects of, 1428–1429
   for bacterial vaginosis, 1842–1429
   bioequivalency with, 23
   contraindications to, 1430
   drug interactions with, 1430
   mechanism of action of, 1429
   pharmacokinetics of, 1864
   resistance to, 1429
   therapeutic uses of, 1429–1430
   for inflammatory bowel disease, 1352
   topical, for acne, 1817
   toxicity of, 1430
   for trichomonas, 1842
METVIXIA (methylaminolevulinate), 1815
Metyrapone, 1235–1236
Metyrosine, as antihypertensive agent, 783
MEVACOR (lovastatin), 897
Mevastatin, 893, 894
   structure of, 893
Mexiletine
   antiarrhythmic use of, 828, 836
   contraindications to, 833
   dosage of, 836
   electrophysiological actions of, 829
   pharmacokinetics of, 836
   structure of, 842
MEXITIL (mexiletine), 842
MEXORYL SX (ecamsule), 1827
Mezlocillin, 1484
   chemistry of, 1479
   properties of, 1479
Mianserin, potencies at human transporters for monamine neurotransmitters, 406
Mibefradil, and statins, interactions, 896
Michaelis constant, 95
Michaelis-Menten equation, 95
Miconazole, 1587
   for cutaneous fungal infection, 1818
   for vaginal candidiasis, 1842
MICRONASE (glyburide), 1257
MICRONOR (norethindrone), 1836
MIDAMOR (amiloride), 690–692, 690
Midazolam
   administration of, 466
   metabolism of, 128
   pharmacokinetics of, 1864
   polymorphisms and response to, 159
   therapeutic uses of, 466
Midbrain, 364
Midodrine, 295
MIFEPREX (mifepristone), 1837
Mifepristone, 1184–1185
   as abortifacient, 1837
   for postcoital contraception, 1837
   risks (black box warning), 1837
   in therapeutic abortion, 952
Miglitol, 771
   for heart failure, 805
   Miltefosine, 1430–1431
Mineral(s)
   ethanol and, 638
   homoeostasis, 1275–1277
   homoeostasis disorders, 1286–1290
Mineralocorticoid receptors, antagonists of
   pharmacology of, 693
   structures of, 693
Mineralocorticoids, regulation of gene expression by, 1218
MINOCIN (minocycline), 1817
Minocycline, 994
   for acne, 1817
   adverse effects and side effects of, 788–781
   for androgenetic alopecia, 1829
   as antihypertensive agent, 774
   for inflammatory bowel disease, 1352
   topical, for acne, 1817
   toxicity of, 1430
   for trichomonas, 1842
MIOCHOL-E (acetylcholine), 1788
Miosis, 495, 1776
Miotic agents, for glaucoma, 1788
Miproxifene, 1756
MIRCETTE (ethinyl estradiol/desogestrel), 1835
MIRENA, 1836
Mirtazapine
   disposition of, 409
   dose and dosage forms of, 403
   pharmacokinetics of, 1865
   potencies at human transporters for monamine neurotransmitters, 406
   at neurotransmitter receptors, 410
   side effects of, 403
Misoprostol
   adverse effects of, 1315
   for cervical ripening, 1849–1850
   chemistry of, 1314
   pharmacokinetics of, 1315
   pharmacological properties of, 1314
   for postpartum hemorrhage, 1851
   for pregnancy termination, 1837
   therapeutic uses of, 1315
   for gastric cytoprotection, 952
   in therapeutic abortion, 952
   for ulcers, 1319

glycine in, 379
histamine and, 384–388, 915
H1 receptor antagonists and, 919–920
integrative chemical communication in, 366–371
lipid mediators in, 389–390
meperidine and, 503–505
methadone and, 508
muscarinic antagonists and, 230, 233–234
neuromuscular blocking agents and, 261–262
neurotransmitter receptor-effector coupling in, 371–372
nicotine and, 271
nitric oxide in, 390
organizational principles of, 363–366
plasticity of, 366
repair of, 366
serotonin and, 341–342
stimulants, 392
supportive cells in, 365
synaptic transmission in, 373–376
vasopressin secretion, 704

Neurodegenerative disorders
selective neuronal vulnerability in, 609–619

Neuroleptic malignant syndrome
antidote for, 86
in antipsychotic drug therapy, 437

Neuroleptics, neurological side effects of, 437

Neuromuscular blockade,
measurement of, 265

Neuromuscular blocking agents,
258–268
as anesthetic adjuncts, 554
classification of, 264
competitive vs. depolarizing, 267
dosing ranges for, 265
malignant hyperthermia and, 268
respiratory paralysis with, 268
structural formulas of, 259

Neuromuscular junction,
anticholinesterase agents and, 246

Neuronal nicotinic receptor
composition, 256–258

Neuronal-type nicotinic receptors, 190, 191

Neuropeptides, as pruritogens, 1815

Neuropeptide Y, 182
in autonomic co-transmission, 213–214
storage, 197
synthesis, 197

Neuropeptide Y (NPY), and vasopressin secretion, 704

Neurotoxicity
of alkylating agents, 1682
of organophosphates, 249–250

Neurotransmission, 181–210
adrenergic, 194–210
axonal conduction in, 182–183
cholinergic, 185–189
conduction in, 182
evidence for, 181–182
excitatory, 183
ganglionic, 269–270
historical aspects of, 181
inhibitory, 183
junctonal transmission in, 183–185
purines in, 214
steps involved in, 182–185
transmission vs. conduction in, 182

Neurotransmitters
central, 376–390
destruction of, 185
interference with, 212
dissipation of, 185
Neurotransmitters (Cont.):

interference with, pharmacological, 210
in peripheral autonomic system, 172
promotion of release of, pharmacologic, 210–211
receptors and, 184
release of, 184
in sensory fiber transmission, 172
storage and release of, 183–184
transporters and, 115–116

Neutropenia, angiotensin converting enzyme inhibitors and, 736
Neutropenic patients, TMP-SMX prophylaxis in, 1470

NEVANAC (napafenac), 1789
Nevirapine, 1626
antiviral activity of, 1641
chemistry of, 1641
drug interactions with, 1642
mechanism of action of, 1641–1642
pharmacokinetics of, 1641, 1642
precautions with, 1642
therapeutic uses of, 1642
untoward effects of, 1642

New Drug Application (NDA), 79

NEXAVAR (sorafenib), 1740

NF-xB inhibitors, 1056

NGU. See Non-gonococcal urethritis (NGU)

Niacinamide hydroiodide/potassium iodide, 1153
Niacin (nicotinic acid), 899–901
pharmacokinetics of, 1868
and statins
combination therapy with, 898
interactions, 896
tolerability, NSAIDs and, 972

Nialamide, 200, 207

NIASPAN (niacin), 900, 901

Nicardipine, 761
as antihypertensive agent, 774
cardiovascular pharmacology of, 762
pharmacology of, 764
structure of, 762

Niclosamide, 1458

Nicotinamide, structure of, 899

Nicotinamide N-methyltransferase (NNMT), 139

Nicotinate phosphoribosyltransferase (NPT1), 115

Nicotine, 270–272
addiction, 657–658
cholinergic receptors and, 206
hypoglycemia and, 1248
and vasopressin secretion, 704

Nicotinic acid. See Niacin (nicotinic acid)

Nicotinic receptors, 189, 255–258
ganglionic neurotransmission and, 269–270
ganglionic stimulating drugs and, 270–272
molecular structure of, 257
muscle-type, 190, 191
neuromuscular blocking agents and, 258–268
neuronal-type, 190, 191, 256–258
nicotine and, 270–272
structure of, 255–256
subtypes of, 190

NIDA. See National Institute of Drug Abuse (NIDA)

Niemann-Pick C1-like 1 protein, 878

Nifedipine, 761
adverse effects and side effects of, 765–766
as antihypertensive agent, 774
as dose-dependent toxicity, 75
pharmacokinetics of, 1868
pharmacology of, 764
for prevention of preterm labor, 1848
structure of, 762
therapeutic uses of, 767
antiarhythmic, 830
for hypertension, in pregnancy, 1847

Nifurtimox
absorption, fate, and excretion of, 1432
antiprotozoal effects of, 1431–1432
therapeutic uses of, 1432
toxicity and side effects of, 1432

NILANDRON (nilutamide), 1765

Nimodipine, 761
pharmacology of, 764
therapeutic uses of, 767

Nisoldipine, 761
as antihypertensive agent, 774
pharmacology of, 764
therapeutic uses of, 767

Nitazoxanide, 1432–1433

Nitric oxide (NO), 753, 926, 927
in acetylcholine cardiac action, 221
in central nervous system, 390
diagnostic uses, 563
methods of administration, 564
modulation of vascular response with, 214
as neurotransmitter, 182
in peripheral autonomic system, 172
toxicity of, 563–564

Nitric oxide (NO) donors, for prevention of preterm labor, 1848

Nitric oxide synthase (NOS), 753, 927
isoforms, 753

NITRO-BID (nitroglycerin), 754

NITRO-DUR (nitroglycerin), 754

Nitrofurantoin, 1474–1475
pharmacokinetics of, 1869

Nitrates, organic (Cont.):
dosage and administration of, 754
effects on smooth muscle, 756–757
history of, 753
interaction with phosphodiesterase inhibitors, 758–759
mechanism of action of, 753–754
omenclature for, 754
pharmacological properties of, 753–757
and angina relief, 756–757
cardiovascular, 755
and coronary blood flow, 755
hemodynamic, 755
and myocardial oxygen requirement, 755–756
plasma concentrations of, 757
preparations, 757
structures, 754
therapeutic uses of, 759–761
for heart failure, 794–795
for myocardial ischemia, 753–761
for unstable angina, 760
tolerance, 757–758, 795
toxicity of, 758–759
tolerance, 808
transdermal, for prevention of preterm labor, 1848

Nitrazapam, 138
structure of, 459

Nitroglycerin, 753

Nitric nerves, 172

Nitric oxide (NO), 753, 926, 927
in acetylcholine cardiac action, 221
in central nervous system, 390
diagnostic uses, 563
methods of administration, 564
modulation of vascular response with, 214
as neurotransmitter, 182
in peripheral autonomic system, 172
toxicity of, 563–564

Nitric oxide (NO) donors, for prevention of preterm labor, 1848

Nitric oxide synthase, 64–65

Nitric oxide synthase inhibitors, 1055–1056

Nitric oxide synthase (NOS), 753, 927
isoforms, 753

NITRO-BID (nitroglycerin), 754

NITRO-DUR (nitroglycerin), 754

Nitrofurantoin, 1474–1475
pharmacokinetics of, 1869
Nitrogen mustards, 1668–1670, 1682–1684
Nitroglycerin
absorption, fate, and excretion of, 757
adverse effects and side effects of, 755
cardiovascular effects, with long-term use, 752
chemistry of, 753
cutaneous administration, 760
dosage and administration of, 754
history of, 753
intravenous, therapeutic uses of, for heart failure, 796
oral, 759–760
pharmacokinetics of, 1869
for prevention of preterm labor, 1848
structure of, 754
sublingual administration of, 759
therapeutic uses of
in myocardial infarction, 760–761
for unstable angina, 760
transmucosal or buccal administration, 760
NITROL (nitroglycerin), 754
NITROPRESS (sodium nitroprusside), 793–796
Nitroprusside, 793
Nitrosoureas, 1668
Nitrogen mustards, 1668
Nitrous oxide
Nitric oxide (NO)
respiratory, 551
renal, 552
neurological, 551–552
muscular, 552
hepatic, 552
gastrointestinal, 552
cardiovascular, 551
Nuclear magnetic resonance (NMR) spectroscopy
N-nucleoside reverse transcriptase inhibitors, 1640–1644
delavirdine, 1642–1643
efavirenz, 1643–1644
etravirine, 1644
nevirapine, 1641–1642
Nonsedating antihistamines, 911, 920
Nonsynonymous variant, 155
Nodal depolarizations, premature, 1670
Nocturnal acid breakthrough, 1318
Nocardiosis, sulfonamides for, 1467
Nobel, Alfred, 753
Nocardiosis, sulfonamides for, 1467
Nocturnal acid breakthrough, 1318
Nodal depolarizations, premature, management of, 824
NOLAHIST (phenidamine tartrate), 921
Nolvasad Adjuvant Trial Organization (NATO), 1758
Nomenclature, of genomic regions, 148
Nomifensine, potencies at human neurotransmitters, 406
Nonarteritic ischemic optic neuropathy (NAION), phosphodiesterase inhibitors and, 1792
Noncoding single nucleotide polymorphisms, 148, 155
Noncompetitive inhibition, 96
Nondigestible alcohols, 1332
Nondigestible sugars, 1332
Non-gonococcal urethritis (NGU), 1842
Nonsense variation, 155
Nonsedating antihistamines, 911, 920
Nonsynonymous variant, 155
Nonarteritic ischemic optic neuropathy (NAION), phosphodiesterase inhibitors and, 1792
Noncoding single nucleotide polymorphisms, 148, 155
Noncompetitive inhibition, 96
Nondigestible alcohols, 1332
Nondigestible sugars, 1332
Non-gonococcal urethritis (NGU), 1842
Non-Hodgkin’s lymphoma (NHL), 1755
drugs for, 1668–1670
Nonlinear pharmacokinetics, 33
Nonnucleoside reverse transcriptase inhibitors, 1640–1644
delavirdine, 1642–1643
efavirenz, 1643–1644
etravirine, 1644
nevirapine, 1641–1642
Nonsedating antihistamines, 911, 920
Nonsynonymous variant, 155
Non-small cell lung cancer, 1735, 1736
Nonsteroidal anti-inflammatory drugs (NSAIDs), 937, 959, 962–977
absorption, 965
adverse effects and side effects of, 973–976, 973t
cardiovascular, 973t, 974
CNS, 973t
gastrointestinal, 973–974, 973t
hemodynamic, 974–975
on platelets, 973t
in pregnancy and lactation, 975
renal, 973t, 974–975
renovascular, 974–975
uterine, 973t
and analgesic nephropathy, 975
and antidiuretic response to vasopressin, 707–708
as antiinflammatory agents, 965–971
Nonsteroidal anti-inflammatory drugs (NSAIDs) (Cont.):
antiplatelet effects of, 868 as antipyretics, 971
chemistry, 963
classification of
by chemical similarity, 962f
by COX isofom selectivity, 962f
by plasma pharmacokinetics of, 962f
clinical summary, 992–993
contraindications to, 975
COX2 selective, 962f, 990–992
COX-2 selective, classification of, 970t
cyclooxygenase inhibition, 963–964
diaryl heterocyclic, 990–992
classification of, 970t
distribution of, 965
drug interactions with, 976
elimination, 965
for fever, 961–962
history of, 959
hypersensitivity, 973t, 975
for inflammation, 965–971
and inhibition of eicosanoids, 941
and inhibition of prostaglandin synthesis, 963–965
and low-dose aspirin, concomitant therapy with, 976
mechanism of action of, 962, 963–965
for pain, 961
pharmacokinetics of
in children, 976–977
in elderly, 977
polymorphisms and response to, 159t
and prevention of Alzheimer’s disease, 973
and renin release, 724
therapeutic uses of, 965–973
for cancer prevention, 972–973
in children, 976–977
for ulcers, 1319
ulcers and, 1320–1321
Nonsynonymous variant, 155t
Nonulcer dyspepsia, 1321
Nolvasad Adjuvant Trial Organization (NATO), 1758
Norclomipramine, potencies at human neurotransmitters, 406
Norclomipramine, potencies at human neurotransmitters, 406

PONSTAN (mefenamic cid), 989
PONSTEL (mefenamic cid), 989
“Poor metabolizers,” 157
Population pharmacodynamics, 48–50
Population specific polymorphisms, 150
Porins, 1376
Porphyria cutanea tarda, antimalarials
for, 1819
Posaconazole, 1581–1582
pharmacokinetics of, 1874t
structure of, 1874t
Positive allosteric modulators (PAMs), 220
Posterior chamber (ocular), 1774, 1775, 1776f
Postganglionic fibers, 174
Post-operative ileus, 1335
Postpartum hemorrhage, ergot
alkaloids in, 348–349
Potassium canrenoate
pharmacology of, 693t
structure of, 693t
Potassium channel(s), 59
ATP-sensitive, openers, as
antihypertensive agents, 788–781
and cardiac electrophysiology, 815–816, 816f
in neurotransmission, 182
openers, 1046
Potassium channel blockers, as
antiarrhythmics, 828
Potassium iodide, 1153t
Potassium-sparing diuretics. See
Diuretics, potassium-sparing
chemistry of, 690t
pharmacology of, 690t
structure of, 690t
therapeutic uses of, for heart failure, 791
Potency of drugs, 44–45
Potentiation, 77
Povidone iodine, 1153t
in ocular surgery, 1790
Poxvirus, 1818
PPAR. See Peroxisome proliferator
activator receptor(s) (PPAR)
PRADAXA (dabigatran etexilate), 865–866
Pralidoxime, 250
Pralidoxime hydrochloride, as antidote, 86t
Pramipexole
dosage of, 614t
pharmacokinetics of, 1874t
therapeutic uses of, for parkinsonism, 614t
Pramlintide, 1265–1266
pharmacokinetics of, 1875t
Pramoxine hydrochloride, for pruritus, 1828t
Pranlukast, 942
Prasugrel, 870, 872
antiplatelet effects, site of action, 868f
structure of, 869f
PRAVACHOL (pravastatin), 897
Pravastatin, 893, 894
absorption, fate, and excretion of, 896
chemistry of, 894
dosage of, required to achieve
reduction in LDL-C, 895t
structure of, 893f
therapeutic uses of, for
parkinsonism, 614t
Pravastatin (Cont.):
relative potencies and equivalent
doses of, 1216t
therapeutic uses of, dermatologic, 1809
Pre-eclampsia, 1847
Pre-emptive antimicrobial therapy, 1374–1375
Pregabalin, 599
pharmacokinetics of, 1877t
Preganglionic fibers, 174
Pregnancy
anti-epileptics in, 605–606
benzimidazoles in, 1452–1453
eicosanoids and, 948
gastroesophageal reflux disease, 1319
hypothyroidism in, 1144
inflammatory bowel disease in, 1360–1361
lithium use in, 449–450
placental transfer of drugs and, 25
salicylates and, 981
statins and, 897
termination of, drugs for, 1837
thyrotoxicosis in, 1150
Pregnancy categories, for drugs, 1846, 1846t
Pregnancy-induced hypertension, 1847
Pregnane X receptor (PXR), 97, 140, 141f
prehypertension, diagnostic criteria
for, in adults, 773t
Prejunctional sites, 189
Prekallikrein, 929
Preload, 756
pharmacological modification, 756
PREMARIN (conjugated estrogens), 1839t
PREMARIN (conjugated estrogens cream), 1839t
Premature ventricular beat, ECG of, 825f
Prenalterol, 279t
PREPIDIL (dinoprostone), 1849
Prescription, as commodity,
1882–1883
Prescription Drug User Fee Act
(PDUFA), 9
Prescription pad, 1881–1882
Prescription writing
abbreviations in, 1880–1881
authority for, 1880
compliance and, 1881–1882
confusion in, 1879–1880
Prescription writing (Cont.):
date in, 1881–1882
drug product choice and amount in,
1882
errors in, 1883
history of, 1879
mechanics of, 1879–1883
patient information in, 1881
refills in, 1881–1882
signa in, 1879
subscription in, 1879
Pressure-natriuresis curve, 729, 729f,
730
Pressurized metered-dose inhalers,
1035
Preterm labor
complications of, 1847
definition of, 1847
established, tocolytic therapy for,
1848
etiology of, 1847–1848
prevention of, 1848
risk factors for, 1848
scope of problem, 1847–1848
PREVACID NAPRA PAC, 988
PREVEN (levonorgestrel and ethinyl
estradiol), 1837
Prevertebral ganglia, 174
Pricing, of drugs, 11
Prilocaine, 573–574
Probenecid

structure of, 999
therapeutic uses of, 999
Probiotics, 1337, 1360
Procarbazine
structure of, 1755–1756
for endometriosis, 1840
chemistry of, 1181
for induction of sexual maturat6ion,
1838
mammary glands and, 1182
mechanism of action of, 1182–1183
for menopausal symptoms, 1838
administration routes, 1839–1840
brand names, 1839r
metabolic effects of, 1182
oral
brand names, 1839r
formulations, 1839r
in oral contraceptives, 1833,
1835r–1836r
physiological and pharmacological
actions of, 1182
secretion of, 1181
PROGRAF (tacrolimus), 1822
Progressive familial intrahepatic
cholestasis type 2, 104r
Progressive multifocal
leukoencephalopathy (PML)
efalizumab and, 1825
mycophenolate mofetil and, 1823
Proguanil, 1400–1402
polymorphisms and response to,
159r
Proischemia, calcium channel
antagonists and, 766
Prokinetic agents, 1325–1328,
1334–1335
Prolactin, 1106–1117, 1106r
excess of, 1111
impaired production of, 1111–1112
molecular bases of, 1109–1110
opioids and, 495
pathophysiology of, 1111–1112
physiological effects of, 1110–1111
physiology of, 1106–1111
PROLEUKIN (aldesleukin), 1749
Prolglycarboxypeptidase, 929
Promethazine, 921r, 924
local anesthetic effects of, 920
pharmacokinetics of, 1816r, 1877r
structure of, 919r
therapeutic uses of, 923
for motion sickness, 920
and vasopressin secretion, 704
PROMETRIUM (micronized
progesterone), 1839r
Promotion, of drugs, 12–13
Promethanol, 778
Propafenone
adverse effects of, 843
antiarrhythmic use of, 824r, 828,
843
arrhythmias caused by, 821r
contraindications to, 833r
dosage of, 836r
electrophysiological actions of, 829r
Procarbazine (Cont.):
metabolism of, 128r
pharmacokinetics of, 836r, 843,
1877r
pharmacological properties of, 842
polymorphisms and response to,
159r
side effects of, 138r
structure of, 842
Procaine, 574
PROCAN SR (procainamide), 842
Procarbazine, 1668–1670r
PROCARDIA (nifedipine), 762
PROCARDIA XL (nifedipine), 1847
Procaterol, 292f, 293
PROCHIEVE (micronized progesterone),
1844
Prochlorperazine, as antinausea agent,
921r
Proischemia, calcium channel
antagonists and, 766
Prokinetic agents, 1325–1328,
1334–1335
Prolactin, 1106–1117, 1106r
excess of, 1111
impaired production of, 1111–1112
molecular bases of, 1109–1110
opioids and, 495
pathophysiology of, 1111–1112
physiological effects of, 1110–1111
physiology of, 1106–1111
PROLEUKIN (aldesleukin), 1749

diagnosis of, 83
Pure red cell aplasia, mycophenolate
mofetil and, 1823
QT interval, prolongation, drugs for, toxicity of, 830
QUADRINAL (potassium iodide), 1153t
Quazepam
administration and uses of, 466t
structure of, 459t
QUESTRAN (cholestyramine resin), 899
Quetiapine
arrhythmias caused by, 832
dosage of, 426t
metabolism of, 433t
pharmacokinetics of, 1879t
potencies at neurotransmitter receptors, 427t
side effects of, 426t
Quinaclidone, 1435
in dermatology, 1819
Quinagolide, 1115
Quinapril
as antihypertensive agent, 774t, 784–785
clinical pharmacology of, 733
pharmacokinetics of, 1882t
structure of, 732f
therapeutic uses of, for heart failure, 797
Quinethazone
pharmacology of, 688t
structure of, 688t
Quinidine, 1405–1407
ABC transporters and, 105t
adverse effects of, 844
antiarrhythmic use of, 828, 836
contraindications, 833t
structure of, 844t
RASAIEZ (aliskiren), 799
Raynaud’s phenomenon/disease, treatment of, 767
Raynaud’s syndrome, angina pectoris with, recommended treatment for, 769t
Rebamipide, 1317
Rebetol (ribavirin), 1596t
Reboxetine
disposition of, 409t
potencies
at human transporters for monamine neurotransmitters, 406t
at neurotransmitter receptors, 410t
Receptor binding interaction, 77
Receptors
adrenergic
agonists and antagonists, 211–212
alpha, 201, 203t, 207–209
beta, 201, 205–207
functions of, 205
intracellular signaling pathways, 205
polymorphisms, 160t
subtypes, 204t
classification, 201–205
interference with, 210, 212
localization of, 209
molecular basis of, 205
promoters, 211
representative agents, 206t
structure, 205
Receptors (Cont.):
affinity and, 44–45
antagonism, 78
desensitization of, 67–68
dimerization, 55
drug interaction with, quantitative aspects of, 44–48
effector domain of, 51
efficacy and, 44–45
endogenous ligands and, 51
G-protein-coupled, 52–55
inducing metabolism, 140t
ion channels and, 58–60
ionic milieu and, 51
muscarinic, 189
acetylcholine and, 219–222
allosteric binding sites in, 220
in cognition, 223–224
locations of, 219
properties of, 219–220
salivary secretion and, 222
structures of, 219–220
subtypes of, 190–194, 192t

Receptors (Cont.):
response and, 45–46
second messengers and, 55–58
signal amplification and, 52
subtypes of, 53–54
transcription factors and, 65–66
transmembrane, 53r
transporter expression and, 97, 98–99t
voltage-gated channels and, 59
Recombinant DNA technology, protein therapeutics and, 4, 5
Recombinant human growth hormone, 1115–1117
Rectal administration of drugs, 21–22
Renal anatomy and physiology, 671–677, 672f
Renal cell carcinoma, 1744
drugs for, 1668t–1670t
metastatic, 1740
 Renal clearance, 30
Renal cell carcinoma, 1744
drugs for, 1668t–1670t
metastatic, 1740
Renal epithelial transport, 675f
ATP-mediated transport in, 674
carrier-mediated (facilitated) diffusion in, 674
channel-mediated diffusion in, 674
secondary active transport in, 674
Renal epithelial transport (Cont.):
solvent drag in, 674
symport and antiport in, 674
Renal excretion, 26
Renal failure
ACE inhibitors in, 735
chronic, diuretics for, 699
fibric acid agents and, 903
Renal osteodystrophy, 1289, 1290, 1293
Renal transporters, 111–115
ReNESE (polythiazide), 688t
Renin, 721–724
pharmacological inhibition of, 724f
release
β-adrenergic receptor pathway, 722, 723f, 724
intrarenal baroreceptor pathway, 722, 723f, 724
long-loop negative feedback mechanism and, 723f, 724
macula densa pathway, 722, 723f
regulation of, 722, 723f
short-loop negative feedback mechanism and, 723f, 724
Renin-angiotensin-aldosterone axis, 794f, 797
antagonists, 797
Renin-angiotensin system, 721–730, 927f
and arterial blood pressure maintenance, 730
components of, 721–727, 722f
effects of, 727–730
functions of, 727–730
history of, 721
inhibitors, 730–736, 731f (See also Angiotensin-converting enzyme inhibitors (ACEI))
nonpeptide angiotensin II receptor antagonists, 736–745
local, 725–726
extrinsic, 725–726
intrinsic, 725–726
response to pharmacological lowering of blood pressure, 746t, 747
and vascular disease, 730
Renin inhibitors, direct, 730, 731f
absorption, 786
as antihypertensive agents, 774t, 786
effects on renin-angiotensin system, 746t
excretion, 786
for heart failure, 799
hemodynamic effects of, with long-term administration, 774t
Renin inhibitors, direct (Cont.):
- history of, 745
- mechanism of action of, 786
- metabolism, 786
- pharmacology of, 786
- precautions with, 786
- site of action of, 786
- therapeutic uses of, 786
- toxicity of, 786
- Renin receptor, 725–726
- Repaglinide, 110, 1258
  - pharmacokinetics of, 1883
- Repolarization, cardiac cell, sodium and calcium exchange in, 802f
- Reporting, of adverse effects, 10
- REPRESAIX (hydrocortone + ibuprofen), 988
- Reproduction
  - eicosanoids and, 948
  - platelet-activating factor and, 954
- Reproductive tract, female
  - cyclical gonadal steroids and, 1169
  - infections, 1841, 1842
- RESCRIPTOR (delavirdine), 1626
- Research, preclinical, 6–7
- Reserpine
  - absorption, fate, and excretion of, 783
  - as antihypertensive agent, 774f, 783
  - cholinergic receptors and, 206f
  - mechanism of action of, 783
  - pharmacology of, 783
  - precautions with, 783
  - site of action of, 783
  - SLC transporters and, 102f
  - structure of, 783
  - therapeutic uses of, 783
  - toxicity of, 783
- Resistance
  - antimicrobial
    - evolutionary basis of, 1377–1378
    - mechanisms of, 1375–1377
    - transporters and, 91, 103
  - Respiratory paralysis, neuromuscular blocking agents and, 268
- Respiratory system
  - acetylcholine and, 221
  - amphetamines and, 298
  - beta-adrenergic receptor antagonists and, 315, 316–317
  - carbon dioxide and, 562
  - epinephrine and, 285
  - halothane and, 547
  - ipratropium and, 230
  - isoflurane and, 548
  - methacholine and, 224
  - muscarinic antagonists and, 228, 231
  - opioids and, 493–494
  - oxygen inhalation and, 559
  - tiotropium and, 230
- Respiratory tract, allergies of, H1-receptor antagonists for, 920–922
- Respiratory tract disease, kinins and, 931
- Respiratory tract infections, drugs for, TMP-SMX, 1469
- Response
  - exogenous factors in, 146f
  - pharmacogenetics and, 145–146
  - polymorphisms and, examples of, 159f
  - receptors and, 45–46
- RESTASIS (cyclosporine), 1790
- Retapamulin, for impetigo, 1817
- Retina, 1774, 1776f, 1778
  - systemic agents affecting, 1792
- Retinitis, parasitic, 1783
- Retinoic acid
  - mechanism of action of, 1798
  - structure of, 1796f
  - 9-cis-Retinoic acid, 1809
  - 13-cis-Retinoic acid, 1809
  - all-trans-Retinoic acid, 1809

Sucralfate
- adverse effects of, 1315
- chemistry of, 1315
- mechanism of action of, 1315
- pharmacological properties of, 1315
- therapeutic uses of, 1315

Sufentanil
- actions and selectivities of, 485t
- dosage of, 500t
- structure of, 504f

Sulbactam/ampicillin, hypoglycemia

Sulfamethoxazole

Sulfadoxine
- pharmacological properties of, 1465–1466

Sulfasalazine
- 994
- pharmacological properties of, 1466

Sulfapyridine
- 1354–1356
- pharmacological properties of, 1466

Sulfanilamide, Food and Drug Act and, 1315
- pharmacological properties of, 1466

Sulfapyridine, 1354–1356
- pharmacological properties of, 1466

Sulfopropionate

Sulfonamides
- 1410
- for acne, 1817
- for cancer prevention, 972–973
- compared to aspirin, 967t
- COX isoform selectivity, 962f
- distribution of, 985
- dosage and administration of, 967t
- elimination, 985
- mechanism of action of, 985
- pharmacokinetics of, 967t, 985
- pharmacology of, 962f
- plasma pharmacokinetics of, 962f
- structure of, 985
- therapeutic uses of, 967t, 985

Sulpiride, potencies at neurotransmitter receptors, 427t

Sun protection factor (SPF), 1827–1828

Superscription, 1879

Suppositories, 1335–1336

Sunscreen, 1827–1828

Superior mesenteric ganglion, 173f

Suramin
- absorption, fate, and excretion of, 1437
- antiparasitic effects of, 1437
- contraindications to, 1438
- precautions with, 1438
- therapeutic uses of, 1437
- toxicity and side effects of, 1437–1438

Surrogate end points, 9

Susceptibility testing, antimicrobial agents and, 1369–1371

Sustained-release formulations, 21

Sweet’s syndrome, dapsone for, 1823

“Swiss cheese” model of medication error, 81t

Tolterodine, 232
Tolvaptan, 714, 716
Tomoxetine, potencies at human neurotransmitters, 406
Torsades de pointes
  drug-induced, 821t, 832, 839, 840, 841, 842–843, 844, 845
  ECG of, 825f
  magnesium for, 842
  management of, 824t
Torsades de pointes, second-generation
  H₁-receptor antagonists and, 920
Toreseide, 682–684
  as antihypertensive agent, 774t
  pharmacology of, 683t
  structure of, 683r
  therapeutic uses of, for heart failure, 790
Tourette’s syndrome, drug therapy for, 436
Toxic epidermal necrolysis (TEN)
  cyclophosphamide for, 1821
  IVIG for, 1827
Toxicity
  allergic, 76
  descriptive testing of, in animals, 78
  drug-drug, 77–78
  genotoxic, 76
  idiosyncratic, 76
  pharmacological, 75
  in preclinical testing, 6–7
  therapeutic, 79–80
  transporters and, 91–92
  types of, 75–78
Toxicokinetics, pharmacokinetics vs., 74–78
Toxicology, in risk assessment, 1854
Toxidromes, common, 83
Toxic epidermal necrolysis (TEN)
cyclophosphamide for, 1821
IVIG for, 1827
Toxicity, in risk assessment, 1854
Toxidromes, common, 83t
Toxocara canis, 1444–1445
Toxocariasis, 1444–1445
Toxoplasmosis, 1420–1421
sulfonamides for, 1467
Trabectedin, 1719–1720
Trabecular meshwork, 1774, 1776f
Tracheal muscle, eicosanoids and, 950
Trandolapril, 797
  as antihypertensive agent, 774t, 784–785
  clinical pharmacology of, 733
  structure of, 732f
Tranexamic acid, 867–868
Transcription factors, receptors and, 65–66
Transdermal absorption, 21
  of opioids, 518
Transduction, 1378
Transendothelial flux, 96f
Transepithelial flux, 96f
Transferases, 125
Transmission, definition of, 182
Transnasal administration, of opioids, 518
Transplantation, organ. See Organ transplantation
Transport
  active, 94–95, 94f
  carried-mediated, 19
  kinetics of, 95–96
  vectorial, 96–97, 96f
Transporters, 89–116
  active transport and, 94–95, 94f
  adverse responses and, 91–93, 92f
  blood-brain barrier and, 116
  brain drug action and, 115–116
  channels vs., 93
  mechanism of, 89
  as drug targets, 89–91
  expression regulation of, 97
  facilitated diffusion and, 94, 94f
  gated pore mechanism in, 101f
  genetic variation in, 108, 154
  hepatic, 90f, 108–111
  in hepatic uptake, 110–111
  in kidneys, 111–115

rocker switch mechanism in, 101f
substrates and, 93, 94f
superfamilies of, 99–108
 toxicity and, 91–92
turnover rates of, 93
Tranylcypromine
dose and dosage forms of, 403t
side effects of, 403t
Trastuzumab, 1737, 1745, 1746t
dosage and administration of, 1747t
pharmacokinetics of, 1737
therapeutic uses of, 1737
toxicity of, 1737, 1747t
TRASYLOL (aprotinin), 931–932
TRAVATAN (travoprost), 1787
TRAVATAN Z (travoprost), 1787
Travoprost, 952
toxicity of, 952
for topical use, 1585–1586
Tricyclic antidepressants, 404–405, 923
adverse effects of, 411
arrhythmias caused by, 832
drug interactions with, 412
mechanism of action, 408
for pruritus, 1828t
secondary amine, disposition of, 409t
tertiary amine, disposition of, 409t
terapy, 704
TRIDESILON (desonide), 1225t
Trientine, 1875
Triflupromazine
dosage of, 424t
side effects of, 424t
Trilostane, 1236
for uveitis, 1788
for ophthalmic use, 1788
Trioxxalens, structure of, 1813
Triamipexole, 918
Triamiprex, 918
Triple product, 756
Triple response of Lewis, 917
TRIPS. See Trade Related Aspects of Intellectual Property Rights (TRIPS)
Triptans, 345
Triptorelin, 1122, 1765
structure of, 1765
Trizole, 918
Tripleleminine, 921t
Triralen (tripelennamine), 918
Triprolidine, 492
Trisodium phosphate, 1478
Trimipramine
dosage of, 424t
side effects of, 424t
for parkinsonism, 1470
TRI-NORINYL (ethinyl estradiol/norethindrone), 1835t
Trioxsalen, structure of, 1813
Triparanol, 918
Trifluridine, 1596
for ophthalmic use, 1782
Triglycerides, plasma, classification of, 1445
Triggered cardiac rhythms, 822f
Triggered rhythms, 820
Triglycerides, plasma, classification of, 1887t
Trihexyphenidyl
dosage of, 614t
for parkinsonism, 234
therapeutic uses of, for parkinsonism, dosage of, 614t
TRI-LEVLEN (ethinyl estradiol/levonorgestrel), 1835t
TRILIPIX (fenofibrate), 903
Triilostane, 1236
TRI-LUMA (hydroquinone), 1830
Trimethaphan
colinergic receptors and, 206t
structure of, 273f
Trimethoprim-sulfamethoxazole (TMP-SMX)
absorption, distribution, and excretion of, 1469
for acne, 1817
antibacterial spectrum of, 1468
chemistry of, 1468
efficacy of, 1468
mechanism of action of, 1468–1469
for MRSA infection, 1817
pharmacokinetics of, 1895t
resistance to, 1469
therapeutic uses of, 1469
untoward effects of, 1470
Trimipramine
disposition of, 409t
dose and dosage forms of, 400t
potencies at human transporters for monamine neurotransmitters, 406t
at neurotransmitter receptors, 410t
side effects of, 403t
TRELSTAR DEPOT (triptorelin), 1764t, 1765
Trematode infections, 1448–1449
Trethocanic acid, 1829
Tretinoin (all-trans-retinoic acid), 1809
formulation of, 1810t
irritancy, 1810t
pregnancy category, 1810t
receptor specificity, 1810t
structure of, 1810t
therapeutic uses of, for photoaging, 1810
TREXIMET, 988
TRH. See Thyrrotropin-releasing hormone (TRH)
Triamcinolone, relatable potencies and equivalent doses of, 1216t
Triamcinolone acetonide, 1807
cream, 1225t
lotion, 1225t
ointment, 1225t
Triamcinolone hexacetonide, 1807–1808
Triamterene, 690–692
as antihypertensive agent, 774t, 778
Triamterene (Cont.):
pharmacokinetics of, 1894t
pharmacology of, 690t
structure of, 690t
therapeutic uses of, for heart failure, 791
Triazenes, 1668t–1670t, 1686–1687
Triazolam
administration and uses of, 466t
polymorphisms and response to, 159t
structure of, 459t
Triazoles, 1576, 1817–1818
Trichlormethiazide
administration and uses of, 466t
pharmacokinetics of, 1894
for topical use, 1586–1587
for uveitis, 1788
for ophthalmic use, 1788
for MRSA infection, 1817
for acne, 1817
antibacterial spectrum of, 1468
chemistry of, 1468
efficacy of, 1468
mechanism of action of, 1468–1469
for MRSA infection, 1817
pharmacokinetics of, 1895t
resistance to, 1469
therapeutic uses of, 1469
untoward effects of, 1470
Triamcinolone
administration and uses of, 466t
polymorphisms and response to, 159t
structure of, 459t
Tri-levlen (ethinyl estradiol/levonorgestrel), 1835t
Trihexyphenidyl
dosage of, 614t
for parkinsonism, dosage of, 614t
Triton X-100, 922
Tropicamide
for glaucoma, 1787
for ophthalmic use, 1787
for uveitis, 1788
Tropine, 226
Valacyclovir (Cont.):
methylation of action of, 1594
for ophthalmic use, 1782, 1783
pharmacokinetics of, 1895
resistance to, 1594
SLC transporters and, 102
therapeutic uses of, 1597–1598
untoward effects of, 1597
VALCYTE (valganciclovir), 1783
Valdecoxib, 964–965
COX isoform selectivity, 962
pharmacology of, 962
plasma pharmacokinetics of, 962
Valganciclovir, 1603–1604
for ophthalmic use, 1783
pharmacokinetics of, 1895
Validation, of drug targets, 6
VALIUM (diazepam), 466
Valnoctamide, 130
Valproic acid poisoning, 75
Valproic acid, 596–598
manifestation of overdose symptoms, 75
microsomal epoxide hydrolase and, 130
pharmacokinetics of, 1896
Valproic acid poisoning, 75
Valsartan
as antihypertensive agent, 774
clinical pharmacology of, 738
pharmacokinetics of, 737
structure of, 737
VALTREX (valacyclovir), 1596, 1783
VALTURNA, 786
Valvular heart disease
left-sided, angina pectoris with, recommended treatment for, 769
prophylaxis in surgery, 1488
VAMP2. See Vesicle-associated membrane protein 2 (VAMP2)
Vancomycin, 1539–1542
histamine and, 914
pharmacokinetics of, 1897
Vanillylmandelic acid (VMA), 200–201
VANIQUE (eflornithine), 1841
VANTAS (histrelin), 1764, 1765
VANTIN (cefpodoxime proxetil), 1494
VAPRISOL (conivaptan), 714
Vardenafil, 758–759
effects on optic nerve, 1792
pharmacokinetics of, 1897
Varenicline
pharmacokinetics of, 1897
for smoking cessation, 272
Variability, pharmacodynamic, 48–50
Variants, genetic, types of, 147–149
Variation, genetic, frequency of, 145
Varicella-zoster virus (VZV), 1818
drugs for, 1599
Vascular disease, inflammatory, eicosanoids and, 947
Vascular endothelial growth factor (VEGF), 1738
Vascular endothelial growth factor (VEGF) receptors, 1738–1739
Vascular tone, eicosanoids and, 946–947
Vasculitis, IVIG for, 1827
Vas deferens, alpha adrenergic receptors in, 203
Vasectomy, one-year failure rate, 1834
Vasoactive intestinal peptide (VIP), and vasopressin receptor agonists, 712–714
Vasoactive intestinal peptide (VIP), and vasopressin receptor antagonists, 712–714
Vasoactive intestinal peptide (VIP), and vasopressin receptor antagonists, 712–714
Vasopressin (Cont.):
and renal conservation of water, 707, 707
secretion, regulation of, 703–704
hepatic portal osmoreceptors and, 703
hormones and neurotransmitters in, 704
hypermobility and, 703
hypotension and, 703–704
hypovolemia and, 703
by pharmacological agents, 704
and SIADH, 711–712
synthesis of, 702, 702
outside CNS, 702
transport and storage of, 702
in water-retaining states, 712
Vasopressin analogs, advances in (future directions for), 717
Vasopressin peptide(s), synthetic, 709
Vasopressin receptor agonists
adverse effects and side effects of, 713–714
contraindications to, 713
drug interactions with, 713
pharmacokinetics of, 713
therapeutic uses of, 712–714
toxicity of, 713
Vasopressin receptor antagonists, 708–710, 715–716
chemistry, 710
for heart failure, 799–800
nonpeptide, 715–716
peptide, 715
therapeutic uses of, 714
V₁-selective, 715
V₂-selective, 715–716
Vasopressin receptor-effector coupling,
705–707, 705, 706
Vasopressin receptors, 704–707
V₁, therapeutic therapeutic uses of of vasopressin agonists mediated by, 712–714
V₂, therapeutic therapeutic uses of of vasopressin agonists mediated by, 712–714
V₁ receptor-effector coupling, 705, 705
V₂ receptor-effector coupling, 705–707, 706
VASOTEC (enalapril maleate), 733, 797
VASOTEC INJECTION (enalaprilat), 733
Vasotecin, 709
VECTIBIX (panitumumab), 1737
Vectorial transport, 96–97, 96
physiology, 701–704
nonrenal actions of, 708
evolutionary history of, 701
CNS effects of, 708
cardiovascular effects of, 708
arginine, 1213–1214
and blood coagulation, 708
cardiovascular effects of, 708
CNS effects of, 708
and diabetes insipidus, 710–711
evolutionary history of, 701
nonrenal actions of, 708
physiology, 701–704
plasma levels, plasma osmolality and, 703, 703
Venous thromboembolism, heparin-

Venous limb gangrene, warfarin-

Venom, histamine release by, 914

ZADITOR (ketotifen fumarate), 922
Zafirlukast, 942
Zalcitabine, 1626t, 1634
pharmacokinetics of, 1630t
Zanamivir, 1596t, 1608–1609
Zankiren, 745
ZAROXOLYN (metolazone), 688t
ZD 164384, 1759
ZEMURON (rocuronium), 264t
ZERIT (stavudine), 1626t
ZESTRIL (lisinopril), 733, 797
ZEVALIN (yttrium-90 ibritumomab
tiuxetan), 1749
ZEVALIN (yttrium-90-ibritumomab
tiuxetan), 1745
ZIAGEN (abacavir), 1626t
Zidovudine, 1626t
absorption of, 1632
antiviral activity of, 1632
chemistry of, 1632
distribution of, 1632
drug interactions with, 1633
elimination of, 1632
mechanism of action of, 1632
pharmacokinetics of, 1630t, 1900t
precautions with, 1633
resistance to, 1632
therapeutic uses of, 1633
untoward effects, 1632–1633
Zileuton, 942
Zimelidine, potencies at human
transporters for monamine
neurotransmitters, 406t
ZINACEF (cefuroxime), 1494t, 1496t
Zinc, in ophthalmology, 1795t
Zinc oxide, 1827
Ziprasidone
arrhythmias caused by, 832
dosage of, 426t
metabolism of, 434t
pharmacokinetics of, 1900t
potencies at neurotransmitter
receptors, 427t
side effects of, 426t
ZIPSOR (diclofenac), 986, 987
ZK 191703, 1756, 1759
ZOCOR (simvastatin), 897
ZOLADEX (goserelin), 1119t, 1764t,
1765, 1840
ZOLICEF (cefaclor), 1496t
Zolinger-Ellison syndrome,
1321
Zolmitriptan, 345–347
arrhythmias caused by, 832
Zolpidem, 467–468
pharmacokinetics of, 1900t
ZONALON (diphenhydramine), 1816
Zonisamide, 602
pharmacokinetics of, 1900t
Zonule(s), 1774, 1776–1777,
1776f
Zopiclone, pharmacokinetics of,
1839t
ZOSTRIX (capsaicin), 1830
Zotepine, potencies at neurotransmitter
receptors, 427t
ZOVIRAX (acyclovir), 1596t, 1818
ZYPHURIN (allopurinol), 997
ZYMAR (gatifloxacin), 1781t
ZYRTEC (cetirizine), 921t, 1816
